More recently another synthetic detergent—"triton W.R. 1339"—has been the subject of extensive investigation. The substance was first used as an aid to streptomycin inhalation in the treatment of pulmonary tuberculosis, and it was found to have a marked liquefying effect upon the sputum. Subsequently it was tried in various conditions characterized by excessive or thickened secretion from the respiratory tract and was found to be effective.⁴ Ravenel has carried out studies on babies suffering from asphyxia neonatorum and claimed dramatic results.⁵ Eighteen newborn infants suffering from massive atelectasis or from inhalation of liquor were treated, the diagnosis having been made on clinical grounds in most of the cases, only six being x-rayed before treatment; all eighteen recovered completely. Another six babies, four premature and two full-term, did not appear to be helped by treatment, but at necropsy two of them were found to have severe congenital cardiac malformations and another was reported to have "mesenchymal hyperplasia" of the lungs, with thick-walled alveolar septa. It was suggested that the aerosol detergent should be given prophylactically to newborn infants whenever the delivery has been difficult and respiratory complications are expected. Special nebulizers have been devised to deliver a fine dry mist, and Miller⁶ describes a simple apparatus which he claims gives satisfactory results. The chief requirements are that the particles should be small (0.5 to 3 μ) in order to penetrate the alveoli. Larger particles are apt to be irritating to the respiratory mucosa and cause coughing and gagging. Apparatus that has been devised for giving penicillin by inhalation has also been found to give fairly satisfactory results. Ravenel has also given the indications for the use of aerosol detergents.⁵ Among

⁹ Varga, C., and Wild, J., *Amer. J. Dis. Child.*, 1953, 86, 273.

the conditions he has treated are laryngitis and laryngo-tracheobronchitis, where the results have been very good; asthma and allergic bronchitis; capillary bronchitis; pneumonia with atelectasis; whooping-cough; respiratory or bulbar paralysis in poliomyelitis; laryngeal oedema following bronchoscopy; and, most effectively, neonatal atelectasis.

No toxic effects have yet been reported from the use of triton W.R. 1339, and, unlike other detergents, it does not seem to cause haemolysis even in high concentrations. The product as put up for clinical use is a 0.125% solution combined with a 2% solution of sodium bicarbonate and 5% solution of glycerin. The last two solutions are said to stabilize the aerosol droplets and to assist in the liquefaction of mucus.

A different approach to this problem has been the use of proteolytic agents in aerosol form in order to liquefy tenacious sputum. Streptokinase and streptodornase have been used⁷ with doubtful effect, but excellent results are claimed for the use of trypsin. Limber *et al.*⁸ have used trypsin in the treatment of adults with chronic respiratory disease, and Varga and Wild⁹ report a case of bulbar poliomyelitis in a child in which the use of this agent made the aspiration of secretion from the respiratory tract very much easier and there was considerable improvement in the patient's condition. Because trypsin is a protein there is some danger of sensitization reactions developing from its use, and anti-histamine drugs have therefore been used in conjunction with it in order to minimize possible side effects.

So far there has been little experience in Britain of these forms of treatment. If the claims made for them can be substantiated, they would constitute a real advance in the treatment of acute respiratory disease in childhood.

DANGERS OF INDUCED HYPOTENSION

The effects of a low blood pressure on the reduction of bleeding during operations were known in the pre-anaesthetic era. In that dismal period surgeons hoped that their patients would faint early in the proceedings, not only because their pain would then cease, but also because haemorrhage became more controllable. After anaesthesia became an established practice, and until quite recently, it has been usual to try to maintain the blood pressure within normal limits, and for the surgeon to control the bleeding as he proceeded with the operation; if the blood loss became excessive it was made good by transfusion. In limb surgery a bloodless field could be secured by an Esmarch's bandage or other tourniquet, while in other areas a relatively avascular field could be obtained by infiltration with some vasoconstrictor solution such as 1 in 500,000 adrenaline in saline.

In the last few years, however, the idea of general hypotension to minimize bleeding was revived, and this

was usually obtained in one of three ways. First, arteriotomy and bleeding might be carried out until the desired fall in pressure was obtained, followed by transfusion back of the same blood at the end of the operation; this amounts to induced haemorrhagic shock and is accompanied by vasoconstriction. Secondly, preganglionic sympathetic block might be obtained by high sub-arachnoid or peridural spinal analgesia. Or, thirdly, ganglionic sympathetic and parasympathetic block might be induced by the intravenous injection of a methonium or thiophanium derivative combined with suitable posture. The last two techniques entail vasodilatation. All these methods are effective in producing hypotension, although the adjective "controlled" is open to question. Relatively ischaemic fields were welcomed particularly by plastic and cranial surgeons, and the practice of the technique was spreading rapidly, when it became clear that a heavy price was being paid in fatalities and severe post-operative complications.

The question of the frequency of these unfortunate consequences then arose, and a determined effort to find the answer was made by Hampton and Little.¹ These investigators sent questionnaires to 602 members of the Association of Anaesthetists of Great Britain and Ireland, and received back completed reports from the surprisingly high number of 299 anaesthetists. In brief, this investigation showed that in 21,000 cases of induced hypotension 46 fatalities occurred, of which 42 were probably associated with the technique (one death in 500 cases). Non-fatal complications affecting mainly the cerebral, renal, and coronary circulations occurred on 549 occasions (one in 38 cases). A similar inquiry circulated to diplomates of the American Board of Anesthesiologists showed 50 deaths in 6,805 operations (one death in 136 cases). An interesting result of the latter investigation was that a significantly greater number of complications occurred if the blood pressure was allowed to fall below 80 mm. Hg. Too much must not be deduced from these results in the absence of control cases, but it is evident that induced hypotension does carry a considerably greater risk than normal methods of anaesthesia. Two comprehensive surveys based on all available evidence were made by Armstrong Davison² and Woolmer.³ The general conclusion was that the technique of induced hypotension should not be used except for operations essential to avert death or really serious disability and impossible to perform without a bloodless field.

The general acceptance of the view that hypotension was too risky for general use has stimulated investigators to find out means of making it safer.⁴ The most promising line of research appears to be that of reducing the basal metabolic rate so that a reduced oxygen supply is still sufficient for the vital organs. Delorme⁵ has pointed out that this can be accomplished by hypothermia but that superficial cooling in adults provokes the natural response of shivering, and this must be suppressed either by deep anaesthesia, muscle relaxants, central cooling by means of an arterio-venous shunt, or by one or other of the inappropriately named "lytic cocktails" which contain various

derivatives of phenothiazine such as promethazine and chlorpromazine. These techniques were recently discussed at a meeting of the Section of Anaesthetics of the Royal Society of Medicine and in these columns.⁶ With these varied aids it is possible to reduce the B.M.R. almost to zero for a short time, as with a cut-off cardiac inflow for intracardiac surgery. A few successful cases have been reported in the human subject, but the high degree of cooling and hypotension necessary are undoubtedly dangerous and may lead to irreversible ventricular fibrillation when attempts are made to restart the heart at the end of the operation. In these exceptional cases it is probably better to use a moderate degree of hypothermia (not below 28° C.) and a shunt carried out by means of a heart-lung machine (or pump oxygenator) as described by Melrose.⁶ All this work is unquestionably still in the experimental stage, and individual anaesthetists not connected with a research unit would best rely on well-proved methods, which are suitable for all but very exceptional cases.

MEDICAL AUXILIARIES

Last week we briefly described the regulations¹ which are to come into force on April 1 laying down the qualifications required for medical auxiliaries in the National Health Service. The regulations are stated to be based upon the recommendations made by the Cope Committees in 1951, but, "to avoid certain anomalies and unfairness," those recommendations have not been applied strictly. The question of statutory registration, which was also recommended by the Cope Committees, is to be considered by a working party with a view to "evolving a scheme which will be acceptable" both to the Minister and to the medical auxiliaries.

Many of the qualifications set down as acceptable at present are in accordance with the recommendations of the Cope Committees, but there are important variations in the qualifications of the physiotherapists and the chiropodists. The most important body of physiotherapists is the Chartered Society, which lays down that there shall be a course of training lasting three years. One of the qualifications recognized by the Minister falls short of this standard, and it is to be hoped that after April 1 such lower standards will not be acceptable. A departure from the recommendations of the Cope Committees occurs also in the matter of qualifications required for chiropodists.

Some months ago we emphasized² the need for State registration and for the setting up of a central authority to co-ordinate the various medical auxiliaries. Statutory registration is now the rule for doctors, dentists, nurses, and midwives, and it surely ought to be the rule for medical auxiliaries, who have been growing in numbers and influence during the past decade. There are several groups of professional workers in the National Health Service who are asking for recognition, and a

central council is needed which will be competent to judge whether recognition should be granted to these. At the same time such a council would be the appropriate body to maintain a statutory register of all medical auxiliaries and be the final arbiter on the adequacy of the various curricula. It is to be hoped that the working party to be appointed by the Minister will bear these points in mind. There is now undoubtedly an opportunity for the Minister to achieve a piece of constructive statesmanship which will bring the position of medical auxiliaries into line with the other professions in the National Health Service.

ANTIBIOTICS AGAINST NEOPLASMS

In a search for effective chemotherapeutic agents inhibiting malignant tumours experimentalists have, during the last few years, included antibiotics in their list of substances for screening tests.¹ This was a rational procedure, for Gale² has shown that chloramphenicol, aureomycin, and terramycin inhibit protein synthesis, and bacitracin inhibits protein and nucleic-acid synthesis in *Staphylococcus aureus*—activity that is desirable in a compound to be used against neoplasms. An outstanding problem, however, is to find such a preparation with selective toxicity against tumour cells as compared with normal cells, a difference which fortunately exists so often between the effect on parasites and that on the infected host. The sixth International Microbiological Congress, held in Rome in 1953,³ heard a report by Waksman on the effect of actinomycin C on tumours as observed by Domagk. Now comes the news that American workers⁴ have isolated from another strain of streptomycetes an amino-acid derivative, L-azaserine. The director and some of his colleagues at the Sloan-Kettering Institute for Cancer Research in New York report⁵ that this peculiar product shows a remarkable effect on the transplanted mouse sarcoma 180. Further details of other findings are promised. What does this portend for the treatment of human neoplastic diseases? Will it signify a turning point in the development of therapeutics against cancer and reticuloses such as the discovery of sulphonamides and penicillin did in the treatment of microbial infections? It is hoped that patients suffering from reticuloses might be the first to benefit from the new antibiotic. Its discovery will in any case stimulate further search among fungal products and give a possible lead to the synthesis of suitable agents. The question arises immediately whether the selective action of such material against pathologically proliferating blood elements compares favourably with that of nitrogen mustards, T.E.M., mercaptopurine, "myleran," and other experimental drugs at present in use against lymphatic or myeloid, acute or chronic, forms of leukaemia. Those engaged on this work are well qualified to find the answer quickly to these urgent questions.

CLINICAL PATHOLOGY IN GENERAL PRACTICE

THE NORMAL BLOOD COUNT

BY

GEORGE DISCOMBE, M.D., B.Sc.

Pathologist, Central Middlesex Hospital, Park Royal, London, N.W.10

A blood count offers figures from which the clinician hopes to confirm his diagnosis. Unfortunately, the errors in even the best-conducted blood count are enormous, and in an expert's hands a determination of haemoglobin and an examination of a stained film are usually more informative.

Haemoglobin Level

Methods.—The estimation of haemoglobin is done by one or other colorimetric method, nowadays usually comparison of dilute (1 in 200) oxyhaemoglobin with a grey screen, viewing both through a green filter (M.R.C. photometer) or photoelectric determination of the absorption of light by a dilution of blood in water (oxyhaemoglobin) or in N/10 NaOH (alkaline haematin). The classical Haldane method is dying out because of its inherent inaccuracy, although it and the M.R.C. photometer are the only methods which can be calibrated by the National Physical Laboratory.

Reproducibility.—The modern methods are about as accurate as are the graduated pipettes used for them. In time past, the errors of calibration of haemoglobin pipettes were great; nowadays they are usually bought to British Standard Specification No. 797 and tolerance is $\pm 3\%$, so that a series of replicates taken from a bottle of blood will vary by no more than this. Unfortunately, replicates taken from a patient at different times vary much more than this, for any individual may show fluctuations of 7% in his haemoglobin level. A convenient estimate is that two estimations of haemoglobin made at different times on the same patient differ significantly if the difference exceeds a tenth of the average of the two determinations. The old Haldane method is much less accurate than are the modern methods mentioned above, and with this method the difference should exceed 15% for it to be significant.

Standards.—It was only during the war that E. J. King in London and R. G. Macfarlane in Oxford discovered that Haldane's original calibration of his "100% = 13.8 g." standard had been inaccurate, and that the 100% Haldane standard actually corresponded to 14.8 g. haemoglobin per 100 ml. This explained a series of observations which had puzzled haematologists—for example, why Americans appeared to average about 1 g. haemoglobin per 100 ml. more than Englishmen. The new Haldane calibration is that 100% = 14.8 g. per 100 ml. The Medical Research Council has recently organized a scheme whereby samples of blood of accurately known haemoglobin content are supplied at regular intervals to large laboratories so that they can standardize their instruments. With this and a secondary standard such as a grey glass or wire mesh screen, a haemoglobinometer can be maintained in accurate calibration for years, even if a photoelectric cell has to be changed at short notice.

Normal Values.—For men these can be taken as 14.8 ± 1.5 g. per 100 ml. (13.3–16.3 g.) or 90–110%, which will include more than 19 out of 20 normal subjects. Occasionally normal subjects have lower or higher figures than this, but such subjects are rare: only about 1 in 300 have values below 12.6 g. or over 17 g. (85%–115%). For women, the level chosen depends on the definition of normal. If "normal" is equated to "optimal," then the level for women is the same as that for men; but many women can maintain this only when their average iron intake is much greater than normal—some 30–60 mg. in place of the usual 10–15 mg. If "normal" is equated to "usual,"

however, the range extends much lower: it is quite common to find apparently healthy women with haemoglobin levels of 85% or even 80% (12.6 or 11.8 g. per 100 ml.). Such women nearly all show a rise to levels within the male range if they receive a supplement of 65 mg. ferrous iron daily for 30–60 days (one ferrous sulphate compound tablet, N.F.), though they often fall again as soon as the iron supplement is withdrawn. In such women the menstrual loss is usually excessive or the diet is poor.

Mean Corpuscular Haemoglobin Concentration

The packed cell volume (P.C.V.) indicates the percentage of the volume of the blood which is occupied by the red cells; it is determined with the haematocrit. The standard practice is to collect venous blood into Wintrobe's anticoagulant (potassium and ammonium oxalate) and centrifuge a sample in Wintrobe's haematocrit tube for 30 minutes at 3,000 r.p.m. The normal range for men is 42–48% (mean 45%) and reproducibility is about the same as for the estimation of haemoglobin. Estimation of the P.C.V. gives the same sort of information as does that of the haemoglobin—in fact, one is often substituted for the other, but usually the haemoglobin is slightly more informative. The two estimations can, however, be combined to yield an index of great value—the mean corpuscular haemoglobin concentration (M.C.H.C.), obtained by dividing haemoglobin concentration expressed in grammes per litre by the percentage of blood occupied by cells (P.C.V.). The M.C.H.C. is a direct indication of iron deficiency. Most normal subjects have M.C.H.C. values between 32% and 35%; patients with marked iron deficiency have values below 30%, while values between 30% and 32% may occur in normal subjects, but are suggestive of mild iron deficiency. Because haemoglobin and P.C.V. can both be determined with high and comparable accuracy, the M.C.H.C. is subject to quite a small experimental error, and is reproducible with a high degree of consistency.

Red-cell Count

The red-cell count is greatly overrated as a diagnostic aid, because the errors inherent in it are immense and the labour required by it is considerable. First, the tolerance on volume in the counting chamber is $\pm 5\%$, and that of dilution pipettes $\pm 3\%$, so that duplicate counts by different workers could be performed with instruments differing by as much as 16%. So extreme a variation would, of course, be rare, but in addition to this error of calibration is the uncertainty due to chance variations in the number of cells which settle on unit area; this random error was computed theoretically as long ago as 1879 and demonstrated practically in 1881: it is enormous.* Thus if a count of 4,000,000 per c.mm. is estimated by counting 400 cells, then there is 1 chance in 20 that the true count is less than 3,600,000 or more than 4,400,000. This range can be reduced only by counting more cells: it is halved whenever the number of cells counted is increased fourfold.

In my own laboratory I deprecate the performance of red-cell counts unless 1,000 cells are counted; my clinical colleagues rarely insist on counts when they appreciate how unreliable they are and how much labour they require.

*One count in every 20 may be expected to lie more than $(200/\sqrt{N})\%$ from the true value, where N is the number of cells counted: if N = 400, then $200/\sqrt{N} = 10\%$.

Colour Index

There are three indices which depend on the red-cell count and share with it its unreliability: (1) The colour index (C.I.) (Hb, expressed as percentage of normal ÷ red cells, expressed as percentage of normal; or, since normal red blood cells approximate 5,000,000 per c.mm., $Hb \div 20 \times$ red-cell count in millions per c.mm.). (2) The mean corpuscular haemoglobin (M.C.H.), which is the average Hb content of a cell (Hb contained in 1 ml. blood ÷ 1,000 × red cells per c.mm.: mean 29×10^{-12} g. or 29 $\gamma\gamma$). (3) The mean corpuscular volume (M.C.V.), the average volume of a cell, computed from P.C.V. and red-cell count, as follows: $P.C.V. \div 10 \times$ red cells in millions per c.mm. The normal M.C.V. lies between 82 and 95 μ^3 . Of these three indices the M.C.V. is the most important.

The colour index and M.C.H. do not discriminate between the volume of a cell and the concentration of haemoglobin therein. For example, a patient's count might be $Hb = 42\%$ or 6.2 g., red cells = 2,000,000 per c.mm., $P.C.V. = 24\%$, when $C.I. = 1.05$ and $M.C.H. = 31.2 \gamma\gamma$, well within the normal range, leading to a diagnosis of simple or aplastic anaemia. When the M.C.V. is found to be 120 μ^3 , considerably increased, and the M.C.H.C. is 26%, a subnormal value, one is led to consider a combination of pernicious and iron-deficiency anaemias—a combination less rare than might be expected and quite clearly shown in the stained film. It is its inherent inaccuracy and inability to discriminate between changes in volume and changes in haemoglobin concentration which has made haematologists spurn the colour index and adopt instead Wintrobe's "absolute indices," which facilitate precise diagnosis by separating volume changes from changes in concentration of haemoglobin within the cell. Personally, I usually reduce labour by estimating Hb and P.C.V., computing the M.C.H.C. to assess the degree of iron deficiency, and examine a film to exclude gross changes of size and shape in the cells: I find that only about one erythrocyte count need be performed for 12 to 15 determinations of haemoglobin.

Price-Jones Curve

An index of great value, which is unfortunately too expensive to perform as a routine, is the Price-Jones curve. This is performed by classifying cells according to their average diameter, and drawing the curve showing how frequent are the cells of different sizes. A normal blood yields a symmetrical narrow-based curve because the variation in size of cells (anisocytosis) is small. Severe iron-deficiency anaemia yields a curve in which the peak has moved to a smaller diameter and the base is wider because cells are more variable (anisocytosis increased): pernicious anaemia yields a relatively flat curve, with a peak shifted to a higher diameter and a very wide base (gross anisocytosis). Price-Jones curves are at present mainly of academic interest, though they may become a routine investigation when a new automatic particle counter and measurer comes into use, because this instrument should allow red-cell counts to be done automatically on several thousand cells, which could also be classified automatically into groups differing in diameter by about 1 μ .

The halometer, introduced by Pijper, of Pretoria, is a convenient instrument by which the modal cell diameter ("peak of the Price-Jones curve") can be measured accurately, and the degree of variation in size can be roughly assessed. There are many instruments available, but the simplest is that of the Association of Clinical Pathologists: it consists of a board on which are fixed two flash-lamp bulbs 28 in. (71 cm.) apart. If a thin blood film is held to the eye while looking at the bulbs in a darkened room, each light is seen to be surrounded by (from within outwards) a yellow halo, a dark zone, and a circular rainbow, the red being outside. The observer moves to and from the lights in a line perpendicular to that joining them until the outer edges of the two circular rainbows just touch. The distance from the

blood film to the midpoint between the lights, measured in feet, is equal to the modal cell diameter (peak of Price-Jones curve) in microns. Three unstained films should be measured. If anisocytosis (variation in size) is marked, the rainbows will be less distinct, and in severe pernicious anaemia anisocytosis may be so great that the rainbow cannot be clearly seen and the halometer cannot yield any measure of cell diameter, though even here it does inform one that anisocytosis is excessive.

The ingenious practitioner can devise his own halometer: in emergency I have made a white mark on brown cardboard, made a pencil hole 14 in. (35.5 cm.) from the mark, and hung the card in front of an electric light: I retire until the red of the rainbow touches the white line; then my eye is N feet from the hole, where N is the modal cell diameter of the specimen of blood.

Appearance of the Red Cell

The measures so far considered permit one to estimate the concentration of haemoglobin in the blood, and the size and haemoglobin saturation of the cell. The shape of the cell has been considered only in relation to the Price-Jones curve, and its functional activity not at all.

The shape of the cell is best assessed by examining a stained blood film which is so thin that the cells are separate. Variation in size is described as anisocytosis; it is slight in normal subjects, moderate in iron-deficiency anaemia, and extreme in pernicious anaemia. Misshapen cells are called poikilocytes, and if they are numerous poikilocytosis is said to be present and is always an indication of serious haematological disorder. An estimate of whether the cell tends to be larger than normal, about normal size, or smaller than normal can be made by eye, and these are described by the terms macrocytosis, normocytosis, and microcytosis respectively. If the film is well stained the peculiarities of staining can be seen: when the normal cell is a pinkish yellow, a few cells of slaty blue colour can sometimes be seen; if the colour is uniformly distributed, the cell is polychromatic (shows polychromasia) and polychromatic cells appear to be the same as reticulocytes. Sometimes the slaty blue colour is due to the presence of dots of blue pigment—that is, of methylene blue or other basic dye from the stain—and this is punctate basophilia, common in marked anaemias but rare in the absence of gross anaemia except in patients with lead-poisoning.

The well-stained normal red cell shows a slight central pallor, where the biconcavity is evident. Sometimes this is absent, when it is usually due to bad staining, though occasionally the cell may have a smaller diameter than usual and show no central pallor—this is described as microspherocytosis and is constantly found in congenital haemolytic anaemia (acholuric jaundice) and during haemolytic crises in haemolytic anaemias. The central pallor may increase (hypochromia) until a narrow pink rim surrounds an unstained centre—the pessary cell of severe iron deficiency. Sometimes the periphery and the centre of the cell stain densely, but there is a zone of pallor between the two; this is the target cell, or Mexican hat cell, found in obstructive jaundice, in the severest iron-deficiency anaemia, in Mediterranean anaemia, and in sickle-cell anaemia; it is an abnormally thin cell, a leptocyte, the opposite of a spherocyte.

Typical mild or moderate iron deficiency shows no such extreme change. Some cells show increase in the central pale area, and such cells are usually rather small, but there are always normally staining cells of normal size present; if the size of the central pale area varies greatly from cell to cell, one may speak of anisochromia; this is a very sensitive indication of iron deficiency even if anaemia is only slight.

Some blood samples show other peculiarities of importance. Reticulocytes may be constantly increased in conditions in which blood cells are being produced more rapidly than normal, particularly in haemolytic anaemia and in

leuco-erythroblastic anaemia. Heinz bodies are refractile bodies detected within the erythrocyte after supravital staining: they appear after administration of haemolytic poisons such as phenylhydrazine, but can be produced *in vitro* by the action of ascorbic acid. Pappenheimer bodies are basophilic bodies seen in the red cells in rare forms of haemolytic anaemia. Siderocytes contain granules in which iron can be demonstrated. Howell-Jolly bodies are basophilic bodies 0.2-0.5 μ in diameter derived from chromosomes which have failed to fuse with either nucleus because they became separated from the mitotic spindle. They are particularly common after splenectomy, and are not rare in pernicious anaemia.

There are a few congenital diseases which must be mentioned. In some patients the erythrocytes are elliptical (elliptocytosis), in others crenated: both conditions may be associated with an increased rate of red-cell destruction. They are of considerable genetic interest and should always be referred to a specialist in genetics. In patients with thalassaemia (major or minor) many cells are target cells, and foetal haemoglobin persists in adult life. In sickle-cell trait or anaemia cells appear in films as target cells, but when reduced *in vitro* or *in vivo* the cell elongates and may throw out long terminal filaments; the change occurs because an abnormal haemoglobin is present and its reduced form is almost insoluble and crystallizes out. Since the Mediterranean trait (thalassaemia minor) may have a frequency of 20% in some populations (Cyprus) and sickle-cell trait 50% in others, such as the East African pigmoids, in certain areas they may come to be regarded as "normal"—that is, usual. There are other congenital anomalies involving leucocytes—hypersegmentation, or Alder's anomaly, and failure of segmentation, the Pelger-Huët anomaly—but these are extremely rare in all populations.

The Normal Blood Count

Haemoglobin	12-17 g. per 100 ml.
Erythrocytes	4.3-6.4 mill./c.mm.
Haematocrit	42-48%
M.C.V.	82-95 μ^3
M.C.H.C.	30-35%
Reticulocytes	0-2%
Total leucocytes	4,000-9,000 per c.mm.
Neutrophil	Juvenile 0-100 per c.mm.
	Staff 0-500 per c.mm.
	Segmented 2,500-6,000 per c.mm.
Eosinophils	0-400 per c.mm.
Basophils	0-100 per c.mm.
Lymphocytes	1,000-3,000 per c.mm.
Monocytes	0-800 per c.mm.
Platelets	250,000-500,000 per c.mm.

The White Blood Cells

There are five or six different types of cell included under the generic term leucocyte, and each appears to have a special function. It is the absolute rise or fall of each type which is important, not the proportion which that type bears to the total. This makes it essential to express the differential count as N cells per c.mm.—the absolute count—and not as a percentage as was once the practice. In this way the analysis of a count is actually simplified. If one blood sample showed a leucocyte count of 20,000 and a second a count of 2,000 per c.mm., and both had differential counts of 20% neutrophils and 70% lymphocytes, one would have to think carefully to realize that in the first blood the neutrophils are normal and the lymphocytes greatly increased (suggesting pertussis) and that in the second the neutrophils are greatly reduced. If one sees the counts expressed as: (1) neutrophils 4,000, lymphocytes 14,000 per c.mm.; (2) neutrophils 400, lymphocytes 1,400 per c.mm.; the difference at once leaps to the eye.

The neutrophil polymorphonuclear cells in resting normal adults range from 2,500 to 6,500 per c.mm. The ordinary neutrophil has a segmented nucleus. Some 10% of neutrophils have, however a nucleus with the form of a bent rod without constrictions: these are the "staff forms" or "stab-

kernige" cells, a slightly less mature form; and about 1% of neutrophils have a kidney-shaped nucleus—the "juvenile" or metamyelocyte stage.

The neutrophils increase (1) on exercise—walking about may cause a rise of 500-1,000 and violent exercise a rise of 20,000-30,000; (2) irregularly during pregnancy, though rarely to above 10,000 per c.mm.; (3) when tissue is breaking down, as a result either of trauma or of necrosis due to infarction or to infection.

The eosinophil polymorphonuclear cells are usually said to range from 0 to 200 in normal subjects. Recently techniques for direct counting in a haemocytometer have been developed, and these are far more precise than the differential count; the new techniques reveal a few counts in normal subjects up to 800 per c.mm., and analysis suggests that there is no definable upper limit of normal,* although counts over 600 per c.mm. are more likely to be abnormal than normal. Eosinophils are increased in a variety of conditions in which foreign proteins enter the body—the allergic diseases (asthma, hay-fever, and some eczemas), infections with trichinellae and ascarides while the larvae are passing through the body, some abnormal antigen-antibody reactions such as exfoliative dermatitis, and collagen diseases in some patients.

The basophil polymorphonuclears number 0-100 per c.mm. and are of uncertain function.

The lymphocytes appear to be involved in the production of antibodies. Normally they number 1,500-3,000 per c.mm. and are increased in infancy to 4,000-6,000 per c.mm.; they are also increased in whooping-cough, acute infectious lymphocytosis, and lymphatic leukaemia. Abnormal lymphocytes characterized by foamy cytoplasm and an immature nucleus are numerous (500-10,000 per c.mm.) in glandular fever, and occur in smaller numbers in a variety of virus infections, notably in infective hepatitis, as well as in normal infants during the first 14 days of extrauterine life.

The monocytes are normally 0-800 per c.mm.; they are increased in the recovery phase of acute infections and in many chronic infections.

The sum total of the leucocytes is very variable, but in young men at rest it varies between 3,600 and 8,000 per c.mm., with a very few as low as 3,100 or as high as 9,300. Diurnal variation averages 1,600, but may reach 2,500. There is a slight rise between noon and 3 p.m., but no true digestive leucocytosis. The neutrophilia of exercise and of other conditions is reflected in the total leucocyte count. In infants of over 3 months and children under 4 years, lymphocytes exceed the neutrophils and may reach 6,000 per c.mm.; these two cell types are equally numerous by the age of 4 years, and thereafter slowly progress towards adult levels.

Platelets range from 200,000 to 500,000, the range varying somewhat according to technique. Increases are common in polycythaemia rubra vera and chronic myeloid leukaemia, decreases in thrombocytopenic purpura, acute leukaemia, and, more frequently each year, as a result of the administration of drugs.

Next article on Clinical Pathology.—"Laboratory Investigations in the Diagnosis of Iron-deficiency and Simple Chronic Anaemia," by Dr. George Discombe.

Refresher Course Book.—The first collection of articles in the Refresher Course for General Practitioners (fully revised) are available as a book containing 55 chapters, price 25s. Copies can be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

*The logarithm of the eosinophil count is normally distributed about a mean.

Nova et Vetera

AN EXTREMELY RARE TREATISE

On February 8 there comes to auction a book so rare that only two other copies are known, one of which is in the Wellcome Museum. This is a treatise by John Banester, published in London by Thomas Orwin for Thomas Man in 1589. The full title of this bibliographical rarity is "An Antidotarie Chyrurgicall, containing great varietie of choise of all sorts of medicines that commonly fall into the Chyrurgions use: partlie taken out of Authors, olde and new, printed or written: partlie obtained by free gifte of sundrie worthie men of this Profession within this Land. By John Banester Master in Chirurgie." This is the first edition of Banester's textbook: only one copy (not the Wellcome copy) has been exposed for auction in London during the past 50 years. In the same sale there is offered also *Epistolae Medicinales*, by Aloisius Mundelle, published in Basle about 1550.

John Banester, or Banister, was born in 1540 and began his professional life as surgeon to the forces sent to relieve Le Havre in 1563. On this expedition he met William Clowes, another surgeon, and they remained lifelong friends. For some years Banester practised at Nottingham. In 1585 he accompanied a military expedition to the Low Countries and afterwards settled in Silver Street, London. He died in 1610 and was buried in St. Olave's Church, Silver Street, but the church, with the record of his death, was destroyed in the Great Fire of 1666.

Preparations and Appliances

A CONSTANT STRENGTH TRICHLOROETHYLENE INHALER UTILIZING A NEW PRINCIPLE

Dr. T. H. S. BURNS, Research Fellow, Department of Anaesthetics, Guy's Hospital, writes: The inhaler described here has been designed primarily for the production of a constant percentage of trichlorethylene vapour in air suitable for general analgesia. The proportion of trichlorethylene vapour is kept between 0.4 and 0.6% (vol./vol.) for all types of respiration likely to be met with in practice. To date, most inhalers producing vapour from a liquid drug depend on the "draw-over" principle. The output of such inhalers is obviously affected by a rise of room temperature and also by any shaking of the liquid, which will increase the surface area exposed to the air. Any draw-over machine attempting to produce a constant output must therefore incorporate a

FIG. 1b

FIG. 1a

FIG. 1c

FIG. 1a.—Simplified cross-section of inhaler.

FIG. 1b.—Filling position. FIG. 1c.—Safety device.

thermostat or other device to compensate for changes in room temperature. It must also include some system which will minimize the effects of shaking.

This new inhaler works on the principle of delivering a fixed amount of liquid trichlorethylene into every litre of air reaching the patient. The amount of liquid trichlorethylene necessary to produce a vapour strength of 0.5% in a litre of air is of the order of 0.02 ml. This amount is readily vaporizable at the lowest room temperature likely to be met with in practice. Thus, however much the inhaler is warmed, no more than the desired amount of trichlorethylene will be vaporized. The difficulties involved in shaking are met by a needle valve cut-out device which effectively seals off the liquid trichlorethylene in the machine as soon as it is picked up. Trichlorethylene is delivered into the air stream only when the machine is on a flat surface in its working position.

Fig. 1a shows a simplified cross-section of the inhaler. Compartment A is a container which holds roughly 60 ml. of trichlorethylene. The surface area of this container

FIG. 2.—General view of the inhaler.

is large, so that the depth of the trichlorethylene is small. This minimizes any change in output due to a fall in level of the liquid. The filler (O) is arranged so that the machine is turned on its side for filling. This simplifies the prevention of overfilling (Fig. 1b). Compartment B is a "capacity" of about 1 litre. Its function is to assist in vaporizing the trichlorethylene and to act as a "damper" to reduce sudden changes of pressure during respiration.

Air is drawn by the patient under the hood (C), through the Venturi tube (D), into the capacity (B), and on to the mask via the breathing-tube (E).

The narrowing of the Venturi tube (D) causes a reduction of pressure as air is drawn through it. A jet (F) opens into the Venturi tube at its narrowest point. This jet communicates with liquid trichlorethylene at the bottom of the container (A). This container is kept at atmospheric pressure, and so trichlorethylene tends to pass via the jet into the Venturi tube when a patient inspires. Here it is mixed with the air to form a trichlorethylene/air mixture. There is a critical air flow, below which the pressure is not reduced enough to draw any liquid into the Venturi tube. The faster the air flows the greater is the amount of liquid drawn into the air stream. The resulting mixture does not remain constant but gets richer as the air speed increases. This is shown in Fig. 3.

It should be pointed out that for a "minute volume" of, say, 20 litres the maximum air speed would be of the order of 60 litres a minute at the height of inspiration.

The inhaler is designed to give an output of between 0.4 and 0.6% trichlorethylene vapour in air (vol./vol.) for types of re-

Since these episodes occur in aphasic patients, it is essential that they be recognized and understood. Misinterpretations suggesting other conditions or irascibility of the patient may result in additional discomfort to the individual.—I am, etc.,

New York.

HAMILTON CAMERON.

Clot Retention

SIR,—The copy of the *Journal* containing an annotation on clot retention (October 24, 1953, p. 928) has just come to hand in this country. No mention is made of a simple method which we have been using in Auckland Hospital for several years now in practically all cases of severe clot retention which cannot be cleared by irrigation through a large whistle-tipped catheter.

The method consists simply in evacuating the clot through a special large direct vision cystoscope (approximately F 30), with the patient anaesthetized and in the lithotomy position. The instrument, by the way, is used purely and simply for evacuation of blood clot (as in clot retention) or of stone fragments. The clot can be clearly seen in the bladder when the irrigating system is turned on. The instrument is plunged into the centre of the clot, the irrigation turned off, window removed, and, with a to-and-fro shake of the shaft of the instrument, clot is easily evacuated in large quantities. The process is repeated till the bladder is empty, the operation being easier if the table is tipped with the patient in the "buttocks low" position for the final stages. A bladder full of clot can be emptied in a few minutes, and haemorrhage usually stops as soon as the bladder is empty. The method avoids an open operation and has the advantage over the Bigelow evacuator (mentioned in the annotation) that the procedure is done under vision, and one therefore knows as soon as the bladder is empty.

I was under the impression that this method was now generally adopted, and was thus surprised to find no reference to it in the annotation.—I am, etc.,

Auckland, C.I.,
New Zealand.

L. I. PARTON.

Reaction to Blood Transfusion

SIR,—Justifiably or not, the physician must frequently bear the onus when severe or fatal transfusion reaction has occurred even though his judgment in transfusion practice is often pitted against the emotions of importunate families which in turn have drawn their impressions of transfusion benefit from television promotional campaigns by national blood-collecting agencies.

Dr. G. Discombe (*Journal*, July 5, 1953, p. 45) suggests that dextran infusion would serve as well in many cases where blood had previously been thought to be the proper infusion medium. As Dr. Discombe points out, dextran is an alternative and does have the merit of not conveying homologous serum hepatopathy, but one must not assume that this material is innocuous. All mucinoids, synthetic as well as natural, have "blocking antibody" propensities, and dextran is no exception. It is, furthermore, a sufficiently powerful "conglutinin" that 3% dextran has replaced 20% albumin in the various compatibility testing techniques where weak, incomplete, or dilute haemagglutinins are sought. Four per cent. dextran, a concentration which could be achieved in the affluent veins of a recipient, will itself act as haemagglutinin in the bloods of 20% of subjects with increased circulating glycoprotein. One per cent. dextran, an accomplished concentration in the circulating plasma of any recipient of one 500-ml. unit, will, by its presence, raise any potential anti-A titre in this recipient four-fold and any potential rhesus-type antibody titre as much as eight-fold; these figures result from actual titration of the conglutinative effect of dextran on bloods of normal subjects and of those with adaptation disease. The inference derived from these titration figures has been borne out by the conversion of a blocking-type auto-antibody in the plasma of blood dyscrasia and neoplastic disease subjects to direct haemagglutinins

through dextran infusion. For this reason, reaction to plain dextran infusion (not to mention combined blood-dextran) comprising any or all the features of incompatible transfusion reactions is to be anticipated as the result if this material is extended. Likewise for this reason an *in vitro* compatibility test of the dextran to be infused with the citrated blood or unwashed erythrocyte suspensions of the prospective recipients, along the lines of ordinary "minor-side" match, should never be omitted. Some patients will then be found as unsuitable for dextran infusion as they are for blood transfusion, and we will get just as much into the habit of characterizing unsuitable recipients as we now characterize unsuitable donors, if we are careful to perform such compatibility tests on all infusion colloids.

In covert transfusion reactors, there is usually an increase in the mucoprotein component of the α and β globulin fractions of their plasma; these glycoproteins are demonstrable panhaemagglutinative "blocking" antibodies, having properties similar to the "rhesus antibodies." Some evidence is available to indicate that they arise from that depolymerization of the mucopolysaccharide (hyaluronate-like) ground substance which accompanies, that depolymerization being an accompaniment of severe decompensatory adaptation reactions.—I am, etc.,

New York.

A Cosmetic Amputation

SIR,—Judged by the experience of those who serve on medical appeal tribunals, there is little doubt that the "cosmetic amputation" is now used as a routine by many surgeons, when the marginal fingers require amputation. Although in agreement with Sir Heneage Ogilvie (*Journal*, December 12, 1953, p. 1322) and Professor B. McFarland (*Journal*, January 16, p. 159) that a mobile intact metacarpal with good skin cover is of considerable functional importance to every working man's hand, it would perhaps be unwise to recommend the more distal level of amputation as a routine practice.

Hand surgery is more concerned with the primary level of finger amputation immediately following major hand injury than with what Professor B. McFarland terms "the second bite at the cherry." By implication the "second bite" condones the old teaching in the treatment of major hand injury—namely, "Save all you can at the primary operation and undertake definitive repair at a later date." There is now abundant evidence that the quality of the functional end-result following major hand injury to workpeople is conditioned by the "first bite"—that is, the primary operation. Further, very few, if any, British workmen benefit from, appreciate, or will agree to a series of hand operations.

Immediately following a major hand injury surgical planning can be definite on two matters. Its first aim is to prevent any degree of infection; secondly, a picture of the final functional end-result attainable (in a given injury) should be clearly in the surgeon's mind. To prevent infection, skin cover of the whole wound must be complete at the end of the first operation. In a working man's hand the palm should, if possible, be covered by palmar skin; no other skin in the body is capable of increasing or decreasing the thickness of its horny layer in response to functional demands, no form of skin graft can fully replace the functional quality of palmar skin. Not infrequently in major marginal finger injury, palmar cover by palmar skin is possible only after sacrifice of part or whole of the marginal metacarpal. Therefore there are some real indications for the high level of amputation even when the metacarpal bone has been left intact.

Sir Heneage Ogilvie has been quite specific in his advice and criticism, but his is quite a small bite of a very big cherry. The economic importance of hand injuries to workpeople and their cost to the community are well known. Surely the full challenge is to the organizing

ingenuity of British surgery to provide a good standard of surgical treatment of all injured hands at the acute stage. Further, in the surgery of hand injury, important surgical principles are involved which could well be taught to all undergraduates on a clinical background they would readily understand.—I am, etc.,

Birmingham, 15.

WILLIAM GISSANE.

Fatal Bronchial Asthma

SIR,—I quote sentences from consecutive articles in the same *Journal*: "In the asthmatic patient with an infective sputum penicillin should be given in anticipation of bacteriological results" (Drs. C. Kelman Robertson and K. Sinclair, *Journal*, January 23, p. 187). "It is important that the acute exacerbations [of acute bronchitis] be treated energetically, with antibiotics..." (Mr. John Fry, p. 190).

I think these two sentences, although unfairly taken from their contexts, should be made an excuse to express a warning against the indiscriminate use of antibiotics, especially the broad spectrum variety, in chronic bronchitis and asthma. I know of one sufferer whose death was hastened by the administration of chloramphenicol which thickened the sputum until it could not be expectorated, plugged the bronchioles, and precipitated right ventricular failure. He might well have lived through another summer with more conservative treatment.—I am, etc.,

Cosham, Hants.

V. H. MARTINDALE.

SIR,—The review of cases from the Edinburgh Royal Infirmary by Drs. C. Kelman Robertson and Kenneth Sinclair (*Journal*, January 23, p. 187) is of great value in recording deaths caused by an attack of asthma as opposed to those caused by secondary effects leading to pulmonary failure, etc.

To my mind, the most important finding in these cases is the 100% marked plugging of the bronchi. It is my experience as a bronchoscopist that some cases of "status asthmaticus" which fail to respond to the usual treatment can be relieved by bronchoscopic suction of gelatinous tenacious mucus, and I submit that, in this type of case, bronchoscopy is the measure which gives the patient the best chance of survival, and should always be tried.—I am, etc.,

London, W. 1.

A. M. ZAMORA.

The Winter Vomiting Disease

SIR,—I was extremely interested in the short article on "The Winter Vomiting Disease," by Dr. J. F. Goodall (*Journal*, January 23, p. 197). This Health Department investigated a quite extensive outbreak of infective hepatitis in the city of Exeter during 1953. This was only made possible, of course, by the willingly extended co-operation of the general practitioners practising in the city.

During the course of our investigation we were faced with the occurrence of quite a number of cases in children of general upset, nausea with or without vomiting, abdominal pain, and diarrhoea with the passage of very pale stools, but these cases showed no icterus. We formed the opinion that we were probably dealing with acute non-icteric cases of infective hepatitis, and in this opinion we were fortified by an article by Capps and Stokes in the *Journal of the American Medical Association*.¹ I am therefore interested in the grounds upon which Dr. Goodall came to the conclusion that infective hepatitis could be confidently excluded in his series of cases.

The syndrome of winter vomiting disease had a personal interest for the writer, for in the middle of a morning clinic at this time he suffered extreme nausea and sharp abdominal colic such as to cause him immediately to take up a strategic position in the small annexe to his clinic. In the event, however, he did not vomit, and by the afternoon was feeling quite well again. It is of interest that he had had a moderately severe attack of infective hepatitis in 1947. I am glad that Dr. Goodall has struck a blow at the facile diagnosis of "gastric flu," which satisfies the layman so easily

and only confuses the epidemiologist, and congratulate him on a most useful and needed piece of research in the true Pickles tradition.—I am, etc.,

Exeter.

Death Rate in Singapore

SIR,—Some recent figures received of the crude death rates of the City of Singapore record such an improvement that I think the people in the British Isles should know of them.

In 1911 I was asked by the able Health Officer, W. R. C. Middleton, to advise what could be done to reduce the high death rate by reducing the malaria. At that time Mr. R. J. Wilkinson—later Governor of the Gold Coast—was Colonial Secretary. The population of Singapore was then roughly 280,000 between 1912 and 1919. In 1911 the peak of the death rate was 85.83. The average crude death rate from 1892 to 1911 was 42.33, and from 1912 to 1919 was 34.79. The last report for the year 1951 for the City of Singapore with a population of 747,947 was 12.73. There had been 54 cases of malaria.—I am, etc.,

Peaslake, Surrey.

MALCOLM WATSON.

Training General Practitioners in Psychotherapy

SIR,—The article by Dr. Michael Balint (*Journal*, January 16, p. 115) emphasizes the deplorable state of things which we all know to exist. At least half of the cases seen by the family doctor are in need of psychotherapy, but although he may recognize that need he does not know how to respond to it. At the specialist level the psychiatrist is overwhelmed and can only deal effectively with the more advanced cases. The remedy is undoubtedly to interest and educate the general practitioner. The courses arranged by Dr. Balint for that purpose are admirable in conception and practice, but they cannot do more than influence a very small section of the medical population.

Between the wars the doctor had a much greater interest in medical psychology than he has now, and working in a large city I was able to encourage that interest by sending back full reports on the cases referred to me, and often succeeded in encouraging the practitioner to deal with a proportion of his own cases. That sort of relationship does not now appear to exist between the hospital psychiatrist and the G.P., and the natural interest of the doctor is small. The sweeping victories of biological research have given the education of the medical student a materialistic bias, just as happened in the first half of the nineteenth century when specific germs were found to be responsible for specific diseases. Medicine has to retrace its steps, and the only way to do that is to keep the psychological aspect of man and his *dis-ease* before the student throughout his whole medical course.—I am, etc.,

Scarborough.

R. MACDONALD LABELL.

Medical Needs in the Gold Coast

SIR,—I would like to make a few comments on Professor Ian Fraser's letter (*Journal*, January 23, p. 214). This is a matter in which I am deeply concerned, for I am a West African recently returned to this country, after six years' work on the Gold Coast, to attempt to complete my specialist training.

Facilities on the Gold Coast are poor and conditions are very unattractive especially to doctors who have no permanent interest in the country. The climatic conditions are such that retired practitioners of advancing years are likely to suffer ill-health and be quite unable to maintain any real degree of efficiency. The short-term service, although it would introduce more highly qualified men into the Colony, does not allow for continuity of service or interest.

The solution to me is apparent. It is the provision of an adequate number of well-trained Africans, permanently domiciled in their home country, who, equipped with an intimate knowledge of local problems, and with the real

interests of their country and people at heart, can capably deal with all contingencies. The present difficulty is for these men to obtain specialized training. This cannot be obtained on the Gold Coast, and we look naturally to Britain to help in this matter. It is, however, almost impossible for an African, even though educated in England and a graduate of London University, to obtain any suitable junior post in his chosen specialty. This difficulty almost precludes the African graduate from even fulfilling the requirements for admission to the more important higher qualifications. It is little wonder that with only a handful of basically qualified practitioners the semi-literate population is easily hoodwinked by the unqualified practitioners who flourish in these territories. Unfortunately, there is no adequate legislation on the Gold Coast for dealing with these charlatans.

May I finally make a plea for the more sympathetic approach to the African seeking a suitable house appointment in this country? The Briton who is genuinely interested in the Gold Coast Medical Services can best help us by providing us the opportunity for the first-class training that British hospitals offer.—I am, etc.,

London, W.12.

R. H. BANNERMAN.

The African in Industry

SIR,—I would like to thank Dr. J. H. Jackson for his bold article on the African in industry (*Journal*, January 9, p. 93). The appalling medical and social problems are not sufficiently well known, and public opinion ought to be better informed. In addition to the fearful medical needs of the miners in Southern Africa there exists an increasing moral and spiritual decline which is inevitable in such conditions. It is a burning shame that such chaos can exist in Commonwealth and colonial territories, and everything possible should be done to prevent unplanned exploitation of labour in the development of further industrial resources in these and other African territories. The co-operation of Governments and missions to alleviate and prevent this suffering is very greatly needed.

Dr. Jackson has set a good example in bringing these problems to our notice. Surely it is the duty of our profession, whether as medical missionaries or in Government service, to do so.—I am, etc.,

Cobham, Surrey.

RALPH SCHRAM.

Doctors' Handwriting

SIR,—People do not as a rule boast of their lack of skill in using tools, and a man who habitually takes four putts keeps quiet about it. Parsons and actors who cannot make people hear do not boast of their inarticulate speech, but a great many people speak of their bad writing as if there was something rather clever about it. One would have thought Hamlet had exploded that idea long ago: "I once did hold it, as our statists (statesmen) do, a baseness to write fair." But it is still common for people to believe that illegible writing is a sign of "strong" or in some way desirable character, though it is hard to see how this can be.

Writing is part, and an important part, of a doctor's job. It is idle to say typewriting has superseded it; it has supplemented it—no more. Every medical practitioner carries a pen, even those who never use a stethoscope. If what you see of a man's work—his writing—is careless and slipshod, what reason have you to suppose that his diagnosis and treatment are painstaking and accurate? "Doth a fountain send forth at the same place sweet water and bitter?" There was a time when doctors did not want their patients to know what they were taking, and wrote their prescriptions illegibly on that account. But are we really to believe that every illegible N.H.S. prescription is truly and accurately dispensed? If the chemists sent every patient with an illegible prescription back to the doctor who wrote it to have it made plain, some doctors' surgeries would take about twice as long as they do now, and whose fault would that be?

One of the G.P.'s complaints against the hospitals is not only that they inform him of his patients' discharge or

death about a fortnight after it has taken place (instead of the same day, which would take no longer), but that they cannot read the letter when it comes. Ideally, an examiner should plough quite ruthlessly every candidate whose writing he cannot read; but of course it should also be possible to say of him, as of Chaucer's *povre Persoun*, "he taughte and first he folwed it himselfe."

The writer who tries to save his own time regardless of that of his correspondent is no better than the man who pushes his way first through the door and lets it slam in his neighbour's face. It would be good if some great man were to institute an annual "National Handwriting Week," but, failing that, I ask you, Sir, to lend your authority to the cause of legible handwriting.—I am, etc.,

Norwich.

FREDERICK MOOR.

Hospitals and the Public

SIR,—I was interested in the annotation on this subject (*Journal*, January 9, p. 89). One of the ways in which hospitals could be of much greater service to the public is by providing really adequate accommodation for relatives who have to wait for many hours while a patient is on the danger list. It does not require much imagination to realize that those hours are probably the most distressing that human beings can endure. Anything which can be done to alleviate their distress or add to their comfort at such a time should be regarded as of paramount importance. Unfortunately, in a great many hospitals the accommodation is lamentable; often not more than a draughty corridor with benches or a few hard chairs, or a depressing institution-like room, ill-lit, and without any kind of comfort. No attempt is made to make it cheerful or pleasant. I have tried to find out where the responsibility lies for the provision of such an amenity, but it seems that in many hospitals it is nobody's business. Such an amenity should surely be considered by those who have the handling of amenity funds, or alternatively it could be one of the functions of the voluntary workers who are attached to practically every hospital. It ought to be possible to have such a room properly decorated and furnished, and supplied with flowers and journals, without incurring any great expense.

I feel sure that this is just one of those things that has not been realized, and that once it has been brought to the attention of the hospital committee or voluntary workers there are many people who would be only too glad to help in this way. The pamphlet, *The Reception and Welfare of In-patients in Hospitals*, issued by the Central Health Services Council in 1953 (p. 12, para. 33, H.M.S.O., price 9d.) draws attention to this problem: "Patients who are dangerously ill may have visitors at any time, and a special problem arises when relatives have to attend the hospital for fairly long periods at irregular hours. Provision for their comfort during long waits is difficult with the present restricted accommodation, but the staff should try to ensure that they are made comfortable in accommodation as near the ward as possible during their periods of waiting. Visitors' toilet accommodation in particular is often inadequate." It should also be noted that the relatives are entirely dependent on the good will of the nursing staff for such amenities as a cup of tea or something to eat, since no provision is made for this.—I am, etc.,

London, W.9.

DORIS ODLUM.

Evidence of Gout

SIR,—Dr. Oswald Savage's article on the clinical pathology (*Journal*, December 26, 1953, p. 1424) is very interesting, but the signs and symptoms of gout are so pronounced that the pathologist's aid in its diagnosis is very rarely needed.

Gout, as is known, may occur almost anywhere from tendon sheaths to the knuckles of the fingers, and as a personal sufferer, as also is my brother, I am more than interested when an attack occurs in any of my patients. In my opinion gout is due to auto-intoxication from bowel or liver or kidney; or to a combination of all three not pulling their weight and allowing absorption of excess of

acid into the blood stream. In some cases there is a definite cycle, an acute attack lasting 7–10 days. During this period it may clear up in one place and then attack another. A bilious attack follows with some constipation, and excretion of urine is lessened. A few days, or it may be a few weeks, free and then another attack. An attack may be, and frequently is, started by some slight traumatic injury. It occurs much more often in males, but I have in the last fortnight seen it occur in three females, all of them having passed their menopauses.

What of the cure? Is there anything that will give permanent relief? The colchicum compounds, cinchophen ("atophan"), and the like, eventually, but only temporarily, relieve the condition, but they have the disadvantages of upsetting the digestion, the bowels, and the cardiac rhythm. I have found that "leucotropin" is the least upsetting and most efficient drug, with a tablet of "veracolate" at night. A Scottish doctor friend of mine says he has permanently cured himself by taking daily a tablet of vitamin B, a couple of oranges, and a small whisky with hot water as a nightcap. Another, who used to be a great sufferer, swears by a veracolate tablet every night. A French friend of mine—in France, a wine-drinking country, the incidence of gout is very much less than in England—advises me to drink claret as a specific.

But surely the time has come for concentrated research to find a permanent cure for this most painfully distressing and disabling complaint. Could there be any link between gout, migraine, and narcolepsy—another very prevalent disease?—I am, etc.,

Norwich.

P. B. CORBETT.

Ferrous Sulphate Poisoning

SIR,—In view of the letter by Mr. A. Elliot-Smith and Dr. Pamela Davies (*Journal*, January 16, p. 156) we would like to report another example of ferrous sulphate poisoning, this time a fatal one. In our department we have seen 15 cases in the last seven years, and this is the second fatal one.

A baby aged 14 months swallowed about 50 ferrous sulphate tablets three hours before admission. The child vomited soon after swallowing the tablets. In spite of gastric lavage and intravenous therapy the child died 24 hours later. Necropsy showed the stomach to be denuded of its lining, with considerable blood in the intestines. There were bilateral adrenal haemorrhages. Macroscopically, the liver looked normal.

We hope this further case will strengthen the attempts to force the hand of the manufacturers of "green, sugar-coated ferrous sulphate pills" to do something to prevent these disasters, if only to alter their fatal (literally) attractiveness to small children.—We are, etc.,

Penarth, Glam.

Sterilization of Ampoules

SIR,—Your correspondents, Professor L. P. Garrod (*Journal*, December 5, 1953, p. 1269) and Dr. D. Reckless (*Journal*, January 9, p. 100), speak of the dangers of storing ampoules of solutions for spinal injections in disinfectant solution.

A considerable deal of discussion has taken place on the various ways of sterilizing these ampoules, each protagonist believing that he is describing the ideal method. Dr. Reckless believes in boiling the ampoule; Professor Macintosh¹ advocates steam sterilization; Dr. Dawkins² believes that the ampoules should be kept in tins in which are placed formalin tablets. "... Doctor and Saint, and heard great argument about it and about..." May I suggest that the real question is not, "How to sterilize," but rather, "Should these ampoules be sterilized at all?"

Some time ago it was pointed out by Hewer and Garrod³ that it is wiser to treat all ampoules with gummed labels as frankly

unsterile and not to attempt to sterilize them. Since this was written it has been my almost invariable practice, and in an attempt at a modicum of standardization I have extended it to the treatment of those ampoules which have their contents etched on the glass. I believe that this procedure has certain advantages. To begin with, the ampoule is under the supervision of the anaesthetist from the moment it is taken from the maker's carton until the time he injects it. There is no risk of contamination by sterilizing fluids: the ampoule is never out of the anaesthetist's sight, and its contents are not liable to the chance (remote, I will agree) of change from boiling or steam sterilizing. The ampoule is opened by a nurse: she then holds it by the base, or puts it on a flat surface. It then behoves the anaesthetist to draw it up into his syringe without touching the neck or the sides of the ampoule. This can quite easily be done, but, should the sides be touched with the drawing-up needle, it and the ampoule should be abandoned.

Of the various ways of sterilizing the ampoule, that by steam appears to be the nearest to perfection. Nevertheless it does entail the ampoule passing out of the anaesthetist's control, and I am further disturbed by the thought that inexperienced anaesthetists may, in the absence of facilities for undertaking this, forget that it is possible and permissible to manage without any sterilization of the outside of the ampoule, and may resort to alternative methods with their consequent hazards.

May I make one point clear? I am expressing here a personal opinion based on experience of this technique and on my own thoughts: no more, no less. I make no didactic claim that steam sterilization is wrong; there should be no such statements in the light of our present knowledge of the subject. I offer an alternative for those not wholly convinced about the wisdom of attempting to sterilize ampoules.—I am, etc.,

London, S.W.15.

Senecio Alkaloids and Liver Cancer

SIR,—In a recent paper Hill *et al.*¹ described the occurrence of a liver disease in young children of African extraction in Jamaica. This was characterized by an enlarged sometimes tender liver, varying degrees of ascites, and hepatic cirrhosis in chronic cases. Most of the 150 children examined seemed in quite good nutritional state (particularly those who had asymptomatic liver enlargement), except a group of 11 children in which generalized oedema and other signs of what is known as "kwashiorkor" were present. In the histories of the latter children loss of appetite was recorded for 1–3 months and treatment with "bush tea" as a home remedy. Bush tea is described as an infusion of various unspecified plants, which seems to be a staple supplement of babies' diet among the Jamaican negroes of African extraction. The authors suggested that a low protein diet and possibly a toxic constituent of the bush tea may be the aetiological factors of this liver disease in children.

During the last few years we have been studying the production of primary liver carcinoma in rats by feeding different senecio alkaloids under a variety of conditions. In the course of these experiments many features described by Hill *et al.* as characteristic of "serous hepatitis," as well as those of kwashiorkor² have been frequently observed. These included enlarged liver with fibrosis and haemorrhage into the enlarged sinusoids, pleural and peritoneal effusion of serous fluid, and sometimes subcutaneous or generalized oedema. With larger dosage of alkaloids loss of appetite and stunted growth were seen, even though the animals received the fully adequate normal diet *ad libitum*. These features have been observed in the early stages of treatment with alkaloids of *Senecio jacobaea* L.,³ as well as with isatidine, a senecio alkaloid from South African plants kindly supplied by Professor F. L. Warren, Department of Chemistry, University of Natal, Pietermaritzburg (the details of the latter experiments will be published elsewhere).

Senecio plants are widely distributed throughout the world, and are known to be favourite remedies of the African

negroes, who use them for a variety of disorders, including charming away bad dreams of babies (compare Watt and Breyer-Brandwijk⁴ and Cook *et al.*). It is not unlikely that senecio plants are included in the bush tea or other home remedies for babies used by negroes in Jamaica, who are known to have preserved their old African customs and beliefs. Thus it is possible that senecio alkaloids are the aetiological factor of serous hepatitis and kwashiorkor in children, while malnutrition may develop as a consequence, or be a concomitant factor.

Whether the liver changes seen in children in Jamaica give rise to primary liver carcinoma in adults (as is the case in the experimental rats) is an interesting problem which requires to be investigated.—I am, etc.,

Glasgow, C.3.

Whither Anaesthesia?

SIR.—The letter "Whither Anaesthesia?" by Dr. C. Langton Hewer (*Journal*, January 2, p. 42) is most timely. In recent years, new drugs which have not been fully investigated have been used by people who do not possess the necessary facilities for adequate appraisal. One reason why this happens may be due to the impression, particularly amongst junior anaesthetists, that when applying for a post it is to their advantage to produce evidence of original work. When, therefore, a new drug appears, it is liable to be seized upon, tried out on a few cases, and written up as quickly as possible. The fact that a candidate for a post has written an article may impress a committee, but it does not provide evidence that he is a sound and careful anaesthetist. A safer and more efficient method of assessing the value of a new drug would be for it to be distributed to certain groups or individuals who are recognized by their colleagues as reliable investigators. Having made a thorough trial of the drug, each group should draw up a report and all information, together with any necessary warnings, should then be published.—I am, etc.,

Manchester.

CHARLES E. SYKES.

Controlled Hypothermia

SIR.—The use of an antihistamine drug such as promethazine ("phenegan") seems very reasonable before a major operation, as also does the use of chlorpromazine, which reduces metabolism. Patients who have had these drugs pre-operatively come to the theatre somnolent and co-operative—rather as though they had been given a light dose of bromethol ("avertin"). Much less general anaesthesia is required and also smaller doses of relaxants. So far as my limited experience goes they certainly seem to protect the patient from shock—and in the post-operative period the patient's condition is excellent.

If a sense of proportion is maintained in the use of these drugs, I think they will take their place as useful agents in anaesthesia.—I am, etc.,

Hove.

J. H. CRAWFORD.

College of General Practitioners

SIR.—While in England in 1952, I became interested in the formation of the College of General Practitioners. With the establishment of a New South Wales Regional Faculty of the College just completed, I thought a few words on the reaction of practitioners in Australia to the College might be of interest to your readers.

In this country the College has been received with widespread enthusiasm. Following the lead of New South Wales, regional faculties are now being formed in Queensland and Tasmania. In New South Wales requests for nomination forms are being received from all parts of the State. The

New South Wales Faculty sent a cable to the parent body on the occasion of its first annual general meeting, and this expressed the feeling of the vast majority of practitioners here. Congratulations were offered on the successful completion of the first year of operation, and particular pleasure was expressed at the appointment as president of so distinguished a general practitioner—Dr. William Pickles.

It is felt that the activities of the College will make an important and long overdue contribution to medical education in the future, and will go a long way toward improving standards of practice.—I am, etc.,

Cessnock, N.S.W., Australia.

W. A. CONOLLY.

SIR.—At the Old Bailey recently an employee of the College of General Practitioners was convicted of obtaining money from the bank by forgery. We would like it known that the College's bankers have now re-credited the College's account with the whole of the sum involved. We are, etc.,

G. F. ABERCROMBIE,
Chairman of Council.
H. L. GLYN HUGHES,
Hon. Treasurer.
J. H. HUNT,
Hon. Secretary.

London, E.C.4.

Acetone Tests on the Bed-sheets in Diabetic Coma

SIR.—In the diagnosis of possible diabetic coma in an unknown unconscious patient, it is imperative to know at once if ketones are present in the urine. If the patient is inconsiderately incontinent and no sample of urine available, as happened at King's last week, need we be balked? Indeed not. We rubbed some mixed Rothera's crystals in the wet sheet, dropped on a little strong ammonia, and a beautiful purple patch spread out and confirmed the diagnosis. Indeed, the sheet responded to the ferric chloride test with an appropriate red-wine colour. The diagnosis had been complicated by a series of confusing epileptiform fits.

This is just a little tip which may be useful some time. I am, etc.,

London, S.E.5.

R. D. LAWRENCE.

Histology of Acrosclerosis and Allied Conditions

SIR.—Acrosclerosis is of interest to dermatologist, physician, and surgeon. At a recent conference on the subject in Leeds it was felt that more information was required on the histological changes in this and in the allied conditions of Raynaud's disease and generalized scleroderma. Material is being collected for further investigation, and it would be appreciated if colleagues, medical and surgical, making biopsies of skin, gut, lung, or other tissues in this field would send some unstained sections to be added to this collection to the Dermatological Department, The General Infirmary, Leeds.—I am, etc.,

Leeds, 1.

JOHN F. INGRAM.

Foreign Bodies in the Lung

SIR.—I was interested to read Dr. Bernard Laurance's account of a boy of 5 who developed a lung abscess as the result of inhaling an ear of barley (*Journal*, January 16, p. 125). In 1943 a small girl was admitted to hospital with a lung abscess. While on postural drainage she coughed up part of a spike of wild barley. Following this the symptoms completely subsided.

If any of your readers has idly placed a spike of wild barley in his mouth with the base of the seed cluster pointing towards the throat he will appreciate the mechanism of these accidents. With every movement of the tongue the barley migrates backwards at a surprising rate and becomes difficult to extract once it has reached the back of the mouth. It is easy to imagine the barley moving in this way over the back of the tongue and through the glottis. The reason for this migration is that the hairs on the barley grains are barbed and impart to the spike a unidirectional motion. It

is significant that the second of Dr. Laurance's cases had inhaled the fruit of the common agrimony. This has a ring of hooked bristles at the top.

I suggest, therefore, that there is a difference between the mode of entry of these barbed seed clusters and the inhalation of compact objects such as nuts. A nut may be drawn into the trachea by one incoordinate inspiration, whereas it seems probable that barbed seeds creep to their destination.—I am, etc.,

Bridgend, Glam.

A. W. FOWLER.

Medical Museums: Information Wanted

SIR.—The Museums Association is engaged in producing a revised edition of its *Directory of Museums and Art Galleries in the British Isles*, and I shall be grateful if I may appeal through your columns for information about medical museums and teaching collections.

Only those museums and collections to which the public is admitted either freely or by special arrangement will be included in the *Directory*, and it is details of these which I am most anxious to have. It would, however, be of much use to the Association to have in its records a complete list of medical museums and medical teaching collections in the country, including those to which the public is not admitted, and details of all museums and collections would therefore be greatly appreciated. In the first instance, the information requested is limited to the name and address of each museum or collection, the title of the official in charge from whom further details could be requested if required, and whether the public is admitted.

I should be very grateful if those concerned would send this information to me at the Museums Association, Meteorological Buildings, Exhibition Road, London, S.W.7. I am, etc.,

J. A. SIDNEY STENDALL,
Directory Editor.

The Three Hospitals Orchestra

SIR.—In June, 1952, some members of the St. Mary's Hospital Musical Society approached members of similar bodies at St. Bartholomew's and St. Thomas's Hospitals to find out if they were interested in the formation of a combined orchestra. At St. Mary's Hospital there already existed a small orchestra which had survived for just over a year, but which was gradually succumbing to the depredations which approaching examinations, increasing pressures of hospital duties, and movement of the newly qualified staff inevitably impose on an orchestra recruited from a single hospital. Now well into its second year, the Three Hospitals Orchestra, under the conductorship of Mr. Norman Del Mar, can claim to be fully established, and has to its credit four public concerts, in three of which distinguished soloists have given their services.

Some of the difficulties, however, which beset the parent organization still remain, and even the combined resources of the three hospitals concerned have not always been adequate to make good the periodic loss of instrumentalists. My committee has therefore decided that the time has come to cast our net more widely, and we would now welcome players from all London hospitals (teaching and otherwise) who might be interested in the formation of a United Hospitals Orchestra. Might I, Sir, through the medium of your *Journal*, appeal for any hospital instrumentalists who would be willing to join us? The present orchestra comprises consultants, physiotherapists, housemen, nurses, and students, with the addition, from time to time, of a few professional musicians who have helped us out at rehearsals and concerts.

Any amateur orchestral player from any London hospital who would like to join us, or to obtain fuller information, should apply to: Geoffrey Spencer, Esq., Honorary Secretary, Three Hospitals Orchestra, 8, Hill Road, London, N.W.8.—I am, etc.,

London, W.2.

HARRY L. THORNTON,
Chairman.

Obituary

H. F. MOORE, M.D., D.Sc., F.R.C.P., F.R.C.P.I.

Professor H. F. Moore died at his home in Dublin on January 25, after a very short illness, at the age of 66. He was one of the leading medical men in Ireland.

Henry Francis Moore was born at Cappoquin, Co. Waterford, where his father was an engineer engaged in railway construction. He studied in University College, Dublin, where he graduated in medicine, with first-class honours and first place, in 1912. After serving as a house-surgeon in the Mater Misericordiae Hospital he was awarded a travelling studentship and proceeded to Germany in 1913. The outbreak of the 1914 war forced him to return home after about a year. This proved to be a decisive point in his life. He went to the Rockefeller Institute for Medical Research in New York, working there for four years. At this time researches were being conducted into the value of inorganic copper compounds in pneumonia. He was for some time engaged in this work, on which he published his first papers. During this time he made personal contacts and friendships which he maintained throughout his life, and he married Miss Frances L. Thomas, who was his constant support and companion until her death early last summer.

Admitted M.D. in 1917, he was appointed to the staff of the Mater Misericordiae Hospital on his return to Dublin. Academic and other honours came quickly. In 1922 the degree of D.Sc. of the National University of Ireland was conferred on him for his published work. He obtained the M.R.C.P.I. in 1930, and was elected F.R.C.P.I. in 1932. From 1932 to 1934 he was president of the Section of Medicine of the Royal Academy of Medicine in Ireland, and in 1933 and again in 1952 he was president of the Section of Medicine when the British Medical Association held its Annual Meeting in Dublin. In 1938 he became M.R.C.P. and was elected F.R.C.P. in the following year. He was a member of the Medical Registration Council of Ireland and of the Medical Research Council of Ireland, in each case from the foundation of these bodies. In 1927 he was appointed professor of medicine in University College, Dublin, and occupied the chair until his death.

We are much indebted to Dr. EDWARD T. FREEMAN for the following appreciation: Henry Moore returned to Dublin at a very favourable moment. His careful laboratory training in New York and the scientific approach to problems which he had witnessed and taken part in equipped him to be the forerunner in the introduction of these methods to Irish medicine. In the Mater Misericordiae Hospital he was instrumental in setting up and equipping a biochemical laboratory long before such a department was operating in any medical school in Ireland. He was also in the very beginning of electrocardiography and in the treatment of diabetes by insulin, and of the investigation of thyrotoxicosis by observation on the basal metabolic rate. Henry Moore made many contributions to medical journals—to the *Journal of Experimental Medicine*, to the *British Medical Journal*, to the *Quarterly Journal of Medicine*, the *Lancet*, the *Irish Journal of Medical Science*, and others. Two years ago, through his influence, the firm of Merck placed at the disposal of the Medical Research Council of Ireland a supply of cortisone valued at over £10,000, for the purpose of research. Already suffering from hypertension and knowing the need to go more slowly, he threw himself into this activity with all the enthusiasm of his youth. He

The question of putting fluorine into water was a much more difficult one. A great deal of work had been done in the United States which showed that apparently it stopped dental caries. He thought that it was not entirely proved, and he felt sure that if the Government embarked on an experiment they would merely raise the total quantity to one part in a million—which already existed in many of the water supplies in this country. As people had been drinking water with one part of fluorine per million ever since water was first drunk, with no great trouble, he could see no particular danger in that.

The New Truth

LORD WEBB-JOHNSON said that the attitude of the medical profession towards disease had changed radically in the past century. They were no longer agents for the recognition and treatment of disease, but pioneers in the effort to prevent it. The new truth was often opposed by a fixed opinion or by a bias, and it was necessary to find out whether the opposition was based on scientific principles or arose from total conservatism.

Iodine was an essential to the healthy functioning of the thyroid gland. Fifty years ago, when he saw Kocher operating on goitres in Switzerland, there was no idea how its incidence could be prevented or diminished. Thirty years ago, in Cleveland, Ohio, he saw George Crile operate on 20 goitres in a morning. Crile's whole object was to find out why the people were getting goitres, and how to prevent it. Last week Crile's son was over here, and told him that now in Cleveland he operated on possibly one or two goitres a day, and some days none. Lord Webb-Johnson asked, "Is it because you have iodized salt?" The reply was, "It may be, but we do not dismiss other possible factors. For instance, in Cleveland to-day half the vegetables eaten are grown outside the area, which is an area of endemic goitre. They are grown in the West, where the soil is saturated with iodine, and they get their iodine through canned vegetables." These things righted themselves, but that was no reason for condemning the pioneer who first proved that a disease was due to a deficiency of iodine and urged that artificial means should be used to meet the deficiency.

He protested against the suggestion that "mass medication" was contrary to the ethics and traditions of the medical profession. The proposal Lord Douglas had criticized was not mass medication; it was a reinforcement of Nature's supply in a particular district. He objected to Lord Douglas's remarks about "adding drugs to the water supply." All that was being suggested, if it was actually being suggested as a practical proposition at the moment, was the addition in that particular district of something in which Nature had been deficient. There was no limit to which the opponents of sanitary measures would go. From cancer downwards the whole gamut were paraded as dangers.

Government Reply

LORD CARRINGTON, Parliamentary Secretary to the Ministry of Agriculture, replying for the Government, recalled the recommendation of the B.M.A. Committee on Nutrition that the consumption of calcium should reach 0.8 g. per adult per day, and the report of the National Food Survey that in the first half of 1952 the national average intake would have been about 10% below this had it not been for the addition of calcium to flour. The addition did no harm to anyone, and there was a permitted exception for 100% extraction wholemeal flour.

A special committee of the Medical Research Council on Thyroid Diseases reported in 1948 that goitre appeared to be on the increase, and recommended that preventive action on a national scale should be taken by the addition of a trace of iodine to domestic salt. The recommendation was endorsed by the committee on medical and nutritional problems of the Ministry of Health, and was referred to the Food Standards Committee of the Ministry of Food for investigation of the technical problems. These had not been fully solved. The committee recommended favour-

ably in March, 1950. Representations were received from a large number of people, including the medical profession, the trade, medical authorities, and others. These were considered by the Health Departments and the committee, but the committee had not yet made its final report. In a number of countries where goitre was common salt had been iodized for a number of years, and nowhere had there been any resulting harm; in fact, the experience had been that nothing but good had resulted.

On the fluoridation of water supplies, as this was the only measure which so far gave any promise of preventing or reducing the incidence of bad teeth, the Minister of Health had announced on December 3, 1953, acceptance of the recommendation of the medical mission that had visited the U.S.A.¹ There were many areas in Britain where there was already enough fluorine in the water supply, and where no more would be added. There was no scientific basis for the allegation that fluorides in quantities of 1.0 to 1.5 parts in a million had any harmful effect; but there had been some confusion with industrial fluorosis, which was the result of a heavy concentration of fluorides in the atmosphere in the form of dust.

The last question was that, even assuming these measures were medically justified, they should be withheld on the ground that they infringed the liberty of the subject. A balance could be struck only by going fully into each proposal. He agreed that medical justification was not of itself sufficient. Political and philosophical implications must be considered. Nowadays it was believed that Governments had a general responsibility for ensuring the health of the people. When an overwhelming case had been made on scientific grounds, and they were convinced that what was recommended was practical and could not possibly result in anything but good to the public health, then they must consider taking action of the kind that had been described as mass medication. They would be failing in their duty if they did not take into account the great benefit to the public health that would result.

Hearing-aids

MR. IAIN MACLEOD informed Dr. BARNET STROSS on January 21 that the proportion of bone-conduction hearing-aids required, compared with air-conduction models, was estimated at less than 5%. About 7,000 people had been supplied with them in the 12 months since they became available, and supplies were ample. Within a month or two there would be no waiting-list.

Acidity in Soft Drinks

Dr. BARNET STROSS asked the Minister of Food to state the measure of acidity in the mineral drink "Cola" in terms of the hydrogen ion concentration, and what other substances it contained besides caffeine, phosphoric acid, sugar, and water. Dr. CHARLES HILL, the Parliamentary Secretary, told him on January 25 that the pH of Cola drinks sold in the U.S.A. was 2.6, though a sample taken in this country was slightly less acid. He had no information about the ingredients.

Dr. STROSS said the answer showed that the drink was as acid as vinegar even if it were masked by the sugar content. Evidence was given before a U.S. Congress committee in 1950 about the danger of this drink in relation to dental nutrition, in that it caused teeth erosion. He asked the Ministry to check these facts through the Medical Research Council. Dr. HILL replied that the level of acidity was only slightly more than that for soft drinks containing acid generally. The Committee on Food Standards would soon, it was hoped, consider the position generally, including the question of acidity.

Powdered Milk Code

Lieutenant-Colonel M. LIPTON asked the Minister of Food on January 25 what further investigations had been made to prevent a recurrence of food-poisoning in schools as a result of using powdered milk. Dr. CHARLES HILL, Parliamentary

¹ See *British Medical Journal*, July 11, 1953, p. 88.

Secretary, replied that there had been comprehensive bacteriological tests of the milk powder which caused the recent outbreaks, and the conditions and production at the particular factory had been thoroughly investigated. As a result a code of practice for the manufacture of dried milk was being prepared, and this would be issued to all manufacturers soon.

In the House of Lords on January 26, LORD AMULREE introduced the Abortion Bill, and it was read a first time.

Medico-Legal

DOCTOR A "PUBLIC AUTHORITY"

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

Although there is no time limit for the institution of criminal proceedings, civil actions of all kinds have to be brought within certain fixed time limits, which vary with the type of action. This is plainly necessary so that there is some end to disputes and so that they can be decided before the evidence on which alone they can be decided has vanished. "Interest rei publicae ut sit finis litium." The periods of limitation are now set out in the Limitation Act, 1939, except in the case of actions against some of the public corporations which run the nationalized industries, for which special periods of limitation are provided in their own nationalizing statutes; and there exist certain other special periods. For ordinary actions for damages for breach of contract or for torts, the period is six years. But when the action is brought against a public authority the period within which it must be brought is one year only. "Public authority" is not defined in the 1939 Act, but bears the same meaning as it did under the Public Authorities Protection Act, 1893, which provided a limitation period of six months. Any person who is sued for any act done or for any neglect or default in doing an act, "in pursuance or execution or intended execution of any Act of Parliament, or of any public duty or authority," is a public authority within the meaning of the statute. Nice questions can arise whether or not a particular person or body falls within this definition on any given occasion.

On January 29 Mr. Justice Pilcher,¹ in the Queen's Bench Division of the High Court, decided that a doctor, who as part-time specialist in charge of the physical medicine department of a hospital was acting in the execution or intended execution of a duty imposed by the National Health Service Act, 1946, was a "public authority." Accordingly he dismissed an action for negligence brought against the doctor by a patient because the writ had been issued more than a year after the cause of action—that is, the alleged negligence of the doctor and the damage resulting from it—had first arisen. A private Member's Bill seeking to make all periods of limitation three years was recently introduced into the House of Commons with the support of the Government.

¹ *The Times*, January 30.

The Services

The *London Gazette* has announced the following awards:

Bar to Air Force Cross.—Wing Commander H. H. S. Brown, A.F.C., R.A.F.

Air Force Cross.—Group Captain D. A. Wilson and Wing Commander G. H. Dhenin, G.M., R.A.F. Surgeon Lieutenant-Commander W. H. B. Ellis, R.N.

Surgeon Rear Admiral R. C. May, O.B.E., M.C., R.N., has been appointed Honorary Surgeon to the Queen in succession to Surgeon Rear Admiral T. Madill, C.B., O.B.E., R.N.

The announcements in the *London Gazette* dated October 30, 1953, and in the *Journal* of November 28, 1953 (p. 1227), concerning the award by the President of the U.S.A. of the decoration of Legion of Merit, Degree of Legionnaire, to Colonel G. Anderton, O.B.E., late R.A.M.C. (now R.A.R.O.), in recognition of gallant and distinguished services during the operations by the United Nations in Korea, should have read Legion of Merit, Degree of Officer.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending January 16 (No. 2) and corresponding week 1953.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Medical News

Professor H. A. Krebs, F.R.S.—The Friends of the Hebrew University of Jerusalem gave a dinner on January 27 to celebrate the award to Professor H. A. Krebs of the Nobel prize in medicine for 1953. Sir Henry Cohen, who was in the chair, said that really this dinner had its origin 125 years ago, when Wöhler synthesized urea. This was really the beginning of examination by the chemist of living matter. The chair of biochemistry was established in Liverpool in 1903, and Sheffield had followed suit 40 years later when it appointed Professor Krebs professor of biochemistry. There had been many great figures in the history of medicine and science who had been recommended for the Nobel prize, but only a few of them had been chosen. At the same time Professor Krebs had been awarded the Lasker prize of the American Public Health Service, a recognition of the significance of his work to medicine. Tributes to Professor Krebs were then paid by the Ambassador of Israel and by Sir Ben Lockspeiser. In reply he said that what was not rare was certainly his "dose of talent." He had had quite unusual opportunities for doing the work which had led up to the award of the Nobel prize. After qualification he had had the chance of working on a whole-time basis: then he was associated with Otto Warburg and later with Gowland Hopkins. His great advantage had been that he had had time to concentrate on his own work. He was convinced that there were many talented people in universities who would do exceptional work if they were given the essential prerequisite, time—time free from routine duties of teaching, examination, administration, and committee work. Modern research required a lot of time to master new knowledge and techniques. This requirement of time should always be a consideration in the set-up of universities. He believed that the university was a place where major research should be conducted so that the research worker—a biochemist, for example—could get help and stimulus from mathematicians, physicists, chemists, engineers, biologists, and from philosophers and historians. Turning to the other feature of the present occasion, Professor Krebs said he was gratified to know that the Hebrew University was doing much to promote fundamental research, though one heard critical comments on the usefulness of this in a poor country like Israel where so many practical problems wanted attention. After Dr. A. Lerner had appealed for financial support for the Hebrew University of Jerusalem, Dr. Leonard Simpson proposed the health of the chairman, and Sir Henry Cohen briefly replied.

Cost of In-patient Treatment.—The hospital costing returns for the year ended March 31, 1953, were published last week by the Ministry of Health. Expenses have continued to rise, though there is a good deal of variation between the costs in the different regions. The table below shows the average cost of maintaining a patient for a week in various types of hospital, the figures for 1951-2 being given for comparison.

Type of Hospital	Average Weekly Cost per In-patient	
	1952-3	1951-2
Teaching hospitals, London	£24 18 8	£23 13 8
" " Provinces	18 13 9	17 15 8
General hospitals, under 50 beds ..	13 13 5	12 14 9
" " 51-100	15 7 5	17 7 2
" " 101-300	15 10 6	14 13 3
" " 301-900	15 12 1	14 11 7
Maternity hospitals	17 13 1	16 19 2
Tuberculosis	9 19 5	9 6 7
Mental	4 8 6	4 1 1

The Building for the Job.—The Nuffield Foundation has established a Division for Architectural Studies as part of its headquarters organization. This follows the success of

the research team appointed in 1948 by the Nuffield Provincial Hospitals Trust to investigate the functions and design of hospitals. This team completed its work last year and its final report is expected shortly. The new Division is under the direction of Mr. Richard Llewelyn Davies, A.R.I.B.A., who led the former research team, and besides architects the staff includes a doctor, a nurse, a historian, and a statistician. The Division will work closely with the D.S.I.R.'s Building Research Station. Its first assignments are the problem of the care of children in hospital and the design of research laboratories.

Chloramphenicol.—The first British reports of fatal aplastic anaemia in patients who had been treated with chloramphenicol were published in the *British Medical Journal* 18 months ago.^{1,2} Since then there have been many other references in medical journals to the toxicity of the drug. The risk of blood dyscrasia following chloramphenicol treatment cannot be accurately assessed from the figures available, but the Council on Pharmacy and Chemistry of the American Medical Association has recently published a statement³ advising restriction of the use of chloramphenicol "to the treatment of typhoid fever and other serious infectious diseases caused by organisms controlled by chloramphenicol but resistant to other antibiotics or other forms of treatment." The Ministry of Health has also just issued a memorandum on this subject. After stating that it is impossible to determine the frequency with which blood dyscrasia follows chloramphenicol treatment since the total population at risk is not known, the memorandum concludes: "It is apparent that the incidence is low, since the condition is usually fatal and cases would therefore come to notice. When excessive dosage is avoided, the incidence must be very low indeed; thus no cases have arisen during the Medical Research Council's controlled therapeutic trials in pneumonia, whooping-cough, and infantile gastroenteritis. It cannot be too strongly emphasized, however, that the use of chloramphenicol is not without risk, and prolonged or repeated administration (especially of large doses) should be avoided, particularly in conditions such as chronic respiratory and urinary tract infections."

American Surgeons in London.—A Section Meeting of the American College of Surgeons will be held at the Royal College of Surgeons, Lincoln's Inn Fields, from May 17 to 19. The programme includes symposia on gynaecology, cancer, and cardiovascular surgery, panel discussions on pre- and post-operative care, massive gastro-intestinal tract haemorrhage, and hand surgery, and operating sessions in London teaching hospitals. Further details will be available later.

Travelling Fellowships in Ophthalmology and Otolaryngology.
The Medical Research Council invites applications for travelling fellowships in ophthalmology and otology for the academic year 1954-5, for which special provision has been made by the Alexander Pigott Wernher Memorial Trustees. These fellowships are intended for suitably qualified medical graduates who are likely to profit by a period of work in ophthalmology or otology at a centre abroad before taking up positions for higher teaching and research in these branches of medical science. Candidates will be required to submit an outline of their proposals for work at a selected centre. The awards will normally be tenable for one year: no provision can be made for travelling grants for short-term visits abroad. The fellowships provide for the payment of a maintenance allowance at the rate of £650 per annum for a single Fellow or £900 per annum for a married Fellow, subject to appropriate adjustment in the case of fellowships tenable at centres outside the sterling area; in addition, an allowance is made for travelling and other approved expenses. Forms of application may be obtained from the secretary, Medical Research Council, 38, Old Queen Street, London, S.W.1, with whom applications must be lodged by March 31.

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in December, 1953, was 116, compared with 125 (revised figure) in the previous month and 137 in December, 1952.

The number of cases of industrial diseases in the United Kingdom reported during December was as follows : lead-poisoning, 11 ; other poisoning, 2 ; anthrax, 3 ; epitheliomatous ulceration, 11 ; and chrome ulceration, 10 ; total, 37. There were no deaths.—*Ministry of Labour Gazette*, January, 1954.

The infant mortality rate of 35.2 per 1,000 live births was lower than any previously recorded in Scotland. The general death rate of 12.03 per 1,000 population was lower than any previous rate, except for 1948, when it was 11.0. The still-birth rate continued to fall, being 26.2 per 1,000 total births. The ratio of boys to girls born was 1,048, much lower than the average of 1,063 for the years 1946-51. The birth rate was 17.68 per 1,000 population, slightly less than in 1951, and much the same as in 1937-8. These figures appear in the *Ninety-Eighth Annual Report of the Registrar-General for Scotland, 1952* (H.M.S.O., 10s. 6d.).

A comparison of standardized death rates in Scotland and in England and Wales shows the following death rates per million, those for England and Wales being in parentheses: tuberculosis of respiratory system, 282 (211); malignant neoplasms 2,126 (1,979); diabetes mellitus, 103 (75); vascular lesions affecting C.N.S. 1,936 (1,564); heart diseases, 4,104 (3,366); hypertensive disease, 367 (428); pneumonia, 402 (442); and nephritis and nephrosis 117 (133).

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,138, whooping-cough 2,357, diphtheria 18, measles 1,106, dysentery 490, acute poliomyelitis 37, paratyphoid fever 4, and typhoid fever 3.

A rise occurred in the incidence of infectious diseases in England and Wales during the week ending January 16. The largest increases in the number of notifications were 210 for whooping-cough, from 2,156 to 2,366, 123 for scarlet fever, from 792 to 913, and 56 for dysentery, from 322 to 378.

The only large variations in the local trends of whooping-cough were increases of 57 in Staffordshire, from 78 to 135, and 55 in Warwickshire, from 132 to 187. A small rise in the incidence of scarlet fever occurred in every region, but no large fluctuations were recorded. 1,150 cases of measles were notified, being 16 more than in the preceding week. The only fluctuations of any size in the local trends of measles were an increase of 64 in Staffordshire, from 140 to 204, and a decrease of 40 in Lancashire, from 346 to 306. 21 cases of diphtheria, the same number as in the preceding week, were notified. The chief feature of the returns of diphtheria was a rise in Lancashire, from 2 to 7, 5 of the cases being notified in Liverpool C.B.

40 cases of acute poliomyelitis were notified. These were 8 fewer for paralytic and 4 more for non-paralytic cases than in the preceding week. The largest returns were Gloucestershire 6 (Mangotsfield U.D. 3), Suffolk 4, Essex 3, Lancashire 3, and Yorkshire West Riding 3.

The increase in the incidence of dysentery was mainly contributed by Yorkshire West Riding, where a rise of 35 was recorded. The largest returns were Yorkshire West Riding 83 (Leeds C.B. 45, Bradford C.B. 17), London 81 (Islington 36), Lancashire 40 (Bolton C.B. 23), Middlesex 33, and Norfolk 20 (Norwich C.B. 20).

Grants and Fellowships for Research on Leukaemia.—The trustees of the Lady Tata Memorial Fund invite applications for grants, scholarships, or fellowships for research on diseases of the blood, with special reference to leukaemia, in the academic year 1954-5. Candidates with programmes of research on any aspect of malignant disease which may throw incidental light on the related problem of leukaemia will be eligible for consideration. Grants of variable amount are made for research expenses or to provide scientific or technical assistants for senior workers. Scholarships are awarded for the personal remuneration of workers carrying out approved research under suitable direction; their normal value will be £600 per annum for whole-time research, with proportional adjustment for work on a part-time basis. In addition, the trustees may award one or more Lady Tata Memorial Research Fellowships to workers with considerable research experience; the stipends of these fellowships will be at the rate of £1,000 per annum. All these awards are open to investigators of any nationality, working in any country in which it will be possible to make payments in the coming academic year. Further particulars and forms of application may be obtained from the Secretary of the (European) Scientific Advisory Committee, Lady Tata Memorial Trust, c/o Medical Research Council, 38, Old Queen Street, London, S.W.1. Applications must be submitted before March 31, and the awards will be announced by the trustees in June.

Research Studentships at Cambridge.—Details of the Elmore Medical Research Studentships are given at page 45 of our advertisement columns. They are open to graduates born anywhere in the Commonwealth (except Scotland) who wish to work in the Department of Medicine at Cambridge, under the direction of the Regius Professor of Physic. The studentships carry a salary of between £400 and £850 a year, and preference will be given to those interested in haematology.

Family Doctor.—The February issue, which is now available, contains medical articles on influenza, twins, coronary thrombosis, and phenobarbitone. Dr. Walter C. Alvarez, professor of medicine at the Mayo Clinic, completes his three-part series "How to Live with Your Nerves." Next month he will be writing on "How to Live with Your Blood Pressure." Evelyn Ford describes a valuable social service in "Invalid Kitchens," and Nicholas Ward, adapting the old nursery jingle, takes "This Little Pig Had Penicillin" as the title for an article on the use of antibiotics for fattening livestock. Fish lens protein, a substance alleged to be a medical cure of cataract and which has received considerable publicity in the lay press, is the subject of unfavourable editorial comment. *Family Doctor* costs 1s. 6d. and can be obtained through any bookseller.

Ministry of Health Art Club Exhibition.—Mr. Iain Macleod opened the annual exhibition of his Ministry's art club and the Hygeia Camera Club on February 1. An interesting feature was the showing of 12 pictures presented by individual members of the club to various hospitals.

COMING EVENTS

Study Circle on Medical Statistics.—A meeting will be held at the Westminster Medical School, Horseferry Road, London, S.W.1, on February 23 at 6 p.m. The subject will be "Medical Statistics in the Services."

Pan-American Congress of Otolaryngology and Broncho-oesophagology.—The fourth congress will be held in Mexico City from February 28 to March 4. It is understood that the organizing committee would welcome representatives of British professional bodies.

Seventh Laboratory Animals Bureau Congress.—The congress will be held at Sheffield University on April 5 and 6. Applications for admission, which is normally limited to animal and laboratory technicians, should be made without delay to the Laboratory Animals Bureau, M.R.C. Laboratories, Holly Hill, London, N.W.3.

NEW ISSUES

British Journal of Venereal Diseases.—The next issue (Vol. 29, No. 4) is now available. The contents include:

SURGICAL ASPECTS OF TABES DORSALIS. Robert Lees.
FAMILIAL INVESTIGATION IN SYPHILIS. W. V. Macfarlane.
THE CONTEMPORARY DEFAULTER IN A V.D. CLINIC—FURTHER OBSERVATIONS. Gordon O. Horne.
TRICHOMONAS VAGINALIS INFECTIONS IN THE MALE. F. Lanczley.
THERAPY OF LYMPHOGRANULOMA INGUINALE WITH 7218. C. D. Alcantara.
RECTAL GONORRHOEA IN WOMEN. Tage Jensen.
RESEARCHES IN NON-SPECIFIC URETHRITIS. II. TREATMENT. R. R. Wilcox.
UNITARY V. PLURAL CONCEPTION OF ANTILIPID ANTIBODY IN SYPHILITIC SERUM. Amal Kumar Mitra, Sudil Kumar Biswas, Sukumar Sen, and Narayan Chandra Bhatnagar.
COMPLEMENT-FIXATION TEST FOR LYMPHOGRANULOMA VENEREUM IN NON-SPECIFIC URETHRITIS. A. D. Macrae and R. R. Wilcox.
STABILITY OF THE ANTIGEN USED IN THE PRICE PRECIPITATION REACTION UNDER DIFFERING TEMPERATURE CONDITIONS. L. R. S. Macfarlane.
V.D.R.L. TUBE TEST. Aida Y. Djanian.
ANNOTATION: RECENT PROGRESS WITH THE TREPONEMAL IMMOBILIZATION TEST.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Abstracts of World Medicine.—The February issue (Vol. 15, No. 2), which is now available, contains abstracts of important papers drawn from medical and other scientific journals published in some 20 different countries and in all five continents. The subjects covered range over the whole field of clinical medicine and include pathology, bacteriology, pharmacology, and chemotherapy; there are also sections dealing with public health, industrial medicine and toxicology, anaesthetics, radiology, and the history of medicine.

Issued monthly; annual subscription £4 4s.; single copy 8s. 6d.; a specimen will be sent free on request.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Monday, February 8

INSTITUTE OF PSYCHIATRY.—5.30 p.m., lecture-demonstration by Dr. E. Stengel.
LONDON UNIVERSITY.—At Physiology Theatre, University College, 5.30 p.m., special university lecture in biochemistry by Professor C. Fromageot (Paris): Metabolism of Sulphur Amino Acids and the Cycle of Sulphur in Nature.
MEDICAL SOCIETY OF LONDON.—8.30 p.m., Meeting of Fellows. Discussion to be introduced by Mr. L. N. Pyrah and Dr. C. Enrique Dent: Recurrent Urinary Stone.

Tuesday, February 9

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. J. V. Dacie: Congenital Haemolytic Anaemia.
CHELSEA CLINICAL SOCIETY.—At South Kensington Hotel, a discussion on General Practice, to be opened by Dr. John Hunt, Dr. A. Talbot Rogers, and Dr. E. P. Scott.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. J. Wallace: Ano-genital Pruritus.
MANCHESTER MEDICAL SOCIETY: SECTION OF SURGERY.—At Medical School, Manchester University, 5 p.m., Mr. H. A. Haxton: Physics in Surgery.
ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Milroy Lecture by Dr. D. Long: Pathogenesis of Rheumatic Fever.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Mr. Donald B. Fraser: Ectopic Gestation.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, 5.30 p.m., public lecture by Professor F. Bergel, Ph.D., D.Sc.: Some Chemical Aspects of Abnormal Growth.

Wednesday, February 10

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Practical Aspects of *Trichophyton rubrum* Infections.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. H. P. Winsbury-White: Frequency and Other Disturbances of Micturition.
● LONDON UNIVERSITY: DEPARTMENT OF EXTRA-MURAL STUDIES AND ATOMIC SCIENTISTS' ASSOCIATION.—At Beveridge Hall, Senate House, 7 p.m., Dr. J. F. Loubit: Radiation Hazards of Atomic Energy.
MANCHESTER MEDICAL SOCIETY: SECTION OF PATHOLOGY.—At Medical School, Manchester University, 4.30 p.m., Dr. T. H. Blench: The Law Looks at Medicine.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Finlayson Memorial Lecture by Professor Alan Moncrieff: Marasmus.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. R. A. J. Asher: Lecture-demonstration in psychiatry.

Thursday, February 11

ALFRED ADLER MEDICAL SOCIETY.—At 11, Chancery Street, W., 8 p.m., Mr. J. E. M. Ayoub: Mental Reactions to Visual Abnormalities.
BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor H. B. Maitland: Anti-virus Immunity.
GLASGOW UNIVERSITY MEDICO-SURGICAL SOCIETY.—At Glasgow University Union, 7.30 p.m., Mr. R. B. Wright: Management of Thrombophlebitis of the Lower Limb and its Sequelae.
● HUNTERIAN SOCIETY.—At Savoy Hotel, London, W.C., annual dinner.

● INSTITUTE OF CHILD HEALTH.—5.30 p.m., Dr. K. Soddy: The Invalid Child.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. O. Oliver: Blood and Bone Marrow in Skin Diseases (with colour film: Marrow Puncture).
INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5 p.m., Professor F. C. Ormerod: Malignant Disease of the Oesophagus.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Accidental Extra-venous Thiopentone

Q.—What treatment is advised if thiopentone escapes outside a vein during an intravenous injection?

A.—The treatment of accidental extra-venous injection of thiopentone is by no means decided. Injection into perivenous tissue is usually small in amount and generally requires little or no treatment. If there is much pain the application of heat gives some relief. An immediate infiltration of the area with a solution of 1% procaine with hyaluronidase might prevent tissue damage. In the case of inadvertent arterial injections, characterized by immediate severe pain in the hand and by the obvious flushing or blanching of the hand and forearm, an immediate intra-arterial injection, through the same needle, if possible, of, say, 10 ml. of 1% procaine is advocated, followed by a block of the stellate ganglion or brachial plexus on that side. In addition to this, the intra-arterial injection at the site of the original one of arterial dilators like papaverine and tolazoline is advised. Some have gone further and insist that heparinization of the patient should be started immediately, the operation postponed, and heparinization maintained for some days to avoid intra-arterial thrombosis. The limb should be carefully watched for the ensuing 24 hours, and any evidence of circulatory impairment or nerve involvement demands immediate consultation with surgical colleagues as to the advisability of exploring the brachial artery and the antecubital fossa. Prophylaxis against extra-venous injections, and particularly of the dire consequences of intra-arterial injection, lies in the use of dilute solutions of thiopentone—certainly never stronger than 5%—and in the use of veins other than those which overlie the bend of the elbow. Good veins are usually found near the radial side of the wrist, on the back of the hand, and on the outer side of the biceps muscle and tendon.

Exercises for Hernia

Q.—A lay practitioner claims to be able to cure hernia by abdominal exercises. Has such a claim ever been submitted to controlled investigations, and if so what was the result?

A.—Such a claim has not, so far as the writer knows, ever been submitted to controlled investigation. Bulging of the abdominal wall due to lax muscles can clearly be "cured" by exercises. Certain types of direct herniae, especially that variety sometimes spoken of as Malgaigne's bulgings, will respond to rehabilitation of this kind. An indirect hernia, unless very small, is unlikely to disappear with abdominal exercises alone; and, even if the swelling did go, the sac would still be present with the likelihood of later recurrence. It must be conceded, however, that the wearing of a truss by a young person with a small, narrow sac and a good internal ring, combined with the maintenance of good abdominal muscle tone, can result in apparent cure. The best-authenticated example of this is in the case of Sir Astley Cooper's inguinal hernia. This was first noticed in his late teens, and he wore a truss for about five years night and day. No further swelling was seen after this, and when Sir Astley died at the age of 72 a detailed post-mortem examination was conducted at Guy's Hospital by John Hilton. It is notable that a minute serous canal was found on the affected side. Umbilical, femoral, and incisional herniae will not be cured by abdominal exercises alone, but all sufferers from hernia benefit from maintaining the abdominal muscles in good condition.

APPOINTMENTS

LIVERPOOL REGIONAL HOSPITAL BOARD.—B. M. Sedzimir, M.D., F.R.C.S. Ed., Consultant Neurosurgeon; N. O'Brien, M.B., B.Ch., T.D.D., Assistant Chest Physician to St. Helen's area; G. V. Osborne, M.Ch.Orth., Assistant Chest Physician to St. Helen's area; G. V. Osborne, M.Ch.Orth., F.R.C.S. Ed., Part-time Consultant Orthopaedic Surgeon to Southport Promenade Hospital; G. L. Shatwell, M.Ch.Orth., F.R.C.S., Part-time Consultant Orthopaedic Surgeon to Ormskirk County Hospital and Rainhill Hospital.
MACARTHUR, PATRICK, M.D., F.R.F.P.S., D.C.H., Consultant Paediatrician to Scottish Northern Regional Hospital Board.
MANCHESTER REGIONAL HOSPITAL BOARD.—C. A. Borland, M.B., Ch.B., F.F.A.R.C.S., Consultant Anaesthetist, Lancaster and Kendal Hospitals; P. B. Kunkler, M.D., M.R.C.P., D.M.R.T., and Dorothy Pearson, M.B., Ch.B., D.M.R.T., Assistant Radiologists, Christie Hospital and Holt Radium Institute; A. Clark, M.B., Ch.B., D.P.M., Assistant Psychiatrist, Whittingham Hospital; L. Parker, B.M., B.Ch., Consultant Pathologist, North Manchester Hospital; Group Laboratory; R. S. Savidge, M.D., M.R.C.P., Consultant Physician, Bury and Rosendale Hospitals; S. M. Laird, M.D., F.R.F.P.S., D.P.H., Consultant Venerologist and Director of St. Luke's Clinic, Manchester, and the Venereal Diseases Clinics of Manchester Royal Infirmary, etc.; S. Falk, M.D., D.P.M., Consultant Psychiatrist to Bury and Rochdale Hospital Centres; G. M. Colson, B.M., B.Ch., M.R.C.P., Consultant Physician, Bolton and District Hospital Centre; S. G. McComb, M.D., M.R.C.P.I., Consultant Physician (Geriatrics), Bolton and District Hospitals; K. A. Rowley, M.B., Ch.B., F.F.R., D.M.R.D., Consultant Radiologist-in-charge, Blackpool and Fylde Hospitals.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Burn.—On January 1, 1954, at Guy's Hospital, London, S.E., to Peggy (formerly Bird), wife of Robert Burn, F.R.C.S., a son—Richard William.
Martin.—On January 20, 1954, at Bentley, Hants, to Audrey (formerly Dealer), M.B., B.S., D.A., wife of Peter Martin, a brother for Gillian, Nicholas, and Robert.
Sudbury.—On January 31, 1954, at Swindon Maternity Hospital, Wilts, to Mary, wife of Squadron-Leader J. R. Sudbury, B.M., M.R.C.P., D.R.C.O.G., R.A.F., a son.

DEATHS

Elliott.—On January 6, 1954, in hospital, James May Elliott, M.B., B.Ch., Colonel, R.A.M.C., retired, of Highclere, Hutton Mount, Brentwood, Essex.
Elwin.—On January 8, 1954, at Ashted, Surrey, George Richard Elwin, M.D.
Fraser.—On January 5, 1954, at the Royal Infirmary, Edinburgh, Thomas Lochhead Fraser, O.B.E., M.B., Ch.B., Colonel, late R.A.M.C., retired, of Elie, Fife.
Fuller.—On January 6, 1954, at his home, Kensington, London, W., Francis Frederick Fuller, M.B., Ch.B., formerly of Harley Street, London, W.
Hacker.—On January 4, 1954, at 28, Torrington Square, London, W.C., Henry Pollard Hacker, M.D., D.Sc., D.T.M.&H.
Hale.—On January 9, 1954, at Midhurst, Sussex, Robert Eugene Vaughan Hale, M.B., B.Ch., late of Harpenden, Herts.
Jameson.—On January 3, 1954, at St. Leonards-on-Sea, Sussex, William Ernest Jameson, M.B., Ch.B., C.M., J.P.
Mackenzie.—On January 5, 1954, at 22, Queen's Gate, Glasgow, Alister Thomas Mackenzie, M.D., D.P.H.
Sutherland.—On January 9, 1954, at Edinburgh, Donald Sage Sutherland, T.D., M.D., of 2, Craiglockhart Terrace, Edinburgh, late of Manchester.
Thompson.—On January 6, 1954, at Christchurch Hospital, Bournemouth, Arthur Thompson, M.R.C.S., L.R.C.P., of 997, Christchurch Road, Bournemouth, Hants, late of East Drive, Brighton, Sussex, aged 81.
Tomlinson.—On January 3, 1954, the result of a road accident, Dorothy Sylvia Tomlinson, M.B., B.S., of 20, Eastwood Gardens, Newcastle-upon-Tyne, aged 25.

Clotting Time in Coronary Occlusion

Q.—Is there any change in the blood coagulability of patients suffering from coronary thrombosis? If so, has it prognostic value?

A.—In patients suffering from acute myocardial infarction some workers have detected a change in the heparin-clotting-time, but there is no consistent change demonstrable in ordinary clotting time. Thus in one series¹ of 19 patients with acute myocardial infarction 14 showed rapid heparin-clotting-time (i.e., the blood samples were "resistant" to the action of heparin) compared with only one of 14 controls suffering from other heart diseases. On the other hand, other workers² have found no consistent change in the so-called heparin-tolerance test. On the whole I think it would be fair to say that no great value can be placed on the results of blood coagulation tests in prognosis which in the long run must depend on the state of the myocardium and of its blood supply, especially with regard to the likelihood of further damage, and on complications like thrombo-embolism.

Sympathetic Ophthalmia

Q.—Under what conditions is sympathetic ophthalmia a possibility? Can it occur without a penetrating wound of either eye? What is the mechanism of its causation?

A.—Perforating injury is the commonest cause of sympathetic ophthalmia, and this disaster is particularly to be feared when irritation is prolonged by incarceration of iris tissue or ciliary body in the wound. The next important cause is intraocular operation, especially cataract extraction and other procedures implicating the lens.

Sympathetic ophthalmia without any antecedent perforating injury or operation is exceedingly rare. Probably some of the recorded cases were not genuine, and in others there may well have been an inconspicuous and painless small wound of entry. I would not like to say that the condition is impossible without a perforation, but it probably does not occur.

The mechanism of causation is still not known for certain. Various organisms have been blamed. Some authorities believe that sympathetic ophthalmia is brought about by a virus conveyed by the optic nerve sheaths. Others regard the disease as an allergic outburst.

Treatment of Vitiligo

Q.—What treatment is recommended for vitiligo? I have found autohaemotherapy helpful. Is this the general experience?

A.—Although from time to time cases have been recorded in which vitiligo has healed following some form of local or systemic treatment, such cases are quite exceptional and it may even be doubted whether the treatment has really had any effect at all. The general consensus is, in fact, that no treatment is at all reliable. In recent years El Mofty¹ has recorded successful treatment by the internal and local use of "méladinine." This is a plant extract which has the property of sensitizing the skin; after it is applied the skin is exposed to ultra-violet light and the resulting erythema is followed by a return of normal pigmentation. El Mofty's patients have all been in Egypt; the treatment has also been used in France, apparently with success. Only in recent months have small supplies been available in the United Kingdom, and it is as yet too early to assess results.

In the absence of curative treatment a good deal can be accomplished by the skilful use of concealing creams. It is also sensible to protect the normal skin from sunlight so that it does not present such a contrast with the pale areas.

Will the Eyes Change Colour?

Q.—At what age can one assume that the colour of a baby's eyes will not change from blue to brown? Is it true that the colour change only goes in this direction, i.e., never from brown to blue; if so, why?

A.—At no age can one safely assume that the colour of a baby's eyes will not change from blue to brown, except when both parents are of blue-eyed stock. However, if the change has not occurred by the age of 15 years, gross alteration in colour is unlikely, although I have seen a yellow margin appear in grey- and blue-eyed people after this age. Changes in the reverse direction, from brown to blue, occur only in pathological or senile conditions.

There is some evidence to suggest that little spots or masses of pigment may appear in the later decades of life, and that this tendency towards darkening of the iris is more marked in women than in men.

Renal Glycosuria and Hypoglycaemic Attacks

Q.—Does renal glycosuria ever account for hypoglycaemic attacks?

A.—It is doubtful whether renal glycosuria is ever the cause of true hypoglycaemic attacks. However, it is possible that in those cases in which there is a heavy loss of sugar associated with a very low threshold and an inadequate intake of carbohydrate a mild degree of hypoglycaemia may occur and possibly give rise to a sensation of weakness, etc. Even this must be very uncommon.

Cyanosis after Tattooing

Q.—Is a transitory (24 hours) but very obvious cyanosis a recognized complication of tattooing? If so, what is the explanation? I have seen this in a healthy boy of 17.

A.—Tattooing is performed by introducing colouring matter into fine punctures of the skin. The pigments most generally used are indigo, vermilion, and cinnabar. Indigo is an organic compound, while both vermilion and cinnabar are essentially sulphide of mercury, vermilion being the purest form. None of these materials is likely to cause transient cyanosis. The nature of the cyanosis is not stated, but it is reasonable to assume that it was due to methaemoglobin formation. In place of the usual pigments, it is possible that a tattooer might employ less inert colours, such as indian ink alone or combined with aniline black. In this connexion attention can be drawn to the report of an outbreak of cyanosis (methaemoglobinemia) in newborn babies due to the use of unlaundered napkins marked with a marking ink of aniline black in aniline.¹ Cyanosis of this type is transient.

THE LIVER AS A SITE AND SOURCE OF CANCER*

BY

G. R. CAMERON, D.Sc., M.B., F.R.C.P., F.R.S.

Professor of Morbid Anatomy, University College Hospital Medical School; Pathologist, University College Hospital, London.

The subject of my lecture may well seem to you to be ill chosen, since primary cancer of the liver is uncommon in this country and secondary carcinoma presents few problems to the clinician because of its ill omen as the harbinger of death. My excuse lies in the belief that both the natural history and the experimental study of liver cancer afford precise information from which we may derive hints about the cancerous state and thereby acquire some guidance in the planning of future work.

With the idea of orientating myself to the pathological aspects of the discussion I asked two of my research colleagues, Dr. V. Udall and Dr. Basu Mallick, to analyse the post-mortem records of University College Hospital over the last twenty years for the occurrence and distribution of cancer metastases. During this period it is safe to say that necropsies have been performed with standardized technique, that the type of case admitted to our hospital has not varied greatly, apart from some disequilibrium during the earlier war years, and that careful microscopical search of the main tissues in all instances has been steadily maintained. The results are given in Tables I and II.

TABLE I.—Metastases in Liver and Lungs Grouped According to Relation of Primaries to Circulation. 910 Cancers from 6,047 Necropsies at U.C.H. over 20 Years

Necropsies			
Site of Primary Cancer	No. of Primary Cancers	Percentage Showing Metastases in	
		Lungs	Liver
<i>Blood Flow Passes to Lungs First</i>			
Breast	49	45	64

All other organs under 1% for metastases.

venous blood flow in the first instance to the lungs, is paradoxical. Indeed, in many cases metastases are less frequent in the lungs, where they would have been expected, than in the liver. In other cases, however, lung dissemination predominates over liver. We are thus confronted, at the very outset, with observations suggesting that the liver occupies a special place in the order of metastasis. It will be my endeavour to find out what lies behind this arresting fact.

Sooner or later all pathologists interested in cancer realize the limitations of human studies, and some of them turn to experiments on animals in the hope of achieving a more dynamic and perhaps direct attack on the problem. Since everyone does not agree about the value of animal studies it is worth while considering for a few moments some of the reasons given by cancer workers for this choice.

In the first place, they are quite sure that cancer behaves in animals in much the same fashion as in man, so that some, at least, of the lessons learnt from animal work may be applied with safety to human affairs. Secondly, it is possible to plan experiments whereby the fate of the main tumour or its metastases is influenced by treatment of various kinds. Another matter of some practical importance is the decision whether manipulations adopted during physical examination or surgical operation on the primary tumour increase or diminish the incidence of metastases. This concern certainly lies open to experimental test. Again, they would like to know if there are rules of behaviour shared by metastases and the parent tumour: here may be considered the possibility of an association between the type of tumour on the one hand and its speed of growth, resistance to local conditions, susceptibility to treatment with radiation or operation, and the likelihood of dissemination on the other. Into this category comes, too, the urgent question whether parent tumours

control the life of daughter tumours. And, finally, they wish to understand why certain tissues of the body are picked out with regularity or frequency by metastases. No doubt other equally good reasons could be added to the list, but I am sure you will agree that I have defined a programme which must convince any reasonable person of the need for experiments on cancer.

Without any more ado I shall pass to the experimental study of metastasis, especially as it concerns the liver, and endeavour to show you that progress is being achieved in this fascinating field of endeavour.

1. Invasion of Blood and Lymph Vessels by Cancer Cells

The first and most important step leading to the distant spread of a malignant tumour is invasion or infiltration of a blood or lymph vessel, the natural precursor to the process of embolism. Growth by contiguity may result in invasion of near-by tissues, and if this form of spread is ignored or defences fail there may be infiltration over an extensive territory. In no such case, however, can there be involvement of a far-distant organ; some motive force is necessary for the carriage of malignant cells to the new site of growth. Morbid histologists have long been aware of intrusion into blood and lymph vessels, for by means of serial sections cells can be traced from the outskirts of a tumour along more or less pliant and yielding tissue spaces to the environs of all kinds of vessels. Indeed, in some instances they have been followed through the wall of such vessels to the endothelial lining, where they have been caught in the very act of bursting through this limiting cellular membrane into the fluid contained within the tube. Histologists also recognize a not infrequent precursor of break-through in the form of thrombosis, which for a time seems to hold up the further progress of malignant cells. But all too frequently it encourages distant spread, since such a thrombus may be the breeding ground of tumour cells until it becomes overweighted and snaps off as an embolus. In this way a small mass of living tumour cells can be whisked away if the near-by circulation is still brisk, and the embolus is finally brought to rest where the blood stream is narrowed down to a set of capillaries with diameters smaller than the largest dimensions of the embolus.

But how do such tumour cells progress from their site of origin to vessels? Once again histologists have helped us by tracing columns or sheets of cells between the two focal points. However, this is not always possible, and we have to fall back upon the supposition that tumour cells possess powers of movement whereby they may cover not inconsiderable distances. Indeed, experimentalists have given us evidence of such motility. As long ago as 1863 the great German pathologist Rudolf Virchow stated that cancer cells as well as leucocytes dodge about like amoebae, and many tissue culturists have confirmed this observation (Carrel and Burrows, 1911; Lambert, 1916; Russell and Bland, 1933; Ludford, 1934). This movement actually has been photographed with the cinecamera, and the speed of movement calculated in some cases.

Enterline and Coman (1950) give average velocities for breast cancer cells of 0.7μ per minute, or about 1 in. (2.5 cm.) in 10 hours, for carcinoma of the kidney up to 4.4μ per minute, and for a mouse fibrosarcoma as high as 6.2μ per minute. They have also observed that tiny clumps of carcinoma cells can move about as an amoeboid unit, in a fashion which recalls the astonishing progression of bacterial colonies studied some years ago by Cruickshank. Coman (1944) and his associates (de Long *et al.*, 1950; McCutcheon *et al.*, 1948) make out a case for the importance of adhesiveness between tumour cells in deciding infiltration. Break-away of single cells or tiny clusters of cells depends upon reduction of adhesiveness, which seems to be related in some fashion to deficiency in calcium content of the cells, particularly of their membranes. Here is a field of investigation for the biologist which is certainly related to the fundamental one of movement of cells in general.

The migration of tumour cells in living tissues now can be watched and photographed by means of ingenious techniques, chief among which is the Clark-Sandison and Algire chambers, applicable to the rabbit and the mouse. Before long it should be possible, by their use, to define with precision the factors which favour or prevent the local spread of neoplasms.

2. Carriage of Tumour Emboli in the Blood and Lymph Streams

The demonstration of tumour emboli within the circulating blood or lymph is the next step in the build-up of a theory of metastasis. It has presented many difficulties, since the perceptible growth of even the most active malignant tumour takes many days, weeks, or months, and, so far as we can tell, discharge of tumour cells into vessels is haphazard and on a relatively minute scale. To obtain samples of blood in which tumour cells are demonstrable is a matter of chance, with the odds well against the observer who aims at positive evidence. Success has come the way of several workers who injected blood from tumour-bearing animals into members of the same species (rats, mice especially) and obtained new tumours of the same type at the sites of injection (Blumenthal, 1929; Jonescu, 1931; Gross, 1932). In this way Flaks (1932) confirmed the presence of living tumour cells in lymph nodes receiving the lymph from a sarcomatous area, and could show that such cells were present in the lungs of the affected animals before metastases had made themselves known to the naked eye. From a careful study and review of the subject by Wagner (1938), it appears that the transfer to animals of tumour cells by the injection of heart blood or extract of lung vessels is successful only when such cells are demonstrable microscopically in these fluids. I can recall the excitement that I experienced as a young man when I found cancer cells in smears made from centrifuged blood obtained from a man with a rapidly spreading melanotic carcinoma.

We have no information about the number of tumour cells that must enter the blood of human beings, for instance, in order to produce metastases, but if facts obtained from animal experiments are applicable to man, then the effective number may not be very large. Kahn and Furth (1938) were able to transmit to inbred strains of mice a sarcoma, induced by the carcinogen benzpyrene, with 50 cells. Even more astonishing is the claim of these workers that certain strains of mouse leukaemia can be propagated by injection of a single leukaemic leucocyte into a vein. Obviously many variables come into the story, and a great deal will depend on the growth potentialities and resistance to changed conditions possessed by the tumour cells. Here again is a promising topic for investigation.

We do not know whether metastasis requires the continuous invasion of the blood or lymph stream by small or large numbers of tumour cells or whether discontinuous showers of cells suffice, provided conditions for survival and new growth of the metastasizing cells in their new surroundings are suitable. Some experiments on the influence of massage suggest that the cascading of cells may be important. In Japanese waltzing mice inoculated subcutaneously with a mouse carcinoma by Tyzzer (1913) manipulation and massage of the implanted tumour for a short period over several consecutive days increased the speed with which lung secondaries developed, and in some experiments greatly increased the number of metastases in that organ. These experiments were carefully controlled. Confirmation of Tyzzer's experiments has come from Knox (1921, 1922) and Marsh (1927). We may well believe that the periods of rough handling of these tumours led to vascular invasion on a scale sufficient to induce successful implantation in distant organs. So, too, experiments on incision or partial removal of primary tumours (Clunet, 1910; Tyzzer, 1913) and on the increase of susceptibility induced by haemorrhage (Gaylord and Simpson, 1916) hint at the same sort of phenomenon, although the results are not so convincing as with massage. I agree very strongly with Professor R. A. Willis in his plea for careful experiments on this and allied matters.

But the most persuasive evidence comes from the demonstration (1) that deliberate inoculation of the circulating blood with living tumour cells is often followed by the manifestation of tumours of the same type in various organs of the inoculated animal, and (2) of the need for a break-through into the blood stream of cells from the primary tumour. In support of the first thesis we have the old experiments of Cohnheim and Maas (1877), which showed that finely minced periosteum from rabbits, dogs, and hens injected into the jugular vein lodges as emboli in the lungs and for a time grows there, only to disappear in a few weeks. Cohnheim saw in these observations support for the origin of cancer metastases. Some years later Levin and Sittenfeld (1910) and Gussio (1912) carried out with increasing care, as the pitfalls were realized, inoculation experiments which gave convincing support to the embolic theory of secondaries. Modern work has confirmed the pioneers' results. Even more illuminating are the experiments of Weil (1913) with the Flexner-Jobling rat sarcoma. This actively growing neoplasm can be transmitted from one animal to another by means of subcutaneous inoculation but fails to metastasize spontaneously. If suitable emulsions of the sarcoma be injected intravenously into rats with large subcutaneous tumours then a high proportion of these animals develop lung tumours. In other words, when tumour cells gain access to the veins of tumour-bearing animals metastasis follows. Weil concluded that the absence of spontaneous secondaries is due to failure of the primary growth to effect vascular invasion. We now know that this is an over-simplification of the story; nevertheless blood invasion is indispensable if a tumour is to spread to distant parts.

3. The Development of Metastases

For the development of metastases in an organ such as the liver there must be: (1) the impaction of living tumour cells within the blood vessels, especially the capillaries, of that organ; (2) the initiation of a new focus of tumour growth at the site of impaction; (3) the invasion of the perivascular tissues of the organ by new tumour cells breaking through impacted vessels. Each of these stages has been established by means of animal experiments, and there is equally impressive evidence from human experience.

The frequent impaction of tumour cells in various organs, especially the lungs, was convincingly established by Schmidt (1903) and confirmed by a host of pathologists. In the course of a careful microscopic study of 45 cases of abdominal cancer he found 15 with lungs either free from metastases or showing at the most minute white rice-shaped thickenings, which proved on microscopic examination to be blood vessels obstructed with cancer cells. In all such cases small collections of tumour cells were discovered within the smallest arteries or in the capillaries, either free or enclosed within thrombi. Some of these collections displayed indistinct broken-up nuclei and fused, homogeneous, poorly stained masses of cytoplasm—signs that the cells no longer survived. Others presented mitotic figures and were certainly growing. Occasionally tumour cells entirely filled vessel lumina and formed long columns extending from arteries to capillaries and even to veins. Spread through vessels to perivascular tissues could also be made out and from these areas could be traced the origins of true metastases. Schmidt concluded that the transportation of tumour cells to small lung arteries occurs with great frequency, but that only a small proportion of these passengers are transformed into secondaries. The bulk are killed off by encapsulation with red corpuscles and leucocytes or by the organization of the thrombi which rapidly enclose them.

I would repeat that the studies of Schmidt are exemplary and have never been surpassed. Though chiefly concerned with tumour emboli in the lungs they are applicable to other organs, with certain slight reservations. In the case of the liver, for instance, it is my experience that thrombi around impacted tumour masses are by no means common—an event not altogether unexpected when one recalls the part played by the liver in the prevention of blood coagulation

by its synthesis of heparin. As an instance of the extraordinary fashion in which tumour cells may grow within blood vessels before breaking through the endothelial barrier let me recall a case described by the Canadian pathologist Horst Oertel (1935). A primary pyloric carcinoma came to necropsy without any obvious signs of metastases. Many organs, but especially the liver and the lungs and to a less extent the right adrenal, bone marrow, and bodies of some dorsal vertebrae, and the dura mater, showed widespread, microscopic cancerous masses confined wholly to the blood vessels. The tumour cells had been growing alongside the circulating blood in these localities without displaying any aggressive tendencies for the closely associated tissues.

A further instance of the same sort of event, but this time deliberately induced in animals, are the experiments of the Japanese investigator Takahashi (1915-16) carried out at the Imperial Cancer Research Laboratories, London, during the first world war. White mice were inoculated intravenously with 0.2 g. suspension of various mouse tumours and killed after the lapse of three weeks. In a number of animals no tumours were found within the lungs despite most careful search, but tumour emboli in various stages of degeneration and thrombosis were numerous. Leucocytes were present in considerable numbers around the tumour cells, but the endothelium of the enclosing blood vessels showed no evidence of proliferation. In those mice with lung secondaries after intravenous inoculation, degeneration was certainly not obvious in the tumour emboli and signs of tumour proliferation became apparent after three days. Both carcinoma and sarcoma were equally capable of producing lung metastases, but tumour strains differed widely in their ability to survive intravenous implantation. The majority of the strains used in these experiments grew when inoculated subcutaneously, but no relation existed between success on subcutaneous implantation and tumour take in viscera after intravenous injection. Takahashi concluded that variation in production of metastases is not so much the failure of neoplastic cells to make their way into the blood stream as their inability to survive and grow after arrest in the vessels of an organ.

Modern studies of dissemination in general are worth noticing before we consider special problems of liver metastasis. American investigators have been particularly active in recent years in the design of quantitative studies. Fresh confirmation has come for the belief that the number of emboli reaching a tissue is important in determining the success or failure of spread. Since the mortality of embolic cells is very high, a great number of these cells fail to establish themselves in the organs preliminary to initiating a locus of growth (Warren and Gates, 1936; Zeidman *et al.*, 1950). Zeidman *et al.* determined the number of living cells by means of vital staining with trypan blue, in suspensions of mouse sarcoma, injected such suspensions in serial dilutions intravenously into mice, and counted the pulmonary tumours 18 days later. Table III shows that the number of metastases is directly proportional to the number of viable embolic cells.

These investigators, too, maintain that the number of metastases is proportional to the duration of the primary growth; the longer the primary tumour exists, the greater is the number of metastases. This is not a matter of chance of invading blood vessels, for there is no reason to believe that the final size—that is, the amount—of a primary tumour is a measure of the likelihood of metastasis. Such factors as motility of cancer cells and their power of destroying and overcoming natural defences must play an important part,

TABLE III.—The Number of Metastases is Directly Proportional to the Number of Viable Embolic Tumour Cells. Mouse Sarcoma (Zeidman *et al.*)

No. of Mice	No. of Viable Cells Injected Intravenously	Average No. of Pulmonary Tumours
10	104,400	11.5
10	19,800	2.5
8	5,400	1.7
10	900	0.3

My survey of the position of the liver in the hierarchy of metastasis has led us through a veritable icefield of disappointments and uncertainties heavily littered with crevasses of ignorance. But we need not

despair, since there is, I believe, a perceptible upward trend in our journey towards the goal of enlightenment. Comfort springs invariably from the labours of defining what we know and what we do not know, and many gloomy fears vanish in facing up to the unknown. My endeavour has been to define some of the problems of tumour spread which I believe would repay further investigation. I would plead, especially, for a change in attitude towards matters which are dismissed as insoluble. Why should we throw aside the problem of metastasis as hopeless? Why not strive to find ways of circumventing the growing tumour, by inhibiting or suppressing its powers of growth, by turning it aside into less innocuous channels, perhaps by throwing obstacles in its pathways of spread or even sacrificing healthy tissues in order to hold up the neoplastic invader by means of a "burnt earth" policy?

The search for effective chemotherapeutic measures must go on with the same enthusiasm and imagination displayed by Dr. Blair-Bell throughout his pioneering efforts in this great city of Liverpool. Ideas must be sought after and cultivated. We must not be afraid to attempt the impossible; no device or technique that holds out the faintest hope of discovery can be put aside without proper reference to the work in hand. Above all, I maintain that we teachers have a special duty to perform in firing the imagination and carefully fanning the flame of enthusiasm so that our young men and women may demand an entrance into the domain of cancer research. Perhaps it will be a supreme, audacious flight of youthful genius that will bring the answer to the riddle of neoplasia.

TOXIC REACTIONS AFTER INTRAVENOUS SACCHARATED IRON OXIDE IN MAN

SUGGESTIONS FOR IMPROVED PREPARATIONS

BY

J. A. NISSIM, M.D.

(From the Department of Pharmacology, Guy's Hospital Medical School, London)

It is six years since saccharated iron oxide was introduced for intravenous administration in patients refractory to or intolerant of oral iron (Nissim, 1947). Saccharated iron oxide may be said to have gone through the first critical years of its life with greater success than expected, and as regards the incidence of serious reactions following its administration it compares favourably with blood transfusion. Mild or moderate side-effects, however, have been reported rather too frequently. Holt (1953) made a plea for an assessment of the general toxicity of saccharated iron oxide. It is the object of this paper to give an account of my clinical experience with this preparation, albeit limited, and to submit the findings of various authors to careful analysis in the hope of shedding light on the type, incidence, and possible causation of these reactions. This is followed by suggestions of possible procedures to eliminate or minimize the incidence of such reactions.

Toxic Reactions in Animals

Toxicity studies of intravenous saccharated iron oxide in four species—namely, mice, rats, rabbits, and guinea-pigs—have shown conclusively that the observed toxic effects are associated with precipitation (Nissim, 1949, 1953a; Nissim and Robson, 1949). This iron preparation does not precipitate when mixed in any concentration with plasma or blood *in vitro*, but undoubtedly precipitation occurs *in vivo* above threshold doses, depending on the species. In the mouse and rabbit this threshold is around 45 mg. Fe per kg. body weight, above which gradual precipitation of the compound occurs. The iron precipitates in fine particles rather than clumps as occurs after colloidal ferric hydroxide (Nissim, 1949, 1953b). For this reason the toxic effects of saccharated iron oxide after such doses occur only after an interval when enough iron has precipitated. Precipitation occurs particularly in the lung capillaries.

Plasma iron and histological studies show that at a second and higher threshold—namely, 180 mg. Fe per kg. in the rabbit—saccharated iron oxide is followed by abrupt but partial precipitation, and is therefore capable of producing toxic reactions immediately after the injection of unusually large doses—for example, 360 mg. Fe per kg. The toxic effects are those of multiple embolism. No toxic reactions have been noted which could not be explained on the basis of pulmonary or systemic precipitation.

Types of Toxic Reactions in Man

My experience with saccharated iron oxide includes 28 patients, 19 in the first series (Nissim, 1947) and 9 in the second (Nissim, 1949). The total number of injections was 90, and the dose per injection varied from 10 mg. to 1 g. Fe. Two samples of saccharated iron oxide were used, one with an LD₅₀ in white mice of 180 mg. Fe per kg. body weight, the other with an LD₅₀ of 300 mg. Fe per kg. With the latter sample, which was used in the second series doses of 200–300 mg. were given on 20 different occasions without toxic reactions of any kind. Only four mild or moderate reactions were encountered, all of which were in

the first series and followed doses of 1, 0.5, 0.5, and 0.25 g. Fe respectively. All these reactions came on 15 minutes to several hours after the injection, the interval being shorter with the larger doses. The reactions consisted of pyrexia with headache, pain in the back with weakness, or some degree of collapse with shivering and diarrhoea.

A review of papers on the clinical use of intravenous saccharated iron oxide, however, shows that toxic reactions fall into two groups, early and late. Early reactions usually occur immediately after injection, and certainly within the first ten minutes, while late reactions occur usually one-half to six hours after the injection. The reactions so far reported by the various authors are listed in Table I under the headings of early and late. A number of observations regarding the two types of reaction can be made.

TABLE I

Early Reactions	Late Reactions
Symptoms of pain:	Dizziness, lightheadedness, vertigo, and difficulty in standing upright
Headache	Weakness
Pain in arms and shoulders	Cold feeling, chilliness, rigors
Pain in chest (anginaloid)	Temperature—103° F. (39.4° C.)
Pain in lumbar regions	Sweating
Pain in sacral regions	Nausea, vomiting, anorexia
Pain in front of thighs or back of legs	Diarrhoea
Symptoms suggestive of sympathetic stimulation:	Generalized urticaria or papular rash (in children)
Tachycardia and palpitation	Vague discomfort, tight feeling of skin all over body
Pallor	Tightness in chest
Faintness	Headache
Symptoms suggestive of para-sympathetic stimulation:	Pains over stomach
Feeling of heat or intense burning all over body	Pain in abdomen: may be associated with rigidity
Sweating	Pain in chest (pleuritic)
Lacrimation	" " lumbar regions
Nausea	" " arms
Irritation of throat and coughing	" " legs and feet
Bronchospasm	Collapse, with grey colour, tachycardia, pulselessness, and subnormal temperature in severe cases
Symptoms of circulatory collapse:	
Cyanosis	
Low blood pressure	

Early Type

Reactions of the early type are by far the more common, and occur even after relatively small doses—under 100 mg. Fe (Kartchner and Holmstrom, 1950). The late reactions are infrequent and occur particularly after large doses, their frequency increasing with the size of the dose (Ramsey, 1950). Only once was a delayed reaction reported after a dose of 100 mg. Fe (Mooney, 1950). From publications which record the time of onset of reactions, the incidence of early toxic effects varies from 0 to 10% of all injections

(Govan and Scott, 1949; Briscoe, 1952) and seems to depend on the sample used. Thirteen cases of delayed reaction have so far been reported in this country (Table II), only three of which occurred after doses of less than 300 mg. Fe. Nine were reported by Ramsey, who attempted massive single injections of 300–900 mg. Fe. One delayed reaction occurred after a slow infusion of 1 g. Fe (Slowik, 1950). In America, Briscoe reported only "a few" reactions of delayed onset out of a total of 57.

It is of interest that in both my series of cases (Nissim, 1947, 1949) and that of Slack and Wilkinson (1949) the incidence of reactions was far less than that reported by later authors using commercial samples. In all three series "analar" sucrose was used in the preparation of the iron-sucrose complex, and the samples were fresh—that is, the period of time from manufacture to injection was short. It seems quite possible that both factors are responsible for increase in incidence of reactions, but the purity of sucrose seems to be a particularly important point (see below).

A woman who was treated at Guy's Hospital with 100 mg. Fe of one commercial sample of saccharated iron oxide responded with a typical anginous type of pain in the chest, down the arms, and also in the small of the back after each injection. The pain came on immediately at the end of the injection and lasted two to three minutes. When the same dose of saccharated iron oxide prepared from "analar" ingredients was given on a following day, there was no toxic reaction whatever. On the third day the patient was given another commercial preparation, prepared in the same way as the second sample (Nissim and Robson, 1949), except that the sucrose was not this time of "analar" standard. Exactly the same reaction supervened, and this painful effect thus appears to be due to impurities present in commercial preparations.

Precipitation of Iron Oxide

As already pointed out, toxic reactions in animals are accompanied by precipitation of the compound in capillaries, a precipitation which may be abrupt or gradual. Although no histological evidence of precipitation is available in man, it seems reasonable to presume that the delayed toxic reactions occurring after large doses are due to precipitation, particularly as the clinical superiority of samples possessing high LD₅₀ and high threshold of precipitation (Nissim, 1949, p. 138) seems to be established. Further, this type of delayed reaction (Table II) appears to be in no way different from that described by Goetsch *et al.* (1946) and

TABLE II.—Incidence and Type of Reactions Following Intravenous Saccharated Iron Oxide

Author	Preparation	No. of Cases	No. of Injections	Systemic Reactions			Doses in mg. Fe	Doses Causing Reactions in mg. Fe

by Nissim (1947) after colloidal ferric hydroxide, a preparation known to precipitate in the plasma. If these toxic reactions following doses of 0.3-1 g. Fe (Nissim, 1947; Ramsey, 1950) are assumed to be due to precipitation, then the threshold of precipitation in man is considerably smaller than in the mouse and rabbit—namely, about 4-10 mg. Fe per kg. in the former as compared with about 45 mg. Fe per kg. in the latter.

The common early reactions in man described by many authors are largely different in type from late reactions and are not believed to be due to precipitation. Plasma iron levels in a 60-kg. patient following the injection of 300 mg. Fe gave figures of 10, 4.9, 1.7, and 1 mg. Fe per 100 ml. at 0, 1, 3, and 6 hours (see Chart), and conformed to the type of curve obtained in rabbits.

Plasma iron levels in a 60-kg. patient after intravenous injection of 300 mg. Fe as saccharated iron oxide.

perhaps occur in certain conditions—for example, severe reduction of the pulmonary capillary bed. Those factors present in certain samples which give rise to early toxic reactions in man cause no detectable toxic effects in animals, so that the superiority of samples regarding these early toxic reactions are not shown by their LD₅₀ or by the absence of some typical toxic response.

The anginal type of pain as well as the pain in the back seen among the early reactions, particularly in elderly patients, suggest ischaemia of poorly supplied viscera. The ischaemia may be caused directly by spasmodic action of the material on the coronary or renal vessels. Alternatively, it may be caused by dilatation of vessels in the splanchnic area with diversion of the blood thereto. The list of early reactions shows that sometimes the responses suggest sympathetic stimulation, at other times parasympathetic stimulation. It is of interest, however, that the injection of tetraethylammonium chloride in one case simultaneously with saccharated iron oxide did not prevent this painful type of reaction, but the injection of calcium gluconate in another diminished its intensity (Horrigan *et al.*, 1950). Only a proportion of people (10-20%) seem to be susceptible to these early reactions.

Perhaps the strongest support for the dual mechanism of the reactions is obtained from the paper of Ramsey, who gave doses of 300-900 mg. Fe to 11 patients. Delayed reactions, which are extremely rare in doses under 300 mg., occurred here in 9 out of 16 injections (56%). Early reactions, on the other hand, occurred only in three out of 16 injections (19%), a frequency not much higher than that reported after the usual smaller doses. More interesting still is the fact that two of the latter three patients, having recovered from their transient early reactions, showed the delayed type of reaction several hours later, after a period entirely free of symptoms between the two episodes.

Toxic Reactions in Tuberculous Patients

Librach (1953) described two cases of toxic reactions to intravenous saccharated iron oxide in patients with pulmonary tuberculosis and discussed the possible mechanisms of iron intoxication in detail. It is pointed out here, however, that a different mechanism may have operated in these two cases, both of which had a severe involvement of the lungs with the tuberculous process. One was described as a case of chronic pulmonary tuberculosis complicated by amyloid disease and massive albuminuria; the other had tuberculous bronchopneumonia. In both cases severe limitation of lung capacity was likely, with marked diminution in the lung capillary bed. This may be an important point in the consideration of the mechanism of toxicity of intravenous saccharated iron oxide. Animal studies show that saccharated iron oxide is most likely to precipitate in the lung capillaries after intravenous injection (Nissim, 1953a), since it is through these capillaries that the iron passes before being adequately diluted in the blood. Another favourite site of precipitation is the kidney (Nissim, 1953c), because of the increase in iron concentration following plasma filtration through the glomeruli. Saccharated iron oxide can precipitate both immediately and gradually above certain threshold concentrations, and it seems reasonable to suppose that such precipitation is more likely to occur with small doses when there is severe diminution in lung reserve. This is a point worth bearing in mind when intravenous iron is considered for such cases. Although in Librach's cases the early reaction may have been due to impurities, as discussed previously, the epileptiform fit and pain in the chest lasting for 24 hours in Case 1 and the dyspnoea and cyanosis in Case 2 are compatible with reaction of the second type, in this case due to abrupt precipitation. The restriction in the lung capillary bed may have been made worse by the previous two injections given without untoward effects.

Librach invoked the iron transport mechanism of the β -globulin-fraction iv-4(8) of Cohn, or siderophilin, as being partly responsible for the occurrence of iron reactions in these subjects. The work carried out on plasma iron following saccharated iron oxide throws doubt on this hypothesis. Klopfer (1951) found that toxic effects arose only when the iron-binding capacity is exceeded in the individual injections. It is pointed out here that siderophilin cannot be involved in the transport of the iron of saccharated iron oxide to any extent, since calculation shows that the iron-binding capacity of the total plasma in an adult is only about 16 mg. Of this total a third is already bound to iron, so that doses in excess of 10 mg. should give rise to toxic reactions. This is evidently not so, as shown by the plasma iron levels of 5-10 mg. Fe per 100 ml. maintained for a period of hours without the slightest toxic manifestation.

Saccharated iron oxide is a colloidal compound the iron of which is not split off easily. Its estimation in plasma requires the use of much larger quantities of HCl than is usually employed (Nissim, 1953b), and this accounts for the much lower plasma iron figures obtained by previous workers following intravenous saccharated iron oxide (Cameron *et al.*, 1951b). The proportion of plasma iron estimated by the usual methods—for example Laurell's (1947) method—after injection of saccharated iron oxide is not greater than the proportion before injection (20%), suggesting that little splitting of the compound, if any, takes place *in vivo*. It is possible that certain preparations of saccharated iron oxide contain a small proportion of diffusible or ionic iron as impurities, but until this is shown to be the case toxic reactions due to oversaturation of siderophilin remain hypothetical. Cameron *et al.* (1951a) found that following injections of saccharated iron oxide the total iron-binding capacity of serum was reduced but never approached zero, so that the belief that saccharated iron oxide remains unsplit in the plasma finds additional support here.

Allergy

Librach further believed that the question of allergy is important. Evidence for natural hypersensitivity to impurities in certain commercial samples exhibiting itself in the early and usually transient type of reaction has already been presented. These impurities may have the nature of histamine releasers, as suggested by the bronchospasm reported in some patients (Sinclair and Duthie, 1949). Acquired allergic hypersensitivity to a component or impurity in the preparation, however, is another matter. The repeated injection of saccharated iron oxide in animals has never resulted in allergic manifestations (Cappell, 1930; Nissim, 1953). In man the incidence of reactions of the early type is not greater after later injections than after first injections. The incidence of the delayed type of reactions decreases if anything with repeated injections (Ramsey, 1950) apparently owing to hypertrophy of the reticulo-endothelial system following an injection of saccharated iron oxide when previous doses were well tolerated may possibly be due to differences in batches of the preparation (Dickstein *et al.*, 1952). However, the occurrence of isolated instances of acquired hypersensitivity—for example, the case of Sinclair and Duthie (1949) and the two cases of Librach—cannot be ruled out, but on account of their rarity other possible causes must be considered—for example, change of batch—before such a hypothesis is accepted.

The suggestion put forward by Ramsey for the late reactions is interesting. He noted that they resembled in a striking manner those symptoms of paroxysmal haemoglobinuria from cold, and believed that they "may well be caused by sudden increased activity of the cells of the reticulo-endothelial system." To what extent overactivity of the reticulo-endothelial cells is by itself capable of producing toxic symptoms is a problem difficult to answer. The injection of colloidal dextran in relatively large doses or of vital dyes which are taken up by the reticulo-endothelial cells seems to be devoid of toxic effects. Saccharated iron oxide is certainly taken up by the reticulo-endothelial system, but it is also known that, in animals, saccharated iron oxide precipitates above a threshold level, and this seems the obvious mechanism responsible for the toxic effects in man after large doses. Other hypotheses lack experimental evidence.

Librach (1953) discussed "iron poisoning" in rather general terms, and included in his discussion cases of toxicity after intravenous saccharated iron oxide and after oral ferrous sulphate (Prain, 1949) without adequate distinction. It cannot be too strongly emphasized that, apart from completely ionized ferrous and ferric compounds, many iron preparations are in fact non-ionized complexes with entirely different mechanisms of toxicity, mechanisms which depend on the chemical reactivity and other properties of the whole molecule (Nissim, 1953d). Indeed, some preparations show different mechanisms in the causation of death at different dose levels. Discussion of toxicity must therefore be confined to the compound in question, unless it is shown that the compound is ionized either partly or wholly, when the mechanisms of toxicity for either ferric or ferrous ions may be invoked.

Reaction in a Fatal Case

In the fatal case reported by Barritt and Swain (1953) it seems fairly clear that the reaction was of the early type without evidence of precipitation. The absence of multiple emboli at necropsy and in the toxicity tests carried out on samples before and after injection seems to rule out this possibility satisfactorily. It seems likely that the mechanism of ischaemia discussed previously was responsible for the fatal outcome, especially on account of the post-mortem evidence of calcification of both coronaries with complete occlusion of the right artery. It is difficult, however, to assess the seriousness of the part played by intravenous iron, as such a patient may succumb to an attack of coronary occlusion even after a relatively mild reaction. It becomes

obvious, nevertheless, that particular care should be observed with such cases.

Infants and children seem to tolerate saccharated iron oxide in relatively large doses—25-100 mg. Fe (Bramham, 1952; Dickstein *et al.*, 1952), in contrast to elderly patients, who tolerate it less well than normal adults (M. R. Jeffrey, 1952, personal communication). Reactions in children are mild. In a series of 198 injections in 80 infants and children, Dickstein *et al.* reported three cases of generalized papular rash, which suggest an allergic response. The rash lasted only for one day. All of nine febrile reactions were associated with one sample of the preparation and ceased when a fresh batch was used. Although these febrile reactions were delayed in onset (appearing in about two hours) and lasted some two to three hours, it is difficult to attribute them with certainty either to allergy-producing impurities or to precipitation.

Conclusions

Sucrose and other substances used in the preparation of saccharated iron oxide should be of high standard.

There is evidence from histological studies in animals injected with two- to three-year-old solutions of saccharated iron oxide that the character of the compound undergoes slow alteration in solution with increase in diffusibility, and its uptake by fibrous-tissue elements becomes marked. This change may be associated with increase in toxicity or allergy-inducing properties in man and may be prevented by keeping the compound and ampoules in powder form just as practised with intravenous barbiturates. If this reduces the incidence of toxic effects the additional cost of the procedure would be justified.

It may prove possible to separate impurities from solutions of saccharated iron oxide by dialysis. Further, saccharated iron oxide may consist of colloidal particles of various sizes, and fractional ultrafiltration may give a more uniform preparation of reduced toxicity.

The extent to which these suggestions are compatible with the cost of manufacture can be decided only by the various firms engaged in the preparation of saccharated iron oxide. The use of analar ingredients seems to be the easiest step, and this is believed to have been already adopted by some drug firms.

Summary

The frequency and type of toxic reactions following intravenous saccharated iron oxide are discussed. A review of the incidence of these reactions in the hands of various workers is presented.

Reactions are of two types, early and late; a list of the toxic effects in the two types is given. Early reactions are believed to be due to individual hypersensitivity to impurities apparently present in commercial (B.P.) sucrose and may be allergic in type. Particular care should be taken in patients with arteriosclerosis, as the frequent transient anginal type of pain and back pain suggest ischaemia of the myocardium and kidneys.

The majority, at least, of delayed reactions are believed to be due to the gradual precipitation of the compound as occurs in animals following large doses. Some precipitation of saccharated iron oxide may possibly occur immediately after injection if the capillary bed in the lungs is greatly reduced by disease or the preparation injected too rapidly.

MANAGEMENT OF THE COMMON VARIETIES OF SCALP RINGWORM*

BY

J. MARTIN BEARE, M.D., M.R.C.P.

Consultant Dermatologist, Royal Victoria Hospital, Belfast, and Royal Belfast Hospital for Sick Children

The differential diagnosis of the various types of scalp ringworm is of importance, since good treatment follows accurate mycological diagnosis. It is not necessary to have the result of mycological culture before treating any individual case. Considerable accuracy in clinical diagnosis can be achieved when one has, as a background, full knowledge of the various types of fungi which are endemic or epidemic

TABLE I.

Fungus	Animal	Inflam-matory Reaction	Wood's Light	Outbreaks	Treatment
<i>M. audouini</i>	None	None	Green fluorescence	Large epidemics often occur	X-ray epilation
<i>M. canis</i>	Kitten	None or moderate	Green fluorescence	Usually small outbreaks affecting about 5-15 children	Fungicidal ointments
<i>T. sulphureum</i>	None	None	Nil	No very large outbreak so far reported, but general incidence is apparently increasing	X-ray epilation
<i>T. discoides</i>	Calf	Severe	Nil	Individual cases or 3-4 in a family	Starch poultices; extraction of loose hairs with forceps; soothing local applications

in the area. One can simplify diagnosis and arrive at sound practical treatment by concentrating on the three, four, or five fungi which occur in the locality (Table I). In the North of Ireland there are four important fungi (Beare and Cheeseman, 1953), which accounted for 99% of 1,157 cases of tinea capitis seen between May, 1948, and December, 1952, and

*Based on a paper read in the Section of Dermatology at the Annual Meeting of the British Medical Association, Cardiff, 1953.

from which the responsible organisms were identified. These four fungi are *Microsporum audouini* (889 cases), *M. canis* (178 cases), *Trichophyton sulphureum* (55 cases), and *T. discoides* (24 cases). Three other fungi were encountered during this period—namely, *T. mentagrophytes* (8 cases), *T. equinum* (2 cases), and *T. schönleini* (1 case).

An easy and useful practical classification of the four common types of tinea capitis is by division into Wood's-light-positive and Wood's-light-negative cases, and subdivision of each of these two groups into human and animal types of fungi, as follows. Wood's-light-positive: human, *M. audouini*; animal, *M. canis*. Wood's-light-negative: human, *T. sulphureum*; animal, *T. discoides*. These four main groups are discussed in turn.

M. audouini Infections of the Scalp

Recently there has been considerable discussion regarding the possible effectiveness of local ointment treatment for cases of tinea capitis due to *M. audouini*. Among the best results are those obtained by Schwartz *et al.* (1946), who, in a carefully conducted and very practical trial, claimed 274 cures out of 445 children treated with local medications within a 16-months study period (61.6%). Similar results were obtained by Barlow *et al.* (1950). It would be fortunate indeed if we could cure this type of scalp ringworm by local application of a simple ointment, but the conservative treatment of this variety requires certain ancillary measures which the average general practitioner or school medical officer would find extremely difficult to carry out.

Treatment with Ointment.—The disadvantages of local ointment treatment for this condition, even assuming that this treatment is really effective and that cure is not spontaneous—and this is still in debate—include the following. (1) Treatment has to be carried out by reliable trained persons and not left to parents or friends. (2) During the time that the child is having treatment, unless supervision is very close, he will be infectious. (3) The failure rate over a reasonable period, such as six months, is considerable, as can be seen from an examination of the various clinical trials so far reported. (4) Some of the cures seem to have acted by producing local kerion-like reactions. I have seen these "artificially produced kerions" leave permanent scarring. (5) It is usually necessary to shave the children's scalps. (6) X-ray therapy centres are still required to deal with those children who fail to respond to ointment therapy.

Advantages of X-ray Epilation.—(1) X-ray epilation for this form of scalp ringworm offers an almost 100% certain cure within a period of four to six weeks. The treatment can be carried out in less than an hour, it is completely painless, and from all practical points of view it is safe if used by people who have been thoroughly trained in this method of treatment. Hair regrowth in boys is complete in six months. (2) The amount of co-operation required between hospital staff and parent is reduced to a minimum. One has only to get written consent, have the child for an hour, and then, no matter what the parents do subsequently, that child will almost certainly be free of infection in a month. (3) Unruly and obstreperous children can be conveniently managed under a light general anaesthetic.

Steps Taken in a Series of Cases

In 1948 it was estimated that there were about 1,000 cases of *M. audouini* scalp ringworm in the North of Ireland. The following steps were taken to deal with this campaign. (1) Examination of all schoolchildren within the affected areas by a nurse using Wood's light. In Belfast 50,000 such examinations were made and 225 cases found; 100 further cases were discovered among relatives of non-school age. (2) General practitioners and school medical officers were encouraged to refer their cases to a ringworm centre. (3) Wall maps were made out and coloured pins inserted to denote the homes of infected children. (4) An adequate

follow-up system was started. Infected children were regarded as a danger to the community. (5) Infected children were kept from school, mainly because it was felt that this gave control of the case. If a child is not allowed to go to school then most mothers, however obstinate, will eventually yield and have whatever treatment is advised.

One amusing but troublesome difficulty was encountered over this decision to keep infected children away from school. So many children were away from school—in some cases all the children living in a street had ringworm—that a child who was not infected felt "out of it all." A market in ringworm was started by the more enterprising sufferers from this condition, and infection was sold at a price which at the height of the market reached sixpence a rub. To solve this problem the school authorities opened a special ringworm school: this allowed us to retain control of the case.

Results

About the summer of 1951 a very appreciable drop in the incidence of infection was noted, and by August or September of that year the falling off of cases was considerable. Only two cases from the Belfast and Newtownards areas were seen in 1952, and only one isolated case in 1953.

There is undoubtedly some as yet unknown factor which determines the virulence of *M. audouini*, and therefore the incidence of tinea capitis due to this fungus. Kligman (1952) found great difficulty in inoculating experimentally the scalps of children maintained in an institution in Philadelphia. He expressed the opinion that this disease was not so infectious as had had sometimes been claimed. I cannot agree with this, and the following data indicate the high degree of infectiousness in practice. The incidence of ringworm during the epidemic period in the town of Newtownards was 12%, 368 children from a total child population of 3,000 under the age of 17 years being affected between January, 1948, and August, 1949 (27.2% of the male school population were infected). In another epidemic in the North of Ireland which occurred in a residential school, 31.6%—or 116 children out of a population of 367—were affected (Walby, 1952).

M. canis Infections of the Scalp

During recent years we have carried out few x-ray epilations for cases of tinea capitis due to this fungus. Various authors in the past have stated that the majority of *M. canis* infections of the scalp clear spontaneously, and that x-ray epilation is not always necessary (Lewis and Miller, 1934; Lewis, 1935). When all the non-epilated children who had been seen in 1948 with scalp ringworm at the Royal Belfast Hospital for Sick Children were recalled during the early months of 1949 none were found to be infected by *M. canis*. These children represented a very mixed group of infections, and it can be safely assumed that some of them were originally cases of *M. canis* infection. It was therefore apparent that the great majority of these infections must clear quite quickly and spontaneously. However, during the time when we were primarily concerned with *M. audouini* it was felt that, from the point of view of the welfare of the community, all cases of non-inflammatory scalp ringworm should be subjected to x-ray epilation. Consequently a large number of cases of *M. canis* infection were epilated during 1949-51.

It is possible to make a clinical differentiation between *M. audouini* and *M. canis* infections in the majority of cases (Beare and Cheeseman, 1951).

Treatment

So far as I am aware, no properly controlled experiment estimating the time saved by subjecting children with the *M. canis* variety of scalp ringworm to x-ray epilation has been carried out. Useful information can be obtained by comparing the duration of infection in groups of children presenting with different inflammatory reactions. The in-

flammatory varieties cause no undue worry, and if it can be shown that the non-inflammatory cases, if not epilated, clear as quickly or nearly as quickly, then this would seem to be a strong indication not to use x-ray therapy with its attendant troubles and subsequent temporary alopecia for any case due to this fungus.

In 1949-50 there were 90 cases of *M. canis* scalp infection, and of these 42 were epilated. For the most part these were the non-inflammatory cases. In 1951-2 there were 88 cases and 5 were epilated (4 in 1951 and 1 in 1952). There was no special selection of these five cases for epilation. Of the 83 non-epilated cases the attendances of 61 were regular enough to allow of analysis (the other 22 did not re-attend just when requested, though all were eventually re-examined). These 61 cases were analysed from the point of view of duration of infection, and it is possible to divide them into two groups according to the severity of the inflammatory reaction present.

All patients were treated simply by local application of Whitfield's ointment. Inflammatory reaction was absent in 27 patients and slight or severe in the remaining 34.

Duration of Infection

Table II shows the average duration of treatment, measured from the date when the patient was first seen to the date when judged to be clear of infection. In the group

TABLE II.—Analysis of Average Duration of Time Between Date Patient First Seen and Date Infection Cleared

	No Reaction	Slight to Severe Reaction
Number of patients ..	27	34
Mean duration (first seen—clear): days ..	57.00	47.99
Standard deviation of duration: days ..	22.33	26.83
Standard error of mean: days ..	4.30	4.60
Difference between means: days ..	9.41	
Standard error of difference: days ..	6.75	
Difference + standard error ..	1.4	

with no inflammatory reaction the average duration of treatment was approximately 57 days, while in the group with slight to severe reaction it was 48 days. Although these averages do suggest that the condition takes longer to clear in patients with no reaction than in patients with reaction, the average difference is only about nine days, and, moreover, could quite easily have arisen by chance. (The table shows that the difference is less than twice its standard error and would be described as "not significant" at the conventional 5% probability level.)

Since the two averages are not significantly different, it is legitimate, for these data, to pool the two reaction groups to arrive at statistics for the complete group of 61 patients. When this is done the average duration of time between the date when the patient was first seen and the date when the infection was cured is approximately 52 days, and the series has a standard deviation of approximately 25 days. The latter suggests considerable variation between individual patients.

The absence of a real difference in duration of infection in the two groups from the time the patients were first seen implies that, if both types of case react similarly to the treatment given, there is no evidence, from these data, of a significantly longer duration in the patients with no inflammatory reaction compared with those with slight to severe inflammatory reactions.

Table III is an attempt to arrive at average durations of infection from time of onset—estimated at history taking—to time infection was clear. There is a marked similarity between the durations so obtained in the two reaction groups. Where reaction was absent the average duration of the condition was only four days (approximately) greater than where reaction was present. Again the difference is insignificant at the 5% probability level. When the two groups are pooled it is found that the average duration of

TABLE III.—Analysis of Estimated Average Duration of Infection Between Estimated Date of Onset and Date Infection Cleared

	No Reaction	Slight to Severe Reaction
Number of patients ..	27	34
Mean duration (onset—clear): days ..	72.81	68.38
Standard deviation of duration: days ..	27.87	24.17
Standard error of mean: days ..	5.36	4.15
Difference between means: days ..	4.43	
Standard error of difference: days ..	6.78	
Difference ÷ standard error ..	0.7	

infection from the time of onset to the time cleared for the 61 patients was about 70 days, and the standard deviation about 26 days.

It must be pointed out that in Tables II and III the longer average duration is, in fact, found in the group which experienced no inflammatory reaction. In these data, however, the excess could easily be attributed to chance, but the numbers involved are admittedly small. In view of the results of this tentative examination it seems wrong to accept at this stage the suggestion that, other things being equal, there is a real difference in the duration of the condition between groups of patients with different inflammatory reactions.

One could expect to clear all cases of *M. canis* scalp ringworm with x-ray epilation in approximately four weeks, certainly six weeks (28 to 42 days). This would imply that probably a little over half of the children in the present series (irrespective of the intensity of inflammatory reaction) would have been rendered free of infection more quickly had they been epilated with x rays. Against this, however, must be balanced the fact that these children would have been bald for some four months, long after they would have been free of infection had they been treated conservatively, and the epilated girls, of course, would actually be socially unacceptable for longer than four months.

It is of some interest that the number of new cases seen each year showed little variation (1949, 42 cases; 1950, 48 cases; 1951, 42 cases; 1952, 46 cases), which is further support for the thesis that x-ray epilation is not necessary in this infection. Thomas (1953) also supports this view. One might advocate x-ray epilation for cases of *M. canis* infection in which there is a complete absence of inflammatory reaction. The longest duration one has seen of this variety of tinea capitis is 149 days (about five months). This was exceptional, and if this long duration could be predicted in any individual case x-ray epilation would probably be justifiable.

Many of the non-inflammatory *M. canis* cases which clear within six weeks or so are probably the result of a third or fourth transfer of the organism. Duncan (1948) has pointed out that *M. canis* infections undergo a limited number of transfers; for example, kitten to child A—to child B—to child C, and then the organism probably becomes avirulent.

Our routine now for *M. canis* scalp infections is local treatment with a fungicidal ointment. The advantages of using a rather sticky ointment such as Whitfield's probably lie in the fact that this prevents loose hairs and spores from falling in all directions, not only on to the child's environment, but also on to other parts of the child's scalp.

T. sulphureum Infections of the Scalp

Fifty-five patients with tinea capitis due to this fungus have been seen during the period 1949–52. This variety of ringworm has recently attracted considerable attention. Howell *et al.* (1952) have described 37 cases seen in Texas and California. Under Wood's light there is complete absence of fluorescence, but clinically these infections are often very much like those caused by *M. audouini*.

In the present series 36 of the 55 cases showed little or no inflammatory reaction. Eleven were classified as kerions. It is curious that these kerions were seen for the most part during the last year of the present four-year survey. Forty-one cases were seen within two months of

onset of infection, but four had had the infection for more than one year, and one had had an infection for over two years. Two boys were affected to every one girl. The average age was 7, but there was a fairly even spread throughout the first 14 years of life. No adults with this infection of the scalp were seen.

In the North of Ireland the infection is practically confined to Belfast, and in general is probably a disease of large centres of population. There is no animal reservoir, and infection passes from patient to patient. There was a steady rise in the number of new cases seen each year (1949, 10 cases; 1950, 11 cases; 1951, 13 cases; 1952, 21 cases).

It has usually been extremely difficult to establish the source of infection, and indeed only once, when brother and sister were infected, was this possible. Extensive scalp infections were seldom seen, and the most usual picture was that of a single small scaly non-inflammatory patch, often like a mild seborrhoeic dermatitis, but with some broken-off hair stumps. Thirty-four of the 55 cases had only one patch.

In addition to the cases of tinea capitis, 16 cases of tinea corporis due to this fungus were seen. The areas most often involved were the face and neck.

Local epilation was used in preference to total epilation because so many cases had only one patch, but of 31 cases so treated 6 were failures. In these particular cases the infection appeared in the adjacent non-epilated hair. Eight cases had total epilation, and in one of these it was a failure. A few cases cleared without epilation, including the 11 with kerions. Treatments used when x-ray epilation was avoided included Whitfield's ointment locally and manual epilation of hair stumps. Since the infection is non-fluorescent under Wood's light this is a very tedious and unreliable procedure.

The treatment of choice for non-inflammatory infections is probably a whole-scalp epilation even when only a single patch is present.

T. discoides Infections of the Scalp

This fungus is the common cause of cattle ringworm in the United Kingdom. It causes an extremely severe local reaction which sometimes progresses to a chronic granuloma that may persist for six months or more and often leads to scarring and areas of permanent baldness.

Most Ulster patients first seek cure from the local charmer, and have a smouldering twig waved three times round the affected area on the night of a full moon. This procedure does much less harm than tincture of iodine, and the results are probably just as good. It is extremely doubtful whether anything we do can actually shorten the duration of a *T. discoides* infection. A possible exception to this statement is manual epilation of the loose affected hairs, using a small pair of forceps. For patients who can be admitted to hospital this procedure should certainly be carried out. Sticky starch poultices and removal of the affected hairs by this method are also of value. Symptomatic treatment is, of course, appreciated, since the condition is uncomfortable or even painful.

T. discoides infections can usually be differentiated from *T. sulphureum* infections by (a) the degree of reaction, which is so much greater with *T. discoides*; (b) a history of contact with infected cattle, which is always given for *T. discoides* infections; and (c) in the North of Ireland finding out where the patient lives: a non-fluorescent scalp ringworm from Belfast is *T. sulphureum* and from outside Belfast is *T. discoides*.

Conclusions

It is possible to differentiate the four chief varieties of scalp ringworm by simple clinical inspection and Wood's-light examination.

The presence of *M. audouini* represents a danger to the child community and a challenge to the doctor.

It should be possible to eradicate completely this variety of ringworm from a community. X-ray epilation should ideally be carried out at the child's first attendance at a dermatological clinic. All contacts in the home and school should be examined with Wood's light.

The importance of *M. canis* ringworm lies in its differentiation from the *M. audouini* variety. X-ray epilation is seldom indicated.

T. sulphureum is likely to cause great anxiety and trouble in the near future, since diagnosis of the non-inflammatory varieties is difficult, and the disease may last for years if untreated. X-ray epilation of the whole scalp is probably the best treatment in most cases.

It is very doubtful whether any procedure can actually shorten the duration of *T. discoides* infections, but symptomatic treatment is appreciated by the patient.

My thanks are due to Dr. I. H. McCaw, Dr. R. Hall, and Dr. J. Jefferson for allowing me to study their cases; and to Dr. J. Walker, of the London School of Hygiene and Tropical Medicine, for carrying out all the mycological studies. Dr. E. A. Cheeseman kindly gave much help and advice, particularly for the section concerned with the duration of *M. canis* infections, and prepared Tables II and III.

ATELECTASIS AS A COMPLICATION IN ARTIFICIAL PNEUMOTHORAX

BY

R. L. SADLER, E.R.D., M.B., B.Sc., D.P.H.
 Senior Registrar, the Cheshire Joint Sanatorium

Since 1920 therapeutic pneumothorax has had a vogue which was certainly excessive at first, but lately the balance has swung the other way and some authorities seem to regard it as a dangerous procedure which should be used only in exceptional cases (Harris *et al.*, 1952; Jackson, 1952; Simmonds *et al.*, 1952).

Young (1949) believes that the cause of this trend of opinion is the fact that the technique seems so easy that it has been carried out by workers inexperienced in the proper selection of cases or in the finer points of its conduct. In the management of artificial pneumothorax (A.P.) cases the physician must be experienced enough to recognize the circumstances that demand the immediate termination of the pneumothorax treatment. Also, to give the best chance to his patients who need the help of an A.P., he must know what "complications" may be disregarded with reasonable safety. One such complication often appearing in an otherwise perfect pneumothorax is the occurrence of an area of atelectasis; and the object of the present investigation is to try to decide whether or not such an occurrence is an indication for suspending this type of collapse therapy.

Some writers have associated atelectasis occurring in an A.P. with such sequelae as progressive tuberculous disease (Rafferty and Shields, 1943), with relapse (Maher-Loughnan, 1950), and with tuberculous pleural effusions and empyemata (Houghton, 1950). On the other hand, Scadding *et al.* (1952), Foster-Carter *et al.* (1952), and Beric Wright (1952) have recorded satisfactory results in small groups of cases with atelectatic lobes or segments, while earlier writers (Brooks, 1938; Erwin, 1939) regarded its occurrence as a favourable event.

At the Cheshire Joint Sanatorium the clinical impression has long been that the occurrence of lobar or segmental atelectasis does not of itself warrant the interruption of the course of an A.P. Adequate material is therefore available at this institution for the numerical examination of the prognostic effects of such atelectasis.

Data

Data for this investigation were obtained from consecutive cases of A.P. induced at the Cheshire Joint Sanatorium between early 1935 and the end of 1945. That all these cases were finally complete was shown by thorascopic examination as well as by x-ray films. In all cases sputum was either negative throughout or converted to negative by effect of the A.P.

The collecting of data from earlier sanatorium cases has the advantage of allowing a long period of follow-up—of five years in all cases and of ten years in about half of them. Also, in earlier years case selection for therapeutic pneumothorax, and the subsequent management, were less informed than at the present day. We are thus able to collect for assessment groups of cases which would not be seen in current practice, such as those in which there is a persistent cavity in an anatomically complete A.P. One disadvantage of collecting data from earlier cases is the absence of information from routine bronchoscopic examinations.

Where disease in the contralateral lung was regarded as a possible factor in life prognosis the case was excluded—for instance, if on the contralateral side there was an incomplete A.P., or if an attempt at induction of an A.P. had failed on the contralateral side. With regard to contralateral disease, the cases included had (a) no radiological evidence of disease; (b) disease controlled by an uncontroversial A.P.; or (c) disease of moderate extent, healing, and not sufficient to warrant active intervention and not producing a positive sputum.

Disease in the pneumothorax lung, as it appeared prior to A.P. induction, was classified according to its type and its extent.

The type of disease was dealt with under three headings. (1) Cavitated disease: the cavity was at least 5 cm. in diameter, or multiple cavities had a total diameter of at least 5 cm. (2) Exudative disease: the disease was predominantly of a type with a confluent and ground-glass radiographic appearance. (3) Productive disease: cases not classified under (1) or (2) appeared under this heading, so that a variety of radiographic appearances of tuberculous infiltration are included.

The extent of the disease was classified according to the total number of zones in the P.A. x-ray film of the chest which showed infiltration of tuberculous infection. The zones are demarcated by two horizontal lines passing through the second and fourth costal cartilages, thus dividing each lung field into three zones. This classification of disease extent was used by Hartley *et al.* (1935).

Atelectasis is recorded only if it persisted for three months or more. Transient atelectasis following thoracoscopy (Hess, 1951; Penman and Miller, 1952) is thus excluded. In regard to the extent of atelectasis, the cases were classified into four groups—total, lobar, segmental, and nil. Lobar atelectasis includes that of an upper or a lower lobe, there being

no case of a solitary middle-lobe atelectasis. Segmental atelectasis includes cases in which a recognizable segment is collapsed, but cases with more than one atelectatic segment are also included under this heading.

Pleural effusions were recorded only if they were large enough to cover the diaphragm, and if persistent enough to require aspiration. Small or transient effusions are thus excluded. A proportion of these effusions occurred in the later course of the artificial pneumothorax, and some of the data of this complication were obtained from a questionnaire sent to the chest physicians of clinics. Details of survival and duration of the pneumothorax were also available from this source.

Data concerning the occurrence of contralateral spreads, and the activity of disease in the pneumothorax lung, or the degree of re-expansion of the pneumothorax lung after termination of the A.P., were less readily obtained. This part of the investigation entailed use of records and x-ray films at many clinics, and in some cases these records were inadequate for the purpose. For this and other reasons, only 159 cases of the original 266 were available for this part of the inquiry.

Results are tabulated and analysed according to the four groups of atelectasis, and are considered under the following headings: pleural effusions; re-expansion of the A.P. lung, and re-aeration of the atelectatic area; reactivation of disease in the A.P. lung at the termination of pneumothorax; contralateral spread of disease; and mortality rates.

Pleural Effusions

As already stated, only persistent effusions are recorded. They are classified according to whether purulent or non-purulent and according to culture reports into T.B.-negative effusions, T.B.-positive effusions, and empyemata. All the empyemata were positive for the tubercle bacillus. As in the tables below, it is usually convenient to group all three types of effusion together as "persistent effusions," and the last two types together under the heading of "all positive effusions."

A comparatively high death rate has been associated with groups of A.P. cases having persistent pleural effusions (Edwards *et al.*, 1944; Morriss, 1942). Brock *et al.* (1937) believe that in such cases of pleural effusion the active disease in the underlying lung is the detrimental factor rather than the effusion itself. In considering the subject of the prognosis of atelectasis, however, it is obviously important to note any association between atelectasis and pleural effusion.

Houghton (1950) believes atelectasis in the A.P. to be a direct causative factor of T.B.-positive effusions. In his own words, "atelectasis of a grossly diseased lobe with or without cavitation will be followed almost inevitably by pleural effusion, tubercle bacilli will appear in the fluid and sooner or later an empyema will develop." In support of this view he quotes 50 consecutive A.P. cases in which tubercle bacilli had been demonstrated in the pleural fluid—many cases were empyemic. In 86% of these 50 cases a black

lobe or lung was prominent in the x-ray picture. A corresponding group of T.B.-negative effusions did not show such atelectasis, or showed it only as a transitory phenomenon.

In Table I the occurrence of effusions among the cases of the present investigation is shown. The cases having a persistent cavity in the pneumothorax lung are dealt with separately, and effusions of the three types are shown in relation to the extent of atelectasis. Of the 28 cases with T.B.-positive and the 20 cases with T.B.-negative effusions, 25 (90%) and 12 (60%) respectively had some degree of atelectasis. The former finding is similar to the one quoted from Houghton. However, there seems good reason to analyse the matter further before accepting the view that atelectasis is the causative factor of such pleural effusions.

First of all, the persistent cavity group, which includes atelectatic and non-atelectatic cases, has a significantly higher incidence of effusions than the group of cases without persistent cavitation (Table II).

TABLE II.—Persistence of Cavitation and Effusion Incidence

Cases	No.	T.B.-positive Effusions	All Persistent Effusions
Persistent cavity	20	8 (40%)	9 (45%)
No persistent cavity	246	20 (8.1%)	39 (15.8%)
Difference		31.9% ± 11%	29.2% ± 11%

It is therefore justifiable to omit for the time being the cases with persistent cavitation and inspect the incidence of effusion in the remaining cases. Among the latter it is seen (Table III) that a positive correlation exists between incidence of persistent effusions or of T.B.-positive effusions, and extent of atelectasis. A similar correlation is observed between extent of disease by zones in the A.P. lung and the incidence of persistent or T.B.-positive effusions (Table IV).

TABLE III.—Atelectasis and Effusion Incidence (Persistent Cavity Cases Omitted)

Atelectasis	No.	T.B.-positive Effusions	All Persistent Effusions
Total	13	4 (31%)	7 (54%)
Lobar	44	8 (18%)	12 (27%)
Segmental	102	6 (6%)	11 (10.8%)
Nil	87	2 (2.3%)	9 (10.3%)
	246	20 (8.1%)	39 (15.8%)
	χ^2 :	$p < 0.01$	$p < 0.01$

TABLE IV.—Extent of Homolateral Disease and Effusion Incidence (Persistent Cavity Cases Omitted)

Zones of Disease	No.	T.B.-positive Effusions	All Persistent Effusions
1	45	0	1 (2.2%)
2	154	9 (5.8%)	22 (14.2%)
3	47	11 (23.4%)	16 (34%)
	246	20 (8.1%)	39 (15.8%)
	χ^2 :	$p < 0.01$	$p < 0.01$

On the other hand, between the type of initial disease in the pneumothorax lung and the incidence of pleural effusions there is little or no correlation. Indeed, the differences of incidence of effusion among the three types of disease (Table V) are no greater than could occur by chance.

TABLE V.—Type of Homolateral Disease and Effusion Incidence (Persistent Cavity Cases Omitted)

Type of Disease	No.	T.B.-positive Effusions	All Persistent Effusions
Cavitated	85	8 (9.4%)	17 (20%)
Exudative	36	5 (14%)	7 (19.5%)
Productive	125	7 (5.6%)	15 (12%)
	246	20 (8.1%)	39 (15.8%)
	χ^2 :	$p = 0.25$	$p = 0.25$

TABLE I.—Effusions and Atelectasis

Atelectasis	No.	T.B.-negative Effusions	Non-purulent T.B.-positive Effusions	Empyemata
Persistent Cavity Cases				
Total	1	—	—	—
Lobar	8	—	3	1
Segmental	6	—	1	2
Nil	5	1	1	—
	20	1	5	3
Non-cavity Cases				
Total	13	3	4	—
Lobar	44	4	6	2
Segmental	102	5	3	3
Nil	87	7	2	—
	246	19	15	5

It should be noted that the χ^2 test quoted in the tables above does not measure the strength of an association or indicate whether or not a correlation is statistically significant. It serves to show, however, where differences are no greater than might occur by chance.

The findings in Table V seem to disagree with the views of Rafferty (1947), who states that there is a higher incidence of pleural effusions where the pneumothorax lung originally showed pneumonic tuberculosis or giant cavitation.

The extent of the initial disease and the extent of atelectasis are both correlated with the incidence of pleural effusions. That the first-named two variables are themselves associated is demonstrated in Table VI. The question therefore arises, Which of the two variables is primarily associated with the occurrence of pleural effusion?

TABLE VI.—Distribution of Extent of Disease and of Atelectasis (Persistent Cavity Cases Omitted)

Atelectasis Extent	One Zone Infiltrated	Two Zones Infiltrated	Three Zones Infiltrated
Total	0	4	9
Lobar	1	28	15
Segmental	16	71	15
Nil	28	51	8
	45	154	47

It should be possible to deduce the answer, given sufficient cases. The cases under consideration should be grouped according to the extent of atelectasis, and each such group should be examined to find if the incidence of effusion is still proportional to the extent of the disease by zones and vice versa. With the present number of cases the best that can be done is to analyse the subgroups containing the greatest numbers—that is, "segmental atelectasis" (Table VII) and "two zones of disease" (Table VIII)—for the incidence of persistent effusions.

TABLE VII.—Incidence of Effusion Related to Extent of Disease (Cases with Segmental Atelectasis Only)

Incidence of persistent effusions	Extent of Disease in Zones			
	1	2	3	Total
	0 (16)	8.5% (71)	33.3% (15)	10.8% (102)
	χ^2 : $p < 0.01$			

Table VII demonstrates a positive correlation between effusion incidence and extent of disease, but in Table VIII (with a larger number of cases included) there seems to be no association between effusion incidence and degree of

TABLE VIII.—Incidence of Effusion Related to Degree of Atelectasis (154 Cases with Two Zones of Disease Only)

Incidence of persistent effusions	Degree of Atelectasis				Total Incidence
	Nil	Segmental	Lobar	Total	
	15.7% (51)	8.5% (71)	21.4% (28)	50% (4)	14.3% (154)

atelectasis. This analysis, so far as it goes, suggests that extent of initial disease in the pneumothorax lung is the primary factor in the causation of effusions rather than atelectasis *per se*.

It should be remembered that the classification of the extent of disease in a lung according to the number of zones seen to be infiltrated in a P.A. x-ray film is not an exact method. No allowance is made for the density of involvement of each zone.

Cuthbert and Nagley's (1948) description of the radiological "black lobe" when it is seen at thoracoscopy is of a mixture of collapsed and aerating tissue. The pathological finding associated with this x-ray appearance was of multiple small foci of parenchymal and bronchiolar infection. To

produce the homogeneous radiological appearance of the "atelectatic" lobe or segment, such an infiltration would be expected to be dense in character within the related lobe or segment.

Erwin (1939) notes that lobes which collapse in an A.P. and fail to expand early are extensively diseased ones; and Morland and Price Thomas (1952) state that when atelectasis appears in an A.P. the lobe or segment so affected is usually the part of the lung most seriously diseased.

The extent of the disease as seen in a P.A. film is one factor in the incidence of pleural effusions, and it is logical to assume that the density of infiltration might also contribute to its causation. Both extent and density of infiltration are apparently associated with the occurrence of atelectasis in a pneumothorax. An incidence of effusions in proportion to the extent of atelectasis in the A.P. (Maher-Loughnan, 1950; Farquharson, 1951) may well be accounted for by the extent and density of parenchymatous infiltration initially present in the lung.

Re-expansion of the Pneumothorax Lung

Re-expansion of the pneumothorax lung was noted from its radiological appearance at least one year after cessation of refills. The appearance of the lung and also of the adjacent structures—diaphragm, chest wall, and mediastinal organs—was then observed. Cases were classified into three groups. (1) Full re-expansion. The lung appeared expanded and normal apart from healed disease; no atelectasis was apparent; and there was no displacement of adjacent structures. (2) Incomplete re-expansion. This group included cases in which the lung itself was not fully expanded—commonly an apical space remained. Also included are a few cases in which the lung was expanded except for a persistent atelectatic lobe or segment. Cases in which the lung seemed to be expanded but in which moderate displacement of the mediastinum or other chest structures occurred also appear in this group. (3) Unexpandable lung. In this group either the lung failed appreciably to re-expand and a dead space remained or there was gross displacement of mediastinal structures and contraction of the chest wall and diaphragm.

Of the original 20 in the persistent cavity group and the 246 in the non-cavity group, only 3 of the former and 156 of the latter are available by which to assess re-expansion. These are the numbers of cases which can be followed up radiologically until at least one year after termination of the pneumothorax. Of the 246 cases, 90 are thus excluded for various reasons—A.P.s not abandoned at the time of assessment, adequate records not available, patients moved to inaccessible areas, etc. That the 156 cases are, practically speaking, an "unselected" sample of the original consecutive group of cases is, however, indicated by the fact that the incidence of mortality and of pleural effusion occurs at approximately the same rates as in the original group of 246.

Only six cases which left the sanatorium with a total atelectasis and only three that were discharged with persistent cavitation in the A.P. have been followed up. There was no case with a full re-expansion among these nine, and it is thought reasonable to consider them separately from the main group of 150 cases.

Among these 150 cases a full re-expansion of the A.P. lung occurred in approximately half, while an unexpandable lung was seen in 10%. The distribution of expansion in relation to atelectasis is seen in Table IX.

TABLE IX.—Re-expansion and Atelectasis (Persistent Cavity and Total Atelectasis Cases Excluded)

Atelectasis	Total	Full Re-expansion	Partial Re-expansion	No Re-expansion
Lobar	33	15 (45%)	15	3 (9%)
Segmental	63	31 (50%)	23	9 (14%)
Nil	54	32 (60%)	19	3 (6%)
	150	78	57	15

Table IX shows that a diminished proportion of full re-expansion occurs in relation to the extent of atelectasis. On the other hand, atelectasis is not associated with unexpandable lung.

TABLE X.—Re-expansion According to Effusion Present (Persistent Cavity and Total Atelectasis Cases Excluded)

Pleural Effusion	Total Cases	Full Re-expansion	No Re-expansion
T.B.-positive	12	1 (8%)	5 (42%)
T.B.-negative	11	4 (36%)	2 (18%)
No effusion	127	73 (57%)	8 (6%)
	150	78	15
	χ^2	$p < 0.01$	$p < 0.01$

Two factors which could be expected to restrict the proportion of cases showing full re-expansion in a group of atelectasis cases (Jackson, 1952), as compared with a group with no atelectasis, are: (a) persistence of atelectatic lobe or segment; and (b) a higher incidence of pleural effusions which accompany (though, as previously reasoned, are not caused by) atelectasis.

A lower incidence of full re-expansion among cases having effusions, particularly effusions positive for tubercle bacilli, is shown in Table X.

The importance of effusion, especially empyemata, in hindering lung re-expansion is well known, and has been mentioned, among others, by Mitchell (1951) and Heaton and Ogden (1950).

Persistence of an atelectatic lobe was seen in only two of the 150 cases and of an atelectatic segment in only four cases. So that persistent atelectasis is not here a factor of any great importance in limiting the proportion of cases having a full re-expansion. Incidentally these six cases were not associated with any untoward final result. Erwin (1939) reports that the few lobes which fail to re-expand are always extensively diseased, and permanent atelectasis is to be regarded as a selective collapse maintained automatically; this coincides with my own impression of these six cases.

The duration of the pneumothorax has been shown (Heaton and Ogden, 1950; Mitchell, 1951) to influence pleural thickening, and therefore lung re-expansion. It is worthy of note that 11 out of the 15 cases of unexpandable lung had had an A.P. for over six years. In fact, all of the unexpandable lung cases had either an over-prolonged A.P. or a T.B.-positive pleural effusion, or both. This suggests that pleural thickening is the cause of this undesirable sequel—which is the view of Rafferty (1947)—rather than a possible bronchial factor (Farber, 1942; Mitchell, 1951).

Duration of the A.P. in the cases of this investigation has a "chance distribution," being largely dependent upon the preference of the various physicians working at 15 different clinics.

It may be that a bronchial factor limits re-expansion in the total-atelectasis group, for in four out of six such cases followed up a persisting partial atelectasis was the reason for failure of full expansion. The other two cases exhibited an unexpandable lung. Of the persistent-cavity group only three cases were followed up completely, and these showed partial re-expansion.

Groups of cases with lobar or segmental atelectasis (with no persistent cavitation) may therefore be expected to have a smaller proportion of cases exhibiting a complete re-expansion. This is chiefly on account of the incidence of pleural effusions in such groups. It has already been reasoned that the extent and density of the original lung disease, and not the atelectasis itself, is the underlying factor in effusion incidence.

Reactivation of Disease

The occurrence of active tuberculous disease in the re-expanded pneumothorax lung was investigated in the 156 cases without persistent cavitation which were followed up until one year after the termination of pneumothorax.

Activity of disease was determined by sputum reports and other clinical evidence, as well as by the radiological appearance of the re-expanded lung. Three out of the six cases with total atelectasis showed reactivation. The remaining 150 cases are grouped separately, and in Table XI the in-

TABLE XI.—Reactivation and A.P. Duration (Total Atelectasis Cases Excluded)

A.P. Duration	Cases	Reactivation Cases
Less than 1 year	5	4 (80%)
1 to 2 years	16	1 (6.2%)
2 to 3	14	1 (7.3%)
3 or more years	115	9 (7.8%)

cidence of reactivation is shown according to the duration in years of the pneumothorax. It is apparent that the incidence of reactivation in these cases is independent of A.P. duration if those of under one year are first excluded. For this reason, in examining the incidence of reactivation in relation to lobar and segmental atelectasis, cases in which the A.P. is of longer duration than one year are grouped together (Table XII). It is apparent that there is no association between lobar and segmental atelectasis and the incidence of reactivation.

TABLE XII.—Incidence of Reactivation According to Atelectasis (Total Atelectasis Cases and Cases with A.P. Duration Under One Year Excluded)

Atelectasis	Cases	Cases with Reactivation
Lobar	32	3 (9%)
Segmental	60	4 (6.6%)
Nil	53	4 (7.5%)
	145	11 (7.6%)

It is worth noting that the total incidence of reactivation is of the same order as that found by some other observers of A.P. series—Potter (1942) gives 7%, Morris (1942) 6%, Aycock and Keller (1942) 5%, and Hurst and Schwartz (1942) 10%.

In the persistent-cavity group there is insufficient data for consideration from the point of view of reactivation or of contralateral spread of disease.

Contralateral Spread

The occurrence of a bronchogenic spread of disease into the contralateral lung in A.P. cases is given a varying incidence by different observers. Potter (1942), for instance, noted an incidence of 6%, while Morris (1942) found it in 30% of his cases. In the present 156 cases, followed up in detail, the total incidence seems to be 12%. How this is distributed in relation to atelectasis is shown in Table XIII.

TABLE XIII.—Incidence of Contralateral Spread and Atelectasis

Atelectasis	Total Cases	Cases with Spreads
Total	6	2 (33%)
Lobar	34	2 (6%)
Segmental	62	9 (14.5%)
Nil	54	5 (9%)
	156	18 (11.5%)

With the possible exception of the cases with total atelectasis, the number of which is too small for assessment, the incidence of contralateral spread is not associated with atelectasis (Table XIII).

Mortality Rates

Cedric Shaw (1933) discusses prognosis in artificial pneumothorax cases and says, "The one real ponderable in pulmonary tuberculosis is mortality." But to each death from tuberculosis, sociological and immunological as well as clinical factors make their contribution. Deductions therefore cannot be made from differences in mortality rates

between one group of tuberculous subjects and another unless such differences are obvious and significant. In Table XIV such a significant difference in mortality rates is seen when the cases with and without persistent cavitation are compared.

TABLE XIV.—Mortality Rates in Relation to Persistence of Cavitation

Cases	No. at Risk, 5 Years	Dead at 5 Years	No. at Risk, 10 Years	Dead at 10 Years
Persistent cavity	20	8 (40%)	13	11 (85%)
No persistent cavity	246	13 (5.25%)	122	19 (15.6%)
Difference		34.75% ± 11%		69.4% ± 11%

Farquharson's (1951) results of survival among A.P. cases with atelectasis are in accordance with those of Table XIV. Of 25 cases with cavitated and 75 cases with non-cavitated atelectasis, she reports 19 (76%) and 13 (17.3%) respectively as ill or dead. Also, among the good A.P. cases in the series of Foster-Carter *et al.* (1952) 7 out of 10 with persistent cavitation died within eight years.

In non-cavitated atelectatic cases, evidence of a mortality rate in relation to the extent of atelectasis might well be expected. The association between the extent of atelectasis and that of disease by zones has already been demonstrated (Table VI); and a remarkable correlation between life expectation and disease extent by zones has been demonstrated by Hartley *et al.* (1935) and more recently by Foster-Carter *et al.* (1952). The latter investigators show that the law "Expectation of survival in pulmonary tuberculosis varies inversely as the radiological extent of the disease" applies equally to groups of collapse or non-collapse cases.

In fact, there seems to be a slight trend of association between extent of atelectasis and mortality rates (Table XV). So small a trend, however, argues against atelectasis *per se* being a factor in life prognosis, having regard to the influential factor of disease extent by zones.

TABLE XV.—Mortality Rates in Relation to Atelectasis (Persistent Cavity Cases Omitted)

	Atelectasis			
	Total	Lobar	Segmental	Nil
Dead in 5 years	15.4% (13)	6.8% (44)	5.9% (102)	2.3% (87)
" " 10 "	28.6% (7)	18.5% (27)	14.3% (49)	12.8% (39)

The figures in parentheses show the number of cases followed up.

Foster-Carter *et al.* also note the mortality in 45 of their A.P. cases with lobar or segmental atelectasis but no persistent cavitation. The survival rate in this group was exactly the same as that of the group of A.P.s as a whole.

Discussion

In the group of cases having persistent cavitation in the pneumothorax lung, the comparatively high rates of death and incidence of pleural effusions are striking. It is instructive to note that these mortality and effusion rates are quite similar to those reported in some series of pneumothoraces in which there was demonstrable endobronchial tuberculosis (Chamberlain and Gordon, 1942; Tuttle *et al.*, 1942; Rafferty and Shields, 1943). Most of the cases of the present investigation were treated before routine bronchoscopy became available, but these findings suggest that where there is persistent cavitation in a pneumothorax lung there is concomitant endobronchial tuberculosis.

On the other hand, in the group without persistent cavitation, judging by the course and prognosis, the presence of lobar or segmental atelectasis would not appear to indicate an underlying endobronchial disease. The prognosis regarding life and the occurrence of effusions, as well as the incidence of contralateral spread and ipsilateral reactivation of disease, are no worse than among cases with no atelectasis.

The small number of cases with total atelectasis, however, seem to share the grave prognosis of the persistent-cavity group.

As a result of the work of Coryllos (1933) atelectasis in adult pulmonary tuberculosis was for a long period believed to be synonymous with endobronchial tuberculosis (Pinner, 1945). More recently, alternative mechanisms of lobar and segmental atelectasis have been described—for example, by Cuthbert and Nagley (1948) and Coello and Nagley (1948). According to these writers the aetiology of atelectasis (as defined in the present investigation) can lie peripheral to the major bronchi. Moreover, observance of the recognized tenets in prescribing A.P. therapy, such as withholding it in the presence of "hot" disease, of a "wheeze," or of a tension cavity, will serve to avoid many cases in which tuberculous bronchitis might be present. The fact of sputum conversion by the A.P. also serves to exclude from this series cases of endobronchial tuberculosis (Davies, 1943).

Lobar and segmental atelectasis may thus be observed radiologically in the pneumothorax lung in the absence of endobronchial tuberculosis, and in such cases its occurrence seems to be a benign circumstance.

Summary

Consecutive anatomically complete A.P. cases with sputum conversion were followed up for at least five years. They were grouped according to the presence of persistent cavitation (20 cases) and, in those without persistent cavitation (246 cases), according to the presence of total, lobar, segmental, or no atelectasis in the A.P. lung.

Cases with persistent cavitation showed significantly higher mortality rates and incidence of pleural effusions than the remaining group.

Cases without persistent cavitation showed an incidence of pleural effusion which was in proportion to the extent of atelectasis. There is evidence, however, that this was because of the concomitant extent of initial disease in the pneumothorax lung rather than a result of atelectasis *per se*.

In 156 of the cases without persistent cavitation it was possible to evaluate the incidence of contralateral spreads, of disease reactivation in the A.P. lung, and the completeness of re-expansion after termination of the A.P.

The great majority of atelectatic lobes and segments (excluding cases with total atelectasis) re-aerated at the termination of the A.P. Full re-expansion depended largely on whether or not pleural effusion had been present.

If cases with total atelectasis are excluded there was no connexion between the presence of atelectasis and the occurrence of contralateral spreads or the occurrence of disease reactivation in the A.P. lung.

Mortality rates in the group with no persistent cavitation showed no significant relationship with the occurrence of lobar or segmental atelectasis.

In the light of these findings, alternative aetiologies of atelectasis in a pneumothorax lung are discussed.

It is concluded that the occurrence of persistent cavitation or of total atelectasis in an A.P. lung carries a grave prognosis. The occurrence of lobar or segmental atelectasis, however, does not, of itself, appear to worsen prognosis.

This paper was suggested by Dr. A. C. Penman, and I am also indebted to him for going over all the case records and x-ray films with me, and checking the data at each stage. I am grateful to Dr. Peter Edwards for advice from his great experience, and for permission to make use of the records of the Cheshire Joint Sanatorium. The follow-up section of the latter

is due largely to the work of Mr. Charles Kemp. I am also indebted to the various chest physicians who kindly lent records and x-ray films.

FATAL CASE OF MARROW APLASIA AFTER TREATMENT WITH CARBIMAZOLE

THE EFFECT OF A.C.T.H.

BY

J. S. RICHARDSON, M.V.O., M.D., F.R.C.P.

I. SARKANY, M.R.C.S., L.R.C.P.

AND

C. D. CAMPBELL, M.B., B.S.

(From the Peace Memorial Hospital, Watford)

Carbimazole ("neo-mercazole"; 2-carbethoxythio-1-methylglyoxaline) must now be added to the long list of drugs that may cause marrow aplasia with depression of all the blood-forming elements.

The incidence of marrow depression due to anti-thyroid drugs is relatively low and is still decreasing as less toxic preparations become available. A report on the treatment of 150 patients with carbimazole by Doniach (1953) stresses the absence of any toxic effects in her cases, and only mild toxic reactions were found to follow treatment of 14 patients with this drug by Lawson and Barry (1951). Poate (1953), in a survey of nine cases, states that carbimazole in therapeutic doses does not interfere with the leucocytes. In a recent study on the clinical effects and toxic reactions of carbimazole, Bartels (1953) found that 3 of his 52 patients treated with this drug developed toxic manifestations. Two of these were skin reactions, the third had agranulocytosis, which however, cleared up within 14 days after discontinuation of the drug.

Rosenbaum and Reveno (1953) reported a case of agranulocytosis and toxic hepatitis secondary to methimazole ("mercazole"), the forerunner of carbimazole, and referred to two instances of agranulocytosis due to this drug (Croke and Berry, 1952; Specht and Boehme, 1952). In the experience of Davidson (1953), who discusses the use of methimazole in 44 patients, this drug is definitely less toxic than methylthiouracil, and, although slightly more toxic than propylthiouracil, the incidence of severe toxic reactions is of the same order of magnitude as with the latter drug. The overall incidence of toxic reactions with methimazole is given by various workers as 4.5-6%, that of agranulocytosis as 0.15%.

The following case is, we believe, the first example of a fatal marrow aplasia following the use of carbimazole.

Clinical History

A married woman aged 23 was admitted to hospital on June 8, 1953, suffering from severe thyrotoxicosis. Her B.M.R. was 74%. As she had suffered from extensive bilateral bronchiectasis for several years, surgical treatment for her thyrotoxicosis was considered undesirable, and she was put on carbimazole, 10 mg. three times a day, on June 19. She was discharged from hospital a fortnight later and continued as an out-patient with carbimazole in the same dosage as her sole medication. When seen a month after discharge her thyrotoxicosis was under control and she felt much better.

On August 12, just under eight weeks after beginning carbimazole she noticed red patches on her skin and was coughing up more blood from her bronchiectatic cavities than ever before. The drug was discontinued and she was admitted to hospital. Purpuric haemorrhages were found over most of her body and on her mucous membranes. There was no soreness of her throat, but she had a pyrexia of between 101 and 103° F. (38.3 and 39.4° C.). Hess's test was strongly positive. A blood count on the day of admission showed: haemoglobin, 64%; red cells, 4,110,000; white cells, 4,000, with a normal differential count; platelets, 61,000; bleeding and clotting times, normal.

Four days later her haemoglobin had fallen to 54%, her white count to 1,000 cells with 29% polymorpha, and her platelets to 25,000. She was transfused with 2 pints (1,140 ml.) of fresh blood. Her bone marrow taken at this time showed marked agranulocytosis and only one megakaryocyte in three films. Electrophoretic examination of the serum, both before and after the first transfusion, failed to reveal the presence of any α_2 -globulin such as may be present in certain cases of purpura (Bernfeld and Stefanini, 1951).

Treatment directed to the control of infection consisted of penicillin for one week, which was then replaced by aureomycin, 500 mg. six-hourly, and this was continued throughout the rest of her illness. She was given approximately 2 pints (1,140 ml.) of fresh blood at weekly intervals for the next eight weeks.

Cortisone was begun on August 23, 11 days after the onset of purpura, the initial dose being 100 mg. six-hourly, followed on the next and subsequent days by 50 mg. six-hourly. As she made no detectable response the cortisone was replaced by adrenocorticotrophic hormone (A.C.T.H.) with a dosage of 40 mg. six-hourly. After starting cortisone the patient's condition was reasonably satisfactory and her temperature settled on aureomycin, but she continued to get crops of petechiae, although Hess's test had become negative before cortisone was started. Her blood picture, which was examined daily, remained unchanged. The platelets were virtually absent, her haemoglobin was maintained in the region of 50% with transfusions, and her white cells remained round about 1,000, with 20 to 30% polymorpha.

This state of affairs continued for 17 days, during which time the dose of A.C.T.H. was gradually reduced from 40 mg. six-hourly to 15 mg. twice daily, as supplies were running out. Her temperature rose to 101° F. (38.3° C.) and she had a haemoptysis of 12 oz. (340 ml.). A fresh supply of A.C.T.H. was obtained and her condition improved, but the drug was running short by October 3, and was tailed off and discontinued on October 7. Three days later her temperature, which had been rising, reached 102° F. (38.9° C.); she had a haemoptysis of 16 oz. (450 ml.), and several smaller ones. Her condition became critical. Her pulse rate rose to 140 a minute, and her blood pressure fell from its normal level of 130/80 to 90/50. The bleeding from her lungs was stopped by two transfusions of 2 pints and 1 pint (1,140 and 570 ml.) of blood respectively, but she remained desperately ill.

The next day A.C.T.H. was again obtained and 30 mg. was given intramuscularly with a further pint (570 ml.) of fresh blood. Two hours later her general condition was better, her colour improved, and her pyrexia began to settle. The A.C.T.H. was continued in doses of 15 mg. six-hourly, and a week later, on October 19, her blood count showed the first sign of improvement; haemoglobin, 72%; red cells, 3,890,000; white cells, 3,000 (60% polymorpha); 60 nucleated red cells per c.mm.; platelets 10,000.

The figures of her blood count remained round about the same level and on November 6 A.C.T.H. was stopped. On this occasion after withdrawal of A.C.T.H. her temperature did not rise or her condition deteriorate and her blood count had remained substantially the same, although transfusions of 2 pints (1,140 ml.) were required every two to three weeks instead of weekly. Her bone marrow on November 9 appeared completely aplastic, but the drop in cells was mainly in the red-cell series, her white blood count being constant at 2,000-3,000 and her platelets 10,000-50,000 per c.mm. Her condition appeared to improve for a time, but remained precarious throughout. The haemorrhagic incidents became more frequent. She was admitted for a further transfusion, developed a cerebral haemorrhage, and died before any effect of a new supply of cortisone could take place. She died on December 28—that is, 139 days after the onset of her blood disorder.

Post-mortem examination revealed a pale and fatty bone marrow, the presence of petechial haemorrhages in most organs, and a cerebral haemorrhage on the right side. Bronchiectasis, fatty degeneration of the liver, and deposition of haemosiderin in the liver and spleen were found. No significant histological changes were present in the endocrine organs.

Discussion

It is the experience of several workers that marrow function usually returns spontaneously in about a week after discontinuing the offending drug (Hutt and Lee, 1953). We felt at first that both cortisone and A.C.T.H. were of no value in the management of this case, but, as the aplastic condition of her marrow persisted and she did not deteriorate clinically, we began to think that it might be having a life-saving effect. Coincidentally with the reduction in the dose of A.C.T.H. to an ineffective level she developed on two occasions a pyrexia and severe haemoptysis, and on the second was desperately ill. On both occasions when an effective dose of A.C.T.H. was restarted her general condition improved in a matter of hours.

We found no evidence that cortisone and A.C.T.H. had any effect in hastening recovery of normal marrow function. Sternal marrow puncture was not used throughout as a guide to the amount of regeneration, as daily blood counts showed no signs of recovery and the patient was having to endure many but inevitable needle pricks and discomforts. We felt, however, that we were giving cortisone and A.C.T.H. a proper trial, as they were not begun until 11 days after the onset of purpura and the discontinuation of carbimazole. We suggest that these drugs would have produced signs of regeneration of the marrow after a course lasting 72 days if they were capable of bringing about such an effect.

Summary

A fatal case of marrow aplasia secondary to carbimazole is reported. It is believed that this is the first recorded example due to this drug.

Cortisone and A.C.T.H. were given for 72 days, and on two occasions when the dose was reduced the patient immediately became extremely ill with pyrexia and haemoptysis. A third attempt at withdrawal of the drug was achieved without untoward effects, but only after the peripheral blood picture had shown some improvement over a period of 18 days.

It is believed that cortisone and A.C.T.H. kept this patient alive while they were being administered, but no evidence was found that either of them assisted in the regeneration of the marrow.

Our thanks are due to Dr. H. Schwabacher, Dr. C. Pike, Dr. B. A. Thompson, Mr. R. G. Bowler, and other members of the Pathological Laboratory, Watford, for their unstinted help with this case, and also to Professor J. W. Butler, of the Chester Beatty Research Institute, for his kindness in doing the electrophoretic examination of the patient's serum.

PRURITUS AND ITS MANAGEMENT*

BY

LOUIS FORMAN, M.D., F.R.C.P.

Physician, Skin Department, Guy's Hospital, London

Pruritus implies the peculiar uncomfortable sensation of itching, which leads to the physical response of scratching but is not associated with any inflammatory changes of the skin. As with love, it is difficult to know where it is bred, in the skin or in the head; whether in the nerve endings or in the accelerated appreciation of the sensation. It may even originate in the cerebral cortex.

Whether one itches may depend on the degree of attention paid to somatic sensation. We know that if we are obliged to keep still at attention, within a few minutes an intolerable itch is likely to develop, often near one of the orifices.

Itching is very easily suggested. The sight of a head infested with crawling lice will induce in the novice a crawling itching feeling over the skin, which might even be localized to the same area.

The pleasurable element of itching is a matter of common experience. According to Jowett, Socrates dilates in his dialogues on the sensual pleasure of itching and scratching. The back scratcher of the Chinese, so finely carved in the shape of a hand or a claw, indicates the artistic appreciation of the instrument and equally the pleasure it gives when used.

*Read in the Section of Dermatology at the Annual Meeting of the British Medical Association, Cardiff, 1953.

Allergic Reactions

The peripheral nerve endings are stimulated by the histamine-like and other substances (Feldberg, 1953) produced by allergic reactions. Itching also occurs as a manifestation of physical allergy to heat, cold, and friction. Allergy to roundworms and threadworms can occasionally lead to general itchiness as well as to anal and vulval pruritus. Allergies to foods may be responsible for a generalized or localized pruritus as a manifestation of a specific sensitivity. The itching over the face and elsewhere felt after the consumption of beverages is associated with reflex vasodilatation and may be cholinergic.

Pruritus is an early and valuable warning sign of allergy or of intolerance to many drugs—for example, to heavy metals, mepacrine. Other drugs, such as cocaine, owing to their cerebral action, may give rise to hallucinations of tiny living animals under the skin.

Diabetes and chronic renal insufficiency may present first as a pruritus. The fact that no instance of these diseases was noted in the series of 64 consecutive cases of pruritus (Table I) is no indication of the relative frequency of their occurrence, for the urinary findings lead the diabetic and nephritic patient to the general physician.

TABLE I.—Age Distribution of 64 Consecutive Cases of Generalized Pruritus Without Physical Signs, and the Significant Associations

Age	No. of Cases	Associations
0-19	2	Mother with anxiety state—overtreated . . . 1 case Allergic, hay-fever, and asthma . . . 1 "
20-39	15	Xeroderma (congenital) and cold . . . 2 cases Xeroderma (congenital) . . . 1 case Hodgkin's disease . . . 1 " Pregnancy . . . 3 cases Drug: atropine, codeine . . . 1 case Cardiac insufficiency (severe mitral stenosis) . . . 2 cases Obsessive . . . 2 " Anxiety state . . . 2 " Parasitophobia . . . 1 case
40-59	13	Anaemia . . . 1 case Cardiac insufficiency . . . 2 cases Acquired xeroderma . . . 1 case " " ? thyroid insufficiency . . . 1 " Anxiety . . . 2 cases Depression—testicular atrophy . . . 1 case Manic depressive . . . 1 " Menopausal depression . . . 1 " Parasitophobia . . . 1 " Undetermined . . . 2 cases
60-74	34	Anaemia . . . 1 " Hypertension . . . 3 cases Xeroderma (1 with anaemia, 1 with hypertension) . . . 5 " Deficiency (gastroctomy) . . . 1 case Cardiac insufficiency (right-sided) . . . 1 " Cardiac insufficiency . . . 3 cases Carcinoma—bronchus . . . 1 case Reticulosarcoma . . . 1 " Delusional . . . 1 " Obsessional . . . 10 cases Anxiety state . . . 1 case

It will be noted in Table I that a congenital or acquired dry skin, a deficiency of iron, circulatory insufficiency, psychoneurotic or psychotic mental disorders, and malignancy occur in the age groups above 20 years.

The Deficiency Group

The nutritional disorders due to deficiencies of iron, vitamin A, vitamin-B₂ group, vitamin C, and other essential elements may lead to a loose hyperkeratosis, with a degree of atrophy causing discomfort, and an itching skin.

The associated diminution of sweat and sebum, with their emollient and plasticizing constituents, will also encourage the exposure of terminal nerve endings within the epidermis. Cold weather and friction of clothing will the more readily provoke the sensation of itching under these circumstances, and this also applies to the dry thin skin of old age (see Table II).

TABLE II.—Incidence of Dry Skin, Cardiac Insufficiency, and Hypertension

Age	No. of Cases	Dry Skin	Cardiac Insufficiency	Hypertension
20-39	15	3	2	
40-59	13	2	2	
60-74	34	5	4	7

An example of this deficiency group was the case of a woman aged 43 with a three-years history of generalized itching and a haemoglobin of 45%. When the anaemia was successfully treated with iron and vitamin C her pruritus improved.

The menopause in both sexes may be associated with an itchy skin. In the female the itching and flushing occur together, and the itching is due either to alteration of the skin tension or to increased production of choline-like substances in the skin. The work of Grant *et al.* (1936) suggests that an undue sensitivity or reactivity to acetylcholine occurs in heat and exercise urticaria, and pruritus may be the first and only symptom of this sensitivity.

The alleviation of the itching by the administration of testosterone and/or oestrogen would, I believe, be more readily ascribed to a central effect, for the result of treatment is so rapid. However, testosterone is known to increase by as much as 50% the amount of oxygenated blood in the skin, and the effect of this on enzymic activity and nutrition of the skin is readily appreciated.

The skin may become anoxaemic as a result of circulatory insufficiency, and this may lead to pruritus.

Two examples of severe itching with much excoriation in young adults with well-developed mitral stenosis were observed, and cardiac insufficiency was seen in six other cases (see Table II).

A well-recognized but rare cause of pruritus is that associated with the reticuloses, particularly Hodgkin's disease. This simple itching in one patient aged 38 was present for a period of 16 months. She had a tiny gland above the clavicle which, when removed at a second attempt, showed the histology of Hodgkin's disease. It has been suggested that there is a sensitization to the malignant glandular tissue. Again, pruritus has been associated with carcinoma of the stomach and prostate. Cardon (1943) records the case of a man aged 89 with a generalized pruritus for three years. The haemoglobin was 43%. A large pyloric carcinoma was found; this was removed, with immediate relief of the itching.

A man of 65 years with generalized itching of three years' duration, not included in Table I, without change in the texture of the skin, was found to have rarified areas in the left scapula strongly suggestive of secondary carcinomatous deposits: biopsy of the scapula revealed an adenocarcinoma. Thus the possibility of a visceral cryptic carcinoma must be considered in a patient of mature age with pruritus, with or without any xerodermatous change in the skin.

The fibres transmitting the sensation of itching pass along the spinothalamic track and have cell stations in the thalamus. The character of itching, with its liability to spread, poor localization, and the production of tension, anger, and restlessness, is distinctive.

In reverse, mental fatigue, tension, and anxiety seem to be able to potentiate the cell station in the thalamus and to lower the threshold of sensation of itching, to encourage its intensity, and to facilitate its spread over the body.

Using histamine to excite itching by intracutaneous injection, Cormia (1952) was able to demonstrate that the threshold value was lowered in normal subjects towards the evening. It was also lowered by psychic trauma, and the itching then became more persistent. Reassurance restored the threshold value to normal.

Emotional Reaction

Thus with every pruritus, if at all sustained, there is an element of emotional reaction, and at the end of the scale are those cases of pruritus in which the emotional, psychoneurotic, or psychotic status is the most important causative factor in the pruritus (see Table III).

TABLE III.—Incidence of Psychological Factors

Age	No. of Cases	Psychological Factors and Mental Disorders—i.e., Disorders of Reception and Interpretation
20-39	15	In 5 cases
40-59	13	" 6 "
60-74	34	" 12 "

One sign which is a guide to this group is the degree of excoriation that the patient presents. The deep biopsic scratch marks over the face, shoulders, and arms indicate the exaggerated psychological and physical response to the sensation of itching. The investigation of these cases has shown, besides the more common anxiety and tension states, patients with hysterical or obsessive personalities, with paranoia, delusions, or involutional depression. The hysterics use their dramatic ravelled skin to gain their unexpressed desire for comfort and relief from a situation which for them is an intolerable one, physically or emotionally.

One obsessive with severe pruritus was a man who had complained since joining the Army. In civilian life he had always worked hard, all day long. He was unable to do so while in the Army. A similar case was that of a man of 22 who excoriated his face to escape from nasty thoughts and compulsions.

Patients with acarophobia or parasitophobia will present excoriations on the skin, and are convinced that the rolled-up fragments of horn and epidermis which they bring for inspection are living animals which they have felt crawling under the skin and which are responsible for the itching.

A female schoolteacher aged 57, with a two-years history of itching which had begun on the chest and hands and had persisted around the hips, said that she saw flea-like bodies on her skin and thought that they came from the vagina. Other delusions and hallucinations may follow, when the prognosis, especially in the elderly case, is bad, and the patient may need institutional treatment.

If one is dealing with the hysteric and psychotic individual the treatment must be undertaken by a psychiatrist. On the other hand, most cases of psychogenic pruritus occur in those who are amenable to explanation by the practitioner or dermatologist and are capable of insight into the motivation of their disorder. Reassurance and a discussion of business or family worries is often all that is necessary in many cases of anxiety states and tensions. The family practitioner is well able to undertake this task and to offer suitable advice.

Treatment

Treatment with A.C.T.H. or cortisone is not advised for generalized pruritus without inflammatory changes in the skin. Occasionally, in the severe pruritus associated with the reticuloses, these hormones may be indicated and may be the sole means of controlling a most intractable itching.

The antihistamines are widely, perhaps too widely, applied locally to the skin and by mouth. An attempt to be logical in the use of the antihistamines to control generalized itching would include consideration of the aetiology of the pruritus. Thus, if associated with allergy of the mucous membranes to dust, animal hair, or pollen, then diphenhydramine hydrochloride would be valuable. It is recognized that the antihistamines are, in general, powerful sensitizers when applied to the skin and may rarely by mouth give rise to an urticaria or blood disorder—for example, leucopenia. In most cases, apart from serum sickness, the relief of itching is due, one suspects, to the powerful

anaesthetic, central depressant, and sedative effects of many of the antihistamines. They are unreliable therapeutic agents in the treatment of pruritus.

The use of sedatives is of value only in those cases of pruritus in which there is an important element of anxiety or tension. Small doses of barbiturate or chloral at night might then be helpful. To attempt to suppress itching by the use of sedatives, particularly in elderly patients, is likely to be a failure. Patients have been seen confused, drowsy, and incoherent, but scratching as vigorously as ever.

The principles of topical therapy are simple. When the skin is dry, hyperkeratotic, or atrophied it should be protected by a greasy application—for example, simple toilet lanolin over limited areas, or a mixture of wool alcohol, hard paraffin, soft paraffin, and liquid paraffin (unguentum alcoholium lanae, B.P.). When combined with water up to 50% it is more easily applied and more cooling. Another easily applied base contains emulsifying wax, soft white paraffin, and liquid paraffin (unguentum emulsificans, B.P.), to which varying amounts of water can be added to allow of easier spread.

The addition of small amounts of phenol ¼%, menthol ¼%, and of tar (liquor picis carbonis, 5 to 10%) may be indicated for short periods to satisfy a demand for active therapy in a patient with a prolonged distressing symptom. Bathing is restricted to avoid maceration and separation of horn, the alkaline irritant effect of soap, and the trauma of towelling. In the elderly, one bath a week is adequate, the emulsifying effect of the bran bag being relied on to cleanse the skin. The skin is partially dried by patting with smooth soft towels and then powdered.

When the texture of the skin is not abnormal the antipruritic agents mentioned above, incorporated in lotions or liniments for their cooling and decongestive effect, may give relief.

The underwear should be loose, of smooth cotton, and the bed warmed at night. Sheets should be smooth and a cradle ensures minimum contact with the body.

The diet should be a non-stimulating one. Tea and coffee are best taken cool and weak, and spices and meat extracts used with care.

Hypnosis

Finally, a word on the treatment of pruritus by suggestion while in the hypnotic state. There is no doubt that the symptom of itching in certain individuals can be kept in check by this method, and both in simple pruritus and in the pruritic dermatoses considerable relief has been obtained.

The best-known exponent of hypnotism (or in the use of animal magnetism, as he called it) was Mesmer, who, Gilbert Frankau (1948) recalls, was born in 1734, twelve years after the last witch was burnt at Leith. A century later Mesmer's activities were described as Satanic when the morality of the subjugation of one man's will to another's was discussed.

The dependence and relationship between the practitioner of hypnotism and his subject is one that can scarcely be described as healthy, particularly in a hysteric. However, there is no doubt that the method can be temporarily effective in pruritus associated with anxiety or tension states.

AN ACCOUNT OF 2,500 INFANT B.C.G. VACCINATIONS

BY

HONOR M. PURSER, F.R.C.P.I.

B.C.G. Vaccination Officer, Royal Belfast Hospital for Sick Children

The subject of this paper is the personal experience of 2,500 cases of infant vaccination with B.C.G. The material has been drawn from babies born in the Royal Maternity Hospital, Belfast, and the Malone Place Maternity Hospital, Belfast, and has been carried out under the auspices of the Northern Ireland Hospitals Authority and the Department of Child Health, Queen's University of Belfast.

Compared with the recent literature on vaccination against tuberculosis in older age groups, there is little information about infant B.C.G. vaccinations. This is largely due to the fact that vaccination of the infant age group has not been included in the mass vaccination campaigns sponsored by the World Health Organization. In Great Britain, also, vaccination in the younger age groups has hitherto not been extensive.

Selection of Cases

The cases quoted in this study were all vaccinated personally between March, 1952, and March, 1953. Vaccination is offered to every mother for her baby during the lying-in period. The vaccination is optional, but the medical and nursing staffs use their helpful influence, and explanatory literature is freely available. A personal interview is given to any mother who desires it, and to almost every case in which there is a family history of tuberculosis or liability to exposure. Isolation is provided in the hospitals for the babies from birth and throughout the post-vaccinal period when this is indicated.

The live births in the hospitals for the period in question numbered 2,750, and the vaccinations for the same period 2,500, giving an acceptance rate of 92.59%.

Queries Arising During Course of Investigation

As occurs in most investigations, various small problems arose which had not been anticipated and which necessitated some alterations in the original scheme. For example, it became apparent that many of the premature babies had been one, two, and even three months in hospital before being considered fit for discharge. When this fact was realized pre-vaccinal tuberculin skin-testing was instituted if four or more weeks had elapsed between birth and vaccination, instead of omitting all preliminary testing, as is the usual procedure with infant vaccinations.

In addition, having had doubts aroused about the validity of the current belief in the extreme rarity of congenital tuberculosis, a routine tuberculin test is now done on the infants of all tuberculous mothers. It is hoped, at a later date, to publish a report on congenital tuberculosis as a result of an investigation which is now being carried out in these hospitals.

Technique of Dosage and Administration

With regard to technique, dosage, and administration, the recommendations of Winge and Sigrid Holm, of the Central Tuberculosis Clinic, Copenhagen, and of Tolderlund, of the State Serum Institute of Denmark, have been adhered to throughout the survey (Personal communications). There is a tendency in some centres to reduce the recommended dosage in view of the increased liability of infants to develop regional adenitis and abscess formation following B.C.G. injections. This has not been accepted in the present investigations, for two reasons: in the first place

the majority of these infants (93.36%) had no known tuberculous contact at the time of vaccination and are unlikely to meet tuberculosis in the first few years of life; secondly, it is admitted (Gaisford, 1953) that the percentage of cases giving a positive tuberculin reaction one year after vaccination falls off enormously if a smaller initial dose of vaccine is given. In this series, in which more than 350 cases have already had the first annual test, there has been no single case in which the post-vaccinal conversion had not been maintained. It is probable, also, that it will not be possible to ensure annual tuberculin testing on a large proportion of these children who hail from all over Northern Ireland, and with the smaller dose the immunity may lapse very soon, while the parents continue to harbour a feeling of false security.

The observation that adenitis is due to an injection which is too deep rather than to too large a dose of vaccine (Palmer and Edwards, 1953) has been confirmed in the present series. Adenitis is almost always due to failure in technique, and the reason that it is more frequent in the infant age group is that it is technically more difficult to get a true intradermal injection in these subjects.

The infants in this series therefore received 0.1 ml. of vaccine—that is, 0.075 mg. of B.C.G. intradermally in each deltoid region.

With the exception of premature babies, or some ill babies, or those with birth injuries or congenital abnormalities, all were vaccinated between the first and the eighth day from birth. It is desirable that the infant be removed from its cot for the purpose and that the top part of the trunk and arms should be bared. Before these precautions were taken a few babies were vaccinated too high in the arm, and the adenitis, when it occurred, affected the cervical glands rather than the axillary ones, which is unfortunate for cosmetic reasons and also because these glands are more likely to suppurate through being subjected to frequent nasopharyngeal infective onslaughts.

Post-vaccinal Examination

Post-vaccinal testing is carried out at the Royal Belfast Hospital for Sick Children eight weeks after vaccination, at a special clinic reserved for these babies. The attendance rate at this clinic is about 85% of the original number vaccinated. I am indebted to physicians of the chest clinics throughout Northern Ireland, and most particularly to the health visitors of the Northern Ireland Tuberculosis Authority, for carrying out the tuberculin skin tests on babies whose parents live a great distance from Belfast, and also on the defaulters nearer home.

On the occasion of the visit to the hospital for post-vaccinal testing, mothers are invited to bring older children for preliminary testing if they so desire. The facility is made use of to a considerable extent, and it is interesting to record that a definite, albeit small, proportion of siblings of 3 years and under are Mantoux-positive at this examination. By this means some cases with a definite primary tuberculous complex have been revealed, though in the majority there was no known source of exposure, and the parents and other household inmates were radiologically free from tuberculosis. Two of these cases were from farms, and the children in question had been reared on unboiled milk from untested cows; the infection may therefore well have been bovine in origin.

At the post-vaccinal examination routine questions are asked about neonatal health. In no case has there been reason to suspect any constitutional disturbance as a result of the vaccination, although whooping-cough, bronchopneumonia, gastro-enteritis, operations for congenital pyloric stenosis, and transfusions for erythroblastosis have all been experienced during this period. In spite of advice to the contrary, many of the babies have already had their smallpox vaccination when they return to the clinic, and apparently without adverse effect.

The vaccination sites are examined and a search is made for evidence of regional adenitis. The conversion rate at

the time of post-vaccinal testing is 99.69%. Only seven cases gave a negative result to the tuberculin skin test. In one of these there was no local evidence of vaccination, and it is probable that the child was not vaccinated, but that a card was filled in and filed in error. In the case of the remaining six, four were reported on by local practitioners and two by health visitors; it has not been possible to see the babies in question personally or to repeat the test or confirm the negative findings with a Mantoux 1/100. Table I gives an analysis of the results in this series.

TABLE I.—Analysis of Findings

Vaccinations		2,500
Complete:		
With post-vaccinal control	2,331 (93.24%)	
Successful, with positive P.V. test	2,324 (99.69%)	
Unsuccessful, with negative P.V. test	7 (0.31%)	
Incomplete:		
Without post-vaccinal control	169 (6.76%)	
Untraced	145	
Dead	24	

Premature Babies, or Babies with Congenital Illnesses or Abnormalities

Approximately 12% of the vaccinated babies are premature and inhabit the nursery wing of the Royal Maternity Hospital. A birth weight of under 5½ lb. (2.5 kg.) is accepted as the criterion of prematurity. As already stated, some of these babies have been a considerable time in hospital before vaccination. Discharge takes place when they are 5½ lb. if otherwise thriving and the home conditions are reasonably good. Consequently, the premature babies are vaccinated when they are in or about this weight. There has been no difference in the post-vaccinal behaviour of these infants as compared with full-term ones, and no greater incidence of adenitis.

Babies with congenital abnormalities or diseases—for example, spina bifida, hydrocephalus, mongols, cretins, infants with retrolental fibroplasia, or haemolytic disease—are all included in the vaccination programme, provided that the physician in charge considers that they are likely to survive the first few months of life. This perhaps is a mistake from the statistical point of view, as it follows that the overall death rate of these infants will be higher than the average infantile mortality rate; but this is offset by the fact that it impresses on the parent the idea of the vaccination being a normal routine procedure. It also ensures that the handicapped child, if it survives, will not be at any disadvantage compared with its more fortunate brother when and if exposed to tuberculosis.

Table II gives the number and percentage of deaths in our series of cases and the cause when this could be ascertained.

TABLE II.—Deaths

Belfast City death rate (1952) under 1 year—44 per 1,000 live births	
Deaths in present series of 2,500	24 (0.96%)
Infanticide	1
Haemolytic disease	2
Virus infection	1
Gastro-enteritis	3
Bronchopneumonia	2
Congenital abnormalities	2
Premature, within two weeks of discharge	2
Unknown cause; neighbour's report	11

Tuberculous Contacts

There was either a tuberculous contact in the household or a family history of tuberculosis in 166 (6.64%) out of 2,500 vaccinations. Table III gives a summary of these. Where required isolation was carried out (a) by keeping the infant in hospital till tuberculin conversion occurred; (b) by keeping the infected relative in hospital or away from the home; or (c) by arranging for the baby to be kept,

TABLE III.—Contact of Family History

No. of contacts	166 (6.64%)
Relationship of contact:	
Parent	97 (58.5%)
Grandparent	17 (10.2%)
Aunt or uncle	29 (17.4%)
Sibling	12 (7.2%)
Other	11 (6.7%)
Isolation required in 64 (2.56%)	

for the post-vaccinal period, in an uninfected household or child hostel. Many of the mothers concerned came from the sanatorium for their confinement, returning there afterwards. They do not handle the baby at any time.

Four infants had contact with active though hitherto unsuspected sources of infection during the post-vaccinal period. These have been the subject of two-monthly review, but no signs of tuberculosis have yet been discovered in any of them, and chest x-ray films have all been normal.

Regional Adenitis and Abscess Formation

Regional adenitis or abscess occurred in 46 cases (1.84%) of this series of 2,500 infants. This is a minimal estimate, as no doubt there have been other cases which have been treated elsewhere and are not personally known at the clinic. Table IV summarizes the incidence, treatment, and also the bacteriological report where available.

TABLE IV.—Incidence of Regional Adenitis Among 2,500 B.C.G. Vaccinations in Infants

Cases of regional adenitis	46 (1.84%)
Single	27
Multiple	19
Simple adenitis	28 (1.12%)
Adenitis with abscess formation	18 (0.72%)
Spontaneous rupture	3
Incision required*	15

*Bacteriology of pus: B.C.G. recovered, 4; other organisms, 4; sterile, 4; no information, 3.

As previously mentioned, it is considered that in most cases this complication occurs as a result of faulty technique, where a greater or less amount of vaccine is injected subcutaneously instead of intradermally, and this is especially apt to occur in babies well endowed with subcutaneous fat.

In qualification of this statement with regard to technical failure, it should be noted that the strength and viability of the organism in the vaccine culture are not as constant as assurances would lead one to believe. In this series covering 13 months, in which 56 weekly batches of vaccine have been used, adenitis occurred in 14 different or consecutive batches of vaccine, whereas without this factor being involved one would expect a more even distribution of the complication.

Experience shows that if abscess formation occurs in the first eight weeks after vaccination it is usually due to secondary infection of the vaccination site; if it occurs within six months B.C.G. organisms are almost invariably recovered from the pus; whereas if it occurs after this period the pus is usually sterile.

Treatment of the adenitis is conservative. If an abscess is red, tense, and points on the skin it is dealt with by simple incision and evacuation, and the application of a sterile dressing. Formerly these abscesses were aspirated as recommended by the Danish authorities, but this practice has been abandoned in favour of incision and would appear now to be more generally acceptable. No abscess has had to be reopened, though a second abscess in the same child at a different site has occasionally required incision. Even in cases with multiple abscesses there has not been any case in which the infant's general health has suffered or in which the hilar glands have been involved. A few cases have been reported at the clinic after spontaneous rupture; these have been treated with ultra-violet light and have dried almost immediately, and healed after half a dozen exposures. In a small proportion of cases in which superficial ulceration at the site of the local lesion has discharged for more than a week it has almost invariably been found that an occlusive elastic dressing has been applied at home. This tends to produce a weeping eczematous area around the vaccination, and should be replaced by a loose piece of sterile gauze or lint. The discharge then ceases and the lesion heals.

Summary and Conclusions

This study presents the findings in 2,500 consecutive cases of infant vaccination against tuberculosis with B.C.G. vaccine. The normal procedure with uncompli-

cated cases is discussed, and also the different procedures involved in contact cases and with premature infants.

The complications of vaccination have been estimated and the methods used for combating them are described. A personal view is submitted regarding the desirability of adhering to the recommended dosage. The infant mortality in this series is compared with the death rate in infants under 1 year for Belfast city.

In conclusion it is shown that since the introduction of infant vaccination with B.C.G. no anxiety has arisen and no major problems have had to be overcome. In addition, it is an admirable and simple way of further propagating information about the prevention of tuberculosis in a population which is already very conscious of the problem. There has been an excellent and increasing response to the introduction of B.C.G. among parents, and it has, in general, been warmly welcomed by practitioners and health authorities alike. It will be for posterity to judge the ultimate value of this preventive measure. A most careful follow-up of these cases is indicated.

I have to thank all my colleagues, obstetrical and paediatric, for their co-operation in this work, and particularly Professor F. M. B. Allen for his unfailing support and encouragement in the use of B.C.G. vaccine in Northern Ireland.

CHANGES IN SKIN RESPONSE IN ASTHMA

A SKIN-TEST FOLLOW-UP OF ASTHMATICS

BY

A. G. OGILVIE, M.D., F.R.C.P.

Physician, Royal Victoria Infirmary, Newcastle-upon-Tyne

The use of skin-testing as a method of diagnosis in asthmatic patients, while generally accepted and more or less implicitly relied on by specialists in allergic disease, is still a controversial topic among general physicians and general practitioners. The idea of determining the sensitivity of the bronchial mucosa by applying the suspected agent in one way or another to the epidermis is to many somewhat fantastic. It is, of course, now generally recognized that allergic sensitivity is only one of the aetiological factors in the asthmatic reaction, but it seems to be equally widely agreed that it is an important one.

The disagreement comes when an attempt is made to assess just how important it is. The unbiased observer who nevertheless has some experience of the investigation and treatment of asthmatic persons would probably sum up the position by saying that it all depends. In some patients allergic sensitivity is the major cause of the symptoms; in some it is one among several equally important factors; and in others it is of no importance at all. In the present article this view is accepted as probably correct.

The survey and analysis presented are an attempt to contribute towards the answers to two questions: (1) What changes, if any, occur in skin reactions over

the years? (2) What is the significance, if any, of such changes (or, alternatively, the absence of any changes) in relation to the clinical progress of a series of asthmatic patients?

From a personal study of the literature, as well as from a careful search kindly made for me by the Library of the Royal Society of Medicine, it seemed that such a combined follow-up of a series of cases had not, so far, been carried out.

For some years I have conducted a special out-patient session, to which I can refer those persons suffering from bronchial asthma who attend my general out-patient morning session. This originated from experience of the chaos caused in a general out-patient clinic by an attempt to investigate and advise the asthmatic patient on the spot. Inevitably clinical material accumulates in such circumstances, and one is faced with the obligation to analyse it.

Skin-test Method

An early problem confronting anyone who attempts to do more than pacify the asthmatic and his relatives is the skin-test method. How important is it? What does it mean? At first I took the view that it probably had a place in the confirmation of allergic sensitivities suggested by the history of the case. I was warned that most people would show reactions, and that I would either be deceived or merely confused by the high proportion of positive results. It was therefore with some surprise that I found my difficulty to be the large number of negative results in patients with strongly "positive" histories. The potency of the solutions used seemed to be proved by the intensity of the reactions when they did occur.

Confidence in the method as a valuable aid to diagnosis naturally declined, and for a number of years relatively few patients were investigated in this way. However, clinical experience forced one to the conclusion that allergic sensitivity was a most variable quality, appearing, disappearing, and varying in an inconsequential manner, for which the skin-testing method could not be blamed; and it seemed worth while to see if this was clearly shown in the records of those cases which were available. About six years ago, therefore, a number of energetic skin testers, armed with a battery of syringes, were assembled, and those patients previously tested were summoned. The response was so poor that the survey did not yield any significant results.

It was therefore determined to carry out a minimum routine number of skin tests on every adult patient attending, and to repeat the follow-up testing on a larger series at a later date. This has just been done, and the results, though not as numerically valuable as was originally hoped, are interesting enough to warrant publication.

The actual testing was carried out by two independent observers, who also noted the patient's own assessment of his symptoms over the intervening years since the previous testing. I did not see the patients at all when they attended for this special purpose, and the observers who did see and test them took no part whatever in the original assessment, the original testing, or in the analysis.

The tests carried out in this series were group mixtures for the most part, including the common inhalant allergens (household dusts, clothing materials, pollen dusts, etc.), but excluding foodstuffs. Friedewald (1952), in a study of 1,900 cases, came to the convincing conclusion that skin-testing with solutions or other preparations of foods was so much waste of time. No apology is therefore made for the policy adopted in this connexion, nor is it thought necessary to go into all the arguments for and against the testing of foods by any method other than that of dieting.

The survey comprises only a small proportion of the total number of cases attending the special out-patient session, and indeed not many of those in whom skin tests had been

at one time made. Many patients did not attend the skin-testing sessions, which were arranged for the purpose of this investigation, saying that they were now well, did not require any further attention, and were afraid that any injections might cause a recurrence. A few complained that they were no better, and did not believe that they would receive any benefit from a repetition of the tests. The attendance of the "unimproved" group was generally good, however. There is thus some bias in favour of the unimproved cases as a whole; but this bias is not important for the present purpose.

Results

It is possible to survey the results in 209 cases, followed up over varying periods up to 17 years, the shortest period being two years, and the average seven years. This period is long enough to allow any variations in skin sensitivity to manifest themselves, and the number, though not large, has been found adequate for the immediate purpose.

Some general figures may be given before the general analysis is described. Of the 209 subjects available for analysis, 31 were under the age of 15, mostly between 12 and 14 (Table I).

TABLE I

Condition	No.	No. Under 15
Improved	138	25
Unchanged, or slightly improved	55	6
Worse	16	0
Total	209	31

It should perhaps be stated that improved means a very considerable change for the better—one quite outside the normal shift of symptomatic emphasis so often shown by the asthmatic person. For example, a patient must have been free of attacks for over a year, or have reached a state in which attacks of moderate or slight severity occur only occasionally. Lesser degrees of improvement are placed among the unimproved group, the changes being regarded as within the limits of normal variation.

Of the 209 cases, 21 had received "desensitizing" injections, 5 being under the age of 15. These 21 patients all showed a change in skin reactions from positive to negative shortly after the injections. It is of interest to note that the reactions had reverted to the original state in eight.

Thirteen of these cases were improved and eight unchanged or only slightly improved. These eight patients included five in whom the skin reactions had reverted to the original state.

In five cases a "combined" reaction was observed. By this is meant changes in both directions. Four of these were improved, and the remaining patient was unchanged. These five patients have been excluded from the analysis, leaving 204 cases to be classified. In 21 patients the result was difficult to place. In these, a change in one direction or the other occurred in some of the tests, but not in all. For example, a patient in whom the test was completely negative on the first occasion would yield a strong positive reaction to one or more pollen solutions at the final follow-up test, the other tests still showing negative results. In such a case the change in the pollen reaction was regarded as significant, and the case was placed in group 3 (-to+).

Another problem was presented by patients who yielded several positive reactions at the first test and who at the final test showed negative results to all except one of the formerly positive solutions. This type of change was somewhat of a puzzle as regards classification, and each case was judged separately on its merits. If the remaining positive reaction was a really strong one, then the patient was placed in the "unchanged" group, but if it was less convincing he would be placed in group 2 (+to-).

All tests were carried out by the intradermal method, using a dose of 0.1 ml. A positive reaction means a definite weal of at least the size of a silver threepenny-piece, with pseudopodial irregularities and surrounding erythema. Any "weal" of smaller size, or one without pseudopodia or erythema, was disregarded.

TABLE II

Group	Results of Skin Tests	No. Tested	Clinical Progress		
			Improved	No Change	Worse
1	No change	114	74 (65%)	31 (27.2%)	9 (7.0%)
2	+ to -	40	26 (65%)	13 (32.5%)	1 (2.5%)
3	- to +	50	34 (68%)	10 (20%)	6 (12%)
Totals		204	134	54	16

Table II shows the similar composition of the three groups when analysed according to clinical progress. There are, it is true, minor variations. For example, the percentage of patients whose condition had deteriorated over the period of study is highest in group 3 (12%) and lowest in group 2 (2.5%). The small total number of these worsening cases (16 in 204) makes any conclusion based on percentages of very doubtful validity, however. It will be noted that in this group, although the difference is slight, the improved cases also are relatively numerous.

The improved cases are of almost exactly the same percentage in each group, and those showing no significant change in either direction do not differ significantly from one group to another, although in group 3 there is the natural reflection of the higher numbers of improved and worse cases, in the lower relative proportion of the unchanged.

Discussion

It seems permissible to draw certain conclusions from the evidence that is here presented. In the first place, it is clear that the skin-test response is a variable quality, former skin sensitivity disappearing and new sensitivities arising as time goes on. This is in general accord with clinical experience in allergic conditions, although the correspondence between the clinical variations and the skin reactions is often far from close. The most common example of this divergence is the persistence of seasonable asthma long after the skin reactions to all pollens become negative. It is nevertheless evident that skin sensitivity is not a static quality.

Secondly, it is apparent that negative skin reactions may alter to positive in association with no corresponding clinical change, with well-marked improvement, or with deterioration; and that the chances of each of these variations occurring is about the same as it would have been had the skin reactions altered in the opposite direction or not at all. Skin-testing on the whole, therefore, seems to be an unreliable indication of clinical progress, and of little or no prognostic value.

The two questions posed at the beginning have therefore been answered by the survey and analysis which has been made.

It seems natural, and possibly useful, however, to consider briefly the relationship between allergic sensitivity in asthma and the skin-test response. It is recognized, as has already been stated, that allergic sensitivity is but one of the factors which influence the clinical progress of the asthmatic. The exact role of allergic sensitivity in this or, indeed, in any similar series cannot be stated with real accuracy, unless it may be assumed that the skin-test response is of pathognomonic significance in every case. Without such a "yardstick" the classification becomes too much a matter of personal opinion for reliable statistical analysis.

If skin sensitivity is accepted as the criterion it would seem that allergy was a dominant or important feature in a small minority of the cases in the present series; otherwise the

results would have been expected to show at least some significant correlation with the clinical condition of the patients.

It is true that this study does not provide enough evidence to enable one to judge the reliability of the skin-test response as an indication of allergic sensitivity in asthma; and the literature, vast as it is, does not give us a clear and unequivocal answer. It would, however, seem fair at least to say that the absence of any significant relationship of change in skin sensitivity to clinical progress in this series of asthmatic patients may not necessarily indicate that allergic sensitivity was an unimportant factor in the series as a whole, and that the skin response is perhaps not a completely reliable indication of allergic sensitivity. On the other hand, it must be said that in a number of cases skin-testing may give valuable and helpful information—always provided that its significance is judged in relation to all other available information.

Summary

The skin-test responses to the common inhalant allergens were followed in 209 asthmatic patients (of whom 31 were under the age of 15) over an average period of seven years, with extremes of 17 and 2 years, and were compared with the clinical progress of the patients.

The series was, as a whole, somewhat biased against the "improved" cases by the reluctance of asthmatic persons who were well to submit themselves to "repeat" skin-testing. This was not found, however, to affect the purposes of the survey and analysis.

Of the 209 cases, 138 were improved (no asthma for at least one year, or only occasional or moderate attacks at infrequent intervals), 55 were unchanged (or slightly improved), and 16 were worse.

The skin-test responses were found to have altered widely or significantly in 90 of the 209 cases.

These changes in skin sensitivity were found, however, to bear little or no relation to the clinical progress of the patients.

Skin-testing may not be a completely reliable indication of allergic sensitivity in general, but in the individual case it may give valuable information if used with discretion.

I am grateful to Dr. Christopher Strang and Dr. Michael Evans, who carried out the follow-up skin tests; to the Librarian of the Royal Society of Medicine and his staff, who kindly conducted a detailed research of the literature; and to Mr. Campbell, of the Department of Industrial Health in the University of Durham, who kindly checked the statistical analysis.

Friedewald, V. E. (1952). *J. Allergy*, 23, 420.

The new neurosurgical theatres and extensions to the department of neurosurgery, which Sir Geoffrey Jefferson, F.R.S., opened at Frenchay Hospital, Bristol, last October, are now in commission. The theatres embody many modern improvements. Full air-conditioning on a plenum system has been installed, which provides 16 changes of air per hour, the intake being high above the roof and the air filtered. Glass-screened galleries help reduce aerial contamination by spectators, and allow a 70° angle of view on to the operation field. Communication with the galleries is by throat-microphone. The twin operating theatres share a common instrument store and sterilizing rooms; in the latter there are special arrangements to prevent excessive humidity. The department, which is the base for the neurosurgical service of the South-western Hospital Region, will ultimately have accommodation for 72 patients, including children.

INVESTIGATION OF AN OUTBREAK OF BOVINE TUBERCULOSIS IN A RURAL AREA IN LEICESTERSHIRE

BY

R. W. KIND, M.R.C.S., L.R.C.P., D.P.H.

District Medical Officer of Health, Market Harborough
Rural District Council; Assistant County Medical Officer,
Leicestershire County Council

AND

M. C. BROUGH, M.D.

Consultant Chest Physician, County of Leicester

The *British Medical Journal* (1953) again drew attention to the importance of tuberculosis of bovine origin when it summarized in a leading article a survey undertaken by the Medical Research Council on this problem (Wilson *et al.*, 1952). The survey showed that tuberculosis of bovine origin still remains a serious problem. It was estimated that in 1944 there occurred 550 deaths in Great Britain from tuberculous meningitis and 1,050 deaths from other varieties of non-pulmonary tuberculosis due to infection by the bovine type of bacillus. It is realized that a survey at the present moment would not show such a high mortality, on account of the effects of streptomycin and P.A.S., but it is logical to assume that the amount of illness and disability from infection by the bovine bacillus still remains a very great problem. The survey showed that such infection occurred more often in children between the ages of 5 and 9 years. It was suggested that this could be explained by the fact that, whereas infants had previously been fed on cows' milk when breast-feeding failed, now, largely through the efforts of welfare clinics, they are fed on dried or other safe forms of milk, and it is when the child goes to school and moves around in other households that the possibility of infection from raw milk may arise. That leading article has stimulated us to report a recent survey which was undertaken in a rural Leicestershire area where there seemed to have been an abnormal incidence of tuberculosis associated with a known source of infection from a single cow in an otherwise healthy herd.

In January, 1952, notifications were received of two cases of non-pulmonary tuberculosis in children aged 9 and 5 living in the same village (Cases 1 and 2). Abdominal glands were evident in one and cervical glands in the other. The occurrence of these two cases in the same village at the same time led us to inquire from the chief county sanitary officer about the milk supply for these two households. It was found that both children were obtaining milk from the same source, and it was reported that on December 20, 1951, a routine biological sample of milk from this source contained tubercle bacilli. On December 22 a clinical examination of the herd was carried out by the divisional veterinary officer, and this revealed that a cow in the herd was suffering from tuberculosis of the udder. This cow was slaughtered under the Tuberculosis Order of 1938.

Since most of the children in this area were obtaining their milk from this known infected source, inquiries were made to find other children who might be suffering from tuberculous glands of the neck and other tuberculous conditions, and at the same time it was thought

advisable for a tuberculin survey to be undertaken of all children in the area. In addition to the two original cases of tuberculosis a further three children were found to have tuberculous glands of the neck which required treatment.

Case Reports

Case 1.—A case of tuberculous glands of the abdomen in a boy aged 9 was notified on January 18, 1952. Six weeks before examination he had erythema nodosum and later abdominal pain. He was seen by Dr. J. V. C. Braithwaite, who diagnosed tuberculous abdominal glands.

Case 2.—A girl aged 5 developed a gland on the right side of her neck in October, 1951, and was later admitted to the Leicester General Hospital, where the gland was excised and found to be tuberculous. The child was subsequently treated with streptomycin and P.A.S., making an uneventful recovery. This case was notified on January 21, 1952.

Case 3.—As a result of our inquiries a boy aged 14 with an enlarged gland in the neck was referred to the Leicester County Chest Clinic by his general practitioner on February 6, 1952. His history was that in September, 1951, he developed a gland at the right side of his neck which at first settled down. When he was first seen at the clinic the Mantoux test was strongly positive, but the gland itself did not seem to require any active treatment, although his tonsils were somewhat enlarged. These were removed and found to be tuberculous. In January, 1953, the gland increased in size, and after a preliminary course of streptomycin and P.A.S. it was excised.

Case 4.—A girl aged 4 was referred to the Chest Clinic on April 2, 1952, with a history of repeated sore throat for the past five months. She had a gland at the left side of her neck and an enlarged tonsil on that side. The tonsils were removed and culture revealed tubercle bacilli of the bovine type. The gland has since settled down without any further treatment.

Case 5.—A child aged 2 who was tuberculin-positive when we undertook the survey developed a gland in the right side of the neck two months later. This increased in size and was treated with streptomycin and P.A.S., and finally by excision. This case is interesting because it is the only one of the five which presented no clinical signs at the time of the survey but subsequently developed clinical evidence of tuberculous adenitis.

Commentary

At the time of writing we have these five clinical cases of tuberculosis arising in children, all of whom had been obtaining milk from the same source and whose infection can, in our opinion, be directly attributable to a tuberculous cow.

We decided that the problem should be investigated as soon as the first two cases were notified from the same village. The population of the area is 9,660 people, scattered in 31 villages over an area of 45,000 acres. Two of these villages have a population of about 1,600; two have between 600 and 900; 12 have 100 to 500; and 15 have fewer than 100. In the area there were 154 milk producers, of whom 38 retailed their products. For two years prior to this outbreak all raw milk sold in this district had been sampled quarterly and subjected to examination for living tubercle bacilli by guinea-pig inoculation. By this means four infected milks had been discovered and the appropriate action taken. In the particular herd with which we are concerned one of us (R. W. K.) found that the customary veterinary inspection due in July, 1951, had not been carried out and that the infected cow had been under treatment for at least four weeks before its detection in December, 1951. It therefore seemed likely that the milk from this herd, which was bulked together, had contained tubercle bacilli for several weeks before bacteriological confirmation was available, and that the consumers in this area had been exposed to the risk of infection for a period of several months. The producer

made available to us his register of customers, which showed that he supplied 106 families in five villages, including 63 children under school-leaving age.

The five villages catered for by this particular supplier, together with seven other villages, send their children between the ages of 5 and 11 years to one central primary school, and from there, at the age of 11 plus, they pass to an adjacent secondary modern school, where they are joined by children of a similar age from a further 32 outlying villages. It was administratively easy to investigate the entire child population of these 12 villages, but the whole of the older children's school was included in the survey, in order to distract attention from the local nature of the real investigation. Since the majority of the older children attending the secondary modern school lived in villages too far away from the area at risk for their tuberculin results to be of any statistical significance in this survey, they are not included in any of the tables in this paper.

The county medical officer circularized all parents in the area, pointing out the desirability of such a survey, and at the same time he advised the general practitioners that such a survey was to be undertaken and asked for their co-operation. The co-operation of the parents and general practitioners was readily given and was universal in the villages at risk. The refusals received were from parents of older children coming from outside the infected area. It is interesting to see how much co-operation can be obtained in a survey of this nature; the response is shown in Table I.

TABLE I.—Parent Co-operation

Age Group	Total No.	Refusals	Absentees from Testing	No. Tested
Under 5 years	123	—	5	118
5-7	61	—	—	61
8-11	63	—	—	63
12-15+	37	—	—	37
Total	284	—	5	279

The high response in the age group under 5 was largely due to the fact that the health visitor personally visited many of the houses to carry out the tuberculin test. The method of tuberculin testing was that in children under the age of 10 Allen and Hanburys' tuberculin jelly was used in the routine manner—that is, the skin was cleaned with acetone and rubbed gently with flourpaper. In children over the age of 10 we contented ourselves with a single dose of 1/1,000 of old tuberculin. The results of the survey are shown in Table II. All children who were tuberculin-positive were x-rayed by the mass radiography unit; no abnormalities were found. The outstanding points in Table II are the variations between groups A and C, which

TABLE II.—A Summary of Test Results

Village Group	Under 5 Years			5-7 Years			8-11 Years			12-15+ Years

Group A—Five villages at risk—subdivided into group A (infected), those children known to have been supplied from the infected source; and group A (other), the remaining children in these villages not receiving milk from the infected source.

Group B—Five adjacent villages; no known source of infection.

Group C—Two adjacent villages; milk supply known to be safe.

clearly demonstrate the beneficial effects of a milk supply which is known to be safe (group C). Group A indicates what may occur when there is a known infected supply. We do not intend to introduce any discussion on the alleged

value of drinking raw milk as a means of immunization, but merely mention it in order that we may dismiss it as a tragic form of immunization.

The Medical Research Council (1952) published the results of a national tuberculin survey which was undertaken in 1949-50, and, while no figures are given for those under 5, the figures for a rural area in the age groups indicated showed a tuberculin sensitivity rate as follows: 5-7 years, 26.5%; 8-11 years, 35.6%; 12-15 years, 50%. Compare these with our figures, which were also taken from a rural area but which are not unnaturally boosted up by this known source of infection. Hall (1950) did a similar survey on children in a village where there was a proved source of infection associated with a tuberculous gland; his results are shown in Table III. In this particular outbreak the

TABLE III.—Results in Hall's Survey

	Children Tested	Positive	Negative

1-4 ..	7	1	6
5-15 ..	15	12 (80%)	3
1-15 ..	38	28 (74%)	10
1-15 ..	53	40 (75%)	13

milk supplier had served the school as well as the village. In the Leicestershire survey the milk supply to the school was from an outside approved source.

As most of us in the tuberculosis service feel we are approaching the possible end of tuberculosis as a major problem in the community, it does seem more evident than ever that there is absolutely no justification for bovine tuberculosis playing such an important part in the incidence of tuberculosis. Not only may the bovine type cause a mortality of well over 1,000 a year in Great Britain, but it produces many crippling forms of tuberculosis. John Francis (1947) states that, according to the most reliable estimate, 20% of cattle in England are tuberculous, 7.5% in Wales, and 14% in Scotland. The incidence in dairy cows is probably 30 to 35%, but there is a great deal of variation in incidence in various parts of the country. It is lower in Wales, the North and South-west of England, and the North of Scotland. The Midlands of England are the most heavily infected. Furthermore, he states that complete healing of lung lesions is much less common in cattle than in man. He estimates that probably 0.5% of all cows in Great Britain have tuberculosis of the udder, and it is this type of tuberculosis which is the most important from the point of view of milk-borne infection. The result of infection in a small community by a single cow such as we have described emphasizes the need either for ensuring that the milk supply throughout the country must eventually come from accredited tuberculin-tested herds or for the general pasteurization of milk.

Conclusion

This survey demonstrates the following facts as well as the statistical data outlined.

(a) The importance of close liaison between the chest services and the local authorities in the prevention of tuberculosis. The chest physician can deal with a problem such as this only by obtaining the fullest assistance from the county medical officer and the staff of the county health department and the district medical officer of health.

(b) The desirability of a tuberculin test in all cases of glands of the neck. In our opinion this should become a routine: it is a very simple procedure, and any chest clinic would willingly undertake the necessary investigation. It must be borne in mind that only about 50% of cases of tuberculous adenitis are, in fact, bovine in origin. The tonsil is the recipient of the human bacillus

by inhalation and the tonsillar glands are subsequently involved. This fact was proved by the classical work of A. S. Griffith (1937, 1938).

(c) The high response of such a survey can be obtained only if the parents, general practitioners, and school authorities are all acquainted with the problem, and it is hoped that this article will show the willingness of both the local authority and the chest service to investigate any such similar outbreak and will again prove that the notification of a case of tuberculosis may have much wider ramifications than at first supposed.

We wish to acknowledge the help given to us by Dr. G. H. Gibson, County Medical Officer of Health for Leicestershire, Mr. S. A. Gregory, Chief County Sanitary Inspector, and all the other members of the County Health and Education Department who assisted us in making this survey as complete as possible. We also thank Dr. J. V. C. Braithwaite, Mr. T. M. J. d'Offay, and Mr. N. E. Kendall.

DIAGNOSTIC DIFFICULTIES IN CONSERVATIVE TREATMENT OF PERFORATED ULCERS

BY

T. G. CROMBIE, M.B., F.R.C.S.

Surgical Registrar, St. Mary's Hospital, Portsmouth

It was only 60 years ago that Hastings Gilford treated a case of perforated peptic ulcer by operative closure—the first case so treated in this country. Since then this has become the accepted method and, until recently, the only method; but for some time a conservative regime has been advocated by a few authorities (notably Hermon Taylor, 1946, 1951).

The prerequisite of any form of treatment is accurate diagnosis, a problem which, in this matter, troubles us to-day almost as much as it did Mikulicz at the end of the last century. He indeed, before performing laparotomy, confirmed his diagnosis by puncturing the distended abdomen with a trocar.

Gastro-duodenal perforation causes the clinical syndrome of acute peritoneal irritation, hence the problem of accurate diagnosis consists first in eliminating the various extra- and intra-abdominal conditions which may simulate peritoneal irritation—for example, tabetic crisis, diaphragmatic pleurisy, coronary infarction, acute cholecystitis—and, second, in eliminating the other conditions which also cause peritoneal irritation.

If the treatment be conservative a misdiagnosis of one of the first group of conditions is not likely to be a tragic error, but a misdiagnosis of one of the second group may well be. On the other hand, if the treatment is to be operative a misdiagnosis of one of the first group will lead to an unnecessary and possibly dangerous procedure, whereas a misdiagnosis of one of the second group will automatically be corrected at operation.

Present Investigation

It is with the second group of conditions that this paper is concerned. Seventy consecutive cases of "widespread peritoneal irritation" are presented: "widespread" because the term "generalized" is regarded by many as synonymous with impending death, and "irritation" because that is a clinical term, and "peritonitis" is an inflammatory reaction generally, though not accurately, believed to be associated with infection.

The 70 cases fall into the following groups:

1. Gastro-duodenal perforations	34
Duodenal ulcer	22
Gastric ulcer	7
Stomal ulcer	1
Carcinoma	4
2. Appendicitis	17
Without abscess	13
Intraperitoneal rupture of abscess	4
3. Haemoperitoneum	9
Tubal pregnancy	4
Ruptured liver	2
Ruptured spleen	1
Ruptured left gastric artery	1
Ruptured ovarian cyst	1
4. Perforated small bowel	2
Jejunal diverticulum	1
Multiple chromaffinoma	1
5. Perforated large bowel	6
Spontaneous perforation of pelvic colon	1
Carcinoma of caecum	1
Carcinoma of descending colon	2
Diverticulitis of pelvic colon	1
Radionecrosis of pelvic colon	1
6. Lesions of female genital tract	2
Salpingitis	1
Intraperitoneal rupture of tubo-ovarian abscess	1

The purpose of this investigation is as follows. (1) An attempt is made to derive from a study of the clinical features of the gastro-duodenal perforations a "diagnostic screen," to be applied to all cases diagnosed as "acute peritoneal irritation." (2) The diagnostic screen is applied to those cases of "acute peritoneal irritation not of gastro-duodenal origin" which were pre-operatively considered as probably or possibly suffering from gastro-duodenal perforation. The persistent diagnostic error is noted. (3) The results of treatment of all cases by laparotomy are considered, to find out how many of those with gastro-duodenal perforations succumbed because of the operation, and how many of the other patients with peritoneal irritation survived when laparotomy was not delayed by a mistaken initial diagnosis. (4) In the light of these findings, the advisability or otherwise of the non-operative method of treating gastro-duodenal perforations is considered.

Main Features

The principal features of the cases of perforation were as follows:

Of the 34 cases, 27 were male. The average age was 49 years, with extremes of 17 and 73 years. The temperature averaged 98.1° F. (36.7° C.), ranging from 97° F. (36.1° C.) to 100.2° F. (37.9° C.); the pulse averaged 80 (48 to 120); and the respirations averaged 22 (18 to 40).

Previous Dyspepsia.—Twenty-nine cases had a previous history of dyspepsia. One case had had a previous perforation closed and a gastro-enterostomy performed. Four cases had had previous perforations with simple closure only.

Exacerbation of Symptoms immediately before Perforation occurred in 28 of the cases; there was increased dyspepsia for one to several days before the actual perforation occurred.

Sudden Onset.—All patients were able to state the exact time of onset—for example, "I had just laid down the newspaper, when suddenly . . ."

Time of Onset.—All but five cases occurred during waking hours.

Duration of Acute History.—The average time was five and a half hours, with extremes of one and fourteen hours; these times do not show the delay in "calling the doctor," but the delay from onset to examination in hospital.

Trauma.—In only one case was trauma present. This patient walked into the casualty department and stated that he "strained the abdominal muscle lifting a heavy weight and it has given way."

Easing of Pain.—In only seven cases had the pain eased off.

Site of the Pain.—In 18 cases the pain was indicated as epigastric, in 15 cases generalized, and in one case in the right hypochondrium.

Vomiting.—Eighteen of the patients had vomited, some excessively; 16 had not.

Bowels.—There were no cases of diarrhoea. Six cases had constipation, and 28 had normal bowel function.

General Condition.—Twenty-five cases were classed as "ill" or "very ill"; nine had a good general condition.

Tongue.—In 28 cases the tongue was dry.

Tenderness and Rigidity.—This was maximal in 33 cases.

Site of Tenderness and Rigidity.—Generalized in 19 cases, epigastric only in nine cases, right hypochondrium and right iliac fossa in three cases, epigastrium and right iliac fossa in one case, right iliac fossa only in one case, and right hypochondrium only in one case.

Liver Dullness.—This was lost in 15 cases, impaired in 10, and normal in nine.

Bowel Sounds.—These were present in 21 cases and absent in 13.

Evidence of Other Acute Disease was absent in all cases.

From these findings the following points might be considered as being those in whose absence nothing more than a tentative diagnosis of gastro-duodenal perforation should be postulated: male patients only; temperature, pulse, and respiration not far from normal; previous history of dyspepsia; recent exacerbation of dyspeptic symptoms; sudden onset; onset during waking hours; duration of less than 12 hours; no history of trauma; epigastric or generalized pain; no history of diarrhoea; dry tongue; maximal tenderness and rigidity; generalized, epigastric, or right-sided tenderness; no evidence of other disease.

The value of many of these clinical features is well known. Strang and Spencer (1950) found that more than 90% of their cases gave a history of dyspepsia and over 70% had an exacerbation of symptoms immediately before the perforation. Jamieson (1947) found that in his series of cases perforation at night was rare. He further reports that "severe exertion plays little part in precipitating perforations."

The longest acute history of this series was fourteen hours. Cases of much longer duration have been reported. Beattie (1951) describes four cases with an acute history of over 20 hours, but it seems that since the National Health Service, with the financial anxiety of illness removed, patients call their doctor far more readily.

X-ray diagnosis has not been considered in this series, as in many instances it was not available, and often the patient had too much pain to co-operate sufficiently if it had been available. Stead (1951) discusses the difficulties encountered in x-raying patients before reaching a diagnosis. He demonstrated free gas in 38 out of 47 cases, and in 10 cases treated conservatively radiography was either not available or failed to demonstrate gas.

In diagnosing the cases of "acute peritoneal irritation not of gastro-duodenal origin" nine of them closely resembled gastro-duodenal perforations. These case histories are summarized below.

Case Histories

Case 31.—Male aged 15. No previous dyspepsia; sudden onset of epigastric pain, persisting for 12 hours. No vomiting; constipated. Examination: General condition very ill. Tongue dry. Abdomen tender and rigid all over; normal liver dullness; no bowel sounds. P.R.: N.A.D. T., P., R.: 100° F. (37.8° C.), 100, 25. Diagnosis: Widespread peritonitis due to a perforated appendix, the caecum being completely undescended and in the midline. Differential diagnosis: Distinguished from gastro-duodenal perforation by absence of dyspepsia.

Case 33.—Male aged 56. No previous dyspepsia, but abdominal discomfort for seven days, followed by sudden severe generalized abdominal pain, persistent for 48 hours.

No vomiting; normal bowel function. Examination: General condition—very ill. Tongue dry. Abdomen tender and rigid all over; normal liver dullness; no bowel sounds. P.R.: N.A.D. T., P., R.: 97.6° F. (36.4° C.), 120, 24. Diagnosis: Intra-peritoneal rupture of appendix abscess causing widespread peritonitis. Differential diagnosis: Distinguished from gastro-duodenal perforation by absence of dyspepsia; a duration of acute history of 48 hours.

Case 38.—Female aged 38. No previous dyspepsia. Sudden onset of generalized abdominal pain while pushing a garden roller. Pain had persisted for 48 hours. No vomiting; normal bowel function; no upset of menstruation. Examination: General condition—good, but slight pallor. Tongue moist. Abdomen tender and rigid all over; normal bowel sounds; normal liver dullness. P.R. and P.V.: No abnormality. T., P., R.: 98° F. (36.7° C.), 100, 20. Diagnosis: Haemoperitoneum due to ruptured tubal pregnancy. Differential diagnosis: Differentiated from gastro-duodenal perforation by sex, no previous dyspepsia, duration of acute history, trauma.

Case 44.—Female aged 36. No previous dyspepsia. Sudden onset of generalized abdominal pain when her husband and she fell and he landed on her abdomen. Pain had persisted for four hours. No vomiting; normal bowel history; normal menstrual history. Examination: General condition—ill. Tongue dry. Abdomen tender and rigid all over; normal liver dullness; normal bowel sounds. P.R. and P.V.: N.A.D. T., P., R.: 99.7° F. (37.6° C.), 94, 30. Diagnosis: Intra-peritoneal rupture of serous ovarian cyst. Differential diagnosis: Distinguished from gastro-duodenal perforation by sex, no previous dyspepsia, trauma.

Case 41.—Male aged 21. Previous dyspeptic history suggestive of chronic duodenal ulcer. Slight abdominal pain for 24 hours following a kick while playing football. Sudden onset of severe epigastric pain after this, persistent for 12 hours. No vomiting; bowels constipated. Examination: General condition—ill. Tongue dry. Abdomen tender and rigid in upper part; liver dullness normal; absent bowel sounds; slight abdominal distension. P.R.: N.A.D. T., P., R.: 100° F. (37.8° C.), 110, 20. Diagnosis: Haemoperitoneum due to rupture of liver (lacerated concave surface). Differential diagnosis: Distinguished from gastro-duodenal perforation only by the presence of trauma.

Case 45.—Female aged 48. Several attacks of epigastric pain at intervals of about one month or more, each lasting several days and then subsiding. She had suffered from this form of dyspepsia for several years. Sudden onset of epigastric pain, persistent for 12 hours. No vomiting; normal bowel function. Examination: General condition—ill. Tongue dry. Abdomen tender and rigid all over; normal liver dullness; normal bowel sounds. P.R. and P.V.: N.A.D. T., P., R.: 98.4° F. (36.9° C.), 88, 24. Diagnosis: Widespread peritonitis due to perforated jejunal diverticulum situated 2 ft. (60 cm.) from duodenal-jejunal junction. Differential diagnosis: Differentiated from gastro-duodenal perforation only by sex.

Case 67.—Male aged 57. Indigestion for four months—epigastric pain and vomiting. For seven days symptoms much worse and accompanied by sensation of food sticking at lower part of chest. Sudden onset of generalized abdominal pain eight hours before admission; persistent. Vomited since onset. Bowels constipated. Examination: General condition—ill, with marked weight loss. Tongue dry. Abdomen tender and rigid all over; no mass palpable; diminished liver dullness; no bowel sounds. P.R.: N.A.D. T., P., R.: 99.8° F. (37.7° C.), 120, 24. Diagnosis: (1) Widespread peritonitis from perforated appendicitis. (2) Carcinoma of cardia of stomach. Differential diagnosis: Indistinguishable from perforated peptic ulcer.

Case 68.—Male aged 51. Partial gastrectomy 15 months previously for peptic ulcer. Recurrent attacks of epigastric pain for three months. Sudden onset of severe generalized abdominal pain three hours before admission; persistent. Vomited since onset. No bowel upset. Examination: General condition—ill. Tongue dry. Abdomen tender and

rigid all over; no mass palpable; no loss of liver dullness; no bowel sounds. P.R.: N.A.D. T., P., R.: 100.2° F. (37.9° C.), 106, 18. Diagnosis: Peritonitis due to perforated carcinoma of descending colon. Differential diagnosis: Indistinguishable from perforated stomal ulcer.

Case 69.—Male aged 75. Vomiting for about one month before admission; no previous abdominal pain. Recent loss of weight. Sudden onset of abdominal pain 12 hours before admission; pain persistent; vomited once. No bowel upset. Examination: General condition—very ill; marked weight loss. Tongue dry. Abdomen tender and rigid all over; distended; no mass palpable; loss of liver dullness; no bowel sounds. P.R.: N.A.D. T., P., R.: 100° F. (37.8° C.), 90, 20. Diagnosis: Widespread faecal peritonitis due to spontaneous perforation of the pelvic colon. Differential diagnosis: Indistinguishable from perforated peptic ulcer.

Comment on Above Cases.—It will be seen that, after rigidly applying the diagnostic screen already described, three cases remain that might easily be diagnosed wrongly as gastro-duodenal perforation (Cases 67, 68, and 69). Case 45 is distinguished only by sex, Case 41 only by the history of trauma, and Case 31 only by the absence of dyspepsia.

Results

Although this paper is primarily concerned with diagnosis, it is obvious that a diagnosis confirmed by laparotomy is worthless if the laparotomy adversely affects the patient's survival. On the other hand, a laparotomy delayed by a mistaken diagnosis in a case in which its necessity is urgent is equally undesirable.

The results in the cases of gastro-duodenal perforation and in those of acute peritoneal irritation from other causes are dealt with. Among the perforations there were no deaths attributable to the laparotomy, but three subsequent deaths were noted (see below).

With the following exceptions all cases made satisfactory recovery after simple closure of the perforation.

Case 18.—Male aged 70. Perforated pre-pyloric ulcer, immediate subtotal gastrectomy; section later proved to be non-malignant. Alive and well, having been followed for three years.

Case 21.—Male aged 54. Perforated carcinoma of the stomach: unfit for immediate gastrectomy; simple closure only. Laparotomy 14 days later revealed peritoneum full of metastases. He died four weeks later.

Case 22.—Female aged 50. Perforated carcinoma of the stomach infiltrating transverse mesocolon; immediate subtotal gastrectomy and transverse colectomy. Died at home suddenly three months after her discharge from hospital (? cerebral thrombosis).

Case 23.—Female aged 29. Perforated carcinoma of stomach, immediate subtotal gastrectomy. Patient alive and well, having been followed up for 12 months.

Case 54.—Male aged 73. Perforated duodenal ulcer. Died on seventh post-operative day from myocardial degeneration and uraemia (300 mg. per 100 ml.) following a violent haematemesis on the fourth post-operative day.

Case 55.—Male aged 70. Perforated carcinoma of pyloric antrum (inoperable). Perforation closed and gastro-enterostomy performed. Alive and well, having been followed up for 6 months.

Among the other cases there were four deaths.

Case 42.—Male aged 79. Ruptured spleen. Died on the table from cardiac arrest.

Case 43.—Male aged 77. Ruptured left gastric artery. Died seven days later from purulent bronchopneumonia.

Case 46.—Male aged 60. Multiple chromaffinoma of small bowel (perforated). Died from leaking anastomosis at the suture where enterectomy had been performed.

Case 47.—Male aged 73. Inoperable perforated carcinoma of caecum. Died five days later from peritonitis, drainage only having been done.

Discussion

Comment on this investigation is centred on four points. (1) Despite careful screening of 36 cases of acute peritoneal irritation from non-gastro-duodenal causes, three remain indistinguishable from gastro-duodenal perforations. In this series, which is too small to be statistically significant, for every 11 true perforations there occurred one case requiring immediate laparotomy, the clinical features being exactly similar to those of a perforated peptic ulcer. Therefore the conservative method of treatment applied to this series would have suffered from a 10% diagnostic error despite rigid selection, and a correspondingly greater error with rigid selection.

(2) It must be considered that the results by the non-operative method may be so vastly superior to those by the operative method that this small diagnostic risk should be accepted. This is not so. Hermon Taylor (1951), Stead (1951), and Beattie (1951) all quote at least one death in their respective series which would not have occurred under operative approach. There were no deaths among the small series of perforations reported here that were attributable to the laparotomy.

(3) The "poor risk case" must be considered. The above authors all report a satisfactory outcome to such cases, which would almost certainly have been fatal if subjected to laparotomy. Here they are on very firm ground in accepting the small risk of a mistaken diagnosis in a patient whose clinical features are typical of gastro-duodenal perforation, but who is a poor risk for laparotomy.

(4) The results of the cases of non-gastro-duodenal origin show that the fatality rate is nowadays small when laparotomy is not unnecessarily delayed. It is wrong to assume that a case will benefit by the delay which results from the mistaken application of the conservative measures for perforations, although some pre-operative treatment is often desirable in these cases. It is also wrong to assume that a patient with perforation of the large bowel would have died in any case.

The final conclusion must be that when a case is diagnosed as a gastro-duodenal perforation it should be treated by laparotomy unless the risk of the operation is thought to be greater than the risk of a mistaken diagnosis.

Summary

Seventy cases of acute peritoneal irritation are presented.

The clinical features of perforated gastro-duodenal lesions are evaluated, and a "diagnostic screen" is described.

The case of peritoneal irritation from all causes are tabulated, and details are given of those non-gastro-duodenal cases in which differential diagnosis was a problem.

The results of treatment are given.

It is suggested that laparotomy be performed on all cases diagnosed as gastro-duodenal perforation if the patient is fit for the operation, and the conservative method be reserved for those cases in which laparotomy would be a serious ordeal.

I am indebted to Mr. E. G. Dingley and Mr. G. C. C. Taylor for permission to treat and publish those cases admitted under their care at the Warneford Hospital, Leamington Spa, and to Surgeon Rear-Admiral J. A. Maxwell for those cases admitted to St. Mary's Hospital, Portsmouth.

Medical Memoranda

Weber-Christian Disease: Relapsing Febrile Nodular Non-Suppurative Panniculitis

Panniculitis by definition means inflammation of adipose tissue. Parkes Weber (1925) reported one case in which this happened in various areas of the body and caused pain and discoloured swellings of the skin. He examined a nodule microscopically, and reported his case under the heading of "Phagocytosis of subcutaneous fat cells by macrophages." There was no enlargement of the lymph nodes. Christian (1928) reported a similar case in greater detail, adding that fever also occurred. No organisms were found in either case. Despite intensive investigations no cause was discovered for this condition. Alice Carleton (1949) added a further example of this interesting disease to the fifty or so cases in the literature. A further case is now reported, showing the characteristic lesions, relapses, and histopathology.

CASE REPORT

A married woman aged 65 was admitted to hospital as a case of coronary artery thrombosis. A history of breathlessness on exertion, choking sensation, and swelling of the ankles was given, which had been intermittently present in the previous six years. An electrocardiogram revealed no definite myocardial infarction. Concurrently, the patient stated that she had been troubled with small painful swellings of the legs. These became red, did not break down, and after three weeks disappeared. These swellings had appeared in both legs and in both arms. The pain had been severe enough to cause loss of sleep. At the time of admission several such swellings were present, one of which, at the region of the right elbow, was removed for histopathological examination. The swellings recurred at irregular intervals, affecting the legs and arms indiscriminately. After recovery from particularly large and painful swellings a dimple resulted in the skin (see illustration).

The patient has been seen over a period of 18 months, and in that time has had several recurrences of nodules. On May 19, 1952, she was again examined and a large crop of lesions was seen, affecting both lower legs, three smaller lesions being present in the left forearm, and one on the palmar aspect of the right wrist. The lesions were variable in size, some were visible as purplish-red areas which on palpation could be identified as discrete nodules. Others

were palpable only. The distribution of the lesions was asymmetrical. There were none on the face, back, or neck, and there has been no evidence of suppuration. A low-grade pyrexia was present during each observed attack, but the general health has been moderately satisfactory.

The history, together with the typical lesions and characteristic microscopical appearances, confirms the diagnosis. Photographs were shown to Dr. Parkes Weber, who considered the appearances to be consistent with this diagnosis.

Histological examination revealed necrosis of the subcutaneous fat. The epidermis was intact and normal. The subcutaneous fat showed extensive foci of necrosis of the fat cells, these areas being replaced by groups of lipid-filled phagocytes. Some giant-cell reaction was seen, together with lymphocyte infiltration.

I am indebted to Dr. Alexander Smith, medical superintendent, Stonehouse Hospital, for permission to publish this case.

Lymphosarcoma of the Appendix

Since Kundrat (1893) first described lymphosarcoma of the appendix many different names have been used to describe this condition. Ewing (1939) endeavoured to clarify the position by stating that lymphoid tissue contained three cellular elements—namely, lymphocytes, reticulum cells of the pulp and follicles, and endothelial cells of the pulp and cavernous sinuses. Thus he maintained that there were two possible types of sarcoma—a malignant lymphocytoma and a reticulum-cell sarcoma.

Lymphosarcoma can appear in the tonsils, lymph nodes, spleen, and thymus gland, and to a less extent in the lymph follicles of the gastro-intestinal tract. Geschlechter (1935) stated that sarcoma comprises 3% of all malignant growths of the gastro-intestinal tract—mostly lymphosarcoma. In his series of 46 lymphosarcomata 13 were in the stomach, 20 in the ileum, 10 in the caecum, 2 in the rectum, and 1 in the duodenum.

Our patient had a lymphosarcoma of the appendix, and we record the case to draw attention to the possibility of misdiagnosis as chronic appendicitis, which is so frequent and which may give rise to a false sense of security.

CASE REPORT

A man aged 38 was seen on May 17, 1950. He had a 10-year history of intermittent diarrhoea and vague abdominal discomfort, which during the last 12 months had become a more definite pain localized to the right iliac fossa. Examination revealed no abnormal finding except tenderness localized to the lower pole of the distended caecum. A magnesium sulphate barium meal examination on May 24 showed that the appendix failed to fill.

He was admitted to hospital on August 30. Routine questioning revealed that the pain in the right iliac fossa was a sporadic dull ache which occasionally radiated to the left side of the abdomen. During the previous month his appetite had diminished and his abdomen had become "swollen and tender." His bowels were regular, with a slight tendency to loose motions, during which the pain was accentuated. The pain was relieved by rest and codeine. His only relevant past history was migraine since the age of 16 and glandular fever at 32. His weight was 8 st. 8 lb. (54.4 kg.) and his temperature and full blood count were normal. Chest radiography revealed only a calcified focus at the left apex. On the day before admission the symptoms of pain and nausea became prominent, and it was thought that an acute attack might be supervening.

An operation was performed on September 1. Through a gridiron incision a bulbous-ended pear-shaped appendix 2½ in. (5.7 cm.) long was found lying retrocaecally, with a

hyperaemic base and a similarly hyperaemic caecum. The appendicular mesentery was thick, contained much firm fat, and was extremely vascular. On the serous surface of the organ there was a purplish discoloration close to the base, which was attributed to the local necrosis in the appendix. Post-operative convalescence was uneventful, and the patient was discharged on September 10. Section of the appendix showed replacement of the mucosa and submucosa by masses of lymphoid cells with penetration of the muscle coat in one area. The appearances were those of lymphosarcoma.

During the following 10 months he was seen on eight occasions by both of us. In November, 1950, his weight was 9 st. 4 lb. (58.9 kg.). His appetite has been good, his bowel action normal, and he has been in full active employment. The only clinical finding has been a slightly tender boggy caecum, without any lymphatic glandular enlargement. A barium meal examination and blood count were normal at this time and also in February, 1951. It is significant that tenderness in the right iliac fossa over what might be described as a thickened caecum and a fatty mesentery was still present. This tenderness does not seem to alter. In November, 1953, the patient was still in good health.

COMMENT

Charache (1934) reported a case of primary leiomyosarcoma of the appendix. He summarized 22 reported cases of sarcoma of the appendix. Every one of these cases was diagnosed only on histological section. Clinically the diagnosis was an appendicitis of one kind or another, and the cases were reported only because of the rarity of the lesion. Most of these 23 patients were in the first or third decade of life. The symptoms in all instances were referable to the right iliac fossa, but their duration varied between four weeks and a year, although in two cases there had been symptoms for 10 and 13 years. The occurrence of "attacks" was noticeable in seven cases, whilst in all but two of the remainder the attack persisted for several weeks or presented as acute appendicitis. One case was an incidental finding at necropsy in a man aged 55 who had died of cerebral haemorrhage. Bizard *et al.* (1938) recorded a case of a 27-year-old man who had a lymphoblastic sarcoma; a three-year follow-up showed that the patient was still well. Knox (1945) described a further case in a boy aged 4, a 15-months follow-up recording that the patient was then essentially asymptomatic.

In our patient an interesting feature was the 10-year history of vague and repeated abdominal upsets. Is it that the repeated subacute attacks of appendicitis had slowly altered the structure of the lymphoid tissue and that a gradual change took place from an inflammatory reaction to a state of malignancy? The attack of glandular fever is of particular interest: had it any influence on the presumed development of the sarcomatous change? Other questions may be asked. How many appendices are removed and never sectioned? What is the true incidence of sarcoma in the organ? Is a right hemicolectomy the correct treatment, or local excision followed by radiotherapy?

The prognosis seems to be about seven months. Three years is the longest period of freedom from recurrence that has so far been recorded.

Our grateful thanks are due to Mr. R. Vaughan Hudson, senior surgeon, Middlesex Hospital, for permission to publish this case; to Professor R. Scarff, director of the Bland-Sutton Institute of Pathology, for the section report; and to Sir Harold Graham Hodgson, director of the X-ray Diagnostic Department.

Reviews

JOSEPH BARCROFT

Joseph Barcroft, 1872-1947. By Kenneth J. Franklin. (Pp. 381; 61 plates. 37s. 6d.) Oxford: Blackwell Scientific Publications. 1953.

Your reviewer took this book with him on a visit to the United States and Canada. Wherever it went (and it will do the same in many other countries) it recalled affectionate memories and stories of J. B., of his humanity, gaiety, and wit, of his scientific skill, persistence, and imagination. Dr. Franklin had special qualifications for writing it, not only by his facility in historical studies (physiologists the world over are grateful to him for his history of the physiological congresses, prepared for the Zurich meeting in 1938), but also by his long association with Barcroft's work on foetal circulation. Franklin has tapped many sources and drawn on memories or photographs by many friends for his material; but largely also on the diaries and records of Lady Barcroft, J. B.'s perfect partner, to whom "with admiration and affection" the book is justly dedicated. It is faithful in fact and emphasis, as befits its author's scholarship, but it is a tribute also of world-wide admiration and affection for its subject.

Starting with the Barcroft family in Lancashire in the thirteenth century and in Northern Ireland from the seventeenth, Franklin brings us in Chapter II to The Glen at Newry, Co. Down, where J. B. was born, and from where he learnt his love of boats, sailing in sight of the Mourne Mountains in Carlingford Lough. Thence in Chapter III we are led to Cambridge, where for fifty-five years his life was based. Chapter IV deals with the fruitful period which includes his first expedition to high altitude (Teneriffe). Chapter V covers the second such expedition (Monte Rosa) and the publication (1914) of *The Respiratory Function of the Blood*. It contains the story of J. B.'s part in the first German war, starting with the use of chlorine in the second battle of Ypres in 1915, and mentions the characteristic reply to Quaker friends, "I thought of the parable of the Good Samaritan and obviously I did not want to pass by on the other side." The side he took led to courageous experiments on himself and to a continuing association, lasting into the second German war, with methods and problems of chemical warfare and defence. Could not a Quaker be an Irishman, too?

Chapter VI contains the account of J. B.'s experiments at Cambridge under reduced oxygen pressure and of his third expedition to high altitude (Peru). Few achievements are due to one man only, but the knowledge which gave conviction that oxygen should be used in the final assault on Everest can be attributed as much to J. B. as to any other man. How glad he would have been to hear of its success. Chapters VII and VIII deal with the period of his professorship at Cambridge, Chapters IX to XI with the 10 years, no less fruitful, after he had "retired." Then comes a list of his publications (some 400 of them) mostly jointly with colleagues. He had a remarkable capacity for setting other people to work.

The book is illustrated with many attractive photographs, most of them informal, of J. B. and his colleagues, including a supremely good one of him lecturing in 1935 (Plate 49). These may mean less to those who did not know him personally, but they will add very greatly to the pleasure and interest of his friends.

A reviewer would not be treated seriously if he found no mistakes. In what sense (p. 286) had Japan been "our enemy" since July, 1941? And it is well known to his friends how Dr. D. P. O'Brien celebrated the attack on Pearl Harbour at the Athenaeum Club, not in America; while Houssay's initials are B. A. and not A. E. Apart from these, your reviewer has no complaints.

A. V. HILL.

THE CANADIAN MEDICAL SERVICES

Official History of the Canadian Medical Services: 1939-1945. Edited by W. R. Feasby, B.A., M.D. Volume 2: Clinical Subjects. Published by Authority of the Minister of National Defence. (Pp. 537; illustrated. \$5.) Ottawa: Edmond Cloutier. 1953.

The official history of the Canadian Medical Services is to comprise two volumes, the administrative and the clinical. Though issued first in time, this account of the clinical subjects is to form the second of the two volumes. It is published earlier because, as the editor wisely states, "If any useful medical knowledge were to be shared with others as a result of a war, it was felt that it should be set forth as quickly as possible."

This volume not only deals with both medicine and surgery, but it gives four chapters to research carried out in the Services, and no less than a quarter of the book is devoted to statistics. In order to cover such a wide field within a relatively small compass "the accounts leave out the usual details and touch only on the subjects which were new and in which advances were made." This has the advantage that the reader can quickly learn the main lessons of the war, but probably many would have liked a little expansion of some of the articles. Some articles are signed, some unsigned; in the latter the opinions expressed are for the most part authoritative and the result of consultation between experts. It is interesting to note that orthopaedic surgery was not recognized as a separate specialty by the Canadian Army, and a statement is made which might well provide matter for discussion: "No one can say that it would have been better if this specialty had been recognized." There is a good account of the discovery and development of penicillin and of the important part played by the Connaught Research Laboratories in the large-scale manufacture of that substance. We should have liked to see the pioneer work of Guttman mentioned in the section on rehabilitation of spinal cord injuries. The editor is to be congratulated on the way in which he has marshalled the material at his disposal. The book is well produced.

ZACHARY COPE.

LONG-TERM DIABETES

Long-Term Diabetes: The Clinical Picture in Diabetes Mellitus of 15-25 Years' Duration, with a Follow-up of a Regional Series of Cases. By Knud Lundbaek. Ophthalmological Section in collaboration with Professor V. A. Jensen, M.D., Copenhagen. (Pp. 197; illustrated. 32 Danish crowns.) Copenhagen: Ejnar Munksgaard. London: Lange, Maxwell and Springer. 1953.

Since the discovery of insulin in 1922, diabetics have lived longer, and it is only in recent years that it has been possible to assess the various complications which may develop in diabetics of many years' standing. "Long-term diabetes," as Knud Lundbaek calls it, is an important syndrome, and by its study much can be discovered and a greater understanding obtained about the fundamental disorders in the syndrome of diabetes.

This book enumerates the findings of exhaustive examination in a follow-up of 165 live and 69 dead diabetics, who had had diabetes 15 or more years, and who had resided in a Danish municipality of about 115,000 people some time during the years 1924 to 1950. Every abnormality and complication occurring in this series of cases has been carefully recorded and discussed under its appropriate heading of disorder or system affected. Each has been preceded by a very complete review of the world literature on the subject, with no fewer than 309 references, covering the whole field of research in these subjects.

Such a detailed analysis must, of necessity, make for heavy reading, but the completeness of the work compensates for this. The bibliography alone is useful, quite apart from the extremely interesting results, which are much in accord with the views of other workers elsewhere. The observations are sound and the conclusions fair and reasonable, none being extravagant. Although not for the student,

this book should prove of value and interest to all those interested in the study of diabetes. Every possible long-term complication of diabetes is carefully described and its incidence recorded. The book is an excellent, painstaking piece of work.

JAMES ROBERTSON.

CONGENITAL HEART DEFECTS

Congenital Abnormalities of the Heart and Great Vessels. By Maurice A. Schnitker, M.D., F.A.C.P. (Pp. 306. £3 3s.) London: Oxford University Press (Geoffrey Cumberlege). 1953.

There is much to commend here. But one may first of all deplore the small number of illustrations. Some of those which should enliven the development of the heart are sure to obscure it, particularly figures 5 and 6; the formation of the interatrial septum should be well and clearly shown. To make up for this the pictures of aortic abnormalities are good, and the lack of diagrams showing development of the heart is not felt so much because the account is so clear; it is indeed one of the best I have read. There is a very good chapter on cyanosis and also finger-clubbing. The section on the use of the cardiac catheter is clear and practical, the objects and the risks being well set out. The author describes the various types of lesion in the traditional three groups of acyanotic, late cyanotic, and cyanotic; perhaps it is time for a new and better classification, but in any case many would question whether defects of the aorta should come under the cyanotic type.

The bronchial arteries get very little attention and are not listed in the index. There is not one x-ray photograph. This is a serious fault, for the evidence given by the skiagram on the flow of blood to the lungs is important. Pulsation of the hilar vessels needs more consideration. The point that will interest most readers is the part played by surgical measures in alleviating these defects. This is well and sensibly described. Apart from the omissions mentioned above, this book reads well and provides a clear and up-to-date presentation of the subject.

TERENCE EAST.

MONGOLISM

Mongolism: A Clinicogenetical Investigation Comprising 526 Mongols Living on Seeland and Neighbouring Islands in Denmark. By Jakob Øster. (Pp. 206. Danish Kr. 21. U.S. \$3.) Copenhagen: Danish Science Press. 1953.

This monograph is one of the series of clinical and genetic studies of individual abnormalities that are coming from the Institute of Human Genetics at Copenhagen. Like all these monographs, it is a thorough study based on large numbers. In this case over a thousand mongols were ascertained in three counties of Denmark between 1929 and 1949, and 562 were still alive. No definite new conclusions about mongolism emerge from the study, but even so the work has considerable interest.

The incidence of mongolism is put at about 1 in 600 births. The diagnosis can be made only by finding that a child has several of the signs which are common in mongolism. The author's table of the frequency with which different signs were found is most instructive. He notes, however, that even if one takes the ten best signs there are still children with only two or three of them who are indubitably mongols. The book appears to have been written in 1951, and the author did not use Penrose's useful contribution of a precise method of measuring the abnormality of the dermal ridges of the palms. The author includes mental deficiency in his criteria for diagnosis and so side-steps the interesting point whether an occasional mongol may have average or even above-average intelligence.

It is agreed that there is no specific treatment but that every effort must be made to educate the child to make the best social adjustment it can. In discussing aetiology the author notes the usual finding that mongols become

commoner as the mother gets older. He also found that the interval before and after the birth of a mongol child is unduly long when compared with intervals before and after births of the same order in other families where there is a mongol. But he does not appear to have allowed for the effect of maternal age on fecundity or the natural reluctance of a mother to start another pregnancy after the birth of a mental defective. There was no consistent history of maternal disease early in the pregnancy which gave rise to a mongol. There was, too, only a low incidence of mongolism among the brothers and sisters of mongols. Unfortunately, in contrast to the usual practice in monographs from the Copenhagen Institute, the sibships are not set out in detail except for the five in which a sib is also a mongol and the one in which a half-sib is also a mongol; and the section discussing the sibships is confused and perhaps mistranslated. It appears that 6 of the 354 children born alive after a mongol were also mongols. It is not stated which was the index case in these sibships, but, even if the first mongol in the sibship was always the one ascertained, this gives a low proportion of subsequent children affected, perhaps not significantly greater than the chance expectation. The references given at the end are very comprehensive up to 1951, and the list will be welcome to all who study mongolism.

C. O. CARTER.

CLASSICS IN DERMATOLOGY

Classics in Clinical Dermatology: With Biographical Sketches. By Walter B. Shelley, M.D., Ph.D., and John F. Crissey, M.D. Introduction by John H. Stokes, M.D. (Pp. 485; 111 illustrations. 75s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1953.

It is always pleasant and profitable to live with the masters both old and new. This is particularly true for the clinician, whose masters are those men whose ability, curiosity, and observations, combined with lucid exposition, have done most to advance the art of clinical medicine. The authors of this volume present pertinent extracts from about 150 original papers from 90 eminent dermatologists past and present. They divide the contributions into four periods, the early and middle periods, a golden age from Dühring to Caesar Boeck, and finally more recent observations from such masters as Brocq and Darier, Jadassohn and Bloch, Fox and Parkes Weber. A brief but adequate biographical note on each master precedes the extracts from original contributions, and it is not difficult to get a picture of the man as well as an accurate account of his observations. The abstracts are meant to reflect the enthusiasm and temperament of the authors. The book starts with the observations of Robert Willan, a Yorkshireman and the father of dermatology, and ends with those of John O'Brien, an Australian and perhaps dermatology's youngest son.

Dr. Shelley and Dr. Crissey must have derived great satisfaction as well as instruction from these researches, and dermatologists will be grateful for this easy and useful work of reference. The authors do not pretend that it is a complete account of all the great names in dermatology, as indeed it is not, though it is well proportioned and a valuable addition to the history of dermatology.

It is to be hoped that further editions may enlarge the work. It would be interesting to read Civatte's description of poikilodermie beside the excellent report of Riehl's melanosis, and to find such names as Sabouraud, Rasch, Haxthausen, and Whitfield in the list, to name only a few who would further enrich the book.

It is well and attractively produced on good paper, with hardly a printing error. There are more than 100 illustrations of dermatologists and of the affections they describe. The literary value of the contributions, especially of the older masters, is in such contrast to that of much modern medical literature that students might well be directed to the book for this as much as for its historical interest.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY FEBRUARY 13 1954

CORTISONE AND INFECTION

Cortisone has moved with astonishing speed from pharmacological curiosity to therapeutic stand-by, and much is now known about its secondary ill-effects. In the course of treatment they need constant attention. The most important of them in practice is the drug's tendency to promote infections. This action is as difficult to understand as some of its therapeutic actions. Now a useful review of the evidence comes from Lewis Thomas,¹ of the University of Minnesota, and not the least important part of it is his demonstration that several apparently obvious explanations fail to fit the known facts. The most notable fact is the width and non-specificity of the action. We are used to antibiotics of wide range, but no drug has a range of favourable action at all comparable to cortisone's range of unfavourable action. It seems that, whenever cortisone has been administered to a vertebrate host parasitized by an invertebrate, the course of events has been altered to the detriment of the host. This may be obscured by the symptom-masking effect of the drug, so much so that some of the earlier publications reported clinical improvement.^{2,3} These were soon shown to be illusory, and it is now fairly well established that all the common bacterial infections are enhanced, including those with spirochaetes and the tubercle bacillus. The effect is the same with viruses, a fungus,⁴ and protozoa. The effect on helminths remains slightly doubtful, though a clear answer to the disputed effect⁵ in trichiniasis seems to have come from Stoner and Godwin,⁶ who found

increased susceptibility in mice. So far as the host is concerned, cortisone has been shown to promote infections of one sort or another in man and all the ordinary experimental mammals, though the only non-mammalian host for which any data are available is the chick embryo.

This striking breadth of effect might be compared to that of gross malnutrition or of sublethal doses of whole-body irradiation, but these both produce many diverse changes in the host: cortisone enhances all infections in an otherwise fit animal. This suggests that the defence mechanisms of the body, which often seem so diverse in combating different parasites, all have something in common—that the tree has a single trunk to which cortisone lays the axe. Thomas examines six mechanisms by which cortisone might possibly act, on the worthwhile assumption that only one is needed to account for all the various manifestations. He first considers the possibility of a direct action on the organisms. For this there is no experimental evidence, and *a priori* it is improbable that any single substance would directly stimulate the growth of so exceedingly diverse a group of organisms. Secondly, he considers the possibility of a direct effect on polymorphs, and this it seems can be as quickly dismissed, for they are not concerned in the defence against most fungus, virus, and protozoal infections. It may be difficult to deny to cortisone some effect on polymorphs, but evidence from many independent studies (Rebuck and Mellinger's⁷ is worth special notice) shows that they are the least affected of all the better-known elements of the inflammatory reaction. A third possibility seems plausible at first. The capacity of cortisone to suppress, reduce, or delay the formation of antibodies is well established and applies to a wide variety of antigens.⁸⁻¹² Certainly there must be circumstances under which this is important. Yet cortisone enhances virus infections in the chick embryo, in which no antibodies are produced. Again, the effect is often so rapid as to preclude any possibility of involvement of antibody reaction. If, fourthly, we consider the local defence mechanisms, we find ourselves in similar difficulties. Local inflammatory responses are hindered by cortisone,¹³ and no doubt this action must sometimes be important, but it cannot account for cortisone's capacity to enhance all infections. Most specifically, it cannot account for the promotion of septicaemia after intravenous injection of organisms, where no local inflammation has occurred. There are several naturally occurring generalized infections in which no stage of local reaction at the point of entry or elsewhere can be

traced, and yet cortisone enhances them. Fifthly, various serum components are known or suspected to take part in defence against infection—complement, preformed antibodies, C-reactive protein, hyaluronidase inhibitor, and others. Little relevant is known of most of them, but it is unlikely that any are of importance here.

Finally we come to the sixth hypothesis—a direct effect on the cells of the reticulo-endothelial system. The R.E. system clears particulate matter from the blood, and there is no doubt it plays some part in practically all infections. Critics may object that the details of the local effect remain vague; and it seems, at least to the histologist, that the brunt of the action of cortisone on the lymph nodes and spleen falls on the lymphoid elements rather than on the phagocytic. But here Thomas presents some interesting experiments. If this sixth hypothesis is true, other methods of damaging the R.E. system should have the same effect as cortisone. The only available method—that of “blockade” by overloading the system with injected material—is of doubtful value, but in this case it seems to have been used effectively. Thorotrast and saccharated iron were used as blocking agents. In animals treated with them three close parallels with the effect of cortisone were found. First, both blockade and cortisone interfere with the clearance of particulate matter from the blood, whether the particulate matter is colloidal gold or streptococci. Secondly, both promote the dissemination of streptococci and pneumococci, injected intradermally in doses normally giving rise only to localized infections. Thirdly, both promote the absorption of meningococcal toxin injected intradermally. The first of these effects might well have been expected, but that R.E. blockade should have so striking an effect on local defences and on toxin absorption was *a priori* unlikely and affords strong evidence that cortisone and blockade are acting in the same way. While these experiments seem convincing, independent confirmation is needed. The effect of cortisone on the host-parasite relationship may after all prove to be simply the summation of a number of independent mechanisms concerning antibodies, tissue permeability, phagocytosis, and others, all of which happen to work in the same direction. On the other hand, it may be something more fundamental—a differential effect, perhaps, on the protein metabolism of vertebrates and invertebrates. Even if its effect on the R.E. system is the explanation, many questions remain to be answered. To most people the practical therapeutic problem will seem of chief importance, for a method of preventing the infection-

promoting action of cortisone, other than the blunderbuss one of combining it with antibiotics, would be a major advance. Thomas's work opens up at least the possibility of an approach to this.

THE SPREAD OF CANCER

In both Britain and North America, in spite of modern methods of treatment and intensive efforts to secure early diagnosis, breast-cancer mortality rates for defined age groups maintain an almost constant level.¹ The reason for this is that with few exceptions the early dissemination of tumour cells which later produce metastases defeats all forms of local therapy, even when this is applied promptly and efficiently. Metastasis is indeed the sinister shadow hanging over the treatment not only of mammary cancer but of many other kinds of cancer also. The thorough study of metastasis by every possible means—morphological, experimental, and chemical—should therefore be a major part of cancer research. Willis² has stressed this view in these words:

“Elucidation of the chemical and other factors which determine the success or failure of disseminated tumour cells to survive and grow in new sites might assist in the search for effective chemotherapeutic agents. The great series of grafting experiments already performed for us in the dissemination and metastasis of tumours is thus worthy of close study; this should be supplemented by experimental investigations of metastasis.”

In the opening pages of this issue we publish Professor G. R. Cameron's Florence Blair-Bell Memorial Lecture. In this he discusses recent work and speculation on the subject of the spread of cancer, with special attention to the high incidence of metastatic tumours in the liver. These are, for most kinds of primary growths, not only more frequent and abundant than metastases elsewhere, but they grow more actively and show higher proportions of cells in mitosis. Abortive tumour embolism, which is often seen in the lungs, is very uncommon in the liver. The “seed-soil” concept of tumour metastasis is thus particularly germane here. Before turning to the liver as a site of metastasis, Professor Cameron broadly reviews the known facts about the invasive properties of tumour cells, and then discusses the various hypothetical factors which may be concerned in rendering a given tissue a fertile or a poor soil for neoplastic growth—blood supply, oxygenation, nutritional properties, possible defence mechanisms.

¹ McKinnon, N. E., *Lancet*, 1954, 1, 251.

² Willis, R. A., *Pathology of Tumours*, 1953, 2nd ed., London, p. 206.

³ Paget, S., *Lancet*, 1889, 1, 571.

metabolic qualities of host and tumour cells, and competition between tumour cells and organ parenchyma.

If, as seems certain, chemical factors are important in the development of blood-borne secondary growths from disseminated tumour cells, the explanation of these will probably come from a study of metastasis in the liver; and to this study histopathologists, experimentalists, and chemists have each their essential contribution to make. There has been a tendency in recent years for some experimentalists to belittle the value of morbid anatomy—“dead-meat” pathology—and to suppose that little remains for it to contribute to knowledge of disease processes. Professor Cameron, himself an expert morbid anatomist as well as an experimentalist, provides here a timely reminder of the mistakenness of this view. His arguments embrace and depend on morphological and experimental data in equal measure and clearly exemplify their interdependence and complementary character. It was morbid anatomical observations, like those early ones of Stephen Paget³ in 1889, which first pointed to the anomalous distribution of metastatic growths in the body; and it is similar more thorough observations, aided by improved microscopical and staining techniques and by phase-contrast and electron microscopy, which can provide the essential structural basis for progress in our understanding of the fate of disseminated tumour cells in various tissues. It may well be true that pure morphological pathology, unilluminated by controlled experiment, may not be capable of solving these problems, but it is also true that the pure, experimentalist may be equally incapable of their solution. It is by a well-balanced union of both disciplines, so well exemplified in Professor Cameron's exposition, that light will be gained on these and many other obscurities in tumour pathology.

SHIVERING

The cold spell has led to embittered reflections on the deficiencies of British thermal engineering, and consoling thoughts about the perfection of the physiological mechanisms that are brought into play when the body is submitted to thermal stresses have brought little comfort. If a naked man lies at rest in a cold environment, certain acts of “physical thermoregulation” immediately come into play, all with the function of reducing the loss of heat from the surface of the body to a minimum. For example, as a result of the constriction of the cutaneous vessels the skin temperature falls and the rates of evaporative, convective, and radiation losses are minimized. The

remarkable feature of this response, where man is concerned, is that there is no increase in heat production, so that if these physical adjustments are inadequate to prevent a sustained negative heat balance the whole body cools. When the temperature of the blood has fallen by about 0.5° C., further cooling is arrested by the onset of shivering, a rhythmical, well-coordinated contraction of the voluntary musculature that may increase the total heat production of the body by as much as 400%.

A cat's love of warmth is only too obvious, yet its owner who remorselessly lifts it from the hearth and turns it out for the night in the coldest weather is never worried whether it will catch a chill; his confidence is fortified, moreover, by observing, on its return in the morning, that it is not shivering but only very hungry. The cat, in common with other lower animals and birds, possesses, in addition to its powers of regulating heat loss—physical thermoregulation—a so-called mechanism of “chemical regulation” whereby its metabolism is very delicately adjusted to the thermal demands of its environment. It is presumably this chemical regulation, acting together with restricted heat loss through pilo-erection and vasoconstriction, that permits a cat to withstand such a sudden drop in external temperature without shivering. Man, as we have said, does not exhibit this nice adjustment of his metabolic rate to the environmental demands; instead, mechanisms to restrict the loss of heat (both physiological and artificial, such as the wearing of clothes) have been brought to a high degree of efficiency, and only as a last resort is an increase in metabolic rate invoked—that is, with the onset of shivering.

Shivering therefore appears as a delayed mechanism, only being brought into play when the physical mechanisms restraining the loss of heat from the body have failed to establish a balance of heat production and heat loss at the normal blood temperature; it is thus only one of several physiological mechanisms at the disposal of higher reflex centres concerned with the function of thermoregulation. The neurological aspects of these centres have not been completely elucidated; in lower animals a heat-sensitive centre, stimulation of which leads to vasodilatation, panting, and sweating, has been described in the anterior hypothalamus; stimulation of the lateral hypothalamic area, on the other hand, causes vasoconstriction and pilo-erection, but no shivering. There would thus appear to be two separate reflex centres in the hypothalamus, the one evoked by heat and the other by cold.

The nervous control of shivering, which is not evoked by stimulation of the hypothalamus, is not entirely clear; the other responses to cold are essentially visceral, and it is not surprising that they are under the control of the hypothalamus, a region so closely associated with autonomic function. Shivering is a reflex involving the voluntary musculature, and might be expected to be controlled by centres concerned with somatic activity; according to Beattie and Kerr the centre lies in the caudal half of the medial portion of the thalamus. That the cortex is also involved is

suggested by the work of Aring, who found that primates with lesions in area 4—the somatic motor area—began shivering long before there was any drop in rectal temperature. A lowered blood temperature would appear to be the usual effective stimulus to evoke the shivering reflex; but it may also be evoked by locally applied cold insufficient to lower the blood temperature, and this is presumably mediated by a reflex arc involving, as sensory pathway, the cold receptors and spinothalamic tracts.

The usual concomitants of fear—such as sweating, pilo-erection, vasoconstriction, etc.—may be described as a hypothalamic syndrome released by higher activity, presumably in the frontal cortex. It is interesting that shivering is associated in this complex, because, although it is not a form of autonomic activity, it is released at the same time, thereby showing the close relationship that must exist between the hypothalamic centres of thermoregulation and the thalamic centre controlling shivering. The shivering of fever is only an apparent anomaly: the body temperature is high, but this is a purposive response to an invading pyrogenic agent and would be defeated if the thermoregulatory cooling mechanisms were called into play; instead the warming mechanisms are invoked, among which the most effective is shivering.

THE HAND

In these days of increasingly complex and specialized techniques it is refreshing to be reminded from time to time that good medical practice still depends largely on careful clinical observation. Silverman and Littman,¹ reviewing the value of examination of the hand from the point of view of the cardiologist, have drawn attention to the excessive palmar sweating so often seen in patients with the effort syndrome. Increase in the secretion of sweat from the hand is one of the most constant physical manifestations of emotional tension, a fact made use of in the construction of "lie-detector" machines and similar apparatus used in psychological investigations, and it is a common clinical finding for example in thyrotoxicosis. Pallor of the palm is regarded by many clinicians as more reliable than mucosal pallor as a sign of anaemia, and Wintrobe² states that absence of redness in the palmar creases indicates a haemoglobin level below 7 g. per 100 ml. The orange-yellow pigmentation of carotinaemia may be almost confined to the palms and may direct attention to bizarre dietary habits. The cold, harsh, dry hand of myxoedema is well known; more easily missed perhaps is the palmar hyperkeratosis which may reveal chronic arsenical poisoning, particularly when it is accompanied by the typical pig-

mentation. Of particular interest is the condition sometimes seen in pregnant women and in patients with chronic liver disease—namely, a bright red colour of the palms, usually most intense in the hypothenar eminence and central part of the thenar eminence but sometimes seen also on the palmar surface of the finger-tips, in association with arterial "spiders" over the upper half of the body. It is attributed to the high oestrogen levels which occur in these two conditions.

Cirrhosis of the liver is also one of the less common causes of clubbing of the fingers, one of the oldest of physical signs but still one of the most obscure. An increased peripheral blood flow was found by Mendlowitz³ in patients with clubbing; and Lovell⁴ believes that this leads to an increase in connective tissue, the localization in the distal finger segment being attributed to the predominance there of arterio-venous communications. But the cause of the increased blood flow remains unexplained. The full syndrome of pulmonary osteoarthropathy, which in its early stages is occasionally mistaken for rheumatoid arthritis, is seen most often in patients with bronchial carcinoma and undergoes regression after successful resection of the affected lung. One of the most helpful signs in the fingers is koilonychia, which was shown by Waldenström⁵ to be usually a direct effect of iron deficiency. Osler's nodes in the pads of the fingers are almost pathognomonic of subacute bacterial endocarditis, but splinter haemorrhages occur quite often also in other diseases, being seen for example in most patients with trichinosis.^{6,7} Another disease associated with Osler's name, hereditary telangiectasia, may be suggested in a patient with mucosal bleeding by purplish, round, sharply circumscribed lesions in the finger pads or nail bed; microscopically these are seen to consist of tortuous coils of tiny aneurysmal vessels. Finally, the familiar Heberden's node has recently been given more precise significance by Kellgren and Moore,⁸ who regard it as forming part of a constitutional syndrome they have called primary generalized osteoarthritis, which mainly affects middle-aged women and can be distinguished clinically from the degenerative arthropathies.

VIOMYCIN

No antibiotic hitherto discovered is the equal of streptomycin in activity against the tubercle bacillus, but there are certainly two with somewhat less activity which may be turned to practical account. Terramycin has been used in combination with streptomycin on the principle that combined therapy delays the development of resistance, one object in view being to substitute it for P.A.S. in patients intolerant of that drug. The findings of Des Autels¹ in a limited number of cases encourage this policy; after a 120-day course of streptomycin given twice weekly, streptomycin-resistant bacilli were found in 17% of patients also given P.A.S. and in only 5% of those also given terramycin. The other antibiotic of secondary usefulness is viomycin, earlier studies of which have previously been referred to in these columns.² This drug has chiefly been used

in a different way—namely, as a substitute for streptomycin when bacillary resistance to the latter has developed. In the very unfavourable cases in which it was first tried little benefit was obtained, and a rather forbidding triad of toxic effects was observed—disturbances of the eighth nerve, the kidney, and the plasma electrolytes.

Despite these unfavourable initial findings, and because they could be discounted by the unpromising nature of the clinical material and perhaps by the excessive dosage used, a trial of viomycin was instituted in the Veterans' Administration (U.S.A.) study of the chemotherapy of tuberculosis, the results of which have been described in two reports.^{3,4}

It was decided in the first place to reduce the dose of viomycin to 2 g. twice weekly in the hope of minimizing toxic effects, and on the basis that streptomycin given as infrequently as this has proved effective. The three regimens adopted were viomycin alone and together with either 1 g. streptomycin twice weekly or 12 g. P.A.S. daily, the duration to be at least four months. Of the patients chosen for treatment the great majority had had previous streptomycin treatment and had streptomycin-resistant bacilli: 93% were classified as far advanced and the remainder as moderately advanced; all had cavities and all were sputum-positive at the start of treatment. The drug caused toxic effects in 24% of patients, and in 13% the treatment had to be discontinued on this account. Some clinical improvement was produced in 34%, and moderate or marked improvement in 17%, of the patients on combined regimens. The corresponding figures for viomycin alone were 14% and nil. Combination with another drug thus gave clearly superior results, and this difference is also reflected in the numbers of patients whose condition deteriorated during treatment, which were 24% of those on viomycin alone and only 7% on combined treatment. Sputum conversion did not show this difference, occurring in about 15% of each group. Acquired bacillary resistance to viomycin developed to a maximum of about 40% of cases after longer periods of treatment, and was rather commoner in patients receiving this drug alone.

These are not impressive results, but they must be interpreted with due regard to the unpromising clinical material on which they are based. Patients in whom treatment with streptomycin has failed to arrest the disease can naturally not be expected to respond invariably to another and somewhat less potent drug. On the other hand it clearly has a place in the treatment of such patients, provided the disease is not too far advanced. A recent communication from the Ministry of Health states that limited quantities of viomycin will soon be available for use in N.H.S. hospitals only. It is accompanied by a memorandum of instructions for use, advocating the bi-weekly 2-g. dose used in the

American study, combined with streptomycin, P.A.S., or isoniazid "as dictated by the drug resistance position."

THE ORGANS OF ZUCKERKANDL

The medulla of the adrenal gland, which contains adrenaline and also a small proportion of noradrenaline, is described as chromaffin tissue because it stains with potassium dichromate. This stain depends on the formation of brown pigments by the oxidation of the adrenaline, and other oxidizing agents give the same stain. It has long been known that chromaffin tissue occurs in the body outside the adrenal gland, and in 1901 Zuckerkandl¹ described the presence of a mass of cells of this kind on the anterior surface of the aorta near the origin of the inferior mesenteric artery. Two years later Kohn² showed that these cells originated, like the cells of the adrenal medulla, from the neural crest. This collection of cells on the aorta has since been known as the organ or organs of Zuckerkandl. They are normally not present in the adult, and in 1925 Ivanoff³ stated that they reach their greatest development in children aged 12–18 months, after which they become fibrosed and atrophic.

West, Shepherd, Hunter, and Macgregor⁴ have recently compared the changes which take place during foetal life and after birth in the organs of Zuckerkandl with those in the adrenal medulla, making both pharmacological and histological examinations. Their general conclusion is that the organs of Zuckerkandl are the main site of formation of noradrenaline in foetal life, during which the adrenal medulla is immature. They examined the organs of Zuckerkandl and the adrenal medulla collected from a series of subjects 6–48 hours after death. Histologically the organs are mature at about twenty-two weeks of gestation, and from then do not change until some months after birth. At about 8 months after birth there is a decrease in vascularity and in the size of the cells and an increase in fibrous tissue. The adrenal medulla, on the other hand, begins to develop only after birth. The pharmacological investigation showed that the amount of noradrenaline increased steadily in the organs of Zuckerkandl from 15 weeks up to 2 months after birth, the total being appreciably greater than that in the adrenal medulla during this period. Thereafter the amount in the organs declined and that in the medulla shot upwards.

Perhaps the most important aspect of this work is the indication that tumours of the organs of Zuckerkandl may occur and lead to repeated hypertensive crises in the same way as tumours of the adrenal medulla. These can be successfully diagnosed by the amount of noradrenaline present in the urine. The surgeon who then fails to find an adrenal tumour should inspect the area of the organs of Zuckerkandl. Engel and Euler⁵ have already reported one case.

CLINICAL PATHOLOGY IN GENERAL PRACTICE

LABORATORY INVESTIGATIONS IN THE DIAGNOSIS OF IRON-DEFICIENCY AND SIMPLE CHRONIC ANAEMIA

BY

GEORGE DISCOMBE, M.D., B.Sc.

Pathologist, Central Middlesex Hospital, Park Royal, London, N.W.10

Iron-deficiency anaemia occurs when the body gains iron more slowly than it should to provide for the needs of growth or to compensate for loss by haemorrhage. Only this factor of iron balance is of importance, so that nutrition enters into consideration only in so far as the food contains iron. Once iron deficiency has been demonstrated the laboratory tests to be used will be those which detect imperfect absorption of iron or loss of iron—that is, bleeding. It is easy to demonstrate iron deficiency, but not so easy to demonstrate its precise aetiology. The diagnosis of iron deficiency is complete only when the relative importance of growth, iron absorption, and blood loss have been assessed and when the site of blood loss is known. Every pathologist has performed necropsies on patients with carcinoma of the colon who had been treated for months for their iron-deficiency anaemia—treated without investigation until their resectable carcinoma had metastasized. It would be, of course, impossible to investigate exhaustively every patient, so the choice of investigation must depend on knowledge of the natural history of iron-deficiency anaemia.

Iron deficiency occurs during the first six months of life in premature infants, whose parasitism on their mother is cut short before they have obtained all the calcium and iron they need: the anaemia is more severe the more premature the birth. Childhood is usually free from iron deficiency, unless nose-bleeds are very severe, or bleeding occurs from peptic ulcer in a Meckel's diverticulum, or a peptic ulcer develops in a hiatus hernia. The menarche may lead after a few years to chlorosis in a young woman whose dietary fads are more extreme than usual; each pregnancy costs the mother at least 300 mg. of iron—a year's absorption from food (and bleeding from peptic ulcer in a hiatus hernia is commoner in pregnant women than in other subjects); and an abortion may cause even greater losses. In the fourth and fifth decades fibroids cause menorrhagia and absorption of iron is less because achlorhydria becomes common. Throughout adult life, in men as well as women, peptic ulceration and piles contribute to anaemia, and from the fifth decade malignant disease of the gastro-intestinal tract must always be considered. There are other causes of blood loss, such as ulcerative colitis, Crohn's regional ileitis, diverticulitis, and tuberculous ileitis, but in these anaemia is rarely the presenting symptom.

Iron deficiency is usually accompanied by some reduction in haemoglobin level, to 12.4 g. (80%) or below, but one occasionally sees anaemic polycythaemia with haemoglobin levels of 100% (14.8 g.) or more, though iron deficient.

Recognition of Iron Deficiency

Estimation of haemoglobin and of packed cell volume allows the calculation of the mean corpuscular haemoglobin concentration (see last week's article in this series, February 6, p. 326); if below 30% this indicates iron deficiency, between 30 and 32% iron deficiency may be present, but it is slight, while over 32% it is absent. The

stained film will show anisochromia, and if the anaemia is moderate or severe the cells will tend to be small, misshapen, and to vary excessively in size (microcytosis, poikilocytosis, anisocytosis) while they will contain less haemoglobin than normal (hypochromia). In severe anaemia target cells are often present, and they may lead to confusion with thalassaemia (Mediterranean anaemia or trait), found in Cypriots, Italians, and Greeks, or sickle-cell anaemia or trait, found in Africans and a few tribes of India or Persia, in neither of which congenital peculiarities does iron have any therapeutic value. If it is possible to estimate serum iron, it will be found to be lowered in iron deficiency and normal in the congenital anaemias.

Having established the presence of iron deficiency, one must consider aetiology; and if the history given by the patient clearly indicates a simple cause, such as menorrhagia or addiction to eccentric foods, treatment can be started without delay. If, however, there are no leading symptoms or signs one must first exclude bleeding from the gut.

Gregerson's benzidine slide test is here very useful. Powders of 25 mg. of benzidine and 200 mg. of barium peroxide are dissolved in 5 ml. of glacial acetic acid; a smear of faeces is made on a slide and two or three drops of the reagent added: a blue colour appearing within 30 seconds is presumptive evidence of blood, though this should be confirmed by the standard benzidine or orthotolidine tests after the patient has been on a meat-free diet for three to four days. A positive Gregerson test is not proof of bleeding, but it establishes a *prima facie* case for further investigation. One should, of course, exclude the presence of bleeding piles before using it, and this necessitates proctoscopy, while in older persons a digital examination may reveal a carcinoma.

Refractory Iron Deficiency

Once the diagnosis is made and the patient given iron and ammonium citrate mixture or ferrous sulphate compound tablets improvement should be rapid: the haemoglobin should rise by 4–20% weekly. If this rise fails to occur, it may be because the patient is not taking the iron or because it is not being absorbed.

Patients, especially women, often fail to take iron tablets because they claim that the tablets give them indigestion, diarrhoea, or constipation. This can be avoided by instructing them to take for one week one tablet in the middle of the main meal of the day; in the second week to add a second tablet in the middle of the next meal; and, thereafter, a third tablet in the middle of the third meal. Alternatively one of the preparations of ferrous gluconate may be prescribed, for there is no doubt that these cause less digestive disturbances than does ferrous sulphate. However, some patients take their tablets religiously without in any way affecting their anaemia, and this is an indication for the administration of iron by vein; it is also an indication for examination of the stools, for many patients who fail to respond to iron by mouth can be shown to have steatorrhoea. The classical method of Holt, Courtenay, and Fales for the estimation of faecal fat, which was performed on an isolated dried specimen, is now less used and is being replaced by methods in which an aliquot of the 24-hour stool is analysed without drying. This change in method reflects the interest in fat balance rather than fat excretion. To-day one expects over 90% of ingested fat to be absorbed and but 10% excreted; any greater excretion is considered evidence of steatorrhoea. If steatorrhoea is present, iron absorption virtually ceases, and steatorrhoea is the com-

monest cause of the finding that an iron-deficiency anaemia fails to respond to iron by mouth but responds rapidly to intravenous iron. Steatorrhoea causes iron deficiency far more often than it does megaloblastic anaemia.

Anaemias Secondary to Other Diseases

The production of red cells may be slowed or their destruction made more rapid by a number of diseases which have no direct association with the blood or bone marrow. Red-cell production is diminished by infection, by nitrogen retention (chronic uraemia) as in chronic nephritis, and by other disease states such as rheumatoid arthritis and myxoedema. That an anaemia may be due to one of these causes should be suspected when a steady or slowly progressing anaemia, usually of moderate severity (haemoglobin over 10 g.) is not due to iron deficiency (normal M.C.H.C.), and the cell volume is near or slightly below the lower limit of normal (M.C.V. 70–85 μ^3), though in myxoedema the cells may be slightly enlarged (macrocytosis, M.C.V. 95–115 μ^3).

In all such anaemias, if the blood count gives no clear indication for therapy a series of investigations may be initiated, each designed to exclude one or other cause. Adequate history-taking and physical examination should exclude the grosser forms of disease such as bronchiectasis, diverticulitis, osteomyelitis, or ulcerative colitis, but a differential leucocyte count showing neutrophilia and a raised erythrocyte sedimentation rate would suggest that a further and more intensive search for a site of infection might be desirable. Some infective processes show minimal changes in leucocyte counts, and of these tonsillitis and subacute bacterial endocarditis are very important; in these the count may be quite normal or there may be slight neutrophilia and lymphocytopenia, usually with some monocytosis, though such changes are inconstant. In typhoid fever (though not in the paratyphoids) and in brucellosis there are neutropenia and monocytosis. Brucellosis occasionally becomes very chronic, causing anaemia with only occasional bouts of fever; in such patients the monocytes may be mistaken for lymphocytes and a diagnosis of lymphatic leukaemia entertained. Fortunately, brucellosis is fairly uncommon in Britain, but agglutination reactions may be worth performing in a patient with an obscure anaemia and some fever. Pulmonary tuberculosis is a much more common cause of moderate anaemia, especially in young adults, and now that facilities for chest radiography are available almost everywhere it should be recognized easily.

An important cause of simple chronic anaemia is nitrogen retention, chronic uraemia. If a patient has a very slowly progressing renal lesion he may have no complaints until his blood urea exceeds 100 mg. per 100 ml., and his haemoglobin has sunk to, say, 60%. In such cases the haemoglobin level and blood urea are reciprocally related, so that if the blood urea can be lowered the haemoglobin level will rise. Such patients usually have an acidosis secondary to the renal lesion, and if this is present, as shown by a diminished alkali reserve (plasma bicarbonate), then administration of alkali (sodium bicarbonate) in quantities sufficient to raise the alkali reserve to, and to maintain it at, the middle of the normal range (68 vols. per 100 ml. or 30 mEq per litre) will result in a reduction in the blood urea and an increase in haemoglobin level. By this means a patient with nitrogen retention due to polycystic kidneys may be kept alive and useful for several years after he would have died from uraemia had he not been treated. This may be of great importance to the family of such a man, in whom death usually occurs during the fifth decade, when his children still need him; it is equally important for the child or young adult with renal rickets, whose bony lesion may be healed by precisely the same procedure. It is always desirable to estimate the blood urea in a patient with unexplained simple chronic anaemia, and, if it is raised, examination of the urine for cells and casts, careful palpation of the abdomen for polycystic kidneys, adjustment of the alkali reserve to the optimal figure, and perhaps an excretion pyelogram may be reasonable procedures.

There are other unrelated conditions which diminish red-cell production: some simulate an infective process—for example, rheumatoid arthritis; others appear to be neoplastic, such as Hodgkin's disease and other reticulososes, but in these the anaemia is rarely the presenting symptom, as it is often in uraemia and sometimes in infection, rather is it a symptomatic epiphenomenon. Occasionally one encounters a simple chronic anaemia in an obese woman, usually slow witted, who feels the cold very severely, who snores or who speaks slowly with a nasal intonation, and whose hair and eyebrows are greying and scanty. In such patients one can but suspect myxoedema, and a raised serum cholesterol would support that diagnosis and warrant further investigation, including a B.M.R., though photographs before and after a month's course of thyroid extract offer more convincing diagnostic evidence than does the B.M.R. One form of myxoedema can be caused by absorption of resorcinol from ointments or suppositories containing it, usually in middle-aged women with varicose ulcers.

Drug-induced chronic anaemia or chronic anaemia resulting from poisoning are both rare. Benzene inhaled from rubber solutions, dry-cleaning fluids, paints and varnishes, motor spirit, or from solvents may cause a hypoplastic anaemia, with leucopenia and thrombocytopenia developing during exposure or months or years thereafter, but this is rare in Great Britain. A similar anaemia may develop after the administration of chloramphenicol, though little is known of its frequency. Lead-poisoning is usually accompanied by a moderate anaemia with punctate basophilia, but should not be diagnosed merely because the blood cells show excessive punctate basophilia; one cannot say that a patient has been poisoned unless he develops symptoms or suffers organic damage. Not rarely a subject absorbs and excretes some lead without developing any symptoms, and if on the discovery of punctate basophilia he is said to have lead-poisoning he may well develop a compensation neurosis and manufacture symptoms. If lead absorption or even poisoning is suspected from the blood count, one should not suggest that the patient is "suffering from lead-poisoning" but should suggest that, "since he has been exposed to lead, it would be wise to discover how much he has absorbed" and arrange for an analysis of a 24-hour specimen of urine. If he has wrist-drop or abdominal colic and his lead excretion is excessive one has no alternative but to make the diagnosis of poisoning.

Unusual Blood States

There remain a few conditions which should be regarded as physiological aberrations, or necessary consequences of disease. Chronic retention of carbon dioxide is found in emphysema, and is accompanied by an increase in mean cell diameter up to 8.8 μ without increase in variability—a change also seen occasionally in congestive cardiac failure.

Unexplained macrocytosis without anisocytosis and without anaemia is rare and may be ignored if haemolytic anaemia and carcinomatous deposits in the bone marrow can be excluded. In obstructive jaundice the red cells become excessively thin and target cells are common, even though there is no iron deficiency; rarely, obstructive jaundice can thin the cells of acholuric jaundice (congenital spherocytosis) so much that fragility becomes normal. Occasionally, ovalocytosis, in which the cells are ellipsoidal disks, may be seen and must be differentiated from pernicious anaemia; in ovalocytosis anaemia is slight or absent and anisocytosis minimal. If necessary, a sternal puncture would show megaloblastic erythropoiesis in pernicious anaemia and normoblastic erythropoiesis in ovalocytosis.

It may be noted that no anaemia has been ascribed to vitamin deficiency. In Britain to-day such anaemias are so rare that no haematologist would consider such a diagnosis without a clear history of dietary deficiency and the symptoms of scurvy, beriberi, or pellagra. On the other hand, dysphagia with stomatitis, the so-called "Plummer-Vinson syndrome," may occur in elderly women who are not anaemic, and is then due to riboflavine deficiency.

THE WILLIAM BUDD HEALTH CENTRE

THE FIRST YEAR

BY

R. H. PARRY, M.D., F.R.C.P., D.P.H.

J. SLUGLETT, M.B.

AND

R. C. WOFINDEN, M.D., D.P.H.

The William Budd Health Centre in Bristol, one of the first to be provided under the National Health Service Act, 1946, was opened officially on September 16, 1952, by the Minister of Health, Mr. Iain Macleod.

A full description of the buildings has been given elsewhere (*Lancet*, 1952), but a brief résumé may not be out of place here. It is a prefabricated single-story building of "Orlit" construction containing six general-practitioner suites, each with its own waiting-room, surgery, and examination-room; a main waiting-hall; a large office; a staff room; a medical treatment room; and the usual offices. The practitioners were not in group partnership, and the centre was to cover their branch practices. All rooms were to be used either by general practitioners or by the local health authority, but in general the former used the centre mornings and evenings, the latter in the afternoons. The centre was provided to serve a housing estate covering some 1½ square miles, with a population of 30,000, on which there lived no medical practitioner, although the periphery of the estate was well served with general medical and dental practitioners, pharmacists, and two local authority clinics.

It is a matter of some importance that all those who are interested in the health services of this country should be kept informed of the progress made in the few experimental health centres which have been set up. This article contains the substance of the first annual report of the House Committee.

Throughout the past 12 months the centre has been visited by legislators, administrative, health, and social workers from all parts of the British Isles, Europe, the Americas, Scandinavia, and South-east Asia. Almost without exception the visitors' reports have been very favourable.

The period under review has been one of rapid evolution of the health services in the area served by the centre. It is now true to say that in no other district in Bristol, and possibly in the whole of the country, is there such close co-ordination of medical services or such excellent co-operation between the medical and ancillary staffs employed in the field by various health and welfare administrative bodies.

The original staffing arrangements to cover both practitioner and local authority work within the centre included a sister-in-charge, a deputy sister, and three nurses; two secretary-typists, one general clerk, two porters, and two part-time sisters. Experience has enabled us to effect some economy, and the staff has now been reduced by one nurse and one secretary-typist, although the doctors' evening surgeries necessitate the additional employment of part-time sessional clinic nurses. It should be noted that because of the special circumstances in the area full nursing cover for a day and night service had to be provided (*Lancet*, 1952). The nurses live in a near-by hostel.

Time-table

Although there was some apprehension at first that the accommodation at the centre might not be fully used for large parts of the day, Table I shows that, in fact, almost every room is in full use from 9 a.m. to 8 p.m., Monday to Friday, inclusive.

Adhering to the original plan, the practitioners use the suites in the mornings and evenings and the local authority in the afternoons. This arrangement has proved highly satisfactory, and the fact that the practitioners' surgery hours are staggered (this was purely chance and not planned) has helped to prevent congestion and overloading of staff, and has facilitated the cleaning of rooms. The rooms are prepared by the centre staff for the next user.

TABLE I.—Surgery Hours

			Nutritionist	Sch. med. sess.	A.N., P.N., B.C.C. clinic	

During the period under review 10 doctors attended the centre at some time or other, but the bulk of the work was done by one or other of the principal partners of the six firms mentioned. It should be noted that four of the doctors are now using the centre in the afternoons for the purpose of carrying out antenatal and infant welfare clinics for their own patients. School medical sessions in the charge of a medical officer engaged for the purpose by the local authority have been held on two afternoons a week since January, 1953. A consultant obstetrician session, a nutritionist's session, and relaxation and mothercraft sessions have also been in operation from an early stage.

General-practitioner Work

Statistics are appended of the volume of work undertaken in the centre from August, 1952, to July, 1953.

Patients Registered at the Centre.—Although there is a population of about 30,000 at risk, Table II shows that only just over 10,000 people on the lists of the general practitioners concerned attend there for examination or treatment.

TABLE II.—Total Patients Registered at the Centre

1952	1953
Nov. 9,473	Jan. 9,732
Dec. 9,565	Feb. 9,850
	Mar. 9,993
	April 10,153
	May 10,248
	June 10,332
	July 10,354

Between 20 and 30 practitioners other than the health centre doctors have patients on the estate, and these people, living mostly on the periphery, find it more convenient to attend these doctors or the main practice premises of the participating doctors, which are just outside the area. Two local authority clinics also serve the periphery of the health centre area. Moreover, before the centre came into operation a busy minor ailment school clinic was in operation within the grounds of one of the schools on the estate, and this has remained for continuation treatment. For these and other reasons it cannot be claimed that the health centre is, in fact, serving the main medical needs of 30,000 people.

Patients' Attendances at the Centre.—Table III shows the quarterly attendances of patients to each practitioner firm. On average, 8,261 patients attended each quarter; the busy winter quarters November to January and February to April are noteworthy.

TABLE III.—Quarterly Attendances for Each General-practitioner Firm

Firm of Doctors	1st (Aug.-Oct.)	2nd (Nov.-Jan.)	3rd (Feb.-Apr.)	4th (May-July)

Total	6,768	8,969	9,911	7,397

An average of 8,261 patients were seen by G.P.s at the centre each quarter.

Practitioner Special Clinics.—Table IV relates to the recently started maternity and infant welfare clinics operated by the practitioners. This development is very promising, as the doctors see their expectant mothers in association with the district municipal midwives and health visitors; the hospital specialist obstetrician is also available for consultation if required. Thus the patient, instead of having to visit midwife, general practitioner, local authority doctor, and hospital specialists on separate occasions in different places, has only one place and visit, at which all her antenatal care is given, including mothercraft teaching and relaxation. Only one, instead of four, sets of notes is in existence for each patient. Similarly, the doctors conducting their own infant welfare clinics have the advantage of the co-operation of the health visitor in general health education and special teaching in infant care. A fuller description of this service will be given elsewhere.

TABLE IV.—Attendances During 1953

Firm of Doctors	At G.P.s' Antenatal and Post-natal Clinics	At G.P.s' Infant Welfare Clinics
A	205 (27 sessions)	310 (28 sessions)
B	79 (18 ")	296 (28 sessions)
C	— " —	112 (27 ")
D	239 (28 sessions)	— " —
E	106 (26 ")	— " —
Total	629	718

Work in the Medical Treatment Room.—Table V shows the number of "treatments" given by the nurses for each practitioner firm. The treatments include dressings, injections of penicillin, insulin, liver preparations, and so on. The number of "casuals" given treatment—that is, patients not on the health centre doctors' lists—is also given for each quarter. For the first few months the purpose of the centre was misunderstood; the population regarded it as a casualty out-patient department and used it, often for trivial complaints; a few outside practitioners thought they could refer their patients for treatment to the centre. By personal instruction and group talks to local organizations the purpose of the centre is now better understood. There has been a falling off in the number of casuals until the summer months, when the lighter evenings put local children at longer risk. However, no genuine emergency is turned away from the centre. Arrangements are made to call the appropriate doctor or to order an ambulance to send the patient to hospital, or initial treatment is given and the patient is referred with a note to his or her own doctor.

TABLE V.—Treatments Given for Each General Practitioner (Quarterly)

Firm of Doctors	1st (Aug.-Oct.)	2nd (Nov.-Jan.)	3rd (Feb.-Apr.)	4th (May-July)
A	980	1,334	1,236	948
B	21	80	54	59
C	180	201	153	79
D	666	767	542	380
E	211	126	57	49
F	465	469	344	308
Total	2,523	2,977	2,386	1,823
Casuals	120	48	63	98

The quarterly average of patients treated, apart from casuals, is 2,425.

Night Calls.—Table VI shows the night calls (8 p.m.-8 a.m.) dealt with at the health centre. Here we should explain that the estate residents asked in the planning stage that some form of night service should be made available. At one stage serious consideration was given to the provision of sleeping quarters for a practitioner within the centre. For various reasons this idea was rejected and night cover is now provided by having a porter on duty each night, during which he attends to night inquiries and also cleans the centre. The nursing staff, who live in the vicinity, work a night rota and are on call when needed by the porter. It should be noted that the doctors had estimated the need to cover between 10 and 12 calls a night. It will be seen from Table VI that, in fact, calls have averaged 1 to 2 a night, and in the light of this experience a doctor's flat would have been needless. How far the fewness of the night calls is the result of the psychological reassurance of an ever-open health centre it is difficult to say. Out of 543 "out of hours" calls a nurse had to be called on 150 occasions—that is, an average of 12.5 per month.

TABLE VI.—Night Calls (All Types)

Aug. 19	Sept. 36	Oct. 34	Nov. 30	Dec. 47	Jan. 52	Feb. 35	Mar. 47	Apr. 52	May 51	June 69	July 71

Average per month, 45+.

Use of and Reference to Specialist Services.—(1) The centre consultant antenatal clinic:—From an early stage an obstetric specialist from the professorial unit has held a

regular consultant session at the centre. His services have been freely available to general practitioners and to the local authority doctor and midwives; personal contact with him has been most valuable. Twenty-four sessions have been held, at which 374 patients were seen, an average of 15 per session. (2) Reference of patients to hospital and specialist services:—Table VII shows the number of patients referred

TABLE VII.—Patients Referred to Hospital Diagnostic Units (All Doctors and Local Authority)

Total (Jan.-Sept.)	328	356	79	63

to hospital diagnostic units by practitioners and local authority doctors for some of the more important special investigations. Table VIII shows the number of patients referred to hospital consultants by general practitioners. It should be noted that in accordance with the practice in

TABLE VIII.—Patients Referred to Hospital Consultants (All Doctors)

Total (Jan.-Sept.)	55	41	253	224	45

all Bristol local health authority clinics every expectant mother is encouraged to have a routine chest x-ray examination, which is provided by the local authority at the central clinic; this practice is being followed at the William Budd Health Centre.

Local Authority Work

Antenatal Clinics.—The medical officers hold one session a week at the centre in order to give antenatal care to expectant mothers living in the area whose doctors do not work in the centre. At 24 sessions there have been 403 attendances—an average of 17 patients a session. The district midwives hold two sessions a week, and at 26 sessions have had 371 attendances—an average of 14 a session.

Infant Welfare Clinics.—At 44 sessions 1,992 children were examined or advice was given to the mother:

Under 1 year old	1,237, average 28 a session
1 year old	384 " 9 " "
2-5 years old	371 " 8 " "

Pre-school children on the lists of the health centre doctors are now not seen by the local authority doctor, although the latter's past knowledge and records of the child are useful to the health centre doctors.

School Medical Clinics.—There are two school medical officer's sessions a week. At 57 sessions there have been 1,215 attendances, an average of more than 21 a session. Schoolchildren on the lists of the health centre doctors do not attend these clinics.

Physiotherapy: Antenatal and Post-natal Exercises (Relaxation Classes).—At 21 sessions 105 patients attended—an average of 5 a session. This includes both local authority doctors' patients and those of the health centre doctors.

Nutritionist's Clinic.—The local authority nutritionist attends the centre for one session a week, in order to give dietetic advice to general-practitioner patients. The "gastric ulcer," "diabetic," "reducing," etc., diets prescribed by the doctors have been translated into practical daily diets worked out in accordance with the patient's financial means. There were 127 attendances.

Repercussions on General Practice in the Area

New Patients at the Health Centre.—By agreement, any new patient expressing preference is put on the list of the doctor of his choice. Unattached new patients attending the centre and with no special preference for any one doctor

have been allocated to each doctor in rotation. The number of such new patients on each doctor's list has been reviewed each quarter so as to keep a fair allocation.

Transfer of Patients in the Area ("Drift").—The additions to and deletions from the lists of all doctors working at the centre (including their partners, if any) for the first year were:

Total counts of the lists of the doctors concerned on July 1, 1952	29,206
Additions during the year	3,460
Deletions during the year	32,666
Total counts on July 1, 1953	2,840
Net increase	29,826
	620

It is probable from these figures that there has been no abnormal drift to or from the lists of the doctors connected with the centre during the year.

Co-operation of Health Workers. One of the most important and significant developments in this area has been the tremendous improvement in co-operation between the general practitioner and the local authority health and welfare workers in the area. Mention has already been made of the greatly improved co-ordination of maternity services in the area and of the developing interest of the general medical practitioners in orthodox preventive medicine, as evidenced by their starting infant welfare clinics for their own patients as part of their general medical service. Further extension along these lines would lead to the exclusion of the local authority doctors without any loss in the efficiency of the preventive health services. In addition, there is now excellent co-operation between the three district health visitors based on the centre and the practitioners. The doctors appreciate that the health visitor can be as valuable to them as the midwife and district nurse, and many misunderstandings on both sides have been removed.

Standard of General Practice in the Area. It is difficult to assess the standard of any general practice, and it would be invidious in this report to make extravagant claims about general practice at the William Budd Health Centre. However, the secretarial and nursing assistance has given the doctors more time to examine and advise their patients. The treatment room, in which an increasing volume of work has been undertaken, has enabled many patients to be treated who would otherwise have gone to hospital out-patient departments.

Agreements.—The official machinery set up to deal with the health centre is as follows: (1) The Joint Advisory Committee with no executive functions. On it sit members of the local health authority, the executive council, the local medical committee, and the house committee. It gives advice on policy matters to the two parent bodies—the local health authority and the executive council—and was set up to ensure fair representation of the views of each authority and of the health centre workers as well as the doctors who work in the area but not in the centre itself. (2) The House Committee, consisting of the health centre doctors, the representative of the medical officer of health, the sister-in-charge, and the secretary of the executive council. It deals with domestic matters. The Joint Advisory Committee has met on five occasions—three of them before the centre was opened—and the House Committee on five occasions. No formal agreements have been in force either between the executive council and the local health authority, or between the council and the doctors, or between the doctors themselves. At an early stage the question of rent was informally agreed by all concerned, and as the centre has evolved the various parties have honoured the decisions of the two committees.

Finance

The gross cost of operating the centre for both local authority and practitioner services is within £65 of the estimate made two years ago—namely, £10,000 per annum, or £200 a week. This covers loan charges, salaries, uniforms and laundry, local authority drugs and dressings, equipment, upkeep of nurses' hostel, maintenance and repairs, rent,

rates, heating, lighting, water, printing and stationery, telephone, but does not include capitation fees, the proportion of the salary of the local authority doctor, the regional board specialist, and the cost of the drugs prescribed.

Discussion

No doubt it would be interesting to discuss the first year's experience at the William Budd Health Centre in the light of the Hadfield Report (1953), the Review of General Practice by the General Practice Review Committee of the B.M.A. (*British Medical Journal*, 1953) and the articles by Joseph Collings (1953) on group practice. Space does not permit this, but we would point out that all these reports, in their references to health centres, are discussing a theoretical conception, as none of those authorities have had the opportunity of first-hand experience of the functioning of a health centre under the National Health Service Act. We must limit our discussion to our own experience and try to give answers, albeit provisional, to some of the questions that have been asked.

Let us say at the outset that, so far, the health centre has provided many advantages to the patients, doctors, and other health workers in the area, and few if any disadvantages that we have been able to discover.

The two most promising developments are the relief of the doctors from "unproductive" work by the provision of clerical and nursing assistance, thereby enabling them to devote more care and attention to their patients, and the greatly improved co-ordination of health services and co-operation of health workers in this area.

The theoretical conception that co-operation and co-ordination would be improved by allowing health workers of all types—general practitioners, local authority doctors, district midwives, and health visitors—to work under one roof has been borne out in practice. Reference has already been made to the closely knit maternity services in this centre with the attendant advantages to all concerned, and not least to the expectant mother. The staff room has proved to be the most important room in the building, for it is there that all medical, nursing, and social workers in the district (including probation officers, children's officers, district voluntary case workers, and the like) forgo their families the doctors to discuss particular patients or their families over a cup of tea or coffee. With greater rapidity than had been expected, the health and social workers in this area are welding themselves into a team which has the interest of the patient and family at heart, and each member of the team is now in the favourable position of being fully informed on all known factors operating in each case.

Nevertheless we would not say that such a happy development would necessarily follow in every health centre. Two main factors have helped at the William Budd Health Centre. The relatively small size of the centre, together with the joint use of rooms by general practitioners and local authority staff, instead of resulting in disagreements as might theoretically be expected, has resulted in closer co-operation. Secondly, we feel that our early decision that a nursing sister should be in overall charge of the centre rather than a lay manager was the right one. Much has depended on her in achieving co-operation; her qualifications and experience enable her to smooth out day-to-day difficulties in a manner which could never have been achieved by even the most charming of lay administrative officers.

The original objective in this health centre was to provide suitable premises for general practitioners, and in the planning stage the local authority services were of secondary importance. As time has gone on we have found the need for, and proved the advantage of, other services. For example, the specialist obstetrician has been brought in, relaxation classes for expectant mothers have been started, and the advice of the local authority nutritionist has been made available to the doctors. This nutritionist's clinic is proving a unique and valuable undertaking and will be reported on more fully at a later date. The general practitioners are

unanimous in their belief that the provision of x-ray and minor pathological investigational facilities would be a great advantage to the patients and to themselves, and this is the direction in which they would like to see future developments.

One of the frequently expressed fears about health centres was that there would be local authority interference and dictation in their management. Such fears have proved groundless. Apart from the good will displayed by all concerned, we think the machinery set up, which includes a house committee and a joint advisory committee, has done much to facilitate the smooth running of the centre.

Fears were also expressed that health centre practice would be too remote and impersonal and would interfere with the doctor-patient relationship. This has not happened at the William Budd Centre. We believe that the provision of a separate waiting-room for each doctor's suite has helped to preserve the doctor-patient relationship. But the attitude of the secretarial and nursing staff is just as important. In this we have been fortunate. Most of the patients attending are now well known to the staff not merely as human beings but as human beings who are being attended by Dr. A, B, or C as the case may be.

It is difficult to canvass the opinion of patients attending the centre, but none have complained of an impersonal service or have deliberately transferred to a non-health-centre doctor. The patients have an undoubted sense of security in that they know the health centre is always open and they can always get service if they need it.

It should be noted that so far there has been no move towards a group practice in the sense of financial partnership. In other ways, however, the relationships of the doctors have become a good deal closer; for example, seeing and treating emergency patients on behalf of each other is now customary and relief in other ways is developing. Collings (1953, p. 611), the great advocate of group practice, has written: "The aims of basic group practice are identical with those of ordinary general practice. The primary aim is to provide patients with the highest level of diagnostic and therapeutic service attainable outside hospital, to inconvenience the patients as little as possible, and to preserve the best elements of personal service—all at a cost the patient (or better, the community or nation) can afford."

We think this is being achieved at the William Budd Health Centre without formal financial partnership but with the advantage that each practitioner firm maintains its individuality and that the patient can indeed be sure that he will see the doctor of his choice and not any one of half a dozen or more different members of a group practice.

Collings was careful to qualify these aims by reference to what the nation or community can afford, and here we should like to comment on the financial aspects of this health centre. It is true that it is costing £10,000 a year, but this is for fairly extensive local health and education authority services for 30,000, together with general medical services for some 10,000 people. This is a lot of money, but let us keep a sense of proportion. Even if the general medical practitioners had not participated in this project there would have been a need for, and statutory duty to provide, local authority services. The capital cost for the building would have been about the same and the maintenance may have been halved, but the centre would have been lying idle for many sessions a week. Indeed, there must be many hundreds of good local authority clinics which could be used with advantage by general medical practitioners without necessarily curtailing the local authority services. The sooner arrangements of this kind can be made the sooner many local authority doctors will relinquish their "clinical duties" in maternity and child welfare and minor ailment clinics. Moreover, the practitioners, relieved of non-productive work, can then turn their attention to the preventive and promotive aspects of health work. One other word on finance—and we say

this in no carping spirit—the cost of all the principal activities in the centre is no greater than buying part of the services of two consultants in receipt of a special merit award.

It is already apparent that many patients have been treated who, but for the health centre, would have gone to hospital out-patient departments. With further aids, such as a small laboratory and the help of a laboratory technician and facilities for simple radiography, there can be little doubt that not only will the patients benefit but the practitioners' interest and standard in general practice will be further stimulated and, not least important, the overworked hospital out-patient department must be still further relieved.

Nova et Vetera

RICHARD MEAD: PIONEER AND PATRON

Before Barry built the vast brick and terracotta Hospital for Sick Children at Great Ormond Street, there existed at the corner of Powis Place a fine old Queen Anne mansion where for the last twenty-four years of his life Dr. Richard Mead lived, as Dr. Johnson said, "more in the sunshine of life than any other man." He was pre-eminently great in an age of great practitioners—the epitome of accomplishment in the fullest meaning of that word. For Mead enjoyed the best of both worlds, basking, like Sloane, in the approval accorded to generous patrons, and esteemed, like Cheselden, as a reliable physician. Pope has caught both qualities with his lines:

And Books for Mead, and Butterflies for Sloane

and

I'll do what Mead and Cheselden advise,
To help those limbs and to preserve those eyes.

His life illustrates the rich leaven which Nonconformity brought to English scientific and medical thought in the seventeenth and eighteenth centuries. Born at Stepney in 1673, he was first educated at home by his father, an eminent Nonconformist divine, then by two successive tutors until, at the age of 16, since Oxford and Cambridge were barred to him by the Test Acts, he proceeded to Utrecht, where he studied classics and philosophy for three years. He spent a further three years at Leyden, where he worked alongside Boerhaave, and then, with his brother and two others, he toured Italy, taking his doctor's degree in philosophy and physic at Padua at the age of 22.

At Stepney, too, began his professional career, where his father assisted, even to the extent of recommending him from the pulpit. His first published work showed that he had assimilated the teaching of Archibald Pitcairne at Leyden. Entitled *A Mechanical Account of Poisons* (1702), it accounted for the effects of several poisons by their admixture with the blood. An abstract of this, published in the *Philosophical Transactions* of the Royal Society for 1703, not only secured his election to that body but appointment as physician to St. Thomas's Hospital in the same year.

Moving as he did in wider circles, he took up residence in Crutched, and later in Austin Friars, adding further appointments *en route*—the readership in anatomy to the Company of Barber Surgeons, the vice-presidency of the Royal Society, and the doctorate of medicine of the University of Oxford. This last honour enabled him to be admitted to fellowship of the Royal College of Physicians, of which he subsequently became a Censor, Harveian Orator, and lived to refuse the presidency.

"Mead, I love you," said the irascible but generous John Radcliffe, "and I'll tell you a secret to make you a fortune—use all mankind ill." Though Mead took over Radcliffe's house and practice in Bloomsbury Square in 1714, he did not take his advice. On the contrary. When Watteau, the distinguished painter, came especially from the Continent

to secure his help in arresting his consumption, Mead commissioned him to paint two pictures, and this generous patronage was extended to a variety of others. He secured the liberation of Dr. Freind from the Tower of London, where he was imprisoned, and pardon for the Reverend G. Kelly. He was without a rival as a practitioner, making an average of from £6,000 to £7,000 a year. He attended the King, the Prime Minister, Sir Isaac Newton, and Bishop Burnet among others. A pioneer in public health, his *Short discourse concerning Pestilential Contagion and Methods to be used to prevent it* was first published in 1720 and ran to seven editions in twelve months and more afterwards. In it he recommends, as a first step, the establishment of a Central Council of Health, armed "with such powers as might enable them to see all their orders executed with impartial justice." He urged that the sick should be isolated in "clean and airy habitations" sustained at public expense.

After 1720, when Mead removed to Great Ormond Street, he built a large gallery at the bottom of his garden to house his treasures. Here he would entertain Richard Bentley, the formidable Master of Trinity College, Cambridge (over whom he possessed great influence), and Martin Foulkes, the antiquary. It was here, too, on February 16, 1754, that Richard Mead died, surrounded by over 10,000 books and numerous *objets d'art*. Unlike his great contemporary and friend, Sir Hans Sloane, no steps were taken to acquire his collection, and it was dispersed by auction. Sir Hans Sloane's name lives on both at Chelsea and at the British Museum. John Radcliffe's by the museum and observatory which bear his name at Oxford, but Mead's links with the present are more tenuous if equally binding. For it was he who persuaded the bookseller Thomas Guy to erect a new hospital at a cost of £18,793, increased by an endowment of £200,000 on Guy's death in 1724.

W. H. G. ARMYTAGH.

Preparations and Appliances

A REST CHAIR FOR ARTHRITIS

Dr. H. F. WEST, physician-in-charge, Sheffield Centre for Investigation and Treatment of Rheumatic Diseases, writes: Patients with painful and stiff hips or knees usually find great difficulty in getting in and out of ordinary rest chairs.

Being dependent on others in this matter they often spend too long at rest, stiffening up, or on their feet, developing oedema of the legs. The chair illustrated has been designed for such patients and is made in varying heights. A patient should have the highest chair he can manage to swing himself on and off. These chairs were made by Messrs. Shortall Ltd., Maltravers Street, Sheffield.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Intra-arterial Transfusion

SIR,—Substantial claims have recently been made concerning the life-saving properties of blood transfusion into an artery, and many cases have been reported in which this form of treatment has apparently been instrumental in saving a patient's life. It is difficult to assess from the available evidence how successful intravenous transfusion would have been in these cases, and there must be many who believe that the latter procedure will always be adequate, provided the vein is large enough and not in spasm and adequate pressure is available. There must also be many obstetricians who, in common with myself, have served on an emergency obstetric service ("flying squad") and have seen patients recover with intravenous transfusion following the most calamitous haemorrhage. I am recording the following case because prior to that experience I had believed that arterial transfusion was seldom, if ever, required and I have now changed my mind.

An apparently fit woman aged 35, with two children, delivered her third child to pubes after an exhausting second stage. There was an inert uterus and the placenta was expressed by her own doctor, who called for the "flying squad" after a loss of 40 oz. (1.1 l.). On my arrival the patient, who had continued to bleed, was in poor condition but apparently no worse than many others whom the service had treated successfully. Four pints (2.3 l.) of blood were given into the junction of the right saphenous and femoral veins, but there was steady deterioration of the patient, who continued to bleed slowly, and death occurred while the last pint (0.6 l.) was being run in. Necropsy showed that death had been due to heart failure and there was gross distension of the vena cava and great veins with the blood that had been transfused and which had not been passed on by the failing heart. It appeared that the continued loss had been due to a direct flow from the external iliac vein into the hypogastric and uterine veins on the right side.

There was nothing to suggest that this patient had any myocardial deficiency prior to her pregnancy, and there was no toxæmia. Her cardiac failure was presumably due to inadequate coronary blood flow following severe exertion and considerable haemorrhage. I felt in retrospect that an arterial transfusion might have delivered enough blood to the coronary vessels to save the failing heart, which was being embarrassed still further by the intravenous transfusion. I shall be interested to hear whether similar cases have arisen in the practice of other obstetricians.—I am, etc.,

Birmingham.

W. G. MILLS.

Intra-arterial Thiopentone Injection

SIR,—Dr. M. Swerdlow's medical memorandum (*Journal*, January 30, p. 258) prompts me to describe a case which I encountered three weeks ago. The patient, a man aged 40, was having bouginage for stricture. It was intended to give about 0.7 g. thiopentone, followed by nitrous oxide/oxygen with a little trichlorethylene if needed. The patient's right forearm was covered with a network of very prominent veins, and injection was made into the median cephalic vein. After 0.5 g. of thiopentone had been injected, there was a slight leak, and the needle was withdrawn. It was intended to complete the injection into the median basilic vein, which appeared, as it often does, to consist of two parallel channels, both prominent under the skin. The needle was inserted into the more lateral of the two vessels, approximately at the spot marked X in the photograph in Dr. Swerdlow's article. Only 1 ml. had been injected here when the patient (by this time asleep) responded with a violent spasm of the flexor muscles of the arm; the medial side of the forearm and hand quickly blanched. The pulsation from this artery, which was a subcutaneous aberrant

ulnar, was not transmitted to the syringe, which was immediately disconnected from the needle. Blood came from the hub of the needle in spurts. A syringe containing 5 ml. 1% procaine was immediately connected to the needle and its contents injected. By this time the blanching had passed off, and been replaced by mottling, which soon gave way to normal colour. Pulsation in the limb was normal then and subsequently, and the aberrant vessel could easily be felt pulsating under the skin, and on close inspection could even be seen to pulsate. The operation and anaesthetic were completed without further incident, and there were no untoward signs or symptoms in the arm thereafter. The patient stated subsequently that he had been anaesthetized twice before, but in each case the injection was made into his left arm. His attention was drawn to his abnormality, which was present in one arm only, and it was simply explained to him. He was told that he should draw the attention of anyone about to make an injection in his right arm to the pulsation in this vessel.

Accidents like this can only be avoided by palpating every vessel before injecting thiopentone into it, no matter how like a vein it may look.—I am, etc.,

Manchester, 21.

T. D. CULBERT.

Renal Complications after Using Sulpenin

SIR,—We were interested to read Mr. J. G. Callanan's account of renal complications developing in a patient during treatment with "sulpenin" (*Journal*, January 16, p. 138). We have had a similar experience with this preparation in a child, and believe that the following brief account may be of interest.

A girl of 5 developed a respiratory infection. From the fourth day of her illness and for two days before admission to hospital she had been treated with "sulpenin." She had been given four tablets initially, followed by two tablets every four hours (total dose 20 tablets and 10 g. sulphonamide). On the morning of admission her urine was noticed to be blood-stained, and shortly afterwards she passed several large clots of blood unaccompanied by urine. On examination in hospital she was complaining of central abdominal pain although there was no tenderness in this region or in the renal areas. She had signs of mild bronchitis. Blood pressure was normal. The urine was heavily blood-stained and sulphonamide crystals were seen microscopically. The urinary output was adequate and the blood urea normal. She was treated with a high fluid intake and alkalis. The next day she was better and the urine contained less blood. She was discharged home after eight days, when laboratory examination of the urine was normal.

Fortunately anuria was not a feature in our patient and she recovered rapidly. Mr. Callanan thought that the sulphadiazine fraction of "sulpenin" was responsible in his case, but we have seen similar cases of renal complications caused by sulphamerazine, and many other cases are recorded in the literature (e.g., Dr. E. C. Atkinson, *Journal*, September 15, 1951, p. 674, and subsequent correspondence). We therefore felt more inclined to implicate the latter drug, but the matter is debatable and obviously "sulpenin" is a preparation to be used with caution.—We are, etc.,

Sheffield, 10.

T. COLVER.

J. C. HAWORTH.

Methylpentynol

SIR,—I was interested in your annotation (*Journal*, August 22, 1953, p. 435) on the use of methylpentynol as an alternative to the barbiturate hypnotics. I have tried it on a number of patients in hospital for this purpose, but without notable success. Those who were used to the barbiturates found it ineffective in doses up to 1 g., and, though it sometimes secured sleep rapidly in new patients who were anxious, they were usually awakened several hours later by the customary nocturnal noises of a hospital ward. I have not used it for patients in their own homes, where it might well be effective for insomnia associated with anxiety.

I would, however, like to draw attention to its use for premedication. I have used it successfully in a number of cases

before ward procedures such as paracenteses, biopsies, and lumbar punctures. The patient was given 500 mg. of methylpentynol (two capsules of "oblivon") about 10 minutes before the procedure began. In no case was anxiety marked, though in several of the patients similar procedures, previously performed, had been associated with considerable apprehension. In an endeavour to reduce the suggestion factor, some patients were not told the purpose of the drug; in those cases the drug seemed no less effective. In one case where anxiety was severe, 10 minutes after giving 500 mg. of methylpentynol it was possible to proceed with a patient in a state of calm co-operation. In no instance were there any complaints of side-effects or after-effects, and I observed none. No patient went to sleep as a result of administering the drug, nor was there any complaint of drowsiness at the time.

I have not attempted a controlled therapeutic trial, and I am well aware that it is easy to persuade oneself that an anticipated reaction to a drug has in fact occurred. I believe that methylpentynol is being used in dental practice, which should provide opportunities for just such a trial, and I shall be interested to hear what impressions are gained in this field.—I am, etc.,

London, N.19.

A. G. BOAG.

Piperazine in the Treatment of Threadworms

SIR.—The article by Dr. R. H. R. White and Mr. O. D. Standen (*Journal*, October 3, 1953, p. 755), in which piperazine is recommended for the treatment of threadworms as being a harmless drug without side-effects, has surprised me. The authors have added in their letter (*Journal*, December 5, 1953, p. 1272) that in giving piperazine the weight of the patient should be taken into account in measuring the dose, but this seems to me insufficient, because piperazine is a drug which can paralyse the respiratory centre. I once gave piperazine by mouth to rats and I found it quite toxic. At 4 to 5 g. per kg. there was laboured breathing and twitchings, and some of the animals died. If not enough attention is drawn to the toxicity of this drug there is a risk that mothers, if there is no therapeutic effect, will increase the dose or repeat it at short intervals.

The reason for my letter is to call attention to the danger of this preparation and to recommend that it should be given only under direct medical supervision and not to outpatients.—I am, etc.,

Berne.

T. GORDONOFF.

Inquiry about Anaesthetics

SIR.—At one hospital in which I work, and presumably in other hospitals, a few duplicated foolscap forms have been received under the heading "Ministry of Health. Anaesthetics in Hospitals. January 21 (9 a.m.)—28 (9 a.m.)." In the brief instructions which follow it is stated that details should be inserted on the opposite side of the form of every anaesthetic given during the above week. After explaining how this is to be done on the opposite side of the form, the instructions continue, "If during the week a death has occurred which has been thought to be due to an anaesthetic, information about this case should be given; also details should be supplied of any fire or explosion which has occurred in an operating theatre during the same week. . . ."

The forms in question were not sent to any of the doctors who might be concerned in the giving of anaesthetics, they are not marked "Confidential," and it has apparently been left to the group and hospital officials to see that the forms are completed.

I have written to the Ministry of Health asking for further information about this matter, but it may not be out of place to suggest that the publication of this letter would enable others to comment on this method of inquiry. Quite apart from the many other implications of this form, it does seem most improper that information is asked for about deaths which may be due to anaesthesia. Surely there are already

properly established and legal methods of investigating such cases, and no hospital or individual should be asked to disclose details to the Ministry.—I am, etc.,

Radlett

R. S. MURPHY.

A New Oral Diuretic

SIR.—May I be permitted to comment on your annotator's remarks (*Journal*, January 16, p. 144) on "a new oral diuretic"? His assumption that general practitioners fight shy of administering medicaments parenterally is mistaken. In fact, they are given freely and for as long as they are indicated, provided they are of proven value. In our own practice, as in other practices, patients with congestive heart failure and other conditions requiring diuretic therapy, are given mersalyl regularly. Indeed, two of our patients have had mersalyl weekly for 15 years, with only occasional interruptions.

Your annotator's argument in favour of "mercioran" is surely self-destructive. Does he expect a general practitioner to submit his patient to a treatment which in two-thirds of the cases can produce such violent symptoms as "abdominal cramps, nausea, vomiting, diarrhoea, and bloody stools," and in the remaining one-third, to be discovered "by trial and error," the effectiveness of the oral diuretic is only one-quarter of the standard dose of mersalyl? I am, etc.,

London, E.17.

MYER COHEN.

Atomic Weapons and the Medical Profession

SIR.—President Eisenhower's recent appeal and the Russian reply have again raised hopes of the control or abolition of atomic weapons. Such a hope must be universal, and the need for agreement has been recognized by the Governments of all the big powers. Yet stockpiling increases, and on January 1 the *Daily Telegraph* stated: "One of the achievements (sic) of the New Year is expected to be the explosion of the first true hydrogen bomb."

The medical profession would be outstandingly involved in the event of an atomic war. Is there anything that we can do to help in the present situation? Here is one suggestion: The leaders of the profession could send an independent statement to their respective Governments stating the disastrous effects, in any country, of a hydrogen bomb attack upon the medical services (to which Governments and people alike look for aid in an emergency). This of course must be known to the Governments concerned, but the bald statement from a non-political source would serve to underline the urgency for agreement, and the document might just possibly strengthen their hands in discussion. Are there any other suggestions?

As stated in my previous letter (*Journal*, March 11, 1950, p. 610), any help, however small, that we can give would surely be preventive medicine of the greatest prophylactic value.—I am, etc.,

Hove.

W. V. CRUDEN.

Variation in Human Milk

SIR.—I do not think that the conclusions reached in your leading article on "Variation in Human Milk" (*Journal*, January 30, p. 264) should pass without comment. You say that "if an infant is not gaining satisfactorily the explanation should be sought promptly. First, the possibility of infection or of constitutional disturbance should be considered. Either of these is, in general, more likely to be responsible than faulty or insufficient maternal milk. But if no such evidence is found additions to the diet in the form of complementary feeds should be given."

Surely before complementary feeds are given to babies with a weight gain which is not seriously defective the correct procedure is to try to increase the amount of breast milk which the baby takes—by giving him more frequent feeds if they are rather infrequent, by giving him longer on the breast if he needs it, by trying to ensure that the mother has more rest, and by stimulating her breasts to produce more milk by emptying them fully by manual expression after every

feed, giving the baby milk which has been expressed. Your advice, if taken, would cause a very large number of babies to be put quite unnecessarily on to the bottle.—I am, etc.,

Sheffield, 10.

R. S. ILLINGWORTH.

The Unsaturated Fatty Acids

SIR.—I was very interested to read Dr. John H. S. Pettit's article (*Journal*, January 9, p. 79). During the past 12 months I have used on a number of eczematous patients, infants and adults, (a) the ointment alone, and (b) the ointment in conjunction with the capsules. No outstanding results were obtained, although some cases did respond to one dressing and one capsule daily, the treatment being carried out as well as possible in home surroundings.

From a general practitioner's point of view I agree that this treatment is in no way preferable to the already established ones—in fact, I have obtained quicker and better results from ointments containing coal tar, zinc oxide, etc. However, using the unsaturated fatty acids in cases of gravitational ulcer (predisposing causes established), I have had some very interesting results, mostly favourable—for example, a patient who has had a large and infected ulcer, resistant to all types of treatment for years, has responded well, the lesion now being almost healed. In this particular case one capsule is being taken and the dressing applied twice daily.

It would be very interesting to know if any of my colleagues have had similar results.—I am, etc.,

Leicester.

ERIC LODGE.

The Feeble-minded

SIR.—There are two points arising from the correspondence which followed the publication of our survey of 12 mental deficiency institutions (*Journal*, January 2, p. 16) on which we should like to comment.

It has been suggested by Dr. G. McCoull (*Journal*, January 23, p. 214) that mental deficiency institutions in the London area may not be typical of those in the country as a whole. Fortunately we were able in April of last year to obtain material bearing on this point from Dr. W. Rees Thomas, Senior Medical Commissioner of the Board of Control, and with his permission this is given below. At that time the latest, and, in fact, the only, information possessed by the Board of Control with regard to division of patients by grade was that concerning long-stay patients for the year 1949 (i.e., those who were in institutions vested in the Ministry of Health on January 1, 1949, and who were remaining in them on December 31 of that year). These represented approximately 93% of all patients on the books of those hospitals in December, 1949.

The classification upon which the Board of Control figures are based is the sevenfold one contained in the International Statistical Classification of Diseases, Injuries and Causes of Death (1948). The categories are as follows: idiocy, imbecility, moron, borderline intelligence, mongolism, other and unspecified types, all other diagnoses. This classification is a mixed one, being based partly on the grade of the patient—idiocy, imbecility, and feeble-mindedness (or moronity), partly on clinical type (mongolism), and partly on extraneous and what sometimes appear to be irrelevant considerations.

Dr. Rees Thomas writes of the data: "In the category 'Mongolism' we have no information beyond the diagnosis given. The category 'Other and Unspecified Types' is equally unsatisfactory; of the 219 cases (20 male, 22 female age 0-15) 216 are returned as mental deficiency N.O.S. (not otherwise specified). The heading 'All other Diagnoses' (1,408 patients including 152 male and 120 female age 0-15) has 41 separate categories, none of which relate to grading. Examples are: head injuries, convulsions, encephalitis, epilepsy, asocial personality, and cerebral spastic infantile paralysis. In none of these cases can we find any information which will permit us to give you a grading." The categories "Other and Unspecified Types" and "All other Diagnoses" make up 3% of the total count. Dr. Rees Thomas also points out that the count of heads was made when the new G.R.O. cards were introduced, primarily to deal

with admissions from January 1, 1949. The diagnoses "may or may not have a high degree of accuracy."

The most useful comparison between our London survey data and the Board of Control census figures is probably that between the proportions of adults in each of the three main categories by grade. This is given in the table below. Here mongols have been included among the imbeciles and the categories "other and unspecified types" and "all other diagnoses" have been grouped together under a separate heading.

Percentage of Adult Patients by Grade as Obtained in London Survey, 1951-2, and by Board of Control Census of Long-stay Patients

Grade	Board of Control Census		% of Patients by Grade Found in London Survey
	No. of Cases	% of Patients by Grade	
Idiot	1,721	4	3
Imbecile	14,809	33	39
Feeble-minded	27,122	60	58
Other	1,313	3	
Total	44,965	100	100

Allowing for sampling errors and difference in the manner in which the data were collected, the agreement between the two sets of figures is as close as could be expected. It thus seems very likely that the London data are comparable with what is to be found elsewhere in the country as far as grade of patient is concerned.

We do not wish to take up here in any detail the question of intelligence quotients. We would point out, however, that we did not claim that half the total number of defectives of all grades and ages had I.Q.s above 70 points on the matrices test, but merely that it seemed likely that the average intelligence quotient of adult feeble-minded defectives—that is, excluding idiots and imbeciles—aged between 16 and 29 years of age was above 70 points. The data obtained in the survey merely confirmed findings obtained by ourselves and others who have tested larger samples at individual hospitals on both the matrices and other intelligence tests.¹

What is important, however, is not the average I.Q. of patients in mental deficiency institutions, but that three-fifths of the adult patients are "feeble-minded." Few will disagree that the feeble-minded present radically different problems in management from imbeciles and idiots.—We are, etc.,

N. O'CONNOR.

J. TIZARD.

London, S.E.5.

REFERENCES

- ¹ Tizard, J. (1950). *J. ment. Sci.*, 96, 889.
- ² — and O'Connor, N. (1952). *Lancet*, 2, 620.

SIR.—Although I am sure that Drs. N. O'Connor and J. Tizard intended "A Survey of Patients in Twelve Mental Deficiency Institutions" (*Journal*, January 2, p. 16) to be unbiased, its presentation immediately gave rise to false conclusions and implications in the press (the *Star*, leader, January 4). I think that your own annotation (p. 35), Sir, was also not blameless. The general behaviour of mental defectives in hospital is quite good, but this is no criterion of social competency. The average intelligence quotient of young adult feeble-minded patients is 70 or more as stated, but I.Q., as we all know, is no index of social adjustment. Is the implication that we are not to have these people in mental deficiency hospitals at all, or that we do not supply suitable treatment to bring about social adjustment? Eighteen per cent. of our admissions last year were Section 8 or 9 cases. I consider that if these patients find a regime here, orientated towards social rehabilitation (as they do), they benefit far more by our efforts than by other treatment or punishments available.

To quote Section 8 and 9 cases as the problem groups is quite false. All feeble-minded people present some social problem, either of inadequacy or aggression, and a patient admitted under Section 6 for prostitution and incestuous behaviour in a family where all the members have visited prison, approved or special schools is, although polite and well-behaved here, a graver social problem than many a slight case of larceny. To say that half of our patients need no special nursing or supervision depends on how you look at it. One might as well say that all the boys in

a boarding-school need no special care or supervision. You cannot put untrained people in general charge of high-grade patients, and the good trained nurse who lives with them is worth his weight in gold. Epileptic patients may have no fits, or very rare attacks, but the case papers must show them to be epileptic. Otherwise we will be sending them out to risk falling off scaffolding or into machinery. Whether they are on or off the "live" list in the hospital is a different matter. The bald statement in the survey implies that they are detained in the hospital only because they are epileptic. The term "wages," even in inverted commas, is most unfortunate, and to include 73 children, 15 idiots, and an unspecified number of low grade imbeciles in a "wages" group is inadmissible. The group of patients in outside employment receives adequate spending money in any well-run hospital and many other perquisites besides. The long-stay cases have cinema, concerts, dances, television, outings, etc., in addition to any sum granted to them, and to speak of "wages" is ludicrous. The deduction from the facts that only one hospital sends patients out to factory work may be nearly true, but cannot emerge from the survey. I know the one referred to by the authors. This is another.

Finally, Sir, I think the accompanying table will show your annotator that we do our best not to detain young adults who may become difficult. These are difficult boys, irrespective of what Section of the Mental Deficiency Act they are admitted under.

Distribution of 53 Hospitalized Male Patients Aged 16-30 Years, I.Q. 70+, by Admission Category and Occupation

	Section of M.D. Act		
	6	8	9
Inside the hospital:			
Maintenance work	6	1	0
Vocational training	9	11	3
Outside the hospital:			
"Protected" daily work ..	5	1	0
Normal daily work	5	6	1
Licence	2	2	1
Total	27	21	5

This accounts for nearly the whole of this group within the hospital. The seven on maintenance work have had to be written off for gross physical or psychological disabilities. The 23 on vocational training are passing through to daily employment and licence. The other 23 are already out at work. Although they all have I.Q.s of over 70, I can assure you that the height of that I.Q. is not directly related to the social value of that work.—I am, etc.,

Chertsey, Surrey.

J. M. CRAWFORD.

Appendix in Hernial Sac

SIR,—I would like to add one further case of an appendix in a hernial sac to the several already published in your journal recently.

A woman aged 40 was admitted to hospital complaining of a painful swelling in the right groin. She stated that the swelling had been present intermittently for the previous six years—that it appeared on coughing and straining but was easily reducible. One week prior to admission the swelling reappeared but could not be reduced. On examination she had a round swelling about the size of a hen's egg in the right groin below the inguinal ligament and lateral to the pubic tubercle overlying the saphenous opening. The lump was diagnosed as an early strangulated femoral hernia.

At operation the lump was freed from the surrounding tissues and the sac opened, it then being noticed that the content of the sac was a gangrenous appendix. The inguinal canal was then opened and the neck of the sac freed from above; at the same time the constriction ring in the neck was also divided. The sac was then brought up into the inguinal canal and the appendix and caecum delivered into the wound. The constriction ring in the sac had compressed the appendix about 1 in. (2.5 cm.) from its tip and caused gangrene of its distal one inch. The appendix was removed in the usual manner and the sac ligated and removed.

The patient made an uninterrupted recovery. She was seen recently, and had no recurrence of the hernia.—I am, etc.,

Dublin.

WILLIAM A. L. MACGOWAN.

The Lithotomy Position in Obstetrics

SIR,—There is undoubtedly a danger that students in this country may gain the impression that the lithotomy position is best for all operative deliveries by forceps, and still worse that they may be taught to apply forceps only in that position. The reason for this is not far to seek. It is probably true to say that most teachers of obstetrics do at least 10 gynaecological operations to one forceps delivery, and they naturally feel more at home (if such an expression is seemly) with the patient in the lithotomy position. This does not mean that it is wise to teach the general-practitioner obstetricians of the future that it is the safest position for forceps delivery.

Professor T. N. A. Jeffcoate states (*Journal*, October 31, 1953, p. 951) that "the greatest danger of forceps delivery at the present time is anaesthesia, and this danger has, if anything, increased with the introduction of modern anaesthetic agents." He goes on to quote "six maternal deaths associated with forceps delivery in the Liverpool Maternity Hospital during the 15 years preceding 1950," and states that no less than half of these were the result of inhalation of vomit during the induction of general anaesthesia. In the *Journal* of December 12, 1953 (p. 1324), I ventured to ask "whether these patients were in the lithotomy position, which we know Professor Jeffcoate favours for all operative deliveries" (*Journal*, June 10, 1950, p. 1359). As no answer has been forthcoming, it seems reasonable to suppose that the assumption was probably correct. If fatalities from this cause can occur in a well-equipped theatre replete with suction apparatus, oxygen, and all the refinements, how much more dangerous would it be if the same kind of emergency occurred to the general practitioner working, perhaps shorthanded, in an ordinary bedroom without such facilities. There is, too, the undeniable fact that indications for forceps delivery frequently arise unexpectedly and often there has been no time to give the same careful attention to the preparation of the patient for anaesthesia as is possible in a planned operation. It is often not possible, or even desirable, to withhold food from a patient during a prolonged labour.

After more than 30 years of experience of the lateral position (which, as I have pointed out before, becomes semi-prone on an ordinary bed) it is quite inconceivable to me that fatalities from this cause would occur in that position, and virtual freedom from this very real risk far outweighs the minor disadvantages of the lateral position, for they are largely theoretical and in practice do not amount to much. I would grant, of course, that if only local anaesthesia is used there is no objection to the lithotomy position, but it is at least questionable whether this form of anaesthesia will become widely adopted for forceps delivery, at any rate in domiciliary midwifery, and I venture to doubt whether the patient at the end of a long and tiresome labour would be too pleased about it.—I am, etc.,

MILL HILL, N.W.7.

A. H. MORLEY.

Dysgerminoma of the Ovary

SIR,—Mr. Maurice Hershman (*Journal*, January 23, p. 198) gives an interesting account of a dysgerminoma of the ovary which had undergone torsion, which he states is the first recorded case of such a condition. In view of its apparent rarity I would like to briefly record a similar case which has recently been under our care.

The patient, an unmarried girl of 21, was admitted to hospital on January 13, 1954, complaining of severe colicky lower abdominal pain and vomiting. She was sweating profusely, temperature 103° F. (39.4° C.), pulse rate 100. A clearly visible, tender swelling was found arising out of the pelvis. Previous menstrual history was normal. On catheterization the bladder was found to be empty. A diagnosis of torsion of an ovarian cyst was made and laparotomy performed through a lower right paramedian incision. Almost the whole of the lower abdomen and pelvis was filled with a solid, lobulated tumour arising from the right ovary. The pedicle had undergone torsion and a commencing area of necrosis was apparent on the superior pole of the tumour to

which great omentum was attached. The tumour was removed without difficulty, the patient making an uninterrupted recovery. Histological examination of the tumour showed it to be a dysgerminoma.

There were no signs of pseudohermaphroditism in this case, and the menstrual history prior to operation had been normal. No signs of intraperitoneal metastasis were evident at operation, and subsequent radiography of the chest revealed no abnormality.—I am, etc.,

Sheffield, 6.

BRYAN ROWLANDS.

Fatal Bronchial Asthma

SIR,—I was interested to read the article by Drs. C. Kelman Robertson and K. Sinclair (*Journal*, January 23, p. 187). Sudden death may also occur in an emphysematous patient who has an acute respiratory infection or even on recovery from the infection, and post-mortem examination may not be helpful in deciding the exact cause of death. In some cases, however, I have noticed the presence of a marked cerebellar pressure cone which may, of course, in itself cause sudden death. The cerebellar pressure cone is in keeping with the high C.S.F. pressure seen in these cases. Since long-continued asthma may lead to emphysema I think that this is worth considering as a cause of sudden death in asthma. The difficulty, however, lies in deciding whether a cerebellar pressure cone is abnormal or not, and we are now investigating this.

I should like to issue a word of warning in giving an oxygen-CO₂ mixture to the old-standing asthmatic subject who is suffering from acute anoxia and who will have some degree of CO₂ retention. The inhalation will cause further rise of CO₂ and the production of carbon dioxide narcosis.—I am, etc.,

Enfield, Middlesex.

THOMAS SIMPSON.

SIR,—With reference to the article by Drs. C. Kelman Robertson and Kenneth Sinclair (*Journal*, January 23, p. 187), the following five cases of sudden death at the onset of an attack of asthma may be of interest. They occurred in a series of 700 necropsies, two-thirds of which were hospital cases and one-third coroners' cases. In four instances the only clinical history consisted of the policeman's report stating that the patient was a known asthmatic. The fifth case died suddenly in hospital, having previously been brought round from status asthmaticus. Some particulars of these five cases are shown in the following table.

Case No.	Sex	Age	Month of Death	Evidence of Infection	Drugs Taken Soon Before Death
1*	F	31	December	—	—
2*	F	45	September	—	—
3*	F	60	February	+	—
4*	M	33	September	—	—
5	F	36	September	—	+

* Coroners' cases.

All showed characteristic sticky mucus plugging the bronchioles and ballooning the lungs. Though probably of no significance, two of the cases occurred soon after the administration of drugs (Case 2, two aspirins; Case 5, a barbiturate tablet). Case 3 showed an unusual nodule of pneumonic consolidation about 3 cm. in all diameters, close to the hilum of the left lung, which sectioning showed to be a patch of haemorrhagic bronchopneumonia. The speed at which death can occur is remarkable. Case 1 said she felt an attack of asthma coming on, and sent her young son up to the bedroom to get some ephedrine tablets. On his return he found his mother lying dead on the floor.

Regarding the mode of death, I would favour the authors' first suggestion that the heart fails due to increased resistance in the pulmonary bed. The relative infrequency of petechiae of the lung and heart surfaces implies to me that a respiratory struggle against obstruction did not occur.—I am, etc.,

Braintree, Essex.

A. I. D. PRENTICE.

Symptoms of Dracunculiasis

SIR,—I have just received my *Journal* of December 12, 1953, and have read "A Case of Dracunculiasis (Guinea-worm) in Nairobi," by Dr. A. L. Ribeiro (p. 1310), with interest. Dr. Ribeiro thought it remarkable that his patient did not show the "usual clinical symptoms such as fever, diarrhoea, vomiting, and urticaria" which are associated with the arrival of the worm to the surface. Before I became a medical student I suffered several times from dracunculiasis, and now I am in practice in an area where the disease is endemic. It was only once, and that was my first attack, that I developed a sudden fever and urticaria before the worm made its shocking appearance. On all other occasions all I had was a dull ache followed by intense itching on my leg. This was followed by a blister over the area of itching and soon this burst and I saw one end of the worm.

From experience some of my patients who recognize the aching control their fingers and anxieties, allow the blister to form and burst, and the worm makes its appearance with as little interference as possible. But those who scratch and irritate the area and pull prematurely on the worm, which at first is thin and very delicate, are calling for trouble. The part gets swollen, hot, and tender, with development of fever and, particularly if having the disease for the first time, urticaria; if the patient was foolish enough to get the worm broken then he would have many sleepless nights from a big abscess. My people here, who have had the disease with them for centuries, know all these, and hence "the usual symptoms" expected by Dr. Ribeiro are unusual.—I am, etc.,

Irrua, Nigeria.

XTO. G. OKOJIE.

Unwrapping the "Journal"

SIR,—I second the motion made by Dr. H. Lyndhurst Duke (*Journal*, December 12, 1953, p. 1326) that the *Journal* reinstate that "ingenious old wrapper" which many a reader cherished and librarians adored.—Hopefully, I am, etc.,

Philadelphia.

CATHERINE DELSORDO.

What is a Psychopath?

SIR,—I have noted with interest the discussion which has been carried on in your correspondence columns regarding the definition of a psychopath. May I call your attention to the definition given in the *Psychiatric Word Book*, which was written by the late Dr. Richard H. Hutchings, and which is published by the New York State Hospitals Press? Their definition is as follows: "Psychopathic Personality.—A type of personality afflicted with diminished volitional [sic] control and heightened emotional response to stimuli."

I am quite sure that this definition could not be improved upon. It is very clear, simple, and practical.—I am, etc.,

Fort William, Ontario.

JOHN R. HOWITT.

Weight of British Children

SIR,—The article by Dr. E. M. B. Clements (*Journal*, October 24, 1953, p. 897) concerning heights and weights of schoolchildren, together with the letter by Dr. W. T. C. Berry, Mr. E. R. Bransby, and Mr. W. H. Hammond (*Journal*, December 12, 1953, p. 1324) on the same subject, has been of considerable interest to us. We have recently used data on the heights and weights of over 7,000 Birmingham children attending local authority schools in 1952 to obtain comparisons between children drawn from good, medium, and poor neighbourhoods. The children were of three age groups, the ages at their last birthdays being 6, 11, and 14. The smallest group drawn from any type of neighbourhood was 103 (boys aged 11, from good neighbourhoods). Whilst fairly consistent differences were found in the average heights and weights of both boys and girls coming from the different type of neighbourhoods in each of the three age groups, yet in only certain cases were these differences statistically significant, when a difference of twice the standard error was taken as a level of significance. One

of us (H. M. C.) whilst in Sheffield in 1947 found similar differences, using the same criterion for significance, in a survey amongst schools classified into the three groups. The question of significance seems to be of importance and may account to some extent for the apparent differences in the results of various surveys. Where numbers in the samples are small a greater observed difference is necessary to achieve any conventional level of significance. Other factors accounting for contradictory results are, no doubt, type of school considered and classification system. The classification according to catchment areas of schools is theoretically of very doubtful validity, but in practice seems to yield useful data.

Our results showed significant differences in the heights and weights of both boys and girls at age 6, coming from good and medium neighbourhoods. At the age of 11 only the heights and weights of the girls from these districts were significantly different, and at 14 differences were not significant. In comparing children from medium and poor neighbourhoods, differences in height for both boys and girls at age 6, and in weight at age 14, were significant. There was also a significant difference in the height of girls at age 14. No other differences were significant.

In his article, Dr. Clements states that "to-day, average children of the same age in the middle- and lower-income groups are the same height, while the average child in the upper-income group is about 2 in. taller." If by the term "average child" Dr. Clements requires us in this context to understand "a child of average height," then we should be glad to discover the basis for his statement, since, using the figures given by him in Table 1, the mean of the difference in height between boys of average height and age 5-13 from upper- and middle-income groups was found to be 0.64 in., and for girls this difference was 0.65 in. Also, the mean difference in height between boys of middle- and lower-income groups was found to be 0.46 in. and between girls 0.1 in. These figures are more in agreement with our own.

Similarly, while in disagreement with the statement that "weight differences between comparably aged boys of the three income groups have now been eliminated," we do not find our figures to be very different from those given by Clements. The range of differences in weight between comparably aged boys of the upper- and middle-income groups obtained from Table 11 is 6 lb. to 13.6 lb., while the mean difference is 1.75 lb. Thus the range is greater than that of 1-6 lb., quoted by Bransby *et al.* for boys aged 5-15 in Sheffield. We find, however, neither in our figures nor in Clements' any progressive increases in weight differences with age to correspond to those quoted for boys of 5, 8, and 12 in Liverpool, attending schools in good and poor neighbourhoods.

Because of the conflicting results obtained by surveys in different towns, and even within the same town with a different system of classification and a different size of sample, it seems important to stress the point that at present any results obtained by surveys such as those considered above provide estimates which relate with certainty only to the local community sampled. To treat that community as a sample of a more widely defined population involves assumptions which have yet to be validated.—We are, etc.,

"Status Lymphaticus"

SIR,—Dr. H. B. Dodwell (January 16, p. 149) states that no reference to this syndrome can be found earlier than 1850; it seems, however, that Kopp in 1830 first drew attention to thymic asthma and "thymic death."¹ While one can agree with Dr. Dodwell that status lymphaticus is a hotch-potch of all kinds of cases with low resistance and sudden death, and while thymic compression or "thymic dysendocrinism" as a cause of death most probably does not exist, the syndrome should perhaps not be regarded as a myth in the light of modern medical knowledge. On the contrary, it seems remarkable that this syndrome was conceived as a clinical entity so long ago and on purely anatomical grounds. It would not be the first time that science has detected some truth in an old "myth."

The anatomical findings indicating hyperplasia of lymphoid tissue and persistence or enlargement of the thymus gland appear in an interesting light if one remembers that injection of pituitary corticotrophic hormone and/or adrenal cortical glucosteroids rapidly causes involution

and depletion of lymphoid follicles and of the lymphatic and thymus glands. This conspicuous change is accompanied by an increase in the number of circulating lymphocytes and in the urinary excretion of uric acid which is presumably formed by the breakdown of lymphatic nuclei. Other pertinent changes which occur simultaneously are not important for the present argument. However, it seems certain that the amount of lymphoid tissue and its rate of breakdown is regulated by the adrenal cortex via the pituitary. This breakdown occurs as an important physiological response to stress, in the sense of Selye, and seems to form part of the mechanism by which the body is protected against injury and for which an adequately functioning pituitary-adrenocortical system is necessary.

As I have previously suggested,² the assumption seems close at hand that decreased resistance to stress in connexion with lymphoid and thymic hyperplasia i.e., the status thymolymphaticus—is an expression of (constitutional?) pituitary-adrenocortical deficiency in respect of corticotrophin and/or adrenal glucocorticoid secretion, the anatomical findings merely being a consequence of the deficiency but not the cause of the syndrome. This assumption would explain the association of lymphoid hyperplasia with lack of resistance to stress which is known from other endocrine diseases with adrenocortical deficiency (e.g., Addison's, Simmonds's, and Graves's disease). The hypothesis could easily be verified by investigations into the adrenal cortical reserve of cases with suspected status thymolymphaticus. I am, etc.,

Penicillin-resistant Gonococci

SIR,—In view of the question which must be exercising the minds of many venereologists whether there is any near danger of gonococci becoming penicillin-resistant, the following case may be interesting.

X.Y.Z. attended the V.D. Department, Central Middlesex Hospital, on the evening of October 23, 1953, with a slight urethral discharge and a history of having been treated the same morning with 600,000 units of penicillin in the form of "distaquine." No gonococci were found in the discharge and the patient was treated with potassium permanganate irrigations. On November 5 he reattended with a profuse urethral discharge containing gonococci as seen in slide and culture. I personally injected 600,000 units of penicillin in the form of "prolophen."

When he was next seen on November 12, the discharge had disappeared, but on November 19 when he reattended he reported that the discharge had reappeared on November 15; on his reattendances the discharge was profuse, with myriads of gonococci in the smear, more than I have ever seen in a slide in my thirty years' experience. The culture was positive and the gonococci there were reported as sensitive to penicillin. I gave him a mega unit of penicillin in "prolophen" and the discharge again disappeared, but it had returned by December 7.

When I saw him on December 10 gonococci were profuse in smear and the culture was again positive. There was no evidence of infection in the prostate, and, as far as I was able to see later when under local treatment, the inflammation had died down. There seemed to be no closed focus in the anterior urethra.

Under very close cross-examination the patient denied any fresh exposure to infection after the first sign noted above, and I believe him. Is this the writing on the wall? I am, etc.,

London, N.W.10.

P. A. CLEMENTS.

Carcinoma of Colon and Salmonella Infection

SIR,—This male patient, aged 62 years, was admitted to the hospital on October 24, 1953, with a medical history and diagnosis of a possible subacute intestinal obstruction. In addition, however, he had inflammatory congestive chest symptoms for one week previous to admittance which had not responded well to penicillin.

On admittance he had definite signs of bilateral basal congestion and there was some abdominal distension. He was put on

500,000 units of intramuscular penicillin six-hourly, but his pyrexia continued although his chest symptoms improved. Blood was sent for agglutination reaction on October 30, 1953. A barium enema was done on November 2, 1953, and this confirmed the clinical diagnosis of obstructed large bowel (obstruction was present in mid-third of transverse colon). On November 3, 1953, a laparotomy was performed by me under general anaesthesia, and the patient was found to have a string carcinoma in the mid-third of the transverse colon. There were multiple secondaries in the surrounding glands and the liver was full of nodular secondary growths. A side-to-side anastomosis above and below the obstruction was performed to relieve symptoms of obstruction. Following the operation signs of ileus developed, but these resolved within a day or two. The bowels were functioning normally within three days.

The final pathological report dated November 13, 1953, was: "The organism isolated from this patient's clot culture has been identified by the salmonella reference laboratory as *Salmonella anatum*." Following the diagnosis of a salmonella blood infection the patient was treated by chloramphenicol and he eventually responded quite well. When he was discharged home on November 28, 1953, his bowels were functioning satisfactorily, his abdominal wound was well healed, and he was able to get about. Since discharge home, however, he has developed further pyrexia and has required a further course of chloramphenicol.

The interesting point here, however, is the association of salmonella infection with carcinoma of bowel with multiple secondaries. In the past I think that most of us have been of the opinion that the temperature often met with in patients suffering from a carcinoma with multiple secondaries was due to absorption of the breakdown protein products, but this case probably indicates that in some cases, at least, normal protective mechanisms to combat blood infections are thrown out of gear, and it may well be that if blood cultures were performed on such cases some at least might yield a positive blood culture.—I am, etc.,

Oswestry.

A. LUTTON.

Disease and the Pig Bin

SIR,—Dr. Kathleen Vaughan's biting fly (*Journal*, January 30, p. 279) is almost certainly *Stomoxys calcitrans* L., the "biting house fly" or "stable fly." Their habits are consistent with their being able to breed in pig bins, and there is some evidence that they may be able to transmit pathogenic organisms.

These insects have, however, always been common on farms, where they breed on soiled vegetable matter, and one would have expected that their role in disease transmission in country districts would have been uncovered by now. It would be very interesting if Dr. Vaughan could substitute an entomologist's net for her fly-swatter and see if she could recover any pathogens from the stomachs of these flies.—I am, etc.,

London, E.C.1.

EDWIN R. NYE.

Student International Clinical Conference

SIR,—The British Medical Students' Association has undertaken once again to organize a Student International Clinical Conference in Great Britain from July 15 to 30, 1954, as an activity of the International Federation of Medical Student Associations. It will be divided into three sections: First, there will be seven days in London, when at least five of the teaching hospitals will give lectures and demonstrations, and visits will be made to places of interest; secondly, three days in Birmingham with visits to hospitals, factories, a film show, and a visit to Stratford-on-Avon; and, finally, four days in Edinburgh, where similar activities are being planned. Our greatest difficulty in organizing an attractive programme is to make it sufficiently cheap to enable foreign students to attend, taking into account the expense of travelling to this country. We are therefore appealing for financial support for the Conference. We hope to raise at least £500, so that we can organize a Conference worthy of what Britain has to offer, and within the student's purse, at the same time repaying in some

measure the generous hospitality which British students receive on going to similar courses abroad.

This Association was one of the founder members of I.F.M.S.A., which was set up in 1951 to promote international co-operation between medical students, and at its foundation we were careful to ensure that it would be free of any political activities which seem to predominate in other international student bodies. Its present member countries are Austria, Denmark, Eire, Finland, France, Great Britain, West Germany, Holland, Israel, Norway, South Africa, Spain, Sweden, Yugoslavia. B.M.S.A. was the first chairman nation, and continues to give lead in many fields. The B.M.A., the World Medical Association, and the World Health Organization have expressed sympathy with its ideals. Its aims are strictly limited to promoting and organizing conferences, visits, and exchanges, with some research into student health and education.

There are many foreign students wishing to obtain an insight into British medicine, and we are therefore particularly anxious to make a success of this Conference. I do earnestly hope that your *Journal* can support in this object, and any contributions, however small, will be gratefully received.—I am, etc.,

B.M.A. House, Tavistock Square,
London, W.C.1.

ALAN B. GILMOUR,
President, British Medical Students' Association.

POINTS FROM LETTERS

Polite Surgery

Dr. W. A. J. DONALD (Monifieth, Angus) writes: I am tired of reading about surgical "trauma," surgical "interference," and surgical "aggression." The term surgical "intervention" is more polite and restful to my sensitive, surgical ear.

Requirements for D.T.M.&H. and D.P.H.

Dr. L. R. FLOWERS (Doom Dooma, Assam) writes: By analogy with postgraduate diplomas, such as F.R.C.S., M.R.C.P., D.C.H., D.A., etc., candidates for which are not required to attend a special course but do the requisite amount of work in the respective specialty, I submit that those who have been working for a specified period in the Tropics, dealing with all aspects of tropical medicine and hygiene, should be exempted from the necessity of attending the course for the D.T.M.&H., or the D.P.H., and should be permitted to sit the examination without these preliminaries. This would bring these diplomas into line with all the others, and would eliminate the present factors of time and money spent on a compulsory course, and the resulting unfairness to those who cannot afford these pre-examination requirements.

Measles and Appendicitis

Dr. D. S. BADENOCH (Inverness) writes: Measles is not the only zymotic liable to show up appendicitis in its course. A similar emergency often arises during or following influenza A and B, and indeed many bad colds. The damaging entity common to all is the severe biliary congestion lasting from two to four days. Pathologists have explained, as long ago as thirty years, how the chemistry of the liver comes to a partial standstill, and, in addition, how the flora of the bowel multiplies enormously in the absence of a normal bile flow. If, during the phase of biliary congestion, the patient is fed on converted food, few noticeable sequelae arise. If, on the other hand, he is given fat and starches, he may expect a variety of complications, appendicitis included. Biliary stasis, to my mind, is the commonest cause of acute appendix.

Anaemia and Purchase Tax

Dr. A. PINEY (London, W.1) writes: The only treatment needed in simple iron-deficiency anaemia is administration of an adequate amount of ferrous salt; and the addition of vitamins, folic acid, liver, etc., serves no therapeutic purpose. There seems to be general agreement that ferrous gluconate is less liable to cause gastro-intestinal upset than are other iron compounds. It is therefore amazing that tablets consisting entirely of ferrous gluconate are more expensive than those which contain vitamins in addition to this compound. It appears that H.M. Customs and Excise regard such mixtures as essential drugs, which are therefore exempt from purchase tax, whereas, in fact, this is a stupidity that adds to the size of the drug bill of the N.H.S. and penalizes those patients who prefer to retain their freedom by remaining "private" and paying for their own medicines.

Obituary

O. WYNNE GRIFFITH, O.B.E., L.R.C.P.Ed., J.P.

Dr. O. Wynne Griffith, who died at Pwllheli on January 17 at the age of 97, was one of the oldest medical men in Wales.

Owen Wynne Griffith was born at Nevin, Caernarvonshire, on November 16, 1856. After leaving Bottwnog Grammar School he served as an apprentice with Dr. Evan Roberts, of Penygroes, Caernarvonshire. In his later years he was fond of relating his experiences in those early days, and in 1939 he broadcast some of his recollections. At the age of 17, in 1874, he entered Guy's Hospital as a medical student, and qualified L.R.C.P.&S.Ed. four years later at the age of 21. After qualification he was warned that his health was weak and he took an appointment as a ship surgeon. After two years he returned to Wales and began practice in the Llyn peninsula of Caernarvonshire, living for most of the time at Pwllheli, where he quickly developed a very large country practice. For the first 25 years of his professional life he travelled many thousands of miles on horseback or in an open gig. He addressed nearly all his patients by their Christian names, and was interested in every aspect of their lives. He had great personal charm and a most lovable nature, and it is doubtful if any man in the district has ever had a warmer place in the hearts of those who knew him. For a long time he was known affectionately all over the district as "the old doctor." Although he officially retired from practice about 20 years ago, he was frequently consulted by his colleagues to the end. When interviewed in 1946 on the occasion of his 90th birthday, Dr. Wynne Griffith was asked for his recipe for longevity. "I'll tell you," he said. "Avoid jealousy: always keep an optimistic view and practise moderation in all things." A member of the British Medical Association for 62 years, he was chairman of the South Caernarvon and Merioneth Division in 1907 and president of the North Wales Branch in 1910-11. He also served on the executive committee of the Division and on the Branch council. In his presidential address to the North Wales Medical Association many years ago he emphasized the need for a ministry of health, and he saw it come into being.

In the life of the community in which he lived Dr. Wynne Griffith was an important figure. He was a member of the Pwllheli town council for over 60 years, an alderman of the borough for 55 years, and mayor for 12 years—a record for the office. He was a founder of Pwllheli Grammar School, and until recently chairman of the governing body. As an appreciation of his services to the town he was given the freedom of the Borough of Pwllheli in 1931. He was also a member of the Caernarvonshire County Council for nearly 60 years, an alderman for nearly 50 years, and chairman of the council in 1921. In his early years he took a keen interest in politics, and at one time was chairman of the Caernarvonshire Liberal Association. He was a personal friend and supporter of Mr. Lloyd George, and had presided at a number of the meetings at which Lloyd George made some of his famous speeches before audiences of about 10,000 people at Caernarvon. Religion played a very important part in his life: he was an elder of the

Presbyterian Church for 60 years, moderator of the South Caernarvonshire Presbytery for two years, and a senior deacon of Penmount Church, Pwllheli. In recognition of his public services over many years he was appointed O.B.E. in 1937.

Dr. Wynne Griffith lived a full and happy life, and except for the brief period in his early twenties enjoyed good health until the last two or three months of his life. His cheerful presence will be missed by a large number of friends and acquaintances. He is survived by a daughter and a son, who is a solicitor.

A. E. COOPER, M.D.

Dr. A. E. Cooper, who was for many years consultant anaesthetist to the London, the West London, and the Royal National Orthopaedic Hospitals, died on January 19 at the age of 84.

Austin Edwin Cooper was born at Dublin on February 8, 1869, and was educated at Leeson School and at Trinity College, Dublin. He took the L.M. while at the Rotunda Hospital in 1894, and the degrees of M.B., B.Ch. in the following year, proceeding to the M.D. in 1896. After graduation he held house appointments at the Adelaide Hospital, Dublin, and then came to London to act as resident medical officer at the Pimlico Dispensary. Dr. Cooper was keenly interested in anaesthesia from the start of his professional career. In the controversy which took place in England towards the end of the nineteenth century on the comparative safety of chloroform and ether he was a whole-hearted supporter of the use of ether, and so skilled in its use did he become that a certain deep type of anaesthesia was, and still is, named after him by being referred to as "Cooperization." He became anaesthetist to the Royal National Orthopaedic Hospital and assistant anaesthetist to the West London and other hospitals. Later he was appointed anaesthetist and assistant instructor in anaesthesia at the London Hospital and anaesthetist to Poplar Hospital. During the war of 1914-18 he worked in a number of special hospitals for officers, and at the outbreak of the second world war, although retired for some years, he returned to full active work, dividing his time between the London and Whipp's Cross Hospitals. An active member of the Chelsea Clinical Society, he had held office as treasurer and vice-president.

At the hospitals to which he was attached he took an important part in the teaching of anaesthesia, and his willingness at all times to help and instruct students, his unfailing punctuality, and his efficiency and quietness in his work and manner were all admirably unobtrusive qualities which led to his being accepted without full appreciation of his worth until too late—when it was found that an invaluable colleague had gone and a vacancy remained which could never be filled again with the same old-world courtesy and companionship. He was keenly interested in all forms of sport, particularly racing and fishing. In 1898 he married Miss Mary Hunter, and she died in 1946. There were two sons and one daughter of the marriage.

Dr. H. LINCOLN HATCH, who died on November 16, 1953, at the age of 84, was for many years in practice at Pinner. Herbert Lincoln Hatch was born on February 4, 1869, and studied medicine at St. Mary's Hospital, London, qualifying M.R.C.S., L.R.C.P. in 1892. He took the D.P.H. of the English Royal Colleges in 1894, and in the following year

obtained the Durham degrees of M.B., B.S., having passed the intermediate and final M.B. examinations with honours. After qualifications he held house appointments at St. Mary's and at the Hospital for Sick Children, Newcastle-upon-Tyne, and then went to live at Johannesburg, where he was in general practice for a few years. At that time he was particularly interested in the use of x rays in medical practice, and in 1897 read papers on the subject before the Transvaal Medical Society, of which he was the honorary secretary, and the South African Medical Congress: both papers were published in the *South African Medical Journal*. He served as a civil surgeon with the South African Field Force in the Boer War, and then returned to England in 1902, settling in practice at Pinner, where he was for many years a member of the honorary medical staff of the Northwood, Pinner, and District Hospital. A member of the British Medical Association for 58 years, he was chairman of the Harrow Division in 1925-6, and represented his Division at 16 Annual Representative Meetings from 1920 to 1939. He also served on the Central Ethical Committee and its standing sub-committee from 1930 to 1937, the Committee on the Medical Aspects of Abortion from 1934 to 1936, and the Tests for Motor Drivers Committee from 1929 to 1931. During the first world war he served as a captain in the R.A.M.C. from 1914 to 1916, later becoming ophthalmic specialist at No. 4 General Hospital. Dr. Lincoln Hatch had the confidence and affection of his patients and his colleagues, and his presence will be much missed for a long time to come.

Dr. A. P. PIGGOT, formerly deputy medical superintendent of St. James's Hospital, Balham, died on January 6 at the age of 75. Born of an Essex family on April 24, 1878, Allen Pledger Piggot was a medical student at Guy's Hospital and qualified M.R.C.S., L.R.C.P. in 1903. Until 1915 his main interest lay in psychiatry, and he worked in several mental hospitals. Eventually, however, his growing taste for morbid anatomy led him back into the stream of general medicine, and he became an assistant medical officer at St. James's Hospital. From 1916 to 1919 he served as a temporary captain in the R.A.M.C. After demobilization he returned to St. James's, where he became deputy medical superintendent. During the last war he remained at work while the younger doctors joined the Forces, and acted for several years as medical superintendent of the hospital. During his period at St. James's, first under the old board of guardians and later under the auspices of the London County Council, Dr. Piggot saw a gradual transition from old-fashioned Poor Law medical care to modern specialized medicine and surgery. He played a decisive part in gaining for the hospital the outstanding reputation which it now has. He remained mentally active and alert and keenly interested in every new development. His official duties were mainly clinical, in charge of certain medical wards, but, unofficially, he made morbid anatomy his hobby, and performed over 10,000 post-mortem examinations between 1920 and 1950. Overdue to retire in 1946, he was requested by the London County Council to take part in a scheme of research initiated by the Nuffield Foundation on the pathology of old age. Thus it came about that his closing years were spent in placing his vast experience at the service of others, and he was teaching postgraduate students right up to the onset of his last illness. It was during this period that most of his published work appeared. He had previously been joint author of papers on silicosis and on haemopneumothorax. Later he worked up his records on the morbid anatomy of old age, and under his guidance a series of articles dealing with various aspects of the subject were published in the American journal *Geriatrics*. Based as they were on over 2,500 necropsies of subjects over the age of 65, they represent a treasure house of pathology. Cardiovascular disease, new growths (in particular carcinoma of the bronchus), the arteriosclerotic kidney, chronic bronchitis, rheumatoid arthritis—on all these he shed new light. Piggot was always quiet, modest, and unassuming. He sought for no recognition nor expected

any reward. Always ready to help a younger colleague, he was the kindly friend of hundreds of doctors and nurses who came in contact with him. Equally at home by the bedside and in the post-mortem room, he was one of the last of those physician-pathologists for whom Guy's is so justly famous. He is survived by a widow, a son, and a daughter, who is following her father's profession.—T. H. H.

Colonel J. M. ELLIOTT, who was for many years consultant venereologist to the Essex County Council, died in London on January 6 at the age of 67. James May Elliott was born on March 16, 1886, and came of a medical family. His father, who was Dr. Haslett Elliott, of Rathfriland, Co. Down, had four sons, three of whom became doctors and the other a dentist. James was the third son. He graduated M.B., Ch.B. at Trinity College, Dublin, in 1910, and after two years in an uncle's practice he joined the Indian Medical Service, later transferring to the R.A.M.C. He served in India, Egypt, and the United Kingdom, retiring in 1937 to take up an appointment as venereologist with the Essex County Council. At the outbreak of the last war he was recalled to the Army and was appointed adviser in dermatology to the British Expeditionary Force in France in 1939-40. After Dunkirk he continued to serve in England until being posted to the Gold Coast, where he became ill and was invalided home. When he ceased to belong to the Regular Army Reserve of Officers in October, 1945, on reaching the age limit, he was granted the rank of colonel. After the war he returned to his position with the Essex County Council, holding the appointment until 1952, when he retired. In the subsequent two years he declined in health very rapidly, and it became apparent that he had never fully recovered from the severe illness contracted on the Gold Coast. His charm of manner and infinite courtesy and kindness to patients and colleagues gave him a large circle of friends, to whom his recent loss of health and his death so soon after his retirement have been a great grief. Colonel Elliott married in 1919 and leaves a widow, a son, and a daughter.—R. H. B.

By the death on January 9 at the age of 79 of Dr. W. J. SUSMAN, Henley-on-Thames has lost a prominent resident and one who played a big part in the public life of the borough for over 40 years. Walter James Susman was born on June 10, 1874, and was educated at Rugby and Caius College, Cambridge, where he obtained a Blue for hockey and narrowly missed a Blue for Rugby football. Even so, he was one of the members of the first English fifteen to play against a French international side. He qualified M.R.C.S., L.R.C.P. from St. George's Hospital in 1900, and took the degrees of M.B., B.Chir. three years later. Among the hospitals at which he held resident appointments were the Middlesex Hospital, the Victoria Hospital for Children, Chelsea, and the Westminster Hospital. In 1903 he entered a partnership at Henley, where he practised until his retirement in 1947. In 1919, after his return from service in the R.A.M.C., he was elected a member of Henley Borough Council and was chairman of the housing committee when an important slum clearance scheme was carried out. The public appointments which he held made an impressive list. In 1925 he became mayor of Henley for the first time. He served a second term as the town's chief citizen during the difficult years of 1945 and 1946. A keen member of the Council for the Preservation of Rural England, he was in addition chairman of the Henley, and South Oxfordshire Area Planning Committee from 1935 to 1948, and was a member and vice-chairman of the Henley Area Planning Committee from the time it was formed in 1949 until his retirement from the Council in 1952. He was also chairman of the Henley and District Technical Institute Committee and of the Henley Further Education Committee. He took a close interest in the Henley War Memorial Hospital, to which he was consulting physician, and was a member of its management committee until the introduction of the National Health Service in 1948, when he

became a member of the Reading and District Hospital Management Committee and of the Henley Area Committee. He was a past president of the Reading Pathological Society, chairman of the Reading Division of the British Medical Association in 1919-20, and president of the Oxford and Reading Branch of the Association in 1931. For some years he was deputy coroner for South Oxfordshire. A prominent freemason, he was a member of the Thames Lodge, of which he had been three times master, one of the founders of the Thames Chapter, and a past officer of the supreme grand chapter of England. One of the first members of the Henley Golf Club, he had held the office of captain. In 1914 he married Lena, only daughter of the late Dr. and Mrs. Bransby Brooks, of Sonning, and she survives him. By his death his colleagues have lost the benefit of the experience of a shrewd general practitioner and Henley one who devoted much of his time to the welfare of his fellow townsmen.—N. R. C. L.

Dr. J. W. CRERAR died at Snape, Suffolk, on January 7 at the age of 86. He had been in practice in his home town of Maryport, Cumberland, until eighteen months ago. John William Crerar, the eldest son of Dr. John Crerar, was born at Maryport on November 29, 1867. From Carlisle Grammar School he went on to study medicine at Edinburgh University, where he graduated M.B., Ch.B., with first-class honours, in 1889, having gained the Vans Dunlop scholarships in physiology and in pathology and surgery in 1887. He became resident surgeon at the Edinburgh Royal Infirmary and demonstrator of anatomy in the university. Owing to the state of his father's health he relinquished his work in Edinburgh and entered the practice at Maryport in 1895. He was a fellow and former president of the Royal Medical Society of Edinburgh, and in 1905 he became a fellow of the Royal College of Surgeons of Edinburgh. During the course of his long life he published several interesting papers in this and other journals. In 1911, for instance, he described in this *Journal* a visit to the Mayo Clinic. A lecture he gave before the Edinburgh Pathological Society in 1918 on the subject of the training of medical students for general practice was later published in the *Edinburgh Medical Journal*. In collaboration with the late Professor J. Lorrain Smith he did some of the experimental work which ultimately resulted in the general use of eusol as an antiseptic during the first world war. Less than a year ago the *British Journal of Ophthalmology* published some historical notes on congenital colour blindness which he wrote jointly with Dr. J. A. Ross. A member of the British Medical Association for 62 years, he played a notable part in local medical affairs. He acted as one of the honorary secretaries of the Section of Pathology and Bacteriology when the Association held its Annual Meeting at Carlisle in 1896. He was also president of the Border Counties Branch in 1912-13; chairman of the English Division in 1910-11, and again from 1924 to 1926; and he represented his Division at a number of Annual Representative Meetings. When he could find time to take part in lay affairs his presence could always be felt in deliberation and decision, and all educational and cultural movements could count on his support. A good deal of his affection was centred upon the Victoria Cottage Hospital, Maryport, from its establishment over half a century ago right up to the time of his death, for he had engaged to be present at the opening of the new out-patient department this month. Always a true son of Maryport, he found great pleasure in collecting material in the form of photographs, maps, and slides showing the history and development of the old port. He traced the home of Isabella Harris, mother of Lord Lister; and in the course of his researches he was able to disprove what had previously been claimed to be a historical fact, that the *Alfred*, the first warship commissioned in the United States Navy, was converted from *The Black Prince*, which was built in Maryport. He discovered that the *Alfred* had been converted from a Philadelphia-

built vessel originally called *The Black Prince*, a ship much larger and thirty-two years older than the Maryport vessel. Dr. Crerar was commissioner of the Maryport harbour board, being vice-chairman until his retirement. He was also a justice of the peace for the county of Cumberland for many years. His younger brother, Dr. Charles Crerar, died in Silloth, Cumberland, in 1937.

F. W. C. writes: Dr. J. W. Crerar was the doyen of Cumberland practitioners and only relinquished the chair of the West Cumberland Medical Association after he had given up practice. The parting with him by his colleagues, patients, and the community was very reluctant, and the meeting in his home town, on his going from it after a lifetime's devotion and service, permitted tangible expression by way of a testimonial spontaneously and gladly subscribed, and admitted of things being said in his presence that normally only find their way into an obituary notice. Although he remained unmarried, Dr. Crerar was essentially a family man, the premature death of his father having entirely altered his outlook and the course of his career, bringing him home to his mother, brothers, and sisters. His mother lived to a ripe old age, and it was ever a joy to behold the affection between mother and son. What the lecture room and operating theatre of the larger sphere lost cannot be imagined, but the gain to the home, the general practice, and the community of the small town and countryside was superlative. He slipped quietly out of life without trouble to anyone, just as he would have wished, and we can only express gratitude for a long life lived in altruistic service, and treasure a memory of one who, knowing the struggle of life, ended it as he had always faced it, serenely and with good courage.

Dr. J. M. AHERN, whose death at his home at Kew Gardens on January 12 at the age of 78 will be deeply regretted by his old friends and colleagues, was a member of the prison medical service for nearly 34 years. John Maurice Ahern was born at Glenbrook, Co. Cork, in 1875 and was educated at Belvedere College and at the Royal University of Ireland. He qualified L.R.C.P. & S.I. in 1898 and took the degrees of M.B., B.Ch. three years later. He joined the prison service as deputy medical officer at Liverpool in 1902 and then served successively in that capacity at Parkhurst, Birmingham, and Wakefield until 1917, when he left to enter the R.A.M.C. and saw service in Salonika in the first world war. He returned to his prison duties in 1919, being posted to the Borstal Institution at Rochester, where he acted as deputy governor in addition to his work as medical officer. Within a few months he was promoted to medical officer, class I, and two years later assumed medical charge of the prison at Liverpool. There he soon became a well-known figure in the courts, and his opinion on the mental condition of the prisoners under his care was regarded with respect. In 1930 he left Liverpool to become medical officer at Parkhurst and Camp Hill, where he remained until he retired in 1936. Ahern, however, was still an active man, and in the earlier part of his retirement undertook further medical work, including that of assistant medical officer at various mental hospitals. He was an able clinician and a man of considerable learning and acumen. He had, perhaps, a slightly eccentric personality, but this quality, with his irrepressible witticisms, only served to endear him the more to his colleagues and patients alike. He was for some years a member of the Royal Medico-Psychological Association, and among the papers he wrote were "An Inquiry into the Mentality of Juvenile Adult Delinquents" (1920) and "Certification as a 'Moral Imbecile'" (1925). He was a versatile man who enjoyed his family life and was in his younger days an enthusiast over his hobbies, such as poultry keeping and carpentry. Some of the furniture from his bench was very well made. He married Evelyn, daughter of the Hon. Edwin Reed, and there were two sons of the marriage. Mrs. Ahern died in 1949.—H. K. S.

Dr. ROBERT TINDALL, who was in practice at Hurworth, near Darlington, for over twenty-five years, died at Croft-on-Tees on January 12 at the age of 68. Robert Tindall was born on October 21, 1885, and studied medicine at Aberdeen University, where he graduated M.B., Ch.B. in 1909. After holding house appointments at Aberdeen Royal Infirmary and at Birmingham General Hospital, he was in general practice for two years, first with his uncle, Dr. F. M. Tindall, at Bedlington, and then at Stanhope. In the first world war he served in France for four years with the 27th Field Ambulance, 9th Scottish Division, retiring with the rank of major. He was mentioned in dispatches three times and in 1918 was awarded the Military Cross. In 1919 he settled in general practice at Hurworth-on-Tees, where he made many friends over a wide agricultural and residential district. He was soon accepted as an able, painstaking, and kindly doctor. An excellent diagnostician, he did invaluable work in the community he served and will be long remembered. He also took a prominent part in the life of the village, being chairman of the local district nursing association and of the village hall committee for many years, besides being an active member of the local branch of the British Legion. In the last war he served as medical officer to the 20th battalion of the Home Guard, with headquarters at Darlington, where he was also chairman of a medical board. He was chairman of the Darlington Division of the British Medical Association in 1929-30, and again from 1945 to 1948. While still apparently a robust and tireless man he was struck down in 1946 by a sudden illness, which compelled his retirement, to the great regret of all who knew him. Crippled as he was, he settled quietly at Croft-on-Tees and accepted his enforced idleness with more philosophical calm than could have been expected from one who had always been a man of action. He had always been keen on outdoor sports, especially golf and fishing, but he was now condemned to inactivity. He read widely, and constantly fell back on the Waverley novels, which he devoured completely in the first year of his illness. He was a man of decided views, and, though very outspoken, his comments were always enlivened with humour and a racy wit which endeared him to his friends. During his long illness the constant devotion and cheerfulness of his wife were a great solace to him. His elder son, Maxwell, was a major in the Gordon Highlanders and gained the Military Cross in the last war, but was killed at the crossing of the Seine. The only surviving son is Captain Angus Tindall, who is serving in the same regiment in the Regular Army. To him and to Mrs. Tindall we extend our deepest sympathy.—G. G. F.

Dr. LINA MARY POTTER, who died in the German Hospital, London, on January 15, was for something like 40 years a general practitioner in inner North London. She was a woman of marked personality, enthusiastic in a number of causes, and hail-and-well-met to a wide company of friends. In the 'twenties and 'thirties she was prominent in the affairs of the British Medical Association, reaching the chairmanship of the City of London Division and serving as a representative for many years. She was born in 1875, the daughter of a well-known physician in his day, John Baptist Potter, who was on the staff of Westminster Hospital. On her mother's side she was related to the late Dr. Lancelot Burrell, senior physician to the Royal Free. She received her medical training at the London School of Medicine for Women, qualifying in 1910, and she undertook some further studies at the University of Geneva. In the first world war she served with a women's medical unit which went out to Serbia, and seemed to have enjoyed the improvisations and emergencies which such an expedition entailed. She returned with a love for the Balkan country, and only a year or two ago revisited what is now Yugoslavia. She also went to Russia in 1916, and of medical work there on the eve of the revolution she had many strange tales to tell. After her war experiences she settled in general practice in one of the lovely old houses over-

looking Highbury Fields, and there, on the fringe of the city, she cultivated a big country garden. She carried out an astonishing amount of work in one form and another. She was on the panel of lecturers for the L.C.C.; she was attached as medical adviser for special cases to Scotland Yard; at one time she was director of the section of child welfare of the League of Red Cross Societies, a work very near her heart; she had great enthusiasm for the St. John Ambulance Brigade, giving lectures and attending committees and parades. At one time she was medical officer to the old Greenwich Union Infirmary. She also found time to contribute to medical literature, mostly on the subject of nutrition and child care. In the British Medical Association Lina Potter was a well-known and respected figure. She had been a member for just over 30 years. In the centenary year of the Association, when the principal gatherings were held in London, she was one of the four vice-presidents of the Metropolitan Counties Branch and vice-chairman of her own City Division, becoming chairman the following year. She was also a keen member of the Medical Women's Federation, and the meetings of the Hunterian Society were not quite complete without her presence, and the more Bohemian they were the better she fitted in. She was a friendly soul as well as something of a "character." To younger women starting practice she was constantly encouraging. She served on the council of Byng Hall, the hall of residence for women students of the University of London. Her circle of friendship included all dogs and cats in her neighbourhood, and her love of animals extended beyond the domestic hearth; she was an active Fellow of the Zoological Society. In recent years she had given up continuous general practice but helped her colleagues as locumtenent. At many medical gatherings in and around the City of London her hearty greeting and veteran gaiety will be sadly missed.

Medico-Legal

ANTIHISTAMINES AND ALCOHOL

A warning about the effects of antihistamine drugs coupled with alcohol was given by Mr. Victor Durand at London Sessions on January 26. He was appearing for Donald Charles Shuter, 49, company director, who pleaded guilty to being under the influence of drink or a drug when in charge of a car. Shuter was fined £15 with 15 guineas costs, and his licence was endorsed, but he was not disqualified from driving.

Mr. Durand said that Shuter, who had been driving for 35 years and had no previous convictions, was allergic to tinned crab, and after eating some developed a skin complaint. His doctor had prescribed antihistamine capsules for Shuter. They were delivered straight from the doctor's surgery. No warning, no qualification, was made save as to the number he should take and the rate at which he should take them. He said that Shuter was a gentleman who did partake of alcohol in moderate quantities, and on this particular night he had taken these capsules between 11 and 11.30 p.m., having already partaken with his wife and a friend of a bottle of wine and before that one pink gin. Although there was no immediate effect, it seemed now quite certain that there was disorientation as a result of the capsules affecting the alcohol.

The doctor said in evidence that the drug magnified considerably the effect of alcohol. He had given Shuter no warning, but he realized now it would be as well to give one, particularly to a motorist.

Mr. Durand, submitting that there were "special circumstances," said that the doctor was rather shaken after Shuter's arrest to find he had landed his patient in a predicament.

Mr. Henry Elam (Deputy Chairman) agreed with the submission and said Shuter would not be disqualified from driving.

Medical Notes in Parliament

A.C.T.H. and Cortisone

In the House of Lords on February 3 Viscount SAMUEL asked the Government whether a patient requiring treatment by A.C.T.H. or cortisone could obtain it if he was registered under the Health Service but not otherwise, and, if so, whether the regulation controlling the supply of these drugs would be altered to remove that discrimination.

Viscount WOOLTON, Chancellor of the Duchy of Lancaster, said the answer was "No," but the Minister of Health was glad of the opportunity to remove any uncertainty. The supply of A.C.T.H. and cortisone was controlled, but there was no question of having to be registered under the Health Service to obtain them. They were recent drugs which could have harmful effects, and experience in them was limited. For that reason they were supplied only to hospitals which had the necessary laboratory facilities and experienced medical staff. That staff enjoyed full discretion in the use of the drugs, which might be given to private or other patients at the hospital. In addition, other doctors or hospitals could obtain supplies from those selected hospitals if the drugs were required to treat one of the conditions in which they might be necessary to save or prolong life. Supplies were available to private patients on payment.

Viscount SAMUEL commented that the information might bring some reassurance to private patients. Viscount WOOLTON added that if Lord Samuel would give him particulars of any specific case he was certain the Minister of Health would be glad to follow it up.

Mortality in Amputees

Brigadier F. MEDLICOTT asked the Minister of Pensions and National Insurance what progress was being made by the investigation into the problem of increasing disablement suffered by limbless ex-Service men as they get older. Brigadier J. G. SMYTH, Parliamentary Secretary, stated on February 1 that the vast majority of the medical examinations requested by the Rock Carling Committee (see *Journal*, March 28, 1953, p. 717) had been concluded, and it was hoped to clear the small remainder in the next fortnight or so. The clinical findings relating to over 5,000 concluded cases were being collated, and the results would be sent to the committee for consideration as soon as possible. The Minister would prefer not to prophesy when the investigations, which were of international importance, would be completed. When the final report of the committee was available he proposed to study it in consultation with his principal medical advisers and subsequently with his Central Advisory Committee.

Amputation and Arteriosclerosis

Mrs. B. CASTLE on February 1 asked the Minister of Pensions and National Insurance why, in view of the independent and responsible medical opinion submitted to him in support of the application by Mr. Aaron Barnes, of Blackburn, for an increased war pension in respect of the amputation of his second leg, he had failed to give this applicant the benefit of the reasonable doubt which existed in his case. Brigadier J. G. SMYTH, the Parliamentary Secretary, stated that the consensus of expert medical opinion left no room for reasonable doubt that the amputation of Mr. Barnes's right leg in 1953 was not connected with the loss of the left leg in 1917. Mrs. CASTLE said that she had sent the Minister a report by an independent specialist of high repute that the degeneration of Mr. Barnes's right leg might have been associated with the first amputation. Brigadier SMYTH said he had read the reports of the two medical men Mrs. Castle had sent, and they were very

indefinite, just indicating that it was worth making a claim. During the past seven years the Ministry had heard of only two cases in which it was claimed that arteriosclerosis arose in a sound limb as a result of wearing an artificial limb. One of these cases, exactly similar to that of Mr. Barnes, was referred to two independent medical experts, both of whom confirmed the wealth of medical opinion in the Ministry on these cases, that the wearing of an artificial limb would not cause, aggravate, or precipitate the onset of arteriosclerosis in the sound limb, and that the incidence of arteriosclerosis was certainly no greater among amputees than among civilians who had no wounds.

Nutritional Value of Margarine

Mr. R. W. SORESENSEN asked the Minister of Food what were the main oils used in the manufacture of margarine; what were their respective food values; to what extent vitamins were added in the course of manufacture; and the respective nutritional merits of one pound of standard margarine and butter. Major LLOYD-GEORGE gave him the following information on February 1: The main oils used in the manufacture of margarine are coconut, palm kernel, palm, and groundnut oils, which are of similar food value. Margarine sold for domestic purposes contains 450,550 international units of vitamin A and 90 international units of vitamin D per ounce. Vitamins are not added to margarine used for manufacture. The fat content and energy value of butter and margarine are almost the same. The vitamin content of butter varies with place of origin and season of production. An average vitamin A value is 14,000 international units per lb. compared with 8,000 in special margarine, and an average vitamin D value is 270 international units per lb. compared with 1,440 in special margarine.

Mr. SORESENSEN asked what was likely to be the standard form of margarine available, and if the Minister would consider placing on the labels of margarines some indication of their nutritional value. Major LLOYD-GEORGE said that after de-rationing better-quality margarine would be available, and there would also be a margarine the same as the standard margarine used to-day. He would look into the point about labels.

Acidity in Soft Drinks

Dr. BARNET STROSS returned to his charge that the acidity of "Cola" drinks was harmful (see *Journal*, February 6, p. 340), and supported it with the results of American investigations. Dr. McCay, who was professor of nutrition at Cornell University, New York, had stated in evidence before a Congress Committee in 1950 that human teeth immersed for two days in Coca-Cola became very soft. That, Dr. Stross said, he had proved for himself, with teeth provided for the experiments by two other M.P.s. Professor McCay had also deplored the use of carbonated drinks which were so acid, not only because of damage to teeth, but also because of peptic ulceration, and in the case of children because of the caffeine content. Dr. Stross said that he had not picked out Coca-Cola to make any specific attack on it alone. Other drinks—for example, apple juice, grape juice, sweetened grapefruit juices—had a high acidity, pH 3.1, which meant there was a risk of teeth erosion if they were taken in excess over a long period.

Dr. CHARLES HILL, Parliamentary Secretary, Ministry of Food, said that evidence had been produced that extracted human teeth left in Coca-Cola for 72 hours had lost weight due to the attack on the calcium. They were expected to infer that in the swift passage of acid drinks through the lips and down the throat there was likely to be comparable danger. Had the fluid used been fresh lemon juice the loss of weight would not have been 5 to 10%, but 35%. Had it been grapefruit juice, orange juice, a neutral solution of citrate, or even distilled water, there would have been a loss of weight. These teeth were extracted; there was no protective layer of mucin, no washing by alkaline salivary

juices. Such experiments were of little value either in determining the fortitude of the teeth or the power of the solution. As for the experiments on rats, to make a comparison with an adult one would have to conceive that an adult man drank 25 bottles of Cola a day.

The lower the pH below 7 the higher the acidity, and the assumption was that because the pH was 2.6 there was particular danger from this kind of drink. The Government chemist had worked out for him the pH values of other drinks. Orange barley was 3 in a dilution of one in three, lime juice cordial 2.8, lemon squash 2.75, grapefruit 2.7, orange squash 2.95. After investigations in this country it was reported to the Food Standards Committee in 1951 that British fruit cordials and squashes diluted with four parts of water as usually drunk had a greater erosive action than phosphoric acid drinks.

Dr. Hill did not exclude the possibility of publishing the formula of Cola drinks on the label, although when that was demanded for patent medicines the chemical formula on the labels conveyed nothing to the public except a sense of importance that was aroused in some people when they believed they were taking an unusually complicated medicine. The Food Standards Committee were going to scrutinize the ingredients and acidity of soft drinks generally, not from fear of danger to people's teeth but as a matter of routine because the Food Standards Order was out of date.

Byssinosis Experiments

Mr. H. BOARDMAN asked the Minister of Labour on February 2 how far progress was being made towards the prevention of byssinosis among workers in cotton mills. Mr. HAROLD WATKINSON, the Parliamentary Secretary, informed him that extensive research had been carried out for some years into the problem of preventing the emission of dust in cotton mills which might cause byssinosis. This had been done under the auspices of a joint committee appointed by the Chief Inspector of Factories, with assistance from the Shirley Institute and individual cotton mills. Some progress had been made, though the problem had not been finally solved. Improved methods of dust exhaustion were the subject of further experiment to determine their suitability for general application.

Mental Patients.—The numbers of persons detained in mental hospitals, homes, and hostels at December 31, 1952, were: voluntary 31,402 (10,518), temporary 332 (484), certified 117,407 (152,624). The equivalent figures for 1939 are shown in brackets.

The Acute Rheumatism Regulations, 1953.—In reply to a question about these regulations the Minister of Health explained that their purpose was to assess the value of notification of acute rheumatism and of other procedures of medical interest in the prevention and management of rheumatic heart disease. The areas selected for notification constituted a sufficient sample for this purpose.

Occupational Health Service.—When asked if the Minister of Labour had considered the views received from the National Joint Advisory Council on the subject of a comprehensive occupational health service Mr. Harold Watkinson, the Parliamentary Secretary, said the Minister had received separately from the parties on the council their views on matters arising out of the Dale report on the industrial health services. In the course of these observations proposals had been put forward relating to the development of a comprehensive occupational health service, and this was under active consideration.

Old Age Pensioners' Prescriptions.—The Minister of Health, replying to a question about the cost of supplying medicines to old age pensioners free of the prescription charge, said that many old age pensioners were already entitled to have the charges for prescriptions refunded. It was estimated that the additional cost of relieving all old age pensioners of these charges would be of the order of £900,000 a year.

Agene.—Asked when a decision was likely to be reached on a substitute for agene in flour, Major Lloyd-George stated that everything was being done to expedite the matter. Experiments were involved which had to be watched with great care.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending January 23 (No. 3) and corresponding week 1953.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Vital Statistics

Food-poisoning in England and Wales

An analysis¹ of reports obtained from medical officers of health and bacteriologists shows that 5,797 cases of food-poisoning were reported to the Registrar-General's office in 1951 and 5,885 in 1952. But the reports show that there were in fact over 11,000 cases in each of the two years; it seems likely that the true numbers are much higher. During the two years there were 715 outbreaks (two or more related cases in different families), 627 family outbreaks (two or more cases in one family), and 5,524 unrelated or sporadic cases. *Salmonellae* were isolated from 57% of the sporadic cases, from 34% of the outbreaks, and from 62% of the family outbreaks. The source was unknown in 43% of the sporadic cases, in 47% of the outbreaks, and in 28% of the family outbreaks. *Salmonella typhi-murium* was responsible for 2,804 (41%) of the incidents and had a peak incidence in the third quarter of each year. In the two years 69 deaths were reported, 65 due to salmonella infections, 2 probably due to *Cl. welchii*, and 1 to *Staph. aureus*; in one the causal organism was not found.

In only 509 of the 1,342 outbreaks and family outbreaks was the vehicle of infection reported, so that conclusions on the relative importance of different foods cannot be made. The percentage distribution of the various foods concerned in the 509 outbreaks was 66.4 for meat, 9.0 for sweetmeats, 7.9 for fish, 7.1 for eggs (mainly duck eggs), 2.9 for milk, 2.4 for vegetables, 2.4 for fruit, 1.0 for cheese, 1.0 for other forms of food. Processed and made-up meat foods were responsible for 76.3% of the cases attributed to meat.

The largest outbreaks due to milk were as follows: 600 children in Chard U.D., unpasteurized tuberculin-tested milk infected with *Salmonella dublin*; 200 children in Stoke Newington M.B., unpasteurized tuberculin-tested milk infected with *Staph. aureus*; 126 children in Lincolnshire, accredited milk and causal agent not found, but staphylococcal contamination suspected; 75 people in Whitby R.D., *Staph. aureus*.

In 243 of the 636 outbreaks in which the general public were involved the place where the food was obtained or eaten was given. Of these outbreaks 129 originated in canteens (85 of them school canteens); 39 in restaurants, hotels, cafés, etc.; 31 in various institutions; 28 in food shops; and 16 in private parties, hostels, etc. *Salmonella* infections were the causal agent in 14% of these outbreaks. In the 79 hospital outbreaks salmonellae were responsible for 73% of the cases.

The review of the 1951 and 1952 reports on food-poisoning shows that little or no headway has been made in the campaign for clean food. Processed and made-up meat foods account for more than one-half of the outbreaks, and the report suggests that manufacturers and caterers might respond to practical demonstrations better than to theoretical advice in lectures and publications. Duck eggs present a problem that needs some consideration, and it is suggested that they should be used only in foods which are submitted to a temperature of 100° C. for 10 minutes, or boiled for this length of time.

Infectious Diseases

The number of notifications of infectious diseases in England and Wales during the week ending January 23 increased by 223 for scarlet fever, from 915 to 1,138, and 112 for dysentery, from 378 to 490, and decreased by 154 for acute pneumonia, from 963 to 809, and 44 for measles, from 1,150 to 1,106.

The largest variation in the local trends of scarlet fever was a rise of 35 in Lancashire, from 125 to 160. 2,357 cases

of whooping-cough were notified, being 9 fewer than in the preceding week. The largest rises were 40 in Leicestershire, from 29 to 69, and 32 in Kent, from 93 to 125, and the largest falls were 44 in Warwickshire, from 187 to 143, and 36 in Hertfordshire, from 55 to 19. 18 cases of diphtheria, 3 fewer than in the preceding week, were notified: 9 of these cases were notified in Lancashire (Liverpool C.B. 8). Other areas with multiple notifications were Birmingham C.B. 3, West Ham C.B. 2, and Middlesbrough C.B. 2. The largest fluctuations in the incidence of measles were a rise of 89 in Cumberland, from 107 to 196, and falls of 76 in Staffordshire, from 204 to 128, and 33 in Surrey, from 76 to 43. The chief centres of measles in Cumberland were Whitehaven M.B. 93 and Ennerdale R.D. 72.

37 cases of acute poliomyelitis were notified. These were 3 more for paralytic and 6 fewer for non-paralytic cases than in the preceding week. The largest returns were Gloucestershire 8 (Bristol C.B. 3), Cornwall 3, Durham 3, Essex 3, and Lancashire 3.

The large rise in the notifications of dysentery was due to increases in existing outbreaks rather than to new centres of infection. The largest returns were Lancashire 121 (Swinton and Pendlebury M.B. 42, Bolton C.B. 20, Liverpool C.B. 11), London 100 (Islington 30, Shoreditch 12), Yorkshire West Riding 70 (Bradford C.B. 22, Leeds C.B. 14), Middlesex 62 (Hendon M.B. 16, Enfield U.D. 10), Sussex 17 (Hailsham R.D. 15), and Warwickshire 16 (Birmingham C.B. 16). The 178 cases in Scotland were notified in 16 areas: the largest returns were Glasgow 101 and Edinburgh 20.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus ————, the figures for 1953-4 thus ————. Except for the curves showing notifications in 1953-4, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Week Ending January 30

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,058, whooping-cough 2,240, diphtheria 16, measles 1,190, dysentery 572, acute poliomyelitis 22, paratyphoid fever 3, and typhoid fever 1.

Medical News

General-practitioner Research.—An investigation into the value of prophylactic antibiotics or sulphonamides in measles is the first piece of group research being undertaken by the College of General Practitioners, according to the College's "Research Newsletter No. 2" in the current issue of the *Practitioner*. Participation in this research is open to all those on the College's research register. In September an outbreak of an unidentified P.U.O. at Shere, in Surrey, allowed a trial of the "epidemic observation scheme." Those on the register were put on the alert, with the result that similar outbreaks were reported from other parts of the country and the progress of the epidemic was mapped. The Public Health Laboratory Service co-operated by carrying out virus studies on serum and faeces from some of the cases. In order to define the types of illness most likely to repay study by co-ordinated general-practitioner research, with the help of the Registrar-General's Department a survey of the nation's health is being planned. The idea is to analyse a representative sample of morbidity statistics collected over a year or more by general practitioners. In addition to these major schemes, the research register, in which the research interests of each member are recorded, is bringing together doctors with the same problems, and study groups are being formed. Three subjects are noted as particularly appropriate for group study—respiratory tract diseases, hereditary diseases, and psychosomatic disease. A recorder has been appointed to each group: Dr. John Fry (Beckenham), Dr. R. S. Yager (Scunthorpe), and Dr. K. M. Hay (Birmingham), respectively.

Darling Foundation Prize.—At the seventh World Health Assembly later this year Professor George Macdonald and Dr. G. Robert Coatney will receive jointly the Darling Foundation Prize (1,000 Swiss francs and a bronze medal) for their work on malaria. Professor Macdonald is director of the Ross Institute of Tropical Hygiene in London and is distinguished for his work on the epidemiology of malaria. Dr. Coatney, from Bethesda, U.S.A., is noted for his researches on antimalarial drugs.

H. M. Vernon Prize.—Dr. N. H. Mackworth, director of the Medical Research Council's Unit for Research in Applied Psychology at Cambridge, has become the first recipient of the H. M. Vernon Prize. The prize, which is from funds bequeathed by Dr. H. M. Vernon—himself a well-known worker in the field of industrial psychology—is to be awarded biennially by the council of the National Institute of Industrial Psychology for the most valuable research work in industrial psychology and physiology done by a British worker under 45 years of age. Dr. Mackworth is particu-

larly noted for his studies on the effects of climatic conditions on human behaviour.

Medical Press Congress.—The first congress of the Union Internationale de la Presse Médicale will be held in Turin on May 30 under the presidency of Professor T. Oliaro, director of *Minerva Medica*. Among the subjects already chosen for discussion are the question of abstracts of scientific papers, relations between the Press and the medical profession, the place of the film and microfilm in spreading medical knowledge, and the provision of medical news for the lay public. Papers will be presented by Professor L. Justin-Besançon (*Semaine des Hôpitaux*), Dr. A. Pichet (*Presse Médicale*), and Dr. H. Fiessinger. Other subjects will be announced later. Five prizes of 100,000 lire (£57) each will be presented during the congress for the best original papers to have appeared during the years 1952 and 1953 in journals belonging to the Union. Entries for these prizes must be sent in duplicate to Segretaria Generale del Congresso Internazionale della Stampa Medica, Corso Bramante, 83, Turin, Italy.

Rebuilding of St. Giles' Hospital, Camberwell.—The Minister of Health, Mr. Iain Macleod, opened a new operating suite at St. Giles' Hospital, Camberwell, on February 4. The hospital was severely damaged by bombing during the war, so that its pre-war complement of 800 beds is now barely 350. The first stage of the rebuilding, costing £75,000, is the erection of the new operating theatres and the complete renewal of the administration block. It is expected that a further £75,000 will be needed to replace the other damaged buildings.

Royal Commission on Mental Certification and Detention.—Three weeks ago we announced the appointment of Lord Percy of Newcastle as chairman of the Commission (January 23, p. 221). Now the Prime Minister has given the names of the members. The medical members are Sir Russell Brain, P.R.C.P.; Dr. T. P. Rees, medical superintendent, Warrington Park Hospital; Dr. D. H. H. Thomas, medical superintendent, Cell Barnes Hospital, St. Albans; and Dr. J. G. Wilson, M.O.H. of Cardiff. The lay members are Mrs. E. D. Adrian (wife of Dr. E. D. Adrian, P.R.S.); Mr. Claude Bartlett, president of the Confederation of Health Service Employees; Mrs. Braddock, M.P.; Mr. H. Hylton-Foster, Q.C., M.P.; Mr. R. M. Jackson, LL.D., Reader in Public Law, Cambridge; and Sir Cecil Oakes, member of the Central Health Services Council. The secretary of the Commission is Miss H. M. Hedley, Ministry of Health, 23, Savile Row, London, W.1.

French Government Exchange Scholarships.—Under the terms of a reciprocal arrangement with the Centre National de la Recherche Scientifique, the Medical Research Council invites applications from British workers in medical science, excluding clinical medicine, for two scholarships tenable at research institutions in France during the academic year 1954-5. The scheme is intended for young graduates in medicine or science who have already had some experience in a branch of medical science. Further details and forms of application may be obtained from the secretary, Medical Research Council, 38, Old Queen Street, London, S.W.1. The last date for applications is March 31.

Chesterfield Medal.—Inquiries about the examination for the Chesterfield Medal (in dermatology) should be made to the Dean, Institute of Dermatology, Lisle Street, Leicester Square, London, W.C.2, without delay. The closing date for entries is February 28.

Sir Macfarlane Burnet, F.R.S., director of the Walter and Eliza Hall Institute of Medical Research, Melbourne, has left Australia to take part in the Paul Ehrlich and von Behring centenary celebrations at Frankfurt. While there he will receive a von Behring Medal and prize for his work on virus diseases.

Professor John Yudkin has been appointed to the University Chair of Nutrition tenable at Queen Elizabeth College, London.

¹ *Monthly Bull. Minist. Hlth (Lond.)*, January, 1954.

Mr. William Doolin, Editor of the *Irish Journal of Medical Science* and of the *Journal of the Irish Medical Association*, has been appointed Professor of the History of Medicine in University College, Dublin.

Mr. G. A. Mason, Lecturer in Thoracic Surgery at King's College, Newcastle-upon-Tyne, has gone to Germany for a few days, under the Foreign University Interchange Scheme, to lecture at the Justus Liebig-Hochschule, Giessen.

COMING EVENTS

Professor A. W. Woodruff will deliver the Goulstonian Lectures on February 23 and 25 at 5 p.m. at the Royal College of Physicians. His subject is "The Natural History of Anaemia associated with Protein Malnutrition."

Dr. T. Cecil Gray will deliver the Joseph Clover Lecture at the Royal College of Surgeons, Lincoln's Inn Fields, on March 17 at 5 p.m. His subject is "Disintegration of the Nervous System."

Fourth International Course in Criminology.—This course, organized by the International Society of Criminology with the support of Unesco, will be held in London from March 24 to April 13 under the direction of Dr. Denis Carroll and Dr. Hermann Mannheim. The subject will be "Recent Advances in the Study and Treatment of Offenders." Applications to attend the course should be made at once to "Fourth International Course in Criminology," c/o I.S.T.D., 8, Bourdon Street, Davies Street, London, W.1. The fee is £7.

Week-end Course on the Rheumatic Diseases.—A course with lectures, ward rounds, and practical demonstrations will be held at the Rheumatism Unit of St. Stephen's Hospital, Fulham Road, London, S.W.10, on March 27 and 28. Further particulars may be obtained from the secretary, Fellowship of Postgraduate Medicine, 60, Portland Place, London, W.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Monday, February 15

LONDON UNIVERSITY.—At Physiology Theatre, University College, 5.30 p.m., special university lecture in Biochemistry by Professor C. Fromaget (Paris): Metabolism of Sulphur Amino Acids and the Cycle of Sulphur in Nature.
MEDICAL SOCIETY OF LONDON.—8.30 p.m., First Lettsomian Lecture, by Mr. N. C. Tanner: Surgery of Peptic Ulceration and its Complications.

Tuesday, February 16

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. C. C. Chesterman: Antimalarial Drugs—Their Action in Different Stages of the Malaria Parasite in Man.
EUGENICS SOCIETY.—At 26, Portland Place, W., 5 p.m., Galton Lecture by Professor F. A. E. Crew, F.R.S.: Eugenic Appraisal of the Welfare State.
ILFORD MEDICAL SOCIETY.—At King George Hospital, Ilford, 8.45 p.m., Dr. James H. Cyriax: Lumbar Disk Lesions.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. J. Wallace: Ano-genital Pruritus.
MANCHESTER MEDICAL SOCIETY.—At Medical School, Manchester University, 4.30 p.m., university lecture on the History of Medicine by Dr. Hugh Sinclair: Importance of Boerhaave in the Development of Medical Science.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Mr. R. K. Bowes: Clinical Significance of Amenorrhoea.
SOUTH-WEST LONDON MEDICAL SOCIETY.—At Bolingbroke Hospital, 8.30 p.m., Dr. J. Barrie Murray: Chronic Dyspeptic.

Wednesday, February 17

● **HARVEIAN SOCIETY OF LONDON.**—At Hammersmith Hospital, 8 p.m., clinical meeting.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Benign Tumours of the Corium.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. F. J. F. Barrington: Indications for the Treatment in Enlarged Prostate.
● **LONDON UNIVERSITY: DEPARTMENT OF EXTRA-MURAL STUDIES AND ATOMIC SCIENTISTS' ASSOCIATION.**—At Beveridge Hall, Senate House, 7 p.m., Dr. E. E. Pochin: Medical Uses of Atomic Energy.
MIDDLESEX COUNTY MEDICAL SOCIETY.—At Ashford Hospital, 3 p.m., clinical meeting; 4.45 p.m., Dr. K. D. Keele: Pain Sensitivity in Relationship to Clinical Syndromes.
MIDLAND MEDICAL SOCIETY.—At Queen Elizabeth Hospital, Birmingham, 8.15 p.m., clinical meeting.
OXFORD UNIVERSITY.—At Radcliffe Infirmary, 5 p.m., Litchfield Lecture by Sir Geoffrey Jefferson, F.R.S.: Neurology of the Trigeminal Nerve.
ROYAL MICROSCOPICAL SOCIETY.—5.30 p.m., Dr. R. G. White: Microscopy of Antigens and Antibodies within Tissues by the Use of Fluorescent Antibody.

Thursday, February 18

BRITISH INSTITUTE OF RADIOLOGY.—8 p.m., Dr. W. M. Levitt: Large Volume Radiotherapy; Dr. R. Bodley Scott: Large Volume Irradiation: A Physician's Assessment.
BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. P. M. D'Arcy Hart: Chemotherapy of Tuberculosis.
CAMBRIDGE UNIVERSITY.—At Zoological Laboratory, Downing Street, Cambridge, 5 p.m., Dr. R. R. Race, F.R.S.: Blood Groups and Their Inheritance.
EDINBURGH CLINICAL CLUB.—At 7, Drumsheugh Gardens, 8 p.m., Mr. G. A. Pollock: Surgical Osteoarthritis of the Hip Joint.
● **INSTITUTE OF CHILD HEALTH.**—5.30 p.m., Dr. Barbara Woodhead: Advice in the Infant Welfare Clinic.
LIVERPOOL MEDICAL INSTITUTION.—8 p.m., Dr. J. D. Hay: Diagnosis of Congenital Heart Disease; Dr. H. G. Farquhar: Congenital Heart Disease in Infancy.
LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Medical Society of London, 8.30 p.m., Professor W. C. W. Nixon: Physiological and Clinical Aspects of Uterine Action.
LONDON UNIVERSITY.—At Wright-Fleming Institute Lecture Theatre, St. Mary's Hospital Medical School, 5 p.m., special university lecture in medicine by Professor L. J. Witts: Changes in the Alimentary Tract in Anaemia.
NORTH-WESTERN TUBERCULOSIS SOCIETY.—At Manchester Royal Infirmary, 5 p.m., Professor F. R. G. Heaf: Present Position of B.C.G. Vaccination.
OXFORD UNIVERSITY.—At Southfield School, Glanville Road, Cowley Road, Oxford, 8 p.m., Dr. A. G. M. Weddell: Science and Medicine.
ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—At 26, Portland Place, W., 7.30 p.m., Dr. M. G. P. Stoker and Dr. B. P. Marmion: Clinical Picture and Epidemiology of Q Fever. A discussion will follow.
ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Dr. R. Coope: Tuberculous Enlargement of Intrathoracic Lymph Nodes.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., psychiatry demonstration by Dr. D. Curran.

Friday, February 19

BRITISH INSTITUTE OF RADIOLOGY.—5 p.m., meeting of medical members.
FACULTY OF RADIOLOGISTS.—At Royal College of Surgeons of England, 4 p.m., Radiotherapy Section Meeting. Dr. T. P. Fox: The Art of the Article.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. S. C. Gold: Lupus Erythematosus.
KENT AND CANTERBURY HOSPITAL.—8 p.m., clinical meeting.
LEEDS AND WEST RIDING MEDICO-CHIRURGICAL SOCIETY.—Sir Geoffrey Jefferson, F.R.S.: When Has Headache a Special Significance?
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Mr. J. C. R. Hindenach: Congenital Dysplasia of the Hip.
● **ROYAL INSTITUTION.**—9 p.m., Dr. Karl T. Compton, D.Sc., Ph.D., LL.D. (Massachusetts): High Voltage for Cancer Therapy and Food Sterilization.
ROYAL MEDICAL SOCIETY. Edinburgh.—8 p.m., Dissertation by Mr. J. A. Stewart: Mitral Valvotomy.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, 5.30 p.m., Public Lecture by Dr. W. S. Feldberg, F.R.S.: On Some Physiological Aspects of Histamine.

Saturday, February 20

BIOCHEMICAL SOCIETY.—At London School of Hygiene and Tropical Medicine, 11 a.m., symposium: Chemical Pathology of Animal Pigments.

APPOINTMENTS

NORTH-EAST METROPOLITAN REGIONAL HOSPITAL BOARD.—A. S. Crawford, M.D., F.F.A.R.C.S., D.A., Part-time Consultant Anaesthetist, A. Nelson-Jones, M.D., M.R.C.P., Part-time Consultant Physician, and F. R. Sutton, M.B., B.S., F.R.C.S., Part-time Consultant Surgeon, all at Rush Green Hospital, Romford; D. P. Choyce, M.B., B.S., F.R.C.S., D.O.M.S., Part-time Consultant Ophthalmic Surgeon, Southend General, Rochford General, and Runwell Hospitals and Southend Eye Clinic; H. W. Holland, M.B., B.S., M.R.C.P., D.M.R.D., Part-time Consultant Radiologist, Chelmsford Group of Hospitals.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Ostlere.—On February 3, 1954, at Oxford, to Mary Ostlere (formerly Pattern), M.B., M.R.C.P.Ed., D.A., wife of Gordon S. Ostlere, M.B., B.Chir., D.A., a son.

DEATHS

Ahern.—On January 12, 1954, John Maurice Ahern, M.B., B.Ch., of 10, Ennerdale Road, Kew Gardens, Surrey, late of Liverpool, and Parkhurst, Isle of Wight.
Boyd.—On January 6, 1954, in hospital, James Wood Boyd, M.B., C.M., of 7, Carwinshoch View, Ayr, late of Fallowfield, Manchester, aged 84.
Brims.—On January 13, 1954, Donald Brims, M.B., Ch.B., of 106, West Savile Terrace, Edinburgh.
Edwards.—On January 15, 1954, at Huntington Court, Kington, Herefordshire, Charles Derwent Edwards, M.C., M.D., D.P.H.
Evans.—On January 14, 1954, at Green Hill, Carmarthen, Walter Stuart Evans, M.R.C.S., L.R.C.P., Lieutenant-Colonel, R.A.M.C., retired, aged 64.
Ferguson.—On January 14, 1954, at St. David's Wing, Royal Northern Hospital, London, N., Thomas Ferguson, D.S.O., M.B., Ch.B.
Fielder.—On January 11, 1954, at Cranwell, Rushall, Tunbridge Wells, Kent, Frederick John Fielder, M.D., late of Lockerbie, Brixton Hill, London, S.W., aged 83.
Geoghegan.—On January 15, 1954, at the Churchill Hospital, Oxford, Basil Geoghegan, M.R.C.S., L.R.C.P., Surgeon Lieutenant-Commander, R.N.
Glanville.—On January 15, 1954, at North Street House, Emsworth, Hants, Llewellyn Stanley Howard Glanville, M.D.
Hill.—On January 16, 1954, at the War Memorial Hospital, Selby, Yorks, William Bertram Hill, M.D., D.P.H., of 14, Leeds Road, Selby, aged 74.
Salter.—On January 5, 1954, in hospital, Mombasa, Charles Edward Salter, M.D., F.R.C.S., of Nairobi, Kenya, late of Scarborough, Yorks, and Exmouth, Devon, aged 85.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Blackheads

Q.—A girl of 12 suffers from severe and persistent blackheads on the face. What are the predisposing factors, and how is the condition best treated?

A.—Blackheads at the age of 12 years are caused by the character and amount of sebum excreted by the sebaceous glands under the influence of hormonal activity. This provokes a hyperkeratosis affecting the whole of the epidermis of the affected parts, but naturally most marked at the orifices.

Presuming that the patient is normal in other respects, local treatment is probably the most important and should consist in regular and frequent washing with soap and hot water, and perhaps the occasional use of a weak solution of a detergent such as 1% cetrimide. The application at night of a paste containing sulphur and resorcin, starting with 2% of each and gradually increasing to 6%, will facilitate the shedding of the blackheads by exfoliation. Exposure to ultra-violet light to produce erythema and peeling is also effective, or small fractional doses of x-rays may inhibit the activity of the glands, but such treatment should be prescribed only under expert supervision.

If expression of blackheads is attempted by means of a comedone extractor it should be done with care, otherwise trauma in the region of glands may provoke inflammation or infection.

The taking of vitamin-B complex (on empirical grounds) and small doses of thyroid extract (½ gr.—16 mg.), and the avoidance of chocolate and cocoa, are sometimes desirable.

Abdominal Testicles and Fertility

Q.—Is there any treatment for a man of 29 with abdominal testicles who has on two occasions shown azoospermia on examination of the seminal fluid? He was born with undescended testicles, but by puberty they had reached the inguinal canals. An operation at 18 showed that the testicles, although apparently normally developed, had too short vessels for them to be brought into the scrotum. They were therefore returned to the pelvic cavity extra-peritoneally. He now wants to have children.

A.—With exceptions which are so few as to be of no significance, it may be accepted as an axiom that, unless the testes are within the scrotum at the time spermatogenesis should commence, irreparable damage is done to the germinal epithelium, so that placing them within the scrotum at a later date will not lead to spermatogenesis. Even had the length of the cord allowed the testes to be placed within the scrotum at the age of 18, no hope of a successful outcome from that operation could have been entertained. The view which is becoming generally accepted now is that treatment for undescended testicles should begin at an early age, perhaps at 3 to 5 years. If treatment with chorionic gonadotrophin fails to bring about testicular descent, surgical correction of the condition should be considered without undue delay. In any event, the usual effect of gonadotrophin treatment is to cause growth of the spermatid cord, which, should surgery become necessary, makes the operation easier.

One final point: it is quite probable that in many cases the congenital anomaly manifested as cryptorchidism often includes intrinsic testicular defect, so that even after successful correction of the maldescent spermatogenesis may be less than adequate.

Drugs for Hypertension in Pregnancy

Q.—What place have hypotensive drugs, such as the methonium compounds, in the treatment of hypertension in pregnancy?

A.—Many substances such as hexamethonium tartrate and bromide and tetraethylammonium chloride and bromide have been tried, and the general experience is that the results are very disappointing. They have a negligible effect on hypertension which is part of eclampsia and pre-eclampsia. In cases of chronic hypertension complicated by pregnancy the fall in blood pressure which results from their intermittent use is very short-lived, and side-effects usually prevent repeated or continued administration. For all practical purposes, therefore, they are of little value in pregnancy hypertension.

Assali and Suyemoto¹ have discussed this subject at some length, and they also report on trials of hydrazinophthalazine and thiophanum compounds. They conclude that a single intravenous injection of 30 to 40 mg. of the former produces a significant fall in blood pressure in true pregnancy toxæmia, and the effect may last as long as 24 hours. It is not, however, very effective in essential hypertension. Thiophanum compounds have a similar but stronger action than tetraethylammonium salts, and in essential hypertension they cause a fall in blood pressure which is sustained for 3 to 10 minutes after a single intravenous injection. A continuous intravenous infusion is necessary to produce a prolonged effect, but there are difficulties in employing this technique. Thiophanum compounds have little effect on hypertension associated with pre-eclampsia and eclampsia, no matter what method of administration is used.

It may be added that the alkaloids of veratrine, previously out of favour, are being used again in certain clinics and encouraging results are recorded, especially in eclampsia and severe pre-eclampsia.

Pica in Pregnancy

Q.—What accounts for perversion of the appetite during pregnancy? I have a patient who eats coal when pregnant. Is any treatment likely to be effective?

A.—There is no known anatomical or functional change in the alimentary tract or sense organs to account for bizarre tastes developed by some women during pregnancy. The usual explanations have a psychological basis. It is said, for example, that such women may be found to have shown similar traits at an earlier stage in life and that during pregnancy, and possibly because of some inward conflict or sense of insecurity, they change places with their baby and revert to infantile behaviour. Some authorities invoke a regression to the "oral stage" in development, and a craving for certain articles such as bananas, slate pencils, berries, or caviar is said to reflect ideas of oral impregnation—the particular article representing male or female genitalia. Others, however, point out that perversion of the appetite during pregnancy has been recognized throughout the ages in all parts of the world, and that its origin may lie far back in the ancestry of the mind. It is a common belief amongst primitive peoples that failure to satisfy "longings" results in miscarriage and physical or mental defects in the child. From this it can be argued that the eating of strange articles is blindly purposeful, and that it has as its basis the desire to supply a special need to the foetus or even to give it life. Sometimes an attempt is made to draw an analogy with the habit of a carnivorous animal which occasionally instinctively eats grass or other substance outside the range of its ordinary tastes when it suffers from dietetic deficiency.

These are the sort of views which have been expressed from time to time, and the reader may or may not find them acceptable, or applicable to certain cases. One of the difficulties in accepting them is that a woman some-

times shows perversion of appetite before she has any suspicion that she is pregnant.

There is no specific remedy for pica during pregnancy, nor is any treatment necessary unless the taste is for something which is obviously harmful.

Threadworms and Ammoniated Mercury Ointment

Q.—In the treatment of threadworms I have applied ammoniated mercury ointment (N.F., 1952) to the perianal region and been dismayed to see threadworms actively wriggling across the anointed area. Is this ointment ovicidal, since it is not vermifugal? Is an alternative vermifugal ointment available?

A.—The ointment is used for two purposes: in an effort to kill worms as they deposit their eggs on the perianal skin, and to immobilize eggs and prevent their being disseminated into the clothing and elsewhere. The questioner possibly comes to the conclusion that the ointment is not vermifugal on evidence which is too slender, in that it is not stated for how long the worm was observed to live after wriggling across the anointed area. No alternative vermifugal ointment has as yet been shown to be of value.

White Cell Count in Appendicitis

Q.—What is the value of the white cell count in cases of acute appendicitis? Is it true to say that a rising white count indicates deterioration and that a falling white count shows resolution?

A.—The white cell count is of limited value in the diagnosis of appendicitis. The experienced surgeon usually places little reliance on this investigation, and the inexperienced is not uncommonly seriously misled by it. In nine out of ten cases a diagnosis of appendicitis can be confidently made by clinical means, and in those cases where there are difficulties in diagnosis they are unlikely to be resolved by the white cell count. To take but one example, acute non-specific mesenteric adenitis is clinically similar to appendicitis and commonly gives rise to a leucocytosis of 15,000 or 20,000 with 80% neutrophils.

A rising white cell count is by no means indicative of deterioration and may be seen in a patient who is forming an abscess and whose general condition is improving. On the other hand, in the patient who starts with a leucocytosis, a falling white cell count usually means resolution.

In conclusion, it should be remembered that many a patient with a gangrenous appendix has a normal or but slightly raised white cell count, and in the aged or the very young the count may be especially misleading.

Chlorbutol and the Nose

Q.—What is the action of chlorbutol on the nasal mucosa, and its value in the treatment of nasal disease?

A.—Chlorbutol is a mild sedative and analgesic, and has local analgesic properties. It is also a fungicide. A 1% solution in mineral oil has formed the basis of many popular nasal sprays, though in recent years both chlorbutol and mineral oil have declined in popularity as nasal medicaments. It is used in the nose for its antiseptic, sedative, and analgesic properties; though it is possible that in acute rhinitis the nasal mucosa is further irritated by the volatile preparations, such as menthol and camphor, which are so frequently incorporated with oily solutions of chlorbutol for nasal use.

Deafness from Streptomycin

Q.—What is the prognosis in the deafness caused by streptomycin therapy? For how long may improvement be expected? Is a hearing-aid useful in these cases?

A.—Prolonged treatment with streptomycin, particularly if the di-hydro compound is used, may result in deafness. The original calcium compound of streptomycin was found to be vestibulo-toxic, but only in very large doses or over a prolonged period was it cochleo-toxic. In order to avoid this undesirable property the di-hydro compound was developed, but unfortunately this has a selective affinity for the

cochlear apparatus. As a rule, it has this effect only if more than 1 gramme daily is given over a period of at least three weeks. Any improvement in hearing following deafness due to streptomycin therapy usually takes place within a few weeks of the withdrawal of the drug. After six months it is most unlikely that any further improvement will occur. The amount of help that can be expected from a hearing-aid will, of course, depend upon the quantity and quality of the hearing which remains. Where the hearing has been seriously affected, there often seems to be some recruitment, which means that the patient will not readily tolerate amplification, and so a hearing-aid may not be of great help. Nevertheless, it should be tried in combination with speech reading, for which special lessons will be needed.

Splenectomy for Leukaemia

Q.—Is splenectomy ever indicated as a palliative measure in cases of leukaemia? If so, does it have any effect in prolonging life?

A.—Although splenectomy has been explored for the treatment of leukaemia it has no therapeutic value and does not even serve as a palliative measure. The reason for its trial was probably the extremely satisfactory response in this disease to low-dose splenic radiation. Irradiation of the spleen remains, therefore, the standard treatment for this disease, although various chemotherapeutic agents are now also used, some of equal but certainly of no greater value.

NOTES AND COMMENTS

"Stripping" for Varicose Veins.—Mr. R. ROWDEN FOOTE (London, W.1) writes: In the controversy as to the value of the stripping of varicose veins ("Any Questions?" December 12, 1953, p. 1334), your expert, when criticizing the method, asks, "... How often does deep thrombosis actually occur ... ?" This is something which we are fortunately able to tell him. Among the very numerous reports the following are typical: Linton¹ had one case of deep vein thrombosis in a series of 500 patients. Fenney² obtained an 86% excellent result in a series of 150 limbs without complication. In a series of 250 limbs I have had one case of severe deep vein thrombosis, which reacted to anticoagulant therapy with full recovery. The method cannot be blamed in this case, however, since the instructions regarding immediate mobilization of the limb post-operatively had not been carried out. Finally, Warren, of West Roxbury, in a personal letter tells me that he has had one mild case of deep vein thrombosis in a series of 300 limbs, while using a technique in the main similar to my own. A careful technique is all-important, and I have brought out these points in a film of this method which I made in 1952.³ Sclerosants at the time of operation are more likely to produce deep vein thrombosis than the stripping technique. The performance of local ligations merely spoils the field for the eradication of the varices by stripping.

The Advantages of the non-irritating adhesive used in PoroPlast

Arm photographed after removal of ordinary porous elastic adhesive bandage applied on sensitive skin for 24 hours

Arm of same subject after 7 days' application of non-irritating PoroPlast.

The possibility of skin irritation is always present when applying adhesive bandages. This varies widely from patient to patient, but even the mildest reaction may bring serious discomfort. The risk can be minimized, but porosity alone is not sufficient. PoroPlast has many *additional* advantages.

No irritating solvents nor the irritating resins which are usually embodied in elastic adhesive bandage.

No rubber. The plaster mass and the cloth used in PoroPlast are completely free of rubber.

Porous over its whole surface, for ventilation and permeation of secretions.

The same characteristics of elasticity, stretch,

and compression as in standard elastic adhesive bandages.

Same Price. The advantages of PoroPlast are obtainable at Standard Prices. Widths 2½ in. and 3 in. (5-6 yds. stretched).

N.H.S. Freely available for prescription under the name "PoroPlast."

THE DIAGNOSIS OF THYROTOXICOSIS*

BY

E. J. WAYNE, M.D., Ph.D., F.R.C.P.

Professor of Pharmacology and Therapeutics, University of Sheffield; Physician, Sheffield Royal Infirmary

Parry first described an association between thyroid enlargement and cardiac disease in 1825, and in 1835 Graves published his account of three cases of "violent and long-continued palpitations in females in each of which the same peculiarity presented itself, viz., enlargement of the thyroid gland." Each cited a case in which exophthalmos was present. It is, however, to Basedow, in 1840, that we owe the first complete clinical description of the disease which, in Europe, still bears his name. All the symptoms except tremor and most of the physical signs were described so vividly and accurately that little of importance has been added since. By comparison Sattler's book, published in 1908, though invaluable in providing information about the progress of the disease before any effective treatment was available, gives a picture which is out of perspective.

Perhaps I should apologize for retreading in this lecture much well-trodden ground. I hope, however, to deal in particular with the problem of diagnosis in the doubtful case and to discuss the value of modern laboratory tests, especially those which make use of radioactive iodine. I shall also consider some of the manifestations of thyrotoxicosis in more detail, especially where recent work has shed light on their mechanism.

Thyrotoxicosis is a relatively common disorder. It occurs in all parts of the world, but is especially frequent where endemic goitre is prevalent. Derbyshire has for long been recognized as such a district, and many of our cases have come from this region. It was this local concentration of patients that aroused my interest and provided the clinical opportunities for these studies.

The importance of suspecting the presence of thyrotoxicosis and of carrying out full clinical and laboratory investigations to establish the diagnosis cannot be over-emphasized. The advance in therapeutic measures to deal with this disease has been exceedingly rapid. It is now ten years since Astwood (1943) first treated thyrotoxicosis successfully with thiourea, and the drugs in this series have given us a powerful tool with which we can almost always confirm or refute the diagnosis without subjecting the patient to forms of therapy which permanently destroy a large portion of the gland. Once the diagnosis has been firmly established other forms of treatment are available and we can offer our patients an

excellent prospect of permanent recovery. Improved surgical and anaesthetic techniques have greatly reduced the risks of operation, and no patient is too ill to drink a therapeutic dose of radio-iodine. These rich opportunities in the therapeutic field impose a duty on the physician not to overlook any case in which thyrotoxicosis may be present.

In a florid case the diagnosis is obvious and can be made by the junior clinical clerk who has spent only a few weeks in the ward. On the other hand, some cases of thyrotoxicosis do not present all the classical features of the disease, and in them the diagnosis may be overlooked. This especially happens when the more prominent facial signs are lacking and there is no gross enlargement of the thyroid gland. In such circumstances the diagnosis may be difficult, for it is common knowledge that many of the clinical features associated with thyrotoxicosis may occur in a wide variety of disorders. I refer to such non-specific features as, for example, loss of weight, "nervousness," and tachycardia. Furthermore, the more definite manifestations which are often clearly associated with thyrotoxicosis may occasionally be seen in persons with normal thyroid function. Signs such as goitre, exophthalmos, and lid lag fall into this category.

Grouping of Patients

As the suspicion of the presence of thyrotoxicosis must first be assessed by the presence of some of these signs and symptoms, their incidence and diagnostic significance have been investigated more fully. This has involved dividing the patients with suspected thyrotoxicosis into two definite categories, "toxic" and "non-toxic." Such a distinction may be difficult to make and yet is essential for the practising physician. The former group essentially comprises those who will be benefited by specific therapy for thyrotoxicosis, while in the latter it is clearly not indicated. It is also of interest and importance to inquire into the prevalence of some of the clinical features often associated with thyrotoxicosis amongst people not suspected of having any thyroid disorder. We have accordingly studied the following three groups of subjects.

Group 1.—Patients referred to the thyroid clinic and shown after full investigation to be indisputably thyrotoxic. Some of these patients had clinically obvious thyrotoxicosis, but the majority had presented diagnostic difficulties to at least one clinician. The diagnosis was based on at least two radio-iodine criteria—namely, the four-hour uptake by the gland

*The Bradshaw Lecture delivered before the Royal College of Physicians of London on November 12, 1953.

and the 48-hour protein-bound activity in the plasma. If these were inconclusive or if the patient had received previous therapy, the cases were further investigated before a final decision was made. There were 90 patients in this group.

Group 2.—Patients referred to the thyroid clinic as possible cases of hyperthyroidism but finally shown to be non-toxic—72 patients fell into this group.

Group 3.—This comprised 90 normal individuals drawn so far as possible from the same social class and with the same age and sex distribution as the thyrotoxic cases. None was receiving medical attention.

The individuals in these three groups have been asked a standard set of questions and the presence or absence of certain physical signs has been recorded. Only two clinicians carried out the investigation. Fig. 1 shows

FIG. 1.—Age and sex distribution in non-toxic, and toxic and normal cases.

the age and sex distribution in the normal controls and the thyrotoxic cases and in the non-toxic group. The distribution follows the usual pattern in thyrotoxicosis. Details of the investigation will be published elsewhere (Weetch, 1954) and I shall give only a selection of the figures and a summary of our conclusions. Table I

TABLE I.—Incidence of Signs and Symptoms in Thyrotoxic (T.), Non-toxic (N.T.), and Control (C.) Cases

Symptoms	T.	N.T.	C.	Signs	T.	N.T.	C.
Dyspnoea on exertion	81	61	40	Goitre	87	56	11
Palpitation	75	75	26	Diffuse enlargement	49	37	11
Tiredness	80	68	31	Nodular	32	14	0
Preference for cold	73	53	41	Single adenoma	4	3	0
Excessive sweating	68	54	31	Exophthalmos	34	11	2
"Nervousness"	59	54	21	Lid lag	62	24	16
Appetite:				Hyperkinetic	39	22	9
Increased	32	1	2	Finger tremor	66	54	26
Diminished	13	14	3	Hands:			
Weight:				Sweating	72	54	22
Loss	52	27	2	Hot	76	40	44
Gain	4	7	16	Auricular fibrillation	19	8	0
Bowels:				Regular pulse rate over 90/min.	68	47	19
Diarrhoea	8	2	0				
Constipation	15	20	21	Average pulse rate, Beats/min.	100	85	78
Menses:							
Excessive	3	12	6				
Scanty	18	9	3				

shows a selection of the results of the analysis of symptoms and signs in the different groups. The signs recorded are necessarily only those which could be elicited without a full physical examination on the normal control group.

History-taking

It should be emphasized that this investigation was not made in an attempt to discover the commonest symptoms and signs in obvious cases of thyrotoxicosis, but to try to find out why there had been difficulty in separating doubtful cases into toxic and non-toxic groups on purely clinical grounds. It was decided to include a group of normal individuals when it became apparent that with some symptoms there was often remarkably little difference in the replies given by the toxic and non-toxic groups. The questions were asked in the form, "Do you become unduly breathless on exertion?" "Do you tire easily?" "Do you prefer hot or cold weather?" and it is the answers to these questions which are recorded in the tables. Patients could usually give a date of onset of their symptoms, but the answers of the normal controls to the same questions varied, some having "always been like that" and others stating that "it has come on recently."

An incidental illuminating feature of this investigation was the light it threw on the art of history-taking. I can strongly recommend to any physician with a special interest in some disease, as, for example, pulmonary tuberculosis, that he put his usual questions to a group of patients with chronic anxiety or to women at the menopause. He will be surprised at the number of positive answers he receives. Yet I do not think that the experienced physician would misinterpret these replies. It is, however, this problem which confuses our clinical clerks and house-physicians, who find it far more difficult to know whether a positive answer to a question is significant. They also have less skill in framing the appropriate supplementary questions, and little experience in assessing the patient's personality as a whole. My experience in completing the forms which were used has confirmed my suspicion that methods of history-taking which involve the use of a set list of symptoms are inherently unsatisfactory.

The two surprising features of the analysis are the high incidence of many symptoms in both the non-toxic and the control groups. We believe the explanation lies in the large number of women, and especially of women at or not far past the menopause, that are present in both groups, and in the high proportion of patients with anxiety states in the non-toxic group. We have analysed separately the figures for males and females, and Figs. 2, 3, and 4 illustrate the relative frequency of three symptoms in the toxic, non-toxic, and control groups when they are broken down in this way. In the control group positive answers were given much less frequently by males. In the non-toxic group this was true of most but not of all symptoms. In thyrotoxicosis, on the other hand, the proportions of males and females with symptoms were roughly equal. This was true of all symptoms except hot flushes, which were, as would be expected, much commoner in females in all the groups. A separate analysis of the answers of women over the age of 50 showed with most symptoms a still greater difference from the males, but the numbers were too small to be able to show a statistically significant difference between women of different ages.

I shall discuss the significance of the various signs and symptoms individually, indicating those which have the greatest diagnostic value, but it may be helpful to emphasize again that the comparison is essentially between a group of thyrotoxic patients, many of whom were not severely ill, a cross-section of the community of similar age and sex distribution, and a group of patients, usually with goitre, exophthalmos, auricular fibrillation, or persistent tachycardia, many of whom had in addition the symptoms of chronic anxiety or of the menopause.

Clinical Manifestations of Thyrotoxicosis Considered Separately

I now propose to discuss the clinical aspects of thyrotoxicosis so far as they illustrate points of special diagnostic value.

Family History

There is an undoubted familial tendency to thyrotoxicosis (Rundle, 1941), but this is also true of simple goitre (Brain, 1926). The disease has been reported in identical and in dissimilar twins (Neff, 1932; Bowers, 1948; Bartels, 1953). Martin (1945) and Bartels (1953) conclude that Graves's disease is inherited in a dominant manner. Martin and Fisher (1951) could, however, find no evidence of a hereditary influence in toxic nodular goitre, but Bartels disagrees with this conclusion. Occasionally the presence of thyroid disease in a relative may direct the physician's attention towards a correct diagnosis, but usually little help is derived from the family history.

Psychological Features

In his Bradshaw Lecture last year Bomford (1953) drew attention to the importance of studying disease by psychological as well as by physical methods. Thyrotoxicosis would certainly seem to qualify as a disease with psychological aspects. Sitting in a clinic devoted to the supervision of treated cases, one can hardly fail to be impressed by the unusual temperament of those who have been cured of the somatic side of their disorder. Moreover, a previously thyrotoxic patient who has developed hypothyroidism tolerates the condition far less well than one who has developed the disease spontaneously and becomes irritated with a body which refuses to carry out efficiently the dictates of a still relatively active mind. A psychosomatic theory of thyrotoxicosis has been developed by Ham *et al.* (1951). They find that the condition tends to occur in individuals frustrated in early life who make continued efforts towards premature self-sufficiency, and when these fail develop chronic anxiety. However sympathetic one may be to the psychosomatic approach one cannot help feeling that its exponents would strengthen their case if they could foretell, even occasionally, which of the many patients with early frustration and anxiety will develop thyrotoxicosis and which are more likely to develop some other psychosomatic manifestation such as peptic ulcer, colitis, or asthma. In the few people I have known personally before they developed thyrotoxicosis I certainly would have ventured no prophecy.

A history of mental shock or emotional strain is relatively common in this disease, although patients who develop anxiety states may have been subjected to equally severe stress. It is said that the disease tends to occur at the landmarks in a woman's sexual life—puberty, engagement, marriage, pregnancy, and the menopause—but few women are far removed from one of these events. Some acute cases are clearly associated with physical trauma or pregnancy, but in many the history of a direct emotional stimulus is absent.

It is clear that though the psychological features may be of considerable importance in the management of a case of thyrotoxicosis they are of little or no assistance in the establishment of a diagnosis.

Goitre

The high proportion of our cases in the non-toxic group who are recorded as having a goitre indicates that this is the commonest sign which gives rise to the suspicion of thyrotoxicosis. It must, however, be remembered that Sheffield lies at the tip of an area in which goitre is known to be common (Campbell, 1927), and this presenting feature may not be so common in other parts of the country. A bruit over the gland is frequently heard in severely thyrotoxic individuals but is often absent in milder cases and in toxic nodular goitres. The 11 patients in the control group recorded as having diffuse enlargement of the thyroid gland were all women, and though the abnormality was slight it might have been regarded as significant if they had presented other features of toxicity.

The problem of the distinction between thyrotoxicosis with diffuse glandular enlargement, with multiple nodules, or with a single adenoma is a difficult one. Cope *et al.* (1947) have produced evidence that some single adenomata may take up

most of a tracer dose of radio-iodine while the remainder of the gland takes up very little. It is suggested that such tumours are analogous to the physiologically overactive adenomata of the islets of Langerhans or of the parathyroids, and function independently of the pituitary gland. They are rare, constituting, as in the present series, about 5% of all goitres. The common toxic multinodular goitre, on the other hand, contains nodules which have usually lowered functional activity, and the thyrotoxicosis arises from overactivity of the paranodular tissue. It is, moreover, not unusual to find adenomata in the apparently diffusely enlarged gland of Graves's disease. There is often no clear distinction, and the manifestations of thyrotoxicosis, apart from a few such as the eye signs and muscular weakness, are the result of an excess of circulating thyroid hormone and can be imitated in the normal individual by heavy dosage with thyroxine. Crile (1949), writing from a surgeon's point of view, concludes that the "fundamental issue is the age of the patient rather than the presence or absence of nodules in the thyroid." I feel sure that this is the correct approach and that the distinction between thyrotoxicosis with diffuse goitre and exophthalmos, on the one hand, and toxic nodular goitre, on the other, is worth making only when it affects the management of the case.

Eye Signs

Exophthalmos was present in about a third of our thyrotoxic cases, and, though present in 11%, was found in equal degree in only 8% of the non-toxic group, which included some cases of previously treated thyrotoxicosis. Two members of the control series showed exophthalmos of slight degree, and it should be remembered that this may be a family characteristic. We have not recorded lid retraction separately, but the distinction between lid retraction and exophthalmos, which was first pointed out by Pochin (1938), is important, since the former is much more likely to disappear after therapy (Eden and Trotter, 1942).

It has long been clear that exophthalmos is not caused simply by excess of circulating thyroid hormone, since it is absent in many cases of severe thyrotoxicosis and may be present in its most virulent form in persons with normal thyroid function. It was pointed out by Russell Brain (1945) that males are far more liable than females to develop severe exophthalmos, especially after thyroidectomy. In our series exophthalmos was twice as common in males as in females. So far as the mechanism of exophthalmos is concerned it has been suggested that the thyroid-stimulating hormone of the anterior pituitary (T.S.H.) exerts an influence not only on the thyroid gland but also on the retro-orbital tissues. Rawson *et al.* (1946) have shown that T.S.H. is normally inactivated but not destroyed by the cells of the thyroid gland and that in thyrotoxicosis the degree of inactivation is increased. Some patients, however, are thought to have thyroids less capable of effecting this oxidation, and the excess of active T.S.H. is then capable of affecting the retro-orbital tissues. No simple explanation can cover all the cases nor explain in particular why patients with intact pituitary function developing myxoedema do not exhibit exophthalmos. The possibility that two separate hormones are involved has been greatly strengthened by the recent observations of Dobyns and Steelman (1953), who have been able to obtain from extracts of anterior pituitary two hormones, one of which stimulates the thyroid gland of chickens and another which produces exophthalmos in *Fundulus*, a type of minnow. If further work confirms these separate effects in mammals, much that is at present obscure will be explained.

The tendency for exophthalmos to become progressive in a case of thyrotoxicosis seems to be related to the speed with which the concentration of circulating thyroid hormone is reduced. In our cases orbitonometric observations of the degree of exophthalmos have shown that after radio-iodine treatment, which produces its effects slowly, there is less tendency for exophthalmos to increase than after methylthiouracil or thyroidectomy (Ferguson, 1951).

Lid Lag

This was present in all our toxic and non-toxic cases with exophthalmos, but was also seen in an equal number of patients without exophthalmos. We have therefore confirmed Jackson's (1949) observations that at least 10% of normal people exhibit this phenomenon. If exophthalmos and lid retraction cannot be recognized by simple inspection of the patient it is doubtful if special signs, such as lid lag or failure of convergence of the eyes on accommodation, yield any further information of value.

Nervous and Mental Symptoms

Severe cases of thyrotoxicosis almost always show emotional instability, and milder cases may have phobias and swings of emotional tone. It is probable that the biochemical disturbance unmasks a basic personality defect. It is easy to regard some patients as primarily psychotic unless the physician or psychiatrist has the possibility of thyrotoxicosis in mind.

In our series we asked the questions, "Are you a nervous person?" and "Are you irritable?" and, if the answer was positive, inquired whether this had always been so. About a quarter of the normal controls answered "yes" to

Fig. 2.—Incidence of nervousness in all cases, in males only, and in females only.

both questions, and several members of the older age groups declared that the symptoms were of comparatively recent onset. Females gave a positive answer much more often than males (Fig. 2). In the non-toxic group as many females gave a positive answer as in the toxic group, but the complaints were usually long-standing except in females at or about the menopause. Neither of these symptoms therefore carried much weight diagnostically except in males. Hyperkinetic movements were significantly more frequent in toxic cases, and this sign has some diagnostic value when it is present. Finger tremor was recorded whether it was fine or relatively coarse. It is very common in apprehensive persons and in the older age groups. A fine rapid tremor was much more often seen in the thyrotoxic group, but may occur in normal people. Jackson (1949) found it in about 2% of his series. Unfortunately, this type of tremor, usually considered to be characteristic of thyrotoxicosis, tends to grade imperceptibly into the slightly coarser types seen in anxiety states, and is of little diagnostic help in separating the two groups.

Muscular System

Muscular weakness and easy liability to fatigue are frequent accompaniments of the thyrotoxic state. The muscles may show histological changes which are probably due to excess of T.S.H. rather than of thyroxine (Dobyns, 1946). About a third of the control series said that they tired easily, and as large a proportion of the non-toxic as of the toxic patients had the symptom. Here again a positive answer to the question is of value in the male but of little help in the female unless there has been a definite alteration of recent date.

Cardiovascular Manifestations

I have recently discussed the circulatory adjustments which take place in thyrotoxicosis (Wayne, 1952), and I shall not deal with them in detail here. They are all due to excess of circulating thyroid hormone and can be reproduced in animals. It is, however, still uncertain whether there is a

specific type of heart disease caused by thyrotoxicosis or whether an excess of thyroid hormone acts merely as a precipitating factor in hearts already predisposed to failure from other causes. Levine (1951) takes the former view, but the balance of evidence is in favour of the latter. A distinction between thyrotoxicosis and thyrotoxic heart disease is worth making, since auricular fibrillation or congestive failure, when it occurs in thyrotoxicosis, becomes more important than the purely metabolic effects of the hormone. This is, however, one of the few forms of heart disease which can be treated by removing the cause.

Cases of thyrotoxic heart disease may present with established auricular fibrillation or attacks of paroxysmal fibrillation. Clinical examination of the heart sometimes gives rise to the suspicion that mitral stenosis is present, since the first sound at the apex may be accentuated and so roughened as to suggest a presystolic murmur; systolic murmurs are also often heard. It is in such cases and in cases with congestive failure that tracer tests with radio-iodine may be the only method of making a diagnosis without subjecting the patient to a prolonged therapeutic trial. One feature which may suggest that auricular fibrillation is secondary to thyrotoxicosis is its not infrequent failure to respond by a fall in rate to the administration of digitalis in full doses.

In our series of cases the average pulse rate in patients with regular rhythm was significantly higher than in the non-toxic and control groups, but there was considerable overlap between individual cases. We have, however, seen cases of undoubted thyrotoxicosis with resting pulse rates below 80 beats a minute. A slowing of the pulse rate during sleep occurs in normal and neurotic individuals but not in thyrotoxic patients. This is one of the most valuable

differentiating features after admission to hospital. Breathlessness on exertion and palpitation occur so frequently in anxiety states and in normal women that they have little differential diagnostic value (Fig. 3).

The Skin

Because the metabolic rate is high and excess heat must be eliminated, the skin of the thyrotoxic patient is typically hot and moist. Patients often say that they dislike the heat, and they may complain of hot flushes. A surprisingly large proportion of our group of normal individuals expressed a preference for cold weather, but, as Fig. 4 shows, it is chiefly women who dislike a hot environment. Thyrotoxic patients in general expressed their dislike of hot weather much more

Fig. 3.—Incidence of dyspnoea on exertion in all cases, in males only, and in females only.

Fig. 4.—Incidence of preference for cold weather in all cases, in males only, and in females only.

vehemently than the non-toxic and control groups and complained more convincingly of excessive sweating. These two symptoms have a diagnostic value even in the female if the questions are properly framed.

Although hot and sweating hands are a characteristic feature of the florid thyrotoxic case, they may, of course, be seen in normal persons, and the nature of the environment must be taken into account. If the atmosphere is relatively dry and cool and the hands are sweating they may be cool to the touch. It is very rare for them to be cold except occasionally in cases with severe congestive failure, although we have noted cold feet, especially in elderly patients.

Appetite and Loss of Weight

Although only a third of the patients with thyrotoxicosis said that their appetite had increased, this symptom is so uncommon in the other groups that it has special diagnostic value. Patients with anxiety state usually have diminished appetites. No fewer than 14% of toxic cases, however, said that their appetite was diminished, and these were often the severer cases. Loss of weight is also a valuable differential diagnostic feature, although 4% of toxic patients gave evidence of gain of weight. We adopted the arbitrary figure of a loss of 7 lb. (3.2 kg.) or more. Greene (1953) has recorded a loss of weight in 44% of patients and a gain in weight of 10% of patients with goitre, not all of whom, however, were toxic. Conway (1950) investigated the weights of 50 cases of active Graves's disease and found that 7 were heavier and 33 lighter than the expected weight. Appetite was increased in 38 of the cases and poor in 1. The combination of loss of weight with increased appetite when present is diagnostic of thyrotoxicosis and was not found in any of our non-toxic or control groups.

Bowel Function

Diarrhoea occurred in about 8% of the patients with thyrotoxicosis. Very rarely it may be the presenting symptom. Constipation, on the other hand, is by no means uncommon. It is of some interest that 20% of the normal controls and of the non-toxic group were constipated and most of them took purgatives regularly. This no doubt explains the preponderance of advertisements for purgatives among the medicaments offered to the public in the popular press.

Menses

Irregularity of menstruation was found in about one-fifth of the premenopausal patients in both toxic and non-toxic groups, but scanty periods were more common in the former. The numbers of patients are, however, small. Riisfeldt (1948), in a series of 340 women, found menstrual abnormalities in 31% of cases of toxic diffuse goitre, 21% of toxic nodular goitre, and 10% of patients with non-toxic goitre. Diminution in the menstrual loss was more common than increase.

The Spleen

We have been unable to confirm the belief that clinically determinable enlargement of the spleen occurs in thyrotoxicosis, although Williams (1946) found it in 10% of 247 cases. In the few instances in which it has been present in cases of thyrotoxicosis which have passed through our hands there has always been some other cause, such as chronic microcytic anaemia.

General Conclusions

We had hoped, when we began this survey in our three series of cases, that we might be able to discover some signs or symptoms which would enable a distinction to be made between thyrotoxic and non-toxic cases on purely clinical grounds. In fact, we discovered that most of the classical signs and symptoms are a reliable guide in thyrotoxic males, but that the problem was far more difficult in females. Women, especially women at the menopause, will often say they have symptoms such as breathlessness on exertion or fatigue even if they are carrying out a full

day's work. When in addition they have an anxiety state it is impossible to distinguish thyrotoxic from non-toxic cases on symptoms alone. The problem, however, becomes difficult chiefly when these symptoms are associated with some objective feature usually associated with the thyrotoxic state, such as goitre, exophthalmos, auricular fibrillation, congestive failure, or persistent tachycardia. The most helpful diagnostic features when they are present are increased appetite, loss of weight, preference for cold weather, hot and sweating hands, persistent tachycardia especially during sleep, and hyperkinesia. The value of any diagnostic feature is greatly enhanced if it is of relatively recent onset.

It is clear that in the doubtful case laboratory help is needed, and I shall now discuss the various tests which have been devised to assist the clinician.

Special Tests of Thyroid Function

Further evidence that it is not always easy to arrive at a diagnosis of thyrotoxicosis on clinical evidence alone is provided by the variety of laboratory methods which have been used to assess thyroid function. Some of these are now only of historical interest, but I shall review briefly those which are still in vogue, devoting, however, most of my time to a discussion of the help which may be afforded by tests using radio-iodine.

Estimation of the Basal Metabolic Rate.—This is still the standard laboratory investigation used by most clinicians in an attempt to confirm or refute a diagnosis of thyrotoxicosis. It has the merit that it is comparatively easy to carry out, and it gives some idea of the severity of the thyrotoxic state in clear-cut cases. It is essentially a measure of hypermetabolism, and a raised basal metabolic rate is therefore found in a variety of other conditions, as, for example, leukaemia, pheochromocytoma, cardiovascular disease, and anxiety states. In the last two conditions it may be impossible to achieve truly basal conditions without heavy sedation (Rapport *et al.*, 1951). Thyrotoxic patients may, moreover, have basal metabolic rates lying within the statistically acceptable "normal" range. In our experience (Goodwin *et al.*, 1951) as many as 33% of patients with proved thyrotoxicosis may have basal metabolic rates lying below +20%, and Foote *et al.* (1952), who took special care to obtain reliable estimates, found that 23% of thyrotoxic patients had basal metabolic rates lying within the normal range. Werner and Hamilton (1951) also report 15 cases of hyperthyroidism without hypermetabolism. Robertson (1952) has pointed out that a specially careful technique and standards derived from normal persons in Great Britain should be used, and Robertson and Reid (1952) emphasized the value of carrying out further tests after the administration of iodine in doubtful cases. An estimation of the basal metabolic rate is of undoubted help in a suspected case of thyrotoxicosis, but conditions must be truly basal and observations on out-patients are often unsatisfactory. Duplicate determinations on two or more days are desirable, and in border-line cases further investigation after the administration of iodine may be necessary.

Estimation of Serum Protein-bound Iodine.—This estimation measures the amount of circulating iodine bound to protein molecules, and is generally regarded as an accurate index of the amount of circulating thyroxine. Several groups of workers in the U.S.A. (Salter *et al.*, 1941; Starr *et al.*, 1950; and Hallman *et al.*, 1951) regard a raised level as the most reliable laboratory evidence of thyrotoxicosis. De Mowbray and Tickner (1952), on the other hand, in this country found that the level was raised in only two-thirds of cases of proved hyperthyroidism, and regard the estimation as inadequate in itself as a test of thyroid function. The previous administration of iodine-containing compounds produces a spurious increase in the serum protein-bound iodine figures. We have encountered serious technical difficulties with the method of Barker *et al.* (1951). It is doubtful if this estimation, which is in any case time-consuming, will ever become generally available to the clinician. It is chiefly of interest because it may give a

more complete picture of iodine and thyroxine metabolism when the results of simultaneous studies with radio-iodine are available (Riggs, 1952).

Estimation of Serum Cholesterol.—The serum cholesterol is lower than normal in the majority of cases of thyrotoxicosis. There is an increased rate of hepatic synthesis of cholesterol, but this is accompanied by an even greater rate of destruction and intestinal excretion. The changes are not related directly to changes in metabolic rate (Rosenman *et al.*, 1952). The fall in blood cholesterol level is small in degree, but under treatment a steady rise occurs (McGavack and Dreker, 1945). We have found the estimation of serum cholesterol of little diagnostic help in thyrotoxicosis although it is valuable in suspected cases of myxoedema. Our experience thus agrees with that of Peters and Man (1950) and Bartels (1950).

Estimation of Serum Creatinine.—Creatinuria undoubtedly occurs in all patients with thyrotoxicosis, but its degree bears no relation to the severity of the disease. Griffiths (1951) has suggested that a knowledge of the height of the fasting serum creatinine is of diagnostic value in thyrotoxicosis, especially when considered in conjunction with the basal metabolic rate. Unfortunately, however, he appears to have accepted a level of 0.6 mg. of creatine per 100 ml. as the upper limit of normal in spite of the observation of Tierney and Peters (1943) that normal women often have a serum creatinine higher than this figure. Because of the high degree of overlap which exists between thyrotoxic and normal men and women it is unlikely, even if a more sensitive method of estimating serum creatinine could be devised, that the differences would be clear-cut enough to be of diagnostic value. Similar considerations apply to creatine-tolerance tests.

Blood Picture.—"Leucopenia is fairly common, and it has been claimed that relative or absolute lymphocytosis is a constant finding in hyperthyroidism" (Whitby and Britton, 1950). If this were true an examination of the blood would clearly be diagnostically helpful. My colleague Dr. E. K. Blackburn (1953, personal communication) has studied the peripheral blood in 51 of our proved cases of thyrotoxicosis. In none of these was there a leucopenia or an absolute lymphocytosis, taking the respective normal ranges as 4,000–11,000 per c.mm. and 1,000–4,500 per c.mm. (Osgood *et al.*, 1939). In his view the concept of relative lymphocytosis should be abandoned. The bone marrow has, however, shown a lymphocytic reaction in some cases. This is probably a manifestation of the general tendency to hyperplasia of lymphoid tissue in this disease. Anaemia, when it occurs, is usually of iron-deficiency type unrelated to the thyrotoxicosis, except in so far as the latter predisposes to achlorhydria.

Use of Radio-iodine in Diagnosis of Thyrotoxicosis

Pochin (1950), in his Oliver-Sharpey Lectures, described the ways in which radio-iodine may be used to investigate fundamental problems of iodine metabolism, and Myant (1952) has described and critically reviewed the different types of test which may be used to assess thyroid function. These tests fall into two main groups: they either measure directly or indirectly the capacity of the thyroid gland to take up radio-iodine, or they attempt to measure the output of radioactive thyroxine from the gland. The avidity of the thyroid for iodine, which is greatly increased in thyrotoxicosis, can be estimated by determining the proportion of a given dose taken up by the gland at a fixed time or the maximum amount taken up by the gland. Alternatively, the rate at which the dose is taken up at a given plasma concentration of radio-iodine may be measured, a figure which is termed the thyroid clearance rate by analogy with renal clearance rates. Theoretically this should be a more reliable index of thyroid activity than the total radio-iodine uptake. Since the administered radio-iodine is shared between the thyroid and the kidneys, an estimation of the amount of radioactivity in the urine will give an indirect measure of the capacity of the thyroid to absorb iodine. Samples of urine taken at various times after the test dose are usually analysed separately.

The thyroid converts the radio-iodine into radiothyroxine at a rate and to a degree which is determined by its functional activity. Twenty-four to forty-eight hours after a tracer dose has been given the plasma of normal individuals shows little or negligible radioactivity. On the other hand, the plasma of the thyrotoxic patient contains a significant amount of radioactive material, of which a high proportion is bound to protein. Tests of this type involve the examination of a blood sample at a fixed time after the administration of the test dose, and an estimation of the relative amount of radioactivity in inorganic and organic forms.

Many groups of observers have carried out investigations on normal individuals and on patients with thyrotoxicosis, using one or more of these methods. We (Goodwin *et al.*, 1951) compared seven different criteria in normal persons, in patients with definite thyrotoxicosis and in patients in an "intermediate" but non-toxic group with goitre, treated thyrotoxicosis, or anxiety state. We came to the conclusion that the index which correlated best with the final clinical diagnosis, arrived at independently of the results of radio-

FIG. 5.—Relation of level of thyroid function to uptake of radio-iodine after four hours.

iodine tests, was the protein-bound plasma activity measured 48 hours after the administration of the dose. We thought, however, that, whenever possible, more extensive studies should be carried out. Subsequently we (Ansell *et al.*, 1953) selected three radio-iodine tests and applied them to a group of 179 persons, all of whom had been carefully and independently assessed clinically. These tests were the proportion of the dose taken up by the gland four hours after administration, the clearance rate of radio-iodine from the plasma one hour after administration, and the protein-bound plasma activity 48 hours after administration. Figs. 5 and 6 show the results which we obtained.

All thyrotoxic cases were classified into one of four grades of severity, and the non-toxic group was divided into those cases in which there was no clinical doubt that the patient had normal thyroid function and those about which there had initially been some doubt that the patient might be thyrotoxic. It is this group which any satisfactory test must separate accurately from cases of mild thyrotoxicosis. It will be seen from Fig. 5 that if a 40% uptake by the gland four hours after the radiation had been given was taken as the dividing line it separated fairly well non-toxic from thyrotoxic individuals, and that the results ran roughly parallel with the degree of severity of the disease. High uptakes did, however, occur in non-toxic individuals. If we took a clearance rate of 80 ml. a minute as the dividing line between toxic and non-toxic persons we found that several thyrotoxic patients had clearance rates well below this level. The protein-bound plasma activity, however

FIG. 6.—Relation of level of thyroid function to 48-hour protein-bound plasma activity. (Scale not strictly logarithmic below 0.2%.)

(Fig. 6), showed a fairly sharp division between the two groups, although thyrotoxic patients occasionally had levels well below our normal limit of 0.4% of the dose per litre. We concluded that the tests of four-hour uptake by the gland and protein-bound plasma activity at 48 hours would usually give consistent results and separate toxic from non-toxic cases.

We have now carried out more than 750 tracer tests of this type, and our conclusions, based on the smaller number of cases shown in Figs. 5 and 6, must be modified. Dr. Miller and I have correlated these figures with the clinical findings where they were available. Fig. 7 shows the results plotted so as to emphasize the cases of agreement or disagreement between the four-hour gland uptake and the 48-hour protein-bound plasma activity. Rectangles B and D contain cases in which both tests gave results which were in agreement. When this is so, it is quite exceptional to find a discrepancy between the clinical diagnosis and the radio-iodine tests, and we would place the error at less than 1%. It should be stated, however, that some cases were referred from other clinicians, and we cannot be sure that in some cases the tests have not been taken into account in arriving at a conclusion. A large proportion were, however, patients under our own care, and we can say with certainty that when the diagnosis is clear on clinical grounds the two radio-iodine criteria are always concordant and confirmatory.

We have ourselves examined the records of all the available patients in which the results of the two tests were discordant, that is to say, of cases falling in rectangles A and C. Black points appearing in rectangle A and white ones in rectangle C are examples of correct results by the plasma-activity test but incorrect as judged by the four-hour gland uptake. White points in rectangle A and black points in rectangle C indicate the

converse. It will be seen that the black points fall about equally in rectangles A and C, but the white ones are mainly in rectangle C. The protein-bound plasma activity is therefore a more accurate index than the four-hour gland uptake. It is, in fact, about twice as reliable, but only because it agrees with the clinical diagnosis better in non-toxic cases. A similar analysis of the figures for the thyroid clearance rate shows that they correlate better with the clinical diagnosis than the four-hour uptake, but less well than the protein-bound plasma activity.

There are certain important circumstances in which radio-iodine tests give results which must be interpreted with reserve. These are the previous administration of iodine or iodine-containing compounds, the administration of drugs of the thiouracil series, previous treatment by thyroidectomy or radio-iodine, and in cases of myxoedema or cretinism. We have examined the records of 47 cases which gave discordant results in the two tests and in which one or other of these factors had to be taken into account. These are not plotted in Fig. 7.

The administration of inorganic iodine or iodides diminishes the amount of radio-iodine taken up by the gland, and it is wise to wait for three weeks after stopping these drugs before carrying out tracer tests (Keating *et al.*, 1950). Plasma activity is also reduced (Ansell and Miller, 1952). We therefore carry out a simple test described by Foote *et al.* (1952) for iodides in the urine. The organic iodine compounds used in diagnostic radiography also affect radio-iodine criteria, but do not yield enough iodine to give positive readings in this test. We have found that individuals with normal thyroid function may show complete suppression of radio-iodine uptake 18 months after they have been given iodized oil for bronchography. They should be specifically questioned about previous x-ray investigations.

Drugs of the thiouracil series administered over a period of time may cause an increased uptake of radio-iodine by the thyroid which can persist for as long as three years (Foote *et al.*, 1952). In our series plasma activity was a much more accurate index in such cases.

After thyrotoxicosis has been treated either by thyroidectomy or by radioactive iodine the 48-hour plasma activity tends to be higher than would be expected from clinical estimates of thyroid function. In general, it can be said that the uptake or clearance is a more reliable index than plasma activity in assessing the results of these two forms

FIG. 7.—Relation of four-hour gland uptake to 48-hour protein-bound plasma activity levels.

of treatment (Ansell *et al.*, 1953). Similarly in hypothyroidism not amounting to complete myxoedema, high protein-bound plasma figures may be obtained in spite of clinical evidence of diminished thyroid function. The explanation of these exceptional results is not clear, but it seems probable that in these cases the specific activity of the circulating thyroxine is increased. The thyroid gland is working to the maximum of a diminished capacity to synthesize thyroxine and is turning over the iodine presented to it at an unusually rapid rate, so that a relatively large proportion of the circulating thyroxine molecules contain radioactive atoms. This hypothesis has been shown to be correct in two cases of hypothyroidism in which simultaneous estimations of circulating non-radioactive protein-bound iodine were carried out (Blom and Terpstra, 1953). In familial cretinism, in which hypothyroidism is associated with both a high uptake by the gland and high protein-bound radio-iodine activity, it seems more likely that there is a more fundamental disturbance in iodine or thyroxine metabolism (Hubble, 1953; McGirr and Hutchison, 1953).

We have no doubt that it is always preferable to carry out at least two and preferably three of these tests, and at Sheffield these are always done. An estimation of the 48-hour protein-bound plasma activity alone may, however, be of great diagnostic value. Since the patient need not come into contact with electronic apparatus it is possible to provide a diagnostic service for hospitals far removed from the centre at which the actual estimations are carried out. Doses of radio-iodine are dispatched weekly and a single sample of plasma is returned from each patient. Macgregor *et al.* (1953) have recently reported the results of such a co-operative effort between our centre and Nottingham. The patients were seen by two physicians, and in doubtful cases the final diagnosis was made only after therapeutic trials and follow-up.

Similar tests have been carried out at Derby and Scunthorpe, but the conditions were less rigorously controlled and the final clinical diagnosis may in some instances have been influenced by the results of the test. The correlation between the clinical and laboratory results at the three centres is summarized in Table II. It will be seen that an incorrect conclusion was given by the radio-iodine criterion in about 8% of cases, the test mainly tending to show non-toxic results in clinically toxic cases. This is especially true of borderline or doubtful cases.

TABLE II.—Correlation Between the Final Clinical Diagnosis and the Conclusions Based on a Single Estimation of the 48-hour Protein-bound Plasma Activity

	No. of Cases	Clinical Diagnosis	Correct	Incorrect
Nottingham ..	50	Toxic	25	2
		Non-toxic	22	1
Derby ..	77	Toxic	22	2
		Non-toxic	51	2
Scunthorpe ..	43	Toxic	13	6*
		Non-toxic	24	0
Total ..	170		157	13†

* 5 "mild" or "doubtful."

† 3 clinically non-toxic cases returned as toxic; 10 clinically toxic cases returned as non-toxic.

General Conclusions on Plasma Activity Tests

When we consider together the 1,000 tests of protein-bound plasma activity which we have carried out we arrive at the following general conclusions. The test alone has an error of about 10%, assuming the clinical diagnosis to be correct, but it must be remembered that this itself is not 100% accurate. When the results are supported by simultaneous estimations of clearance rates or uptake figures, great confidence can be placed in the results. If uptake and plasma activity figures are discordant the latter is more likely to be correct. It is unlikely to suggest that a patient is thyrotoxic without this being the case. It is better, how-

ever, in such instances to carry out a therapeutic trial. Little help is gained by repeating the tests, which almost always give the same results. Uptake clearance and plasma activity figures must be interpreted with reserve in patients who have received previous therapy.

All radio-iodine tests have certain drawbacks, and the ones which we use are not immune from criticism. It is possible by using a scintillation counter to determine the uptake of radio-iodine by the gland with as little as 5 microcuries of I^{131} , but to determine with reasonable accuracy the lower levels of plasma activity at least five times this amount must be used. Even so, the radiation hazard is less than that of some common diagnostic x-ray procedures, and the dose is less than a hundredth of that used in the treatment of thyrotoxicosis. Nevertheless, it is desirable to reduce to the absolute minimum the amount of radiation to which the gland is subjected. One way of achieving this result is to administer a drug of the thiouracil series an hour before the radio-iodine is given (Stanley and Astwood, 1948), or, alternatively, sodium iodide may be given together with the radio-iodine intravenously (Newsholme, 1952). Either the clearance rate (Newsholme) may be used or the maximum uptake of I^{131} by the thyroid together with a factor acting as an index of the initial slope of the curve (Foss and Herbert, 1952). These tests also have the advantage of being relatively unaffected by an increase in the iodine intake.

The avidity of the thyroid gland for iodine is most simply measured by determining the proportion of a dose excreted in the urine. The advantages of this method are its applicability to out-patient cases, the small dose of radio-iodine used, and the relative simplicity of the physical measurements. One disadvantage is the difficulty of ensuring that the whole of the urine output has been preserved for analysis, a difficulty which we have experienced with female patients even when they have been in our wards. We found that the excretion of radio-iodine in the urine during the 24 hours after it had been administered was a relatively poor index of thyroid function (Goodwin *et al.*, 1951). Fraser and his co-workers (1953) have, however, shown that by collecting the urine separately during the periods 0-8 hours, 8-24 hours, and 24-48 hours three indices of thyroid function could be derived. These were used to check for errors of collection and technique, and to correct for the presence of renal disease. The deductions made from them usually correlated well with the presence or absence of hyperthyroidism, and could be used to confirm the existence of myxoedema. The method appears to suffer, however, from the general defect of uptake measurements which we have also found since it tends to place non-toxic nodular goitres in the toxic range.

Fraser (1953) has recently shown that a method described by Berson *et al.* (1952) yields satisfactory results in both hyperthyroidism and hypothyroidism. The method has the disadvantage of requiring the intravenous administration of the radio-iodine, but the test, which is essentially a clearance test, can be completed in an hour.

Choice of a Radio-iodine Test

It will be seen, then, that all the tests which are at present available have both advantages and disadvantages. Our experience leads us to believe that it is best to determine both the iodine uptake of the gland and the protein-bound plasma activity. The latter measurement alone is simpler, and can be completed without the patient attending the diagnostic centre. The urine-excretion test as modified by Fraser is technically simple if appropriate samples can be delivered to the centre, and is of especial value in assessing hypothyroid states. Those who contemplate setting up a radio-iodine diagnostic service would be well advised to concentrate on one or two of the available tests, and to establish their own ranges of normal and abnormal values. We have some evidence that there are differences in the levels indicating abnormality in different countries and even in different parts of the same country. Most of our patients

come from an area which is known to be relatively iodine deficient (Murray *et al.*, 1948), and our criteria may not be generally applicable.

Relative Value of Different Tests of Thyroid Function

Each of the available tests measures a different aspect of thyroid function. Those using radio-iodine indicate either the capacity of the thyroid gland to concentrate iodine or its ability to turn out radioactive thyroxine, but they do not measure the absolute rate of iodine metabolism. The former test is affected by the variation in the plasma iodide level, and the latter by the thyroxine content of the thyroid. Both must be interpreted with reserve when the patient has received iodine-containing compounds or has been subjected to any therapeutic procedure. The basal metabolic rate, even after a hypnotic, measures hypermetabolism which may be due to a variety of "extra-thyroid" causes (Meckstroth *et al.*, 1952). It does, however, give some indication of the degree of severity of the condition. The estimation of the non-radioactive serum protein-bound iodine should theoretically give the most direct measurement of circulating thyroxine, but is technically difficult. But even if we knew with certainty the absolute level of circulating thyroxine we should have to take into account the general biological phenomenon of the variability of the response of different individuals to the same stimulus.

Myant (1952) has said, "However we define normality, the limit we set between normal and pathological is an arbitrary one, and no test can tell us what this limit should be." From the point of view of the biologist this is true, and with sufficiently sensitive tests we should probably find a graded response to increasing doses of thyroxine. It is even possible that some of the symptoms of those who have an anxiety state are produced by a slight excess of the thyroid hormone. On the basis of blood iodide studies Brody (1949) has produced evidence that this may be so, and Fraser *et al.* (1953) noted a tendency for his "neurosis" group to have a relatively high gland uptake of radio-iodine. The possibility is intriguing. Yet such persons do not respond to therapeutic tests which diminish the activity of the thyroid gland. Our correlations are ultimately based on this response, and it is this aspect in which the clinician is primarily interested. Our preference for radio-iodine tests is founded on the fact that by their use we are able to make a decision quickly on whether or not specific treatment shall be instituted, and they are of minimum inconvenience to the patient. We believe that they will be widely used in the future.

Conclusion

I hope I have been able to convince you that, while it may be very easy to make a diagnosis of thyrotoxicosis from the history and physical examination alone, it is often very difficult and there will always be patients about whose thyroid function the physician remains in doubt. Some symptoms and signs have greater diagnostic value than others; diagnosis is relatively easy in the male, but difficult in the female, especially if she is in a state of chronic anxiety.

When there is any question about the diagnosis, therapeutic tests should be carried out, but much time may be saved by studies of iodine metabolism, using isotope techniques.

I wish to thank my clinical colleagues at Sheffield who have referred cases to me, and Dr. D. V. Hubble, of Derby, and Dr. J. H. D. Millar, of Scunthorpe, for detailed information about cases at these centres. The work on radio-iodine was made possible through the collaboration of Mr. G. W. Blomfield, the Director, and Dr. H. Miller, the senior physicist of the Sheffield National Centre for Radiotherapy. Figs. 5 and 6 are reproduced by permission from *Radioisotope Techniques*, Proceedings of the Isotope Techniques Conference, Oxford, Volume I. H.M.S.O., 1953.

The Wellcome Trust has set aside a further £10,000 for whole-time Research Fellowships in Schools of Pharmacy in Great Britain. The Trustees made their first grant of £5,000 for Research Fellowships in 1947. They added a further £1,200 last year, when five Fellowships were awarded, and the value of each was raised from £350 to £400 a year. The awarding committee, nominated by the Wellcome Trustees and the Pharmaceutical Society of Great Britain, has discretion to award a senior Research Fellowship at a somewhat higher rate. Fellows must be registered pharmaceutical chemists in Great Britain, or graduates in pharmacy of a University in this country. A Fellowship is tenable for two years on annual award and is renewable in exceptional circumstances for a third year.

IODOTHIOURACIL IN TREATMENT
OF TOXIC GOITRE

St. Bartholomew's Hospital, London

In 1948 Barrett, Goodman, and Dittmer synthesized several organic combinations of halogens with thiouracil, of which 5-iodo-2-thiouracil proved most suitable for clinical trial. Because of the avidity of the hyperthyroid gland for iodine, the concentration of thiouracil in the gland might be expected to be greater after administration of iodothiouracil than after an equivalent dose of uniodinated thiouracil; a lower dosage could then be used, and the frequency of toxic effects would thus be reduced. It was also thought that the concurrent administration of iodine might diminish the hyperplasia and vascularity of the thyroid gland otherwise induced by the thiouracil; a reduction in the duration of pre-operative treatment would thus be possible and the technical difficulties of excision would be minimized.

Animal Experiments.—Experiments on rats and chicks have shown that the reduction in metabolism produced by iodothiouracil was quantitatively the same as that produced by thiouracil with or without the concurrent administration of potassium iodide (Barrett and Gassner, 1951). The thyroid histology of animals treated with iodothiouracil resembled the normal more closely than did that of animals treated with iodine and thiouracil singly or in combination (Barrett, Gassner, and Dittmer, 1951). Gassner *et al.* (1950) have also shown that iodothiouracil was less goitrogenic than thiouracil with and without iodide, and that it inhibited the goitrogenic action of exogenous thyrotrophic hormone, whereas thiouracil, alone or with iodine, augmented it.

Previous Clinical Trials

Reports on the use of this drug in over 190 patients have already been made from North America (Williams *et al.*, 1949; McClintock and Lyons, 1951; Catz *et al.*, 1951; Goldner and Kirschenfeld, 1952; Catz and Starr, 1953). The initial daily dosage varied from 50 to 800 mg., the optimum dosage appearing to lie between 200 and 400 mg., and the maximum clinical response was obtained in from eight to twenty-two days. Most workers found that some patients responded poorly; McClintock and Lyons (1951) believed that full remission was rarely produced. Definitive long-term therapy with iodothiouracil did not appear to be satisfactory owing to the incomplete and erratic control which was obtained; therefore the drug was mainly used in the preparation of patients for subtotal thyroidectomy. All these reports agree that the results obtained were from the surgical point of view satisfactory, the gland being less friable and vascular than after the usual preparation with a thiouracil derivative and iodine. Histologically, the glands appeared to be well involuted, and Catz and Starr (1952)

reported that "in hyperthyroid patients prepared for operation with iodothiouracil, the thyroid epithelium has a lower average mean acinar cell height than in all the other treatment groups," which included groups treated with iodine alone and with iodine and a thiouracil drug together; in other words, the histology most closely resembled that of the normal gland in the group treated with iodothiouracil.

Present Investigation

Twenty-three patients with hyperthyroidism have been treated with sodium iodothiouracil ("itrimil"), 100 mg. of the drug containing 46 mg. each of iodine and thiouracil and 8 mg. of sodium. Eighteen patients were subsequently treated by subtotal thyroidectomy. The first seven patients were given 200 mg. of iodothiouracil daily, but as the condition of the glands at thyroidectomy was not so consistently satisfactory as had been expected the remaining patients were given 300 mg. daily. All patients were admitted to hospital and observed for seven to fourteen days before starting drug therapy; during this period of observation the diagnosis was confirmed clinically, by radio-iodine studies and by estimations of the basal metabolic rate (B.M.R.). The latter test was repeated on three successive mornings, the lowest of the three readings providing a more accurate indication of the level of thyroid activity than a single reading. During the periods of observation and treatment the pulse rate (including the sleeping rate) was noted, the patients were weighed twice weekly, and exophthalmometer readings, measurements of neck circumference, and white blood cell counts were made weekly.

A further group of six hyperthyroid patients admitted thereafter for preparation for subtotal thyroidectomy was observed in a similar way and was treated with methylthiouracil and potassium iodide concurrently in daily doses equivalent to those of the thiouracil and iodine in 300 mg. of iodothiouracil.

Clinical Effects

In most patients, between the third and eighth days of treatment, and usually on the fifth day, a change in the pattern of the pulse chart could be noted, the lowest pulse rate of the day (often the sleeping pulse rate) having fallen by about 10 beats, and the daily range of the pulse rate being also reduced, although to a less extent. This change commonly coincided with an improvement in the general condition of the patient and accompanied, or immediately preceded, an increase in weight. In almost all cases the increase in weight continued until the end of the three weeks' treatment which preceded operation or discharge from hospital. A further fall in the pulse rate was not so common, and in many cases the lowest level and the range of the daily pulse rate rose slightly towards the end of this period of observation; this phenomenon was probably associated with the increase in the patient's physical activity, which was encouraged before operation or discharge, although it may represent an escape from control by the antithyroid drug.

All but one of these patients gained weight during treatment with iodothiouracil, and during the first three weeks of treatment the average daily gain in weight was 5 oz. (140 g.), the gain being higher in those with diffuse goitre than in those with nodular goitre, and higher in those given 300 mg. of iodothiouracil daily than in those given 200 mg. daily.

Estimations of the B.M.R. provide a less reliable means of assessing progress, owing to the difficulty of producing a basal state in hyperthyroid patients. The average daily fall in B.M.R. during the first three weeks of treatment was about 1.5%, and again the average daily fall was greater in the patients with diffuse goitre than in those with nodular goitre, and greater in those treated with 300 mg. of iodothiouracil daily than in those treated with 200 mg. daily.

In none of the six patients treated for two months or more did an increase in the size of the goitre become obvious. Increase in exophthalmos did not occur during treatment in

any patient, but in two, following thyroidectomy, there was a temporary increase of 2 to 3 mm. accompanied by slight ocular discomfort. A transient maculo-papular rash developed in one patient, but disappeared without treatment being stopped. Agranulocytosis, leucopenia, or any other toxic effect was not observed.

Surgical and Histological Findings

All thyroidectomies performed on these patients were done by one surgical team. The surgeon was of the opinion that the glands of patients prepared for operation with iodothiouracil were firmer, less vascular, and less friable than the glands of patients who receive the usual preparation of a thiouracil drug followed by iodine. Particularly was there a reduction in the size of the surface veins of the gland, though periglandular adhesions seemed more dense. In half of the patients the condition of the gland was comparable to that found after preparation with iodine alone. The post-operative course in no case caused anxiety, and was usually uneventful.

Although in four of the seven patients treated with 200 mg. of iodothiouracil daily ideal technical conditions were found at thyroidectomy, in the others the results were not so satisfactory—the gland in one patient who received 200 mg. daily for only twelve days being as vascular and friable as the glands found in patients treated with thiouracil without iodine. It was on this account that the daily dose of iodothiouracil was increased to 300 mg.

Evidence of involution, with good colloid content, was found in most of the excised goitres. In two-thirds of the cases there was, however, some degree of hyperplasia, which was never extreme and was usually slight or moderate. In the remaining third the epithelial cells were cuboidal or flattened (Table I).

TABLE I.—Summary of 18 Cases of Toxic Goitre Prepared for Surgery with Iodothiouracil

* Classification of surgeon's impression of condition of thyroid gland: A=comparable with glands after preparation with iodine alone; B=comparable with the more satisfactory glands after preparation with thiouracil followed by iodine; C=unsatisfactory—excessive vascularity and friability.

Long-term Treatment

One patient with hyperthyroidism complicated by auricular fibrillation and congestive heart failure was treated with 300 mg. of iodothiouracil daily for 60 days, during which time clinical improvement was continuous; at operation the condition of the thyroid gland was ideal, there being little increase in vascularity and no increase in friability or periglandular adhesions. Five patients have been treated with iodothiouracil for four months or more; in one patient with mild hyperthyroidism and exophthalmic ophthalmoplegia, although treatment was continued for nine months, good control of the hyperthyroidism was maintained, decrease in exophthalmos occurred, and there has been no relapse in the three months since treatment was stopped. In the four other patients who have been treated for from four to seven

months control has not been so satisfactory, and iodothiouracil has been replaced, with benefit, by methylthiouracil in two patients.

Comparison with Patients Treated with Methylthiouracil and Iodine

The average daily gain in weight and the fall in B.M.R. were identical in the group of patients treated with equivalent doses of iodothiouracil and iodine. The condition of the thyroid at operation, from the point of view of vascularity and technical difficulty, was a little less satisfactory in the latter than in the iodothiouracil group, and histological evidence of hyperplasia was more frequent and more obvious (Table II).

Discussion

In our experience iodothiouracil in daily dosage of 300 mg. for at least 17 days is a very satisfactory preparation for thyroidectomy in hyperthyroidism. A definite improvement in the clinical state occurs within a week of the start of treatment, there being thereafter a steady rise in weight of over 2 lb. (0.9 kg.) a week and a fall in B.M.R. of about 1.5% daily. The majority of patients are therefore fit for surgery within four weeks of starting iodothiouracil, and the field provided for the surgeon is technically satisfactory. It is thus possible to give all patients the advantage of an anti-thyroid agent in preparation without increasing the difficulties of the subsequent operation and without increasing appreciably the period of incapacity.

It is not so certain, however, that iodothiouracil possesses any new or distinctive features as a drug for the specific treatment of hyperthyroidism. The early clinical response, the tendency to escape from control after two to three weeks' treatment, and the difficulty in maintaining control in long-term treatment are suggestive of an iodine action, and it has yet to be shown that the iodine and thiouracil fractions of iodothiouracil act in the body in the organically combined form. It has been suggested that the studies of Plummer (1950) on the urinary excretion of the iodothiouracil are in favour of such an action, but the implications of these findings are doubtful.

Comparing the results of iodothiouracil treatment with those of methylthiouracil and iodine, we have been unable to show any significant difference beyond the impression that in the iodothiouracil group the operative field showed less excessive vascularity and the histological appearance was more commonly that of complete involution. Catz and Starr (1953), however, found that a shorter period of treatment was necessary to control hyperthyroidism with iodothiouracil than with thiouracil and iodine, that increase in goitre size occurred in the majority of patients treated with thiouracil and iodine but in none of those treated with iodothiouracil, and that the mean acinar cell height was lower in those treated with iodothiouracil, this signifying greater involution.

Astwood (1944) suggested that the actions of iodine and thiouracil in hyperthyroidism might be antagonistic, and that these drugs should therefore not be given simultaneously; it is in fact common practice in this country, when preparing

hyperthyroid patients for surgery, to discontinue the thiouracil two to three weeks before operation and to administer iodine alone for the remaining period (Rundle, 1951; Lange, 1953). However, Maxwell *et al.* (1946) and Williams (1946) reported satisfactory results with the concurrent administration of thiouracil and iodine. Rawson *et al.* (1945) believed that the iodinating and involuting actions of iodine are separate, and that, although the administration of the iodine does not result in the synthesis of thyroid hormone when iodine and thiouracil are given together, it does cause involution of the gland.

Conclusion

Although the number of cases observed in the present series is small we believe that the use of concurrent thiouracil and iodine (whether given as iodothiouracil or as methylthiouracil with potassium iodide) is a most satisfactory method of preparing for operation patients with moderate or severe hyperthyroidism. Those patients with mild hyperthyroidism who require operation are adequately prepared with iodine alone. Preparation with concurrent thiouracil and iodine is more rapid and produces a more satisfactory surgical field than does preparation with thiouracil followed by iodine. In cases of moderate severity the relatively slight increase in the duration of pre-operative treatment, compared with the duration of pre-operative treatment with iodine alone, is fully justified by the increased degree of safety obtained.

Summary

The literature concerning iodothiouracil, an organic combination of iodine with thiouracil, is reviewed, and a further clinical trial of this drug is reported.

Twenty-three patients suffering from hyperthyroidism, 18 of whom had subsequent thyroidectomies, were treated with iodothiouracil in doses of 200 to 300 mg. daily for periods of 12 days to 7 months.

The reduction in hyperthyroidism and the involution produced in the thyroid gland of patients prepared for surgery were most satisfactory; the results of prolonged medical treatment with iodothiouracil were variable.

It is doubtful whether the pharmacological properties of iodothiouracil differ from those of the constituent iodine and thiouracil fractions when the latter are administered at the same time.

Our thanks are due to Ciba Laboratories, Ltd., for the generous supplies of ituramil and to the Pathological Department of St. Bartholomew's Hospital for the preparation of the microscopical sections.

The National Gastroenterological Association announces that the name of its official publication, established in 1934, has been changed from *The Review of Gastroenterology* to *The American Journal of Gastroenterology*. There has been no change in the editorship. An earlier journal of this name was published from 1911 to 1914 by the American Hospital for Diseases of the Stomach, Philadelphia.

LONG-TERM THERAPY OF THYROTOXICOSIS WITH THIOURACIL COMPOUNDS

BY

JOHN F. GOODWIN, M.D., M.R.C.P.*

Physician and Lecturer, Department of Medicine, Post-graduate Medical School of London, W.12

HANNAH STEINBERG, Ph.D.

Honorary Research Assistant, Department of Pharmacology, University College, London

AND

ANDREW WILSON, M.D., Ph.D.*

Professor of Pharmacology and Therapeutics, University of Liverpool

Now that the treatment of thyrotoxicosis by thiouracil compounds has been in use for a number of years, it is becoming possible to determine its long-term effects and, in particular, the conditions under which this therapy is likely to be most successful. Most of the earlier contributions to this aspect of the subject have been reviewed by Astwood (1949), and accounts of more recent investigations have been published by Himsworth (1948), Williams (1949), Dunlop and Rolland (1950), Trotter (1950), Poate (1950), Wing and Asper (1952), and Douglas and Kennie (1952).

The present report is a summary of observations which began in 1944 at the Sheffield Royal Infirmary on the effects of treating thyrotoxicosis by means of thiouracil compounds. The inquiry was planned with a view to throwing light on three main questions which are of special interest to the medical practitioner: (a) How successful are these drugs in initially controlling the signs and symptoms of this disease? (b) To what extent can control be maintained over long periods by continuous administration of maintenance doses of the drug? (c) What are the chances of relapse after maintenance treatment is withdrawn? In particular, is length of remission after withdrawal related to such factors as the age of the patient, length of his illness, and the duration of his treatment before withdrawal?

Procedure

A total of 126 patients with typical signs and symptoms of thyrotoxicosis were treated for varying periods of up to six years with thiouracil, methylthiouracil, or propylthiouracil, according to the scheme already described in previous communications (Wilson, 1946; Wilson and Goodwin, 1947). As was pointed out previously, we have found that, though propylthiouracil was not superior to methylthiouracil, both compounds were less apt than thiouracil to produce toxic effects, and that the therapeutic response was favourable in either type of thyrotoxicosis. For the purpose of the present analysis no attempt is made to distinguish patients with primary from those with secondary thyrotoxicosis, or to differentiate between them according to severity of the disease, presence or absence of specific symptoms, the particular thiouracil compound and dose used, and the length of treatment needed before initial control was achieved. "Initial control" was assessed by the criteria previously described (Wilson, 1946). All patients who were controlled initially were given maintenance treatment, and from 94 of these it was subsequently withdrawn

*Formerly members of the Department of Pharmacology and Therapeutics, University of Sheffield.

after varying periods of treatment. The decision to withdraw it from individual patients who were satisfactorily controlled was made arbitrarily and without regard to their age and previous history.

Results and Discussion

Initial Control.—Fig. 1 shows that of the 126 patients treated with thiouracil compounds 113, or 90%, were initially controlled, usually after three to six weeks of treatment.

FIG. 1.—Results of treating 126 patients with thyrotoxicosis by thiouracil compounds. White columns=Satisfactory. Cross-hatched columns=Relapsed. I.C.=Initial control. M.T.=Maintenance therapy. W.M.T.=Withdrawal of maintenance therapy.

From the remaining 13 patients (10%) the drug was withdrawn without initial control having been established: 6 of these showed no signs of responding to the drug, 3 developed leucopenia, and 4 developed drug fever and nausea.

Maintenance Therapy.—Of the 113 patients who had been controlled initially, 105 were treated with maintenance doses for periods ranging from 3 to 62 months (mean=18.0, S.D.=12.9). Treatment of the remaining eight patients had eventually to be discontinued because two developed leucopenia five and fifteen months respectively after beginning treatment, one became drug resistant after two years, and five were referred for thyroidectomy on account of increasing thyroid enlargement.

Withdrawal of Maintenance Therapy.—Treatment was withdrawn from 94 of the 105 patients who had been on satisfactory maintenance for periods ranging from 2 to 55 months (mean=17.1, S.D.=12.2). Of these, 55 eventually relapsed at various months after withdrawal (relapsed group), while 39, at the time of the last interview, were still in remission after periods which ranged from 3 to 47 months since withdrawal of therapy (satisfactory group).

Factors Influencing the Incidence and Onset of Relapse

In an attempt to determine what factors might influence a patient's response to withdrawal of maintenance therapy, the two groups (satisfactory and relapsed) were compared with respect to four characteristics which a survey of the literature had suggested as relevant. These were: (1) age at first interview; (2) length of illness; (3) length of treatment before drug withdrawal; and (4) length of remission after withdrawal. It will be appreciated, however, that our satisfactory group includes patients who have been observed for only short periods and therefore may yet relapse.

In Table I it will be seen that the two groups were equally matched in respect of the patient's age and length of treatment before withdrawal of the drug. The mean length of

TABLE I.—Summary of Age, Length of Illness, of Treatment, and of Remission of 94 Patients from Whom Maintenance Therapy had been Withdrawn

	Satisfactory (39)			Relapsed (55)		
	Range	Mean	S.D.	Range	Mean	S.D.
Age at interview (years)	13-73	45.48	14.31	19-69	44.02	11.58
Length of illness (months)	1-44	23.41	29.96	1-240	42.22	58.15
Length of treatment (months)	2-55	16.13	10.97	2-54	17.75	12.97
Length of remission after withdrawal of treatment (months)	3-47	25.54	13.56	1-35	8.67	7.54

previous illness in the relapsed group, however, was approximately double that of the satisfactory group, but the scatter is very wide and the difference between the means is not statistically significant.* It is of interest to note that the standard deviation of length of illness in the relapsed group is also double that in the satisfactory group, indicating that the relapsed group has included a greater proportion of patients with illness of very short and of very long duration. The mean length of remission—that is, relief from signs and symptoms after withdrawal of maintenance therapy—is much less in the relapsed group (8.7 months) than in the satisfactory group (24.5 months). The difference between these two means is highly significant ($P<0.001$). This suggests that if relapse is to occur it tends to do so fairly soon after treatment is withheld. This is confirmed by Fig. 2, which shows the distribution of

FIG. 2.—Distributions of relapsed and satisfactory patients in relation to time after withdrawal of maintenance therapy.

length of remission following withdrawal of treatment. It will be seen that 49 out of 55 relapses occurred within the first fifteen months after withdrawal and, further, that of 33 patients with remissions of between 15 and 48 months only 6 have so far relapsed.

The liability to relapse after the withdrawal of treatment can be determined more precisely by arranging the data in the form of a life-table and calculating the probability of an individual relapsing within any given period after withdrawal (Fig. 3). It will be seen that the risk of relapsing is greater within 15 months or so from withdrawal of treatment, and thereafter does not increase greatly. The shape of the curve suggests that not many more relapses are likely to occur after the end of the 36th month following withdrawal. On the basis of our data, the overall probability of relapsing within 48 months after withdrawal of treatment (the maximum time that any of these subjects have been observed) is about 0.66; in other words, the odds are 2 to 1 that a patient will relapse within this period. These results are similar to those of Trotter (1950), except that he found the overall chances of relapse to be about 0.5—rather lower than ours. As he has pointed out, however, since the number of patients studied becomes progressively less, the later parts of this kind of probability curve are less reliable than the earlier. In view of this and the relatively small number of cases involved in each investigation (about 100), the difference between his figure and ours is probably to be attributed to sampling fluctuations.

*In view of the non-normality of the distributions and the discrepancy between the standard deviations, the proportions of satisfactory and relapsed patients above and below the median were compared by a χ^2 test. The results were in agreement with the tests on means.

FIG. 3.—The probability of relapsing in relation to time after withdrawal of maintenance therapy. In calculating the probabilities, allowance has been made for the fact that the satisfactory patients who had been in remission for only a limited period when the observations ended could subsequently be expected to relapse. To fail to make an allowance of this kind would bias the table. It has, furthermore, been assumed that all satisfactory cases were "at risk" for half the three-months period in which they ceased to be observed.

In order to examine further whether length of remission was related to the age of the patient, length of his illness, or length of treatment, correlations were calculated between these four variables for the relapsed group (Table II).

TABLE II.—Correlations Between Age, Length of Illness, of Treatment, and of Remission for 55 Patients who Relapsed After Withdrawal of Maintenance Therapy

	Length of Illness	Length of Treatment	Length of Remission
Age of patient			
Length of illness	+0.064	-0.040	-0.208
" " treatment		-0.144	-0.058
			-0.264

There was no point in calculating similar correlations for the satisfactory group, because for them the length of remission could not be finally determined. As a result, information concerning a number of patients with long and possibly permanent remissions, who from the practitioner's point of view are perhaps the most interesting of all, could not be taken into account. For this reason the correlations we have calculated, using data from the relapsed group only, do not give a complete picture.

It will be seen from Table II that the correlations are all very small. The only one which approaches statistical significance at the 5% level is between length of treatment and length of remission. The correlation is negative, suggesting a possible tendency for longer treatments to be associated with shorter remissions. This is contrary to what might be expected on the basis of previous reports that, if treatment was maintained for longer periods, the patient tended to take correspondingly longer to relapse (Himsworth, Morgans, and Trotter, 1947; Himsworth, 1948; Dunlop and Rolland, 1950). Douglas and Kennie (1952) have shown that the proportion of patients who relapse is much greater among those who have had treatments of less than one year before withdrawal than among patients who have been treated for one to two and a half years or more. However, inspection of their figures also suggests that, of the patients who do relapse, those who have had treatments of one year or longer tend to relapse sooner—in half the time, on an average—than those who have been treated for periods of less than one year. Our own observations provide some striking examples of patients with long remissions following

short treatments; seven patients, for instance, whose treatments were nine months or less were still in remission more than three years after treatment had been withdrawn. Furthermore, out of 12 patients treated for two and a half years or longer, only 2 have not yet relapsed, and in every case the relapse occurred well under twelve months after withdrawal of treatment.

Himsworth (1948) found that in patients with remissions of over two years after withdrawal of the drug the average duration of treatment had been 15 months (S.D.=6.3). This agrees well with our own figures, where the corresponding average for 23 patients with remissions of over two years is 17.6 months (S.D.=8.8). But since this figure is almost identical with the average length of treatment for the whole of our relapsed group (17.8 months, S.D.=13), length of treatment in our sample of patients, at any rate, clearly cannot be used to discriminate between short and long remissions.

The correlation between age of patient and length of remission, though not statistically significant, is negative—suggesting a possible tendency for longer remissions to be more common in younger patients—which is probably what one would expect.

The length of the patient's illness before treatment does not seem to be significantly associated with the length of his remission after withdrawal of treatment. This, however, may not be the case with thyrotoxicosis of several years' standing; for example, out of 13 of our patients who had been ill for more than four years only one had not relapsed at the time of the last recorded interview, and 10 of the 12 who relapsed have done so after remissions lasting only a few months. This high relapse rate among the patients with very long illnesses seems to be the main reason for the discrepancy between the mean length of illness of the relapsed and that of the satisfactory group (Table I).

That there should be no correlation in our sample of patients between length of treatment and age or length of illness is, of course, what might be expected, since length of treatment for each patient was determined at random.

In view of the relative lack of association between length of remission and the three factors which we have examined above, it seems reasonable to conclude that other influences, such as intercurrent infection and social maladjustment (Douglas and Kennie, 1952), may be more relevant in determining a patient's response to withdrawal of maintenance therapy with thiouracil compounds.

Summary

Of 126 patients with thyrotoxicosis who were treated by thiouracil compounds 90% were initially controlled.

Of 113 patients who were continued on maintenance therapy for periods from three to sixty-two months, 105 remained in remission during such treatment.

Maintenance therapy was withdrawn from 94 of the patients after periods of treatment ranging from 2 to 55 months, and 55 relapsed. It has been shown that the probability of relapsing is greatest within about 15 months after withdrawal of treatment. After 36 months the chances of relapsing are slight. On the basis of these figures it has been calculated that approximately two out of every three patients will eventually relapse after withdrawal of treatment.

No consistent relation has been found between the length of the patients' remission and their age, the

duration of their illness, and the duration of treatment. It is concluded that other factors may determine a patient's response to withdrawal of maintenance therapy with these drugs.

We wish to thank Professor E. J. Wayne for the opportunities of studying the cases under his care and the physicians of Sheffield Royal Infirmary for their valuable co-operation. We also wish to thank Dr. A. G. MacGregor for his help and for supplying data on the follow-up of some of the patients, and Mr. Arthur Summerfield for helpful advice on the statistical analysis. Part of the expenses of this research were defrayed by a grant from the Medical Research Council to one of us (A.W.) and to another (H.S.) who is in receipt of a whole-time personal grant.

MILK, *p*-AMINO BENZOATE, AND MALARIA OF RATS AND MONKEYS

BY

F. HAWKING, D.M., M.R.C.P.

National Institute for Medical Research, Mill Hill,
London, N.W.7

This paper describes investigations concerning the effect of milk diets upon the course of malarial infections, and the supplementation of such diets by *p*-aminobenzoate, which is a growth factor for many species of plasmodia.

In 1952 Maegraith, Deegan, and Jones reported that infections of *Plasmodium berghei* do not develop properly if the hosts (rats) are maintained on a milk diet. A preliminary communication from this laboratory (Hawking, 1953) pointed out that a milk diet was deficient in *p*-aminobenzoate, which is apparently needed by many plasmodia. It was shown that if *p*-aminobenzoate was added to the milk diet the infection of *P. berghei* developed normally, and it was concluded that *p*-aminobenzoate (or some derivative) is a growth factor for *P. berghei*. According to our conception the body fluids of animals usually contain very little *p*-aminobenzoate (otherwise sulphonamides would not be therapeutically effective against so many bacteria); *p*-aminobenzoate is present in many diets; when ingested in the food it raises the blood concentration sufficiently for malaria parasites to grow; and it is rapidly excreted or destroyed, so that constant renewal is necessary. The interrelationship of growth factors and malarial infections raises so many questions, both practical and academic, that several years will be needed to investigate them adequately. As, however, the subject is of interest to other workers, the results obtained to date are presented here.

Plasmodium berghei in Rats

The animals employed were obtained from the strain of piebald rats maintained at this institute. After preliminary experiments it was found that rats weighing 200 g. were

preferable to those of 100 g. or 50 g., because with the smaller weights suppression of the infection by milk diet was more difficult to demonstrate. The normal diet of these rats is a stock laboratory one which has been described by Bruce and Parkes (1949). Briefly, it contains wholemeal flour 46%, Sussex ground oats 40%, white fish meal 8%, dried skimmed milk 3%, dried yeast 1%, cod-liver oil 1%, and salts 1%. The milk employed was obtained from the ordinary dairy, and had been pasteurized. One sample of it was found by bioassay (kindly performed by Dr. A. T. Fuller) to contain 3.1 μ g. free and 19 μ g. total *p*-aminobenzoate per ml. The rats were housed three in a cage over a grid to allow escape of faeces. They were supplied with milk from a bottle. The bottles were changed morning and evening, and they were autoclaved in between each change. The quantity of milk was limited to the amount which the rats would probably consume in four to five hours, and all other possible steps were taken to prevent the milk going sour. The rats were placed on the diets for two to four days before inoculation. The strain of *P. berghei* was the RSVP strain obtained from Professor P. C. C. Garnham. The inoculum usually contained about 2 million parasitized cells per rat, and it was injected intraperitoneally. The degree of infection was expressed as the number of parasitized red blood corpuscles in a thin stained film per microscope field; this usually contained about 200 corpuscles.

The result of a typical experiment is shown in Fig. 1, in which the intensity of infection in each cage of three rats is shown as the mean of the logarithms of the number of

FIG. 1.—The development of *P. berghei* in rats on milk diet, milk plus *p*-aminobenzoate (P.A.B.) 1/40,000, and stock diet. Each line represents the mean of the logarithms of three rats, the infections being expressed as the number of parasitized cells per 20,000 erythrocytes. Inoculation intraperitoneally on Day 0 with 100,000 parasitized cells per rat. Weight of rats, 190–220 g.

parasitized erythrocytes per 20,000 cells in a thin blood film. (For this calculation, animals which showed no parasites were deemed to have 1 per 20,000 cells; animals dying of the infection towards the end of the experiment were deemed to have 8,000 parasites per 20,000.) This figure shows that the infection of *P. berghei* does not develop in rats on a milk diet (confirming the report of Maegraith *et al.*), but that if *p*-aminobenzoate is added to the milk the infection develops as well as in the control rats on the complete laboratory diet.

In order to obtain suppression of the infection on milk diet various precautions are necessary. Thus the rats employed should be fully adult—that is, weighing 200 g.—in younger rats the suppression is more difficult to obtain. The

milk must not be allowed to become sour; presumably souring is accompanied by increase of the *p*-aminobenzoate content. Prolongation (beyond three to four days) of the period on the diet before inoculation did not seem greatly to improve the results.

Probably this suppression of infections of *P. berghei* by milk diet is a marginal phenomenon, and a small alteration of the conditions may make the difference between success and failure. The composition of milk, including its content of *p*-aminobenzoate, is not uniform, but will vary according to the season and diet of the cows; at some seasons it was difficult to demonstrate suppression of parasitaemia by milk diet. It was sometimes observed that in two of a group of rats on milk there was complete suppression of parasitaemia, while in the third rat the infection was as great as in the controls; such a result suggests some individual factor present in certain rats, possibly different bacterial flora or syntheses in the intestine.

In some experiments chloramphenicol 1/20,000 was added to the milk in the hope of reducing bacterial growth in the intestine and thus diminishing a factor which might interfere with the effect of the milk diet; in such experiments, however, the malarial infection developed almost as well as in the control rats on a complete diet—that is, the suppression of the malaria by milk diet was reversed. This result was surprising, until it was learnt that chloramphenicol can be decomposed by *Bact. coli* and other bacteria into various derivatives which include *p*-aminobenzoate (Smith, 1953).

The minimum concentration of *p*-aminobenzoate in milk required to permit growth of *P. berghei* as good as in the controls seemed to be about 1/40,000; concentrations of 1/100,000 and 1/1,000,000 were sometimes effective and sometimes not. Assuming that each 200-g. rat consumes 150 ml. of milk a day, a concentration of 1/40,000 corresponds to a daily intake of approximately 20 mg. of *p*-aminobenzoate per kg. body weight.

Rats on a milk diet sometimes get diarrhoea, indicating modification of the intestinal flora. Rats on the control diet lost on an average 5% of weight in two weeks during the experiments, presumably owing to the malaria; on a milk diet they lost 2–3%. Pteroylglutamic (folic) acid 1/10,000 added to the milk promoted the growth of *P. berghei* as well as an equimolar solution of *p*-aminobenzoate—that is, 1/40,000; accordingly, these two compounds seem to be interchangeable, but it is not clear which of them is converted into the other. The suppression of *P. berghei* by milk diets could not be reversed by adding methionine (1/2,000) or *p*-hydroxybenzoate (1/3,000) to the milk or by injecting vitamin B₁₂ (150 µg. per kg. daily).

Infection by *P. berghei* could also be prevented from developing by placing the rats on other deficient diets—for example, a grossly deficient one consisting only of 10% glucose. Rats live well on this diet for over two weeks (end of experiment), with a loss of weight averaging 6–24% in different experiments. Addition of *p*-aminobenzoate 1/1,000 plus methionine 1/500 to this diet was not enough to allow the infection to develop.

Suppression of *P. berghei* infection by milk diet could also be demonstrated in mice, but often the suppression was less complete than that observed in rats.

Plasmodium knowlesi in Monkeys

The suppression of *P. berghei* infections by the administration of a *p*-aminobenzoate-deficient diet—for example, milk—can be correlated with the great susceptibility of this parasite to sulphonamides (which antagonize *p*-aminobenzoate). Accordingly experiments were made to ascertain whether the same phenomenon (suppression by milk diet and reversal by *p*-aminobenzoate) could be demonstrated with other malarial infections known to be sensitive to sulphonamides. The first study was made with *P. knowlesi*, which is known to respond readily to sulphonamide treatment. The strain was derived from the new and virulent strain recently isolated

by Edeson (Edeson and Davey, 1953). Four small *Macaca mulatta* monkeys weighing approximately 1.5 kg. were placed as follows:

Monkey 224 on the normal complete laboratory diet, as used for rats.

Monkey 225 on milk.

Monkey 226 on milk plus *p*-aminobenzoate 1/10,000.

Monkey 227 on milk plus *p*-aminobenzoate 1/1,000,000.

After three days, each of them was inoculated intramuscularly and intraperitoneally with 5×10^7 parasitized blood corpuscles. The course of the resultant infections is shown in Fig. 2. (The infection in Monkey 226 was indistinguishable from that in Monkeys 224 and 227 and has been omitted.)

Briefly the control Monkey 224 showed parasites in the blood five days after inoculation, and the next day it was treated with mepacrine and sulphadiazine to save its life. Monkey 225 (on milk) never showed any parasites during five weeks while it was fed only on milk; four days after it had been transferred to a normal diet its blood contained one parasite in every microscope field. Clearly the infection had been kept at a level too low for recognition while the monkey was on the milk diet, but the parasites multiplied rapidly when a complete diet was given. Monkey 227 (on milk plus *p*-aminobenzoate 1/1,000,000) and also Monkey 226 (milk plus *p*-aminobenzoate 1/10,000) showed the development of parasitaemia indistinguishable from that of the control monkey (224). Monkey 227, weight 2 kg., consumed about 1 litre of milk a day, so that it received about 0.5 mg. of *p*-aminobenzoate per kg. daily; this small amount was apparently enough to make it fully susceptible to infection with *P. knowlesi*. As the supply of monkeys was limited and the results formed such a striking confirmation of expectations, the experiment was not repeated. Possibly with a larger group of monkeys on milk diet the suppression of parasitaemia would not always have been so complete.

Similar experiments were made with *P. cynomolgi* in monkeys and yielded similar results; they are described later in this paper. Preliminary attempts were made to keep chickens on diets of liquid milk or dry milk so as to test *P. gallinaceum* (which is also sensitive to sulphonamides). The chickens did not take well to the diets, and the effects upon the infection were not clear. Further experiments with *P. gallinaceum* were postponed.

Malaria in Baby Animals

As pointed out by Macgrath *et al.*, the suppression of malaria infections in laboratory animals by milk diet raises the interesting question whether a similar suppression may occur in human babies in the Tropics while fed exclusively on breast milk. Certainly *P. falciparum* and *P. vivax* are sensitive to sulphonamides, and so presumably they require *p*-aminobenzoate. Model experiments were made on young laboratory animals.

FIG. 2.—The development of *P. knowlesi* in monkeys on milk diet, milk plus *p*-aminobenzoate 1/1,000,000, and stock diet. The infection is expressed as the number of parasites per 100 microscope fields each containing approximately 200 erythrocytes.

(a) Suckling Rats Inoculated with *P. berghei*

Litters of rats about one week old were taken when the baby rats weighed about 10–15 g., and were tested as shown in the Table. In this experiment the babies (eight in each cage) were inoculated intraperitoneally each with 1 million parasitized cells (Day 0). The mothers were placed on a

Development of *P. berghei* in Suckling Rats Receiving *p*-aminobenzoate (P.A.B.) by Different Routes

Cage	Contents	Mean Parasitaemia			
		4 Days	5 Days	6 Days	7 Days
1	Controls	4.6 (3.8)	13 (4.8)	51 (6.8)	126 (8.8)
2	Babies inoculated with 0.1 mg. P.A.B. i.p.	2,000 (8.8)	3,400 (8.8)	—	2,800 (8.8)
3	Mother smeared with P.A.B.	1,250 (8.8)	2,400 (8.8)	—	3,100 (8.8)
4	Mother inoculated with 10 mg. P.A.B. i.p.	2,000 (8.8)	4,000 (8.8)	—	3,500 (8.8)
5	Young rats (50 g.) on stock diet	—	1,000 (4.4)	3,000 (4.4)	—

Mean parasitaemia is expressed as the geometric mean of the number of parasitized erythrocytes per 20,000 cells. The figures in brackets indicate the proportion of animals showing parasites.

diet of 4 parts starch plus 1 part casein, beginning on the day before the experiments in order to diminish the amount of *p*-aminobenzoate in their diet. In cage 2 the baby rats were inoculated intraperitoneally twice daily with 0.1 mg. of *p*-aminobenzoate each; in cage 3 a mixture of 10% glucose plus 1% *p*-aminobenzoate was smeared on the nipples of the mother twice daily, so that the babies would receive the compound when they sucked; in cage 4, 10 mg. of *p*-aminobenzoate was injected intraperitoneally twice daily into the mother (200 g. weight) with the expectation that some would be excreted in the milk. Cage 5 contained four young rats (50 g.) on stock diet as an extra control. When the blood of these baby rats was first examined four days after inoculation, only three out of the eight controls (cage 1) showed scanty parasites. By seven days all the controls showed parasites, but their numbers were few. Cage 5 (weaned rats on stock diet) showed the usual acute infection developing. In all the three litters which received *p*-aminobenzoate by any route (cages 2, 3, and 4), the infection was already almost at its maximum level even on the fourth day. The fact that this occurred even in the babies of the mother receiving *p*-aminobenzoate by injection (cage 4) confirms the expectation that *p*-aminobenzoate (or a derivative) is excreted in the milk.

This experiment (which is typical of others) shows that infections of *P. berghei* in suckling rats develop much more rapidly and intensely if *p*-aminobenzoate is supplied by some route or other: from which it may be concluded that in normal circumstances the malarial infection is held back by a deficiency of this subject. Theoretically, suckling rats on a diet completely deficient in *p*-aminobenzoate would be insusceptible to infection; in practice suckling rats probably receive a small amount of *p*-aminobenzoate in their mother's milk, derived from her diet or perhaps from her intestinal bacteria, and this is sufficient to account for the low-grade infection which develops. The more stringent the precautions taken to exclude *p*-aminobenzoate from the diet of the mothers, the greater the suppression of parasitaemia in the babies. Thus in some experiments the mother rats were placed on *p*-aminobenzoate-deficient diet (starch 80%, casein 20%), beginning three days before parturition, and the babies were inoculated with malaria three days after they were born: babies of mothers which received *p*-aminobenzoate by twice-daily injection developed a parasitaemia of about 1% in five days, and the parasitaemia rapidly increased; babies of mothers not receiving *p*-aminobenzoate remained free from parasitaemia for 13 days and many of them never developed infection. If, on the other hand, the laboratory diet of the mother rats was rich in *p*-aminobenzoate, it might probably be impossible to demonstrate the above insusceptibility of sucklings to malaria.

(b) Baby Monkeys and *P. cynomolgi*

A few young *M. mulatta* monkeys were available from breeding at this institute. Two of these were about 1 month old, receiving milk from the breast or a bottle, and the others were 5 to 14 months old and had been weaned on to ordinary diet.

In the first experiment there were four monkeys as follows:

Monkey 217, weighing 3.8 kg., fed on the normal laboratory diet (food cubes as for rats and also occasional cabbage).

Monkey 221, weighing 3.5 kg., on milk diet.

Monkey 222, over 1 year old, weighing 2.5 kg., placed on a diet of milk plus *p*-aminobenzoate 1/1,000.

Monkey 223, 4 weeks old, weighing 0.75 kg. It had been brought up on milk from a bottle because its mother had refused to feed it. It had also received 9 ml. daily of a vitamin preparation called "haliborange." (This contains 75 µg. of *p*-aminobenzoate per ml.; Dr. A. T. Fuller.)

After Monkeys 217, 222, and 223 had been on their diets for one week, and 223 was 4 weeks old, all were inoculated intraperitoneally and intramuscularly with blood containing

about 2×10^7 parasites of *P. cynomolgi*.

The infections in 217, 221, and 222 are shown in Fig. 3. Monkey 217 (control on full diet) showed a typical infection with this parasite. Monkey 221 (on milk diet) showed no parasites for 10 days; it was then placed on milk plus *p*-aminobenzoate 1/1,000, but no parasites appeared during the next nine days; it was then inoculated with blood containing *P. cynomolgi* (to demonstrate its susceptibility), and a typical infection developed. Monkey 222 (on milk plus *p*-aminobenzoate 1/1,000) developed a typical infection, similar to that of the control (217) but rather more severe. Monkey 223 showed no parasites until the

FIG. 3.—The development of *P. cynomolgi* after inoculation with infected blood of monkeys on various diets, as described in the text. The infection is expressed as the number of parasites per 100 microscope fields, each containing 200 erythrocytes; for numbers above 100 the scale is greatly reduced for convenience.

fourteenth day, when two rings were discovered in 50 fields; on the fifteenth day the infection was six per 50 fields; on the sixteenth day it was three per 50 fields, and on the seventeenth it was one per 100 fields. On the fifteenth day it was discovered that the monkey had received 9 ml. of haliborange daily from the sixth day onward, which would contribute 0.6 µg. of *p*-aminobenzoate per day; this was stopped. On the nineteenth day one parasite was seen in 50 fields. The monkey ceased to gain weight, and put its hand to its head as though it had headache. On the twenty-second day it was put on chloroquine treatment (15 mg. per kg. daily intramuscularly for three days) and no further evidence of malaria has been seen.

The results with Monkeys 217, 221, and 222 show that a milk diet suppresses blood-induced infections of *P. cynomolgi* and that this suppression is reversed by *p*-amino-

benzoate. In the baby monkey (223) suppression was incomplete, although the parasitaemia was very much later and lower than in the control (217). This incompleteness of suppression may have been due to variation between different animals, or it may have been due to the halib-orange preparation.

Fig. 3 also shows an experiment with another monkey (228) which was performed on a later occasion but which is added here for ease of comparison. This was a baby rhesus monkey, 10 weeks old, which was being nursed on its mother's breast. (In a previous experiment—see below—it had been inoculated twice with sporozoites of *P. cynomolgi* and no infection had developed.) The mother was inoculated intramuscularly twice daily with *p*-aminobenzoate, 0.03 g. per kg.

After this had been done for six days the baby (228) was inoculated intraperitoneally with approximately 3×10^4 parasites of *P. cynomolgi*. Parasites appeared in the blood after four days and reached the stage of two parasites per field seven days after inoculation (after which the monkey was treated). As shown in Fig. 3, the development of infection in this monkey was similar to that of the previous control monkey (217) and of the monkey receiving *p*-aminobenzoate as well as milk (222). This experiment confirms the previous experiments with rats, demonstrating that when *p*-aminobenzoate is administered to nursing mothers it (or a derivative) passes via the milk to the offspring and renders them susceptible to malarial infection.

In the second type of experiment, infection was induced by means of sporozoites of *P. cynomolgi*. There were four *M. mulatta* monkeys:

Monkey 218, was kept on normal diet as a control.

Monkey 229, weight 3.8 kg., was placed on milk diet.

Monkey 230, weight 2.2 kg., was placed on milk plus *p*-aminobenzoate 1/5,000.

Monkey 228, a baby on the breast (mentioned above), was 4 weeks old when inoculated.

After 229 and 230 had been on their diets for five days all four monkeys were inoculated intraperitoneally with a suspension containing the glands of one infected mosquito—that is, each monkey received one-quarter of this amount; 20 days later this inoculation was repeated for each monkey. The results with three of the monkeys are shown in Fig. 4. Briefly, 218 first showed parasites 14 days after the first inoculation, and the infection reached a peak of 10 parasites per field on the twenty-second day; this is a typical infection following the inoculation of small numbers of sporozoites of *P. cynomolgi*. Monkey 228 (breast-fed baby) showed no parasites during eight weeks from inoculation, after which it was used for another experiment. Monkey 229 (on milk diet from a bottle) showed no parasites for five weeks. It was then placed on the normal diet again. Eighteen days after this change it began to show parasites, and mild parasitaemia (maximum 19 parasites per 50 fields) persisted for five days. (As the graph of this monkey was indistinguishable from

FIG. 4.—The development of *P. cynomolgi* after inoculation of sporozoites (on two occasions) in monkeys on diets of breast milk, cow's milk plus *p*-aminobenzoate 1/5,000, and stock food cubes. The infection is expressed as in Fig. 3.

that of 228 it has been omitted from Fig. 4.) Monkey 230 (milk plus *p*-aminobenzoate) showed parasites 14 days after the first inoculation and experienced an infection indistinguishable from that of the control (218).

This work shows that infections of *P. cynomolgi* induced by sporozoites are suppressed by a milk diet, and that again this suppression is reversed by *p*-aminobenzoate. Bray and Garnham (1953) have previously shown that the pre-erythrocytic forms are not abolished by the milk diet; they persist in a latent form, and the infection breaks out again when the animal is returned to a normal diet. The absence of parasitaemia in the breast-fed baby (228) is particularly suggestive as an explanation of the partial insusceptibility of human infants to malaria.

Discussion

In the above work and the papers already quoted it is shown that milk (and other) diets render rats and monkeys insusceptible to infection with malaria, and that this insusceptibility may be due to a deficiency of *p*-aminobenzoate (sometimes together with other factors), which is apparently a growth factor for these species of plasmodia. It has long been known that the course of infections can be modified by the diet of the host. According to a review by McKee (1951), the growth of various plasmodia has been reported at different times to be depressed by feeding the host on diets deficient in *p*-aminobenzoate, methionine, ascorbic acid, vitamin A, riboflavin, or pantothenate, but to be increased by diets deficient in biotin, folic acid, nicotinic acid, choline, or protein.

In particular, Geiman and McKee (1948) found that if monkeys were starved they were not susceptible to infection with *P. knowlesi*, but they became susceptible if given *p*-aminobenzoate or methionine. There is a striking parallelism between their experiment and the ones described above, in which monkeys were not susceptible to this infection when kept on a milk diet, but became susceptible if given *p*-aminobenzoate. Previously, workers of their group had shown that *p*-aminobenzoate was necessary for the growth of *P. knowlesi* in vitro (Anfinsen et al., 1946).

Further evidence for the relation of this compound to the growth of malaria parasites is given by the sensitivity of many species of plasmodia to sulphonamides (which antagonize *p*-aminobenzoate). Thus *P. knowlesi* and *P. berghei* are very sensitive to sulphonamides (and their growth is prevented by a milk diet but promoted by *p*-aminobenzoate); *P. gallinaceum*, *P. cynomolgi*, *P. falciparum*, and *P. vivax* are moderately sensitive to sulphonamides (the growth of *P. cynomolgi* is inhibited by a milk diet, etc.); while *P. relatum* is insensitive to sulphonamides (its response to a *p*-aminobenzoate-free diet has not yet been elucidated). It may be noted, however, that the amount of *p*-aminobenzoate which has usually to be added to the milk diet of rats to promote the growth of *P. berghei*—namely, the equivalent of 20 mg. per kg. of rat per day—is much greater than the amount which is probably provided by the normal stock diet.

Relation to Proguanil and Pyrimethamine

The recognition that *p*-aminobenzoate is a growth factor for the malaria parasites helps to elucidate the antimalarial action of proguanil and pyrimethamine, since (1) under suitable conditions the antimalarial action of proguanil and pyrimethamine upon *P. berghei* can be antagonized by *p*-aminobenzoate (Thurston, 1950, 1954); therefore these drugs probably interfere with the utilization of *p*-aminobenzoate (or some derivative like folic acid); (2) there is often cross-resistance between proguanil and pyrimethamine on the one hand and sulphonamides (which antagonize *p*-aminobenzoate) on the other; (3) pyrimethamine inhibits the growth of *Lactobacillus casei* and of *Str. faecalis* in vitro, and this inhibition can be overcome by folic or folinic acid (Hitchings, 1952).

Functions of *p*-aminobenzoate

The need of many malaria parasites for *p*-aminobenzoate is of particular interest because so much work has been done by microbiologists in elucidating the role of this compound in cell metabolism. Attention was first drawn to it because it antagonized the antibacterial action of sulphonamides (Woods, 1940). The exact details of its action are still the subject of controversy; but, briefly, (1) much (but not all) of the *p*-aminobenzoate absorbed by bacterial cells is built up into pteroylglutamic acid (folic acid), folinic acid, or some similar compound; (2) *p*-aminobenzoate and/or a folic acid derivative acts as a catalyst in various important synthetic reactions, by which (usually) an extra carbon atom is added to some molecule such as an amino-acid; thus homocysteine is converted into methionine, glycine into serine, etc.; (3) *p*-aminobenzoate or its derivative is necessary as a catalyst for the synthesis of purine and pyrimidine rings (probably by the addition of another carbon atom); these are fundamental for the synthesis of nucleic acids and nucleoprotein, and so for the growth and multiplication of nuclei and cells.

In the case of the malaria parasite, morphological evidence for this relation between the supply of *p*-aminobenzoate and the division of the nucleus is provided by the following facts. The utilization of *p*-aminobenzoate by the parasite is antagonized by sulphonamides, proguanil, and pyrimethamine. If malaria parasites—for example, *P. falciparum*, *P. cynomolgi*, or *P. berghei*—are exposed in vivo to the action of one of these drugs the early development of the parasite inside the erythrocyte—that is, from ring to trophozoite—proceeds apparently unaffected. But when the chromatin (nucleus) begins to divide to form the schizont, morphological evidence of profound disturbance becomes manifest; division of the chromatin is arrested or takes place abnormally; and then the parasite gradually degenerates and disintegrates (Black, 1946; McFadzean, 1951; Thurston, 1951). Thus interference with the utilization of *p*-aminobenzoate prevents normal division of the nucleus (chromatin), perhaps because the synthesis of new nucleoprotein has been interrupted. The development of the gametocytes does not involve the need for so much new nucleoprotein, and it is not noticeably disturbed by sulphonamides and similar drugs. However, there is disturbance and suppression of the subsequent development of the gametes after conjugation—that is, the development of the oocyst—during which much nuclear division normally takes place.

Human Malaria

Finally, the application of this work to human malaria may be considered. It is said that there is a widespread belief in Arab countries that a milk diet protects against attack by malaria; on the supposition that this milk diet was not supplemented by other foods containing *p*-aminobenzoate, this belief would seem to possess biochemical justification. Further information of such folk-beliefs relating to milk and malaria would be welcome, even though such situations are of interest rather than of importance. Much more practical is the question of babies and malaria. It has long been recognized that babies in West Africa and similar hyperendemic regions do not contract malaria as early or as intensely as would have been expected from the degree of their exposure to infected mosquitoes (cf. Bruce-Chwatt, 1952; Reed, 1952). It has previously been considered that such early insusceptibility might be due to immunity inherited or acquired from the mother. In view of Macgrath's discovery and of the work reported above, it seems quite possible that their insusceptibility might rather be due to their milk diet—that is, their deficiency of *p*-aminobenzoate. The common human malaria parasites, *P. falciparum* and *P. vivax*, are susceptible to sulphonamides, and therefore they presumably require *p*-aminobenzoate as a growth factor.

Babies in Africa, and presumably most other parts of the Tropics, are at first fed exclusively on the breast; during this period, which may last for five or more months, they

would theoretically be insusceptible to malaria. After this period their diet is supplemented with various pastes or porridges of ground grain, etc.; if these contain *p*-aminobenzoate (as will often be the case) the increased malaria rate in babies at this age group is easily explained. Some babies, however, do get malaria at 3 months or earlier, when it is improbable that their diet is supplemented by solid food. In such cases it is possible that the mother may have absorbed increased quantities of *p*-aminobenzoate (either from her own diet or from unusual bacterial synthesis in the intestine) and she may have passed it via the milk to the baby. All these hypotheses are well supported by the experiments with suckling rats and monkeys described above, but extensive and circumspect observation in the field will be required before they can be proved or disproved.

Summary

Rats fed on a milk diet are insusceptible (or only slightly susceptible) to infection with *Plasmodium berghei* (Macgrath, Deegan, and Jones, 1952). This insusceptibility can be reversed by the addition to the diet of *p*-aminobenzoate, which seems to be a growth factor for many species of malaria parasite. The insusceptibility can also be produced by maintaining rats on other diets deficient in *p*-aminobenzoate.

The addition to the milk diet of 20 mg. of *p*-aminobenzoate per kg. of body weight per day was sufficient to permit normal multiplication of the malaria parasite.

The deficiency in the milk could also be corrected by adding folic acid (in molar amounts corresponding to the amount of *p*-aminobenzoate needed), but not by adding methionine, vitamin B₁₂, or *p*-hydroxybenzoate.

Monkeys maintained on a milk diet were insusceptible to infection by *P. knowlesi* or *P. cynomolgi*, but they became fully susceptible when *p*-aminobenzoate was added to the milk in amounts of 0.5 mg. per kg. of body weight per day.

Baby rats and baby monkeys, while exclusively breast-fed from their mothers, are (almost or completely) insusceptible to infection with *P. berghei* or *P. cynomolgi* respectively, provided that their mothers are fed on a diet deficient in *p*-aminobenzoate. If this substance is administered either to them or to their mothers they become fully susceptible.

It is suggested that the relative immunity to malaria shown by infants under 6 months in many parts of the Tropics may be due to a deficiency of *p*-aminobenzoate in their diet of mother's milk.

Grateful acknowledgments are due to Dr. A. T. Fuller for the estimations of *p*-aminobenzoate by bioassay, and to Mr. K. Broomfield and Miss J. P. Selby for invaluable technical assistance throughout these experiments.

CANCER OF THE TONGUE, MOUTH,
AND PHARYNXSEX DIFFERENCES IN PROGNOSIS FOLLOWING
RADIOTHERAPY*

BY

MARION H. RUSSELL, A.I.S.

Statistician, Christie Hospital and Holt Radium Institute,
Manchester

In the presentation of morbidity and mortality surveys of malignant disease in sites affecting both sexes it is customary for the sex incidence rates to be stated separately. This principle is rarely observed, however, in the presentation of treatment results. Omission of the sex factor, in a series of cases large enough to render separate analyses practicable, may well have the effect of concealing real differences in prognosis. The object of this survey is to demonstrate, by separate sex analysis of the comparative results of treatment of cancer of the tongue, mouth, and pharynx, that such results not only can exist but may be substantial.

It is shown that in females the overall treatment results are much higher, and that post-operative mortality, recurrence rate, and incidence of secondary lymph nodes are lower.

Basis of the Survey.—The data analysed are from 673 cases of cancer of the tongue treated by radium implantation, 916 cases of cancer of the mouth, and 550 cases of cancer of the pharynx—a total of 2,139 cases treated by radium or deep x rays at the Christie Hospital and Holt Radium Institute, Manchester, during the years 1932 to 1942 inclusive. Evaluation of differences in response has been conducted in relation to the state of affairs ten years after treatment.

Criteria of Classification

The primary sites conform to International List Nos. 141-6, with the exception of soft palate, which is excluded from the sites covered by No. 144, and fauces and tonsil, which are excluded from No. 145, for reasons which are explained later.

For the purpose of presenting the findings in concise form, subdivisions in tables have been kept to a minimum, although the data have actually been analysed first in greater detail to ensure that no bias would be introduced by this procedure.

Although this survey is not concerned with the evaluation of particular treatment methods, it is necessary to state—again in the interests of eliminating possible bias—that no sex discrimination was exercised in the application of particular techniques. For tongue cases radium implantation was used; for mouth and pharynx the techniques employed were (a) radium used by intracavity, interstitial, or surface applicator method; (b) deep x-ray therapy. Where technically and physically practicable, cervical lymph node involvement was dealt with by block dissection; in a proportion of cases no form of treatment was deemed useful; in others, radiation was used as an alternative. No significant difference was found between the sexes in the proportions of the various techniques or between the four clinical stages of advancement.

The term "node-free" implies that in the cases so described there was no clinical evidence of cervical lymph node involvement at the time of treatment; the group

*This paper, confined to cancer of the tongue, was read at the 7th International Congress of Radiology held in Copenhagen, July 19-25, 1953. Mouth and pharynx cases have since been investigated on similar lines, and the results are now embodied in the paper.

represents summation of stages I and II according to the convention devised at the Christie Hospital and Holt Radium Institute, and, since its adoption elsewhere, known as the Manchester staging. Full details of the staging convention were given by Paterson, Tod, and Russell (1950). The term "nodes involved" indicates the presence of clinically palpable lymph nodes at the time of treatment, and represents summation of stages III and IV. Distant metastases rarely occurred, and almost invariably there already was cervical invasion. No useful purpose seemed to be served, therefore, by reporting them in this particular study.

Statistical Method

In the tables relating to 10-year survival the description "age-corrected rate" means that the crude rate has been corrected by age as a factor in the assessment of treatment results, this rate having been calculated by application to the crude survival rate of a weighted probability designed to correct for deaths due to intercurrent causes with no evidence of residual or recurrent cancer at the time of death. If any realistic picture of 10-year results is to be obtained such a correction is essential. The crude survival rate is included for purposes of comparison, although it under-evaluates the long-term effect of cancer treatment. A detailed account of the age factor method of correction was discussed and applied by Paterson *et al.*

Percentages are shown rounded off to the nearest whole digit. Statistical tests of significance have been applied to the results, and in commenting on the differences the following convention is adopted: the term "significant" is in general used when the observed differences exceed the conventional level of twice the standard deviation to a limit of 2.57. The probability of the difference in results being due to chance would thus range from 1 in 20 to 1 in 100. Where the differences meet even more stringent tests they are referred to as "highly significant." In some instances, where the distributions indicate the desirability of a different statistical method of evaluation, the same criterion of significance obtains.

Section I. Cancer of the Tongue and Mouth

Sex Differences in Distribution and Response

Table I gives the distribution in terms of sex incidence and primary site of the data for analysis. The sex ratio male to female on the total cases in tongue and buccal cavity respectively is almost identical, but there are marked

TABLE I.—Data for Investigation

Primary Site	Cases	Males	Females	Ratio Males to 1 Female
Tongue:				
Anterior two-thirds	522	422	100	4.2
Posterior one-third	151	138	13	10.6
Total	673	560	113	5.0
Buccal cavity:				
Floor	427	395	32	12.3
Cheek	215	160	55	2.9
Lower alveolus/gum	177	144	33	4.4
Upper	34	20	14	1.4
Hard palate	63	49	14	3.5
Total	916	768	148	5.2

differences between individual sites. It is noticeable, for example, that comparatively few women have lesions arising in the posterior third of the tongue. It is equally noticeable from the distribution of the anterior buccal cavity cases that, in men, lesions arising in the lower part of the mouth predominate, although this is not so in women. The word "incidence" in this context is, of course, used in the restricted sense of describing the relative frequency of the treated cases for investigation. Incidence rates and their changing pattern, based on a defined population, are the subject of a separate survey in course of preparation.

Reference has already been made to the exclusion of the soft palate. Technically and aetiological this site seems to be more suitably grouped with the posterior buccal cavity (or faucial) region. During the years under review 656 cases arising in fauces, tonsil, and soft palate were treated, distributed as follows:

	Males	Females	Ratio Males to 1 Female
Fauces	368	15	24.5
Soft palate	161	2	80.5
Tonsil	100	10	10.0
Total	629	27	23.3

These figures indicate the futility of investigating sex differences in prognosis in this particular region. When the hard-palate and soft-palate cases are grouped together—in the present instance giving a sex ratio male to female of 13.1:1—the great disparity in the ratios for hard and soft palate separately (3.5:1 and 80.5:1) is obscured.

This characteristic of very low incidence in women is, as is well known, also common to the lip—a site which is sometimes included in mouth surveys, but which again is rendered impracticable in this context by the paucity of female cases.

The age distribution by sex, expressed as a percentage, is shown in quinary groups in Fig. 1. In women the disease manifests itself at an earlier age than is the case in men. Thus, in the tongue cases the modal age group occurs a decade earlier, and in the mouth cases five years earlier. Reference is made later to the need for taking into account these disparities in age distribution.

In Table II the 10-year results for the two groups of cases are shown separately by sex. Crude survival and age-corrected rates reveal considerable differences between males and females. Although, as previously stated, age-corrected rates offer a better assessment of the efficacy of treatment, the differences between the crude survival rates are of much the same order and are highly significant.

If the overall survival rate is considered in relation to cervical lymph node involvement at the time of treatment

TABLE II.—Comparison by Sex of 10-Year Survival Rates

Sex	Tongue			Buccal Cavity		
	No. Treated	Crude	Age-corrected	No. Treated	Crude	Age-corrected
Male	560	13%	23%	768	18%	32%
Female	113	31%	42%	148	34%	47%
Total	673	16%	26%	916	20%	32%

(a) $P < 0.0001$. (b) $P < 0.0001$.

TABLE III.—Comparison by Sex and Clinical Findings of 10-Year Survival Rates

Clinical Findings	Sex	Tongue			Buccal Cavity		
		No. Treated	Crude	Age-corrected	No. Treated	Crude	Age-corrected
Node-free	M	352	20%	35%	416	25%	46%
	F	85	38%	51%	91	46%	71%
Nodes involved	M	208	2%	4%	352	9%	16%
	F	28	11%	13%	57	12%	18%

(a) $0.0001 < P < 0.001$. (b) $P < 0.0001$. (c) $P = 0.08$. (d) $P = 0.40$.

of the primary lesion (Table III), the analysis is seen to yield the same trend of a higher rate in women, although, not unexpectedly, the differences in the later stages of the disease are not statistically significant. In the node-free group, however, the differences are highly significant.

It is pertinent to examine next the various factors contributing to the overall differences already demonstrated. The factors for investigation are: post-operative mortality; incidence of recurrence; incidence of cervical lymph nodes before treatment; subsequent cervical involvement.

Post-operative mortality is the first major hazard to be encountered after treatment. It is logical to deal with it first from a statistical point of view also, since its impact somewhat reduces the number of cases available for in-

FIG. 1.—Age distribution of cases of cancer of the tongue and buccal cavity given radiotherapy during 1932-42.

vestigation of other phenomena. Table IV shows that, whereas the post-operative mortality rate for men with cancer of the tongue is 15%, the corresponding rate for women is only 4%—a difference which is highly significant. In the buccal cavity, where there is an apparently lower risk

TABLE IV.—Comparison by Sex and Age of Post-operative Mortality

Age Group	Tongue		Buccal Cavity	
	Males	Females	Males	Females
	No. Treated	P.O. Rate	No. Treated	P.O. Rate
Under 50	38	0%	20	0%
50-59	124	17%	37	0%
60-69	273	16%	36	8%
70+	125	17%	20	10%
Total	560	15%(a)	113	4%(a)

(a) $0.001 < P < 0.01$. (b) $P = 0.20$.

to men, the difference between male and female rates of 7% and 4% does not reach the conventional level of statistical significance, the probability of chance occurrence being 1 in 5. The fact that there is a heavier weighting of men in the higher age groups has already been shown. Nevertheless, the analyses in both tongue and buccal cavity groups reveal a male excess mortality in most age groups.

Having observed striking sex differences in the post-operative mortality rate, it is worth while to look at these

further in relation to the effects of lymph node involvement. The figures for node-free tongue cases show (Table V) a significant difference in the rates of 10% and 2%. Node-free mouth cases provide the only instance of an equal rate for men and women. This is apparently due to the combined effect of known cardiac disease and old age in two

TABLE V.—Comparison by Sex and Clinical Findings of Post-operative Mortality

Clinical Findings	Tongue				Buccal Cavity			
	Males		Females		Males		Females	
	No. Treated	P.O. Rate	No. Treated	P.O. Rate	No. Treated	P.O. Rate	No. Treated	P.O. Rate
Node-free	352	10%(a)	85	2%(a)	416	4%	91	4%
Nodes involved	208	25%(b)	28	11%(b)	352	11%(c)	57	4%(c)

(a) $0.04 < P < 0.05$. (b) $P = 0.15$. (c) $P = 0.12$.

of the four deceased women in this group. Where lymphatic spread had occurred, appreciable differences exist between men and women in the respective rates of 25% and 11% for tongue and 11% and 4% for mouth, although they do not reach the significant level owing to the fact that the female groups are comparatively small. It should be borne in mind, of course, that these mortality rates were experienced in the years before antibiotics were in general use. Substantial reductions in post-operative mortality have been achieved since their introduction. Despite this beneficial effect, it is interesting to observe that an advantage still lies with females.

The next comparison to be made is the important one of recurrence rate of the primary lesion. This is evaluated more clearly by confining analysis to cases originally classified node-free. The term "recurrence rate" is a convenient one to use, but it has a wider application in this context than it has when used in relation to radical surgery. As the post-treatment phase for tumours treated *in situ* is one of regression at varying rates, apparent quiescence of a residual lesion or—in tumours of a completely radio-resistant character—steady advancement of the malignant process, recurrence rate actually implies apparent failure of the primary to resolve completely as well as recurrence after an interval of freedom from sign or symptom.

It has been necessary to deduct the post-operative deaths from this group, since these cases were no longer available for observation. In Table VI, which for tongue cases shows

TABLE VI.—Comparison by Sex of Incidence of Primary Recurrence in Node-free Group (After Deduction of 98 Post-operative Mortality Cases)

Sex	Tongue		Buccal Cavity	
	No. Observed	Primary Recurrence Rate	No. Observed	Primary Recurrence Rate
Male	318	41%(a)	360	36%(b)
Female	83	21%(b)	85	22%(b)

(a) $0.0001 < P < 0.001$. (b) $0.01 < P < 0.02$.

TABLE VII.—Comparison by Sex of Incidence of Cervical Lymph Nodes Before Treatment

Clinical Findings	Tongue		Buccal Cavity	
	Males	Females	Males	Females
	No. Treated	P.O. Rate	No. Treated	P.O. Rate
Node-free	352	10%	416	4%
Nodes involved	208	25%	352	11%
Total	560	11%	768	4%
Proportion with nodes involved	37%	25%	46%	39%

(a) $0.01 < P < 0.02$. (b) $P = 0.10$.

a primary recurrence rate of 41% in men as opposed to 21% in women, a highly significant difference is demonstrated. The rates of 36% and 22% for mouth cases similarly disclose that recurrence is much less frequent in women than in men, the observed difference being significant.

Sex differences in cervical lymph node involvement at the time of original examination are shown in Table VII. In both tongue and mouth lesions a higher rate exists in males than in females: in the former group the difference is near to high significance; in the latter it is not significant at the conventional level, the probability of chance occurrence being 1 in 10. Nevertheless, these trends suggest the desirability of investigating the incidence of lymph nodes after treatment of the primary lesion in the group of cases originally classified as node-free.

The results of the analysis of the final factor investigated are shown in Table VIII. For tongue lesions the greater susceptibility of men to subsequent cervical involvement is

TABLE VIII.—Comparison by Sex of Development of Cervical Lymph Nodes in Cases Originally Node-free (After Deduction of 98 Post-operative Mortality Cases)

Sex	Tongue		Buccal Cavity	
	No. Observed	Lymph Node Incidence Rate	No. Observed	Lymph Node Incidence Rate
Male	318	60%(a)	360	49%(b)
Female	83	47%(b)	85	27%(b)

(a) $P \approx 0.03$. (b) $0.0001 < P < 0.001$.

indicated by the male and female rates of 60% and 47% respectively, and is statistically significant. The same trend is disclosed in the mouth group, in which the difference between the rates of 49% and 27% is highly significant.

Section II. Cancer of the Pharynx

Difficulties implicit in dealing with cancer in this site are inevitably encountered in attempting to investigate sex differences in prognosis according to the pattern adopted in Section I. In a site of such unfavourable prognosis clinical and technical handicaps are unavoidably reflected in any statistical evaluation, and consequently less precision is attainable in the assessment of certain characteristics. The same trends of better prognosis in the female are nevertheless demonstrable, and seem to be worth recording in somewhat condensed form.

TABLE IX.—Data for Investigation

Primary Site	Cases	Males	Females	Ratio Males to 1 Female
Nasopharynx and oropharynx	287	208	79	2.6
Hypopharynx and post-cricoid	263	141	122	1.2
Total	550	349	201	1.7

Sex Differences in Distribution and Response

The data for analysis are divided into two broad groups, as shown in Table IX. In the nasopharynx and oropharynx the frequency ratio indicates much less disparity between the sexes than is the case for the tongue and mouth, and scarcely any for lesions arising in the hypopharynx and post-cricoid region.

Figure 2, giving the age/sex distributions, shows no difference in the modal age group for males and females in the nasopharynx and oropharynx. As there were more patients in the younger age groups than was the case in tongue and mouth lesions, the range of quinary age groups has been expanded. The distribution for hypopharynx and post-cricoid region shows a sharp rise to the modal age of 65–69 for males, the corresponding peak for females being 60–64.

FIG. 2.—Age distribution of cases of cancer of the pharynx given radiotherapy during 1932-42.

Comparison by Sex of 10-Year Survival Rates

A highly significant difference between males and females is shown for the nasopharynx and oropharynx group (Table X). It may also be observed that the 10-year results for women are as good as the survival rates experienced by men with cancer of the tongue. On the other hand, the long-term results for hypopharynx and post-cricoid region cases reveal uniformly poor prognosis.

TABLE X.—Comparison by Sex of 10-Year Survival Rates

Sex	Naso- and Oropharynx			Hypopharynx and Post-cricoid		
	No. Treated	Crude	Age-corrected	No. Treated	Crude	Age-corrected
Male	208	6%	8%	141	3%	5%
Female	79	19%(a)	23%	122	2%	3%
Total	287	9%	12%	263	3%	4%

(a) $0.0001 < P < 0.001$.

TABLE XI.—Comparison by Sex and Clinical Findings of 10-Year Survival Rates

Clinical Findings	Sex	Naso- and Oropharynx			Hypopharynx and Post-cricoid		
		No. Treated	Crude	Age-corrected	No. Treated	Crude	Age-corrected
Node-free	M	28	7%	12%	39	5%	9%
	F	19	16%(a)	21%	48	4%	6%
Nodes involved	M	180	6%	7%	102	2%	4%
	F	60	20%(b)	24%	74	1%	2%

(a) $P = 0.65$. (b) $0.0001 < P < 0.001$.

TABLE XII.—Comparison by Sex and Age of Post-operative Mortality

Age Group	Naso- and Oropharynx				Hypopharynx and Post-cricoid			
	Males		Females		Males		Females	
	No. Treated	P.O. Rate	No. Treated	P.O. Rate	No. Treated	P.O. Rate	No. Treated	P.O. Rate
Under 50	44	9%	27	0%	8	13%	26	12%
50-59	41	5%	21	5%	21	38%	41	17%
60-69	90	23%	26	12%	76	21%	48	13%
70+	33	15%	5	0%	36	17%	7	14%
Total	208	15%(a)	79	5%(a)	141	22%(b)	122	14%(b)

(a) $0.02 < P < 0.05$. (b) $P = 0.09$.

Analysis according to the presence or absence of cervical lymph node involvement (Table XI) is not very profitable in view of the low numbers in the node-free group of nasopharynx and oropharynx cases and the poor results already seen in Table X for hypopharynx and post-cricoid region cases. Nevertheless, the trend in the former again shows an appreciably higher rate for women, which might well prove to be a significant one if more cases were available for study. Where cervical involvement had taken place the higher survival rate for women is highly significant.

Table XII reveals the overall post-operative mortality rates for cancer of the nasopharynx and oropharynx to be almost identical with those for cancer of the tongue, and significantly higher in males. Unlike the tongue and mouth cases, however, the heaviest rate for each sex occurred in the decade 60-69. The difference of 8% between the male and female rates for hypopharynx and post-cricoid, although not great enough to be statistically significant, follows the same trend.

Analysis of the cases according to cervical lymph node involvement also shows a similar trend throughout of a higher rate for men, but the consequent decrease in numbers in each group results in none of the differences being significant. No useful purpose seemed to be served, therefore, by the inclusion of a table in this form.

It is not practicable in this section to include a table dealing with recurrence of the primary lesion in node-free cases, as was done in Section I. Complications such as oedema and stenosis encountered in the hypopharynx and post-cricoid region result in any attempt at assessment being highly presumptive, even with an endoscopic examination and biopsy, and consequently undesirable as a basis of statistical evaluation. In the nasopharynx and oropharynx the same difficulties exist, but in a lesser degree. It seems probable here that 57% of men and 42% of women experienced recurrence in the primary site, but this assessment must be regarded as being less reliable than that quoted for the tongue and the mouth.

TABLE XIII.—Comparison by Sex of Incidence of Cervical Lymph Nodes Before Treatment

Clinical Findings	Naso- and Oropharynx		Hypopharynx and Post-cricoid	
	Males	Females	Males	Females
	No. Treated	P.O. Rate	No. Treated	P.O. Rate
Node-free	28	19%	39	5%
Nodes involved	180	6%	102	2%
Total	208	9%	141	4%
Proportion with nodes involved	87%	76%	72%	61%

(a) $P = 0.03$. (b) $0.04 < P < 0.05$.

Cervical lymph node involvement prior to treatment of the primary lesion, which is the subject of analysis in Table XIII, occurs in both sexes to a far greater extent when the primary is situated in the pharynx than is the case when it is in the tongue or mouth. In each pharyngeal subgroup the rate for males is shown to be significantly higher than that for females.

Assessment of the risk of cervical lymph node involvement developing after treatment of the primary lesion is, of course, influenced by the response to treatment of the latter.

Where the prognosis is poor, the opportunity for observation of various characteristics is correspondingly limited. Furthermore, the node-free groups are small (Table XIII). It suffices to say, therefore, that the respective rates of 22% for males and 16% for females in nasopharynx and oropharynx cases, and 24% for males and 13% for females in hypopharynx and post-cricoid cases, follow the same trend as was observed for cervical invasion before treatment. The fact that these rates are so much lower than the comparable ones shown for the tongue and mouth cases is attributable to the shorter average duration of life. In the event of any future development of more effective methods of controlling the primary lesion they could not be regarded as an authentic estimate of potential lymph node involvement.

Discussion

Summarizing the findings, then, it would seem that in the treatment of cancer of the tongue, mouth, and pharynx female patients may be expected to respond much better than males and to resist lymphatic spread more successfully. In none of the aspects investigated—namely, long-term survival, incidence of post-operative mortality, primary recurrence, secondary lymph nodes before and after treatment of the primary lesion—has any evidence against this thesis emerged.

The fact that such sex differences in prognosis are demonstrable makes it obvious that, in the presentation of the results of treatment, omission of the sex and age distribution may well affect the deductions to be made from survival rates. Failure to keep this in mind may conceivably be the cause of some misinterpretation, since, in making comparisons, a higher survival rate attributed to improved technique may be due merely to differences in the sex ratio in the sample.

Furthermore, the need for the incorporation of an age-factor correction cannot be too strongly emphasized, particularly in countries where there is a rapidly increasing proportion of old people in the population. The consequent rising proportion of deaths from intercurrent diseases invalidates the crude mortality rate for purposes of treatment evaluation.

Revelation of differences in behaviour inevitably arouses speculation regarding the causes. Three obvious lines of inquiry seemed to be: (a) the possible effect of oestrogen changes; (b) the comparative incidence of syphilis; and (c) the respective standards of oral hygiene. Analysis of the results on a pre- and post-menopausal basis failed to reveal any real difference. The cases in which a Wassermann test had been made were invalidated for statistical purposes by the policy of clinical selection. Investigation of dental sepsis could not be undertaken in a survey of retrospective character, but there is a strong suggestion from various sources that the standard of oral hygiene is appreciably higher in women than in men.

It may be that investigation of possible local influences would yield only a partial solution, and that the differences now demonstrated are merely a cogent example of the fact that the female, although lacking equal physical strength, is nevertheless fundamentally possessed of greater stamina than the male. In a comparison of male and female mortality trends, Martin (1951) showed that the disadvantage experienced by males has been increasingly enhanced during the past few decades. An analogy is to be found in various other species in which there is an excess mortality of males over females.

Despite the fascination of speculation, the initial function of the statistician is to indicate where such sex differences in prognosis exist, in the hope that medical research workers from other fields may be induced to explore some of the by-ways.

Summary

Three groups of cancer cases—673 in the tongue, 916 in the buccal cavity, and 550 in the pharynx—treated by radium or deep x rays at the Christie Hospital and

Holt Radium Institute, Manchester, during the years 1932 to 1942 inclusive are analysed separately by sex ten years after treatment, for the purpose of demonstrating a marked difference in prognosis.

Survival rates are given in terms of the whole group irrespective of the degree of clinical involvement at the time of treatment, and also in relation to the presence or absence of extension of the disease to cervical lymph nodes. Relevant factors, including post-operative mortality, incidence of recurrence, and incidence of cervical lymph nodes before and after treatment of the primary lesions are investigated.

In all the directions explored the same trend emerges in support of the thesis that a much better response to treatment is manifest in women than in men. Women are also less prone to develop metastases. Some possible influences are considered.

The opinion is expressed that, in the presentation of the results of treatment of malignant disease, failure to state the sex and age distribution may result in fallacious deductions when comparisons are being made between different series of cases. Attention is also directed to the inadequacy of the crude survival rate for purposes of long-term evaluation, and the necessity for incorporating an age-factor correction is emphasized.

I am indebted to Dr. Ralston Paterson, from whose criticism of my original draft I derived much benefit; to Dr. Edith Paterson for helpful suggestions; to Professor Victor Lambert for useful advice; and to my assistants in the medical statistics department for their aid with the analyses, graphs, and typing of the paper. I wish to record, too, my appreciation of the encouragement and courageous interest of the late Dr. Margaret C. Tod during her terminal illness.

CANCER OF UTERUS: RELATIVE INCIDENCE OF TYPES

BY

J. W. MAGNER, M.D., B.Sc., M.R.C.P.I.
Pathologist, Bon Secours Hospital, Cork

AND

W. KEARNEY, M.D., M.A.O., M.R.C.O.G.
Professor of Obstetrics and Gynaecology, University College, Cork; Gynaecologist, Bon Secours Hospital, Cork

Carcinomas of the uterus are commonly divided into three groups: (1) epidermoid carcinoma of the cervix; (2) adenocarcinoma of the cervix; and (3) endometrial carcinoma of the "body." The first and third groups together account for over 90% of uterine carcinomas.

Cases under Review

During the past four years 1,612 uterine specimens have been examined in this hospital. These were composed of endometrial curettings, 1,135; uteri, 286; and cervical biopsies, 191. During this period carcinoma of the body has been diagnosed in 34 cases, epidermoid carcinoma of the cervix in five cases, and adenocarcinoma of the cervix in one case.

The age distribution of the cases of adenocarcinoma of the endometrium is shown in the Table. The mean age

was 55 years. The marital status was 26 married and 9 single. The age distribution of the cases of epidermoid carcinoma of the cervix is also shown in the Table. The mean age was 45 years. Three were married and two were single.

Age Distribution of 34 Cases of Adenocarcinoma of the Endometrium and Five Cases of Epidermoid Carcinoma of the Cervix

	31-	36-	41-	46-	51-	56-	61-	66-	71-	76-80
Adeno-carcinoma										
Epidermoid carcinoma	1	3	2	3	13	4	3	3	2	1

The relative incidence of cases of carcinoma of the body and the cervix is 7:1. This ratio is so different from the textbook figures that the following points must be noted.

Firstly, the patients are drawn from a selected portion of the community, as this hospital deals almost entirely with the upper- and middle-income groups of Cork City and surrounding country. Secondly, the cases considered to be carcinoma of the endometrium are only those showing frank histological evidence of carcinomatous change; any case showing only atypical hyperplasia was excluded. The fact that the cases were collected over a period of four years would seem to exclude any chance selection in a short period. It would also exclude, to a large extent, the possibility of a number of cases of carcinoma of the cervix having been "missed." To bring the figures to accepted proportions over a hundred cases of cervical carcinoma would have had to escape notice, and so far as we are aware, no patient in this series who was not diagnosed as carcinoma of the cervix has returned with this condition. Lastly, the age distribution and mean age of both groups are atypical. It would thus seem reasonably certain that in this series there is an actual and well-marked reversal of the usually accepted frequency of carcinoma of the body and of the cervix.

To determine whether the atypical distribution was due to an increase in the number of cases of endometrial carcinoma or to a decrease in cases of cervical carcinoma a comparison was made with the figures of the Dublin maternity hospitals (*Irish Journal of Medical Science*, 1949, 1950, 1951). The incidence of endometrial carcinoma occurring per hundred operative gynaecological cases in the Dublin maternity hospitals was compared with that occurring in this hospital, and was found to be very similar. This fact indicates that the variation in our figures is due to an absolute decrease in the number of cases of epidermoid carcinoma of the cervix.

The Dublin reports also show that their relative incidence of the two types of uterine carcinoma is that generally accepted—that is, a preponderance of cervical carcinoma.

Discussion

Figures quoted for the relative incidence of the different types of uterine carcinoma vary, "but broadly it may be said that cervical carcinoma is three or four times as common as endometrial, and that cervical epidermoid carcinoma is at least ten times as common as cervical adenocarcinoma" (Willis, 1948). Novak (1952) gives the proportion as one endometrial carcinoma to eight cervical carcinomas.

It is becoming generally acknowledged that uterine carcinoma has socio-economic and racial distinctions. Stock (1947) has shown uterine carcinoma to be more common among the lower social class in England. He does not, however, distinguish between carcinoma of the endometrium and cervix. Clemmesen and Nielsen (1951) bring evidence to show that cervical carcinoma is more common in the lower socio-economic group, and that its incidence in rural areas approximates to the wealthier areas in the towns. The opinion that cervical carcinoma is more frequent in

the lower-income group is also expressed by Lombard and Potter (1950). They state that "in a sample obtained from a gynaecologist who permitted a study of the records of his wealthy patients . . . the sample was small . . . owing to the fact that only a very small percentage of his private patients had carcinoma of the cervix." Again, Hall *et al.* (1950) found that, while the usual accepted relative incidence of the types of uterine cancer was valid for ward cases, in their private patients endometrial carcinoma was more frequent in the ratio 2:1. Corscaden and Gusberg (1947) also noted that in the private-patient group carcinoma of the endometrium was more common than carcinoma of the cervix.

While showing a much higher proportion than in any of the series quoted, our figures do agree in demonstrating that the usually accepted relative incidence of carcinoma of the endometrium to the cervix does not hold good for all sections of the community. They can also be used to show that in the socio-economic group concerned the disproportion observed is due to an absolute decrease in cases of cervical carcinoma rather than to an increase in endometrial carcinoma.

From the findings of the authors quoted and from our admittedly small group of cases it seems that one definite fact arises—that cancer of the cervix is more common in the lower socio-economic group. Our figures can do little more than suggest that the incidence of endometrial carcinoma may be much the same in all groups.

The reason for this low incidence of cervical carcinoma is obscure. Lombard and Potter (1950) list five factors which they claim have definite significance in the development of cervical carcinoma: marriage before the age of 20 years, unrepai red lacerations, last child born to women before the age of 25 years, syphilis, and individuals divorced or separated at any time. We considered these factors in relation to the class of patient dealt with in this hospital, and it was found, from a sample of married women, that the average age of marriage was 27 years; thus two factors—marriage before the age of 20 years and the last child born before 25 years—do not apply. Divorce and separation are exceptionally rare, as is syphilis. Of all these factors it is only unrepai red laceration of the cervix which might operate.

The relationship of cervical lacerations to cervical carcinoma is still undecided. An interesting contribution in this field is that of Gagnon (1950). This author investigated the medical histories of a large number of nuns, "women whose social state and mode of life protect them from the usual causes of cervicitis or chronic irritative lesions." He found that the ratio of endometrial carcinoma to that of cervical cancer was 6:1, and uses this fact among others to indite cervical lacerations as a factor in cervical carcinoma. In the discussion following this paper, McKelvey objected that the recognized low incidence of cervical carcinoma in the Jewish race still remained to be explained. Weiner *et al.* (1951) indicated that cervical carcinoma in Jewish women is becoming more common, and suggest that the Mosaic laws, which would tend to lessen the incidence of chronic cervicitis, are not now observed as rigidly as formerly. They, however, quote Davidsohn as believing that the difference in incidence of cervical carcinoma may be due to the practice of circumcision, a theory which is supported by the demonstration of the carcinogenic action of smegma.

Ovarian oestrogens have been suspected as a factor in carcinogenesis, and genuine carcinoma of the cervix has been produced in mice by Gardener, Li, and others (Novak, 1951). Ayre (1947) suggests that cervical carcinoma may be due to an abnormal response to cervical infection associated with excessive oestrogen, the latter being due to failure of a liver damaged by vitamin deficiency to inactivate oestrogen. Of interest in this connexion is the fact that Brunelli (1935) showed that in rabbits oestrogen in the blood becomes concentrated and fixed in inflamed tissues. Ayre's suggestions are criticized by Greene and Peckham (1947),

who point out that the previously accepted fact that vitamin-B deficiency, as such, decreases the inactivation of oestrogens by the liver has been shown to be untenable. Drill and Pfeiffer (1946) have shown that "the effect of acute vitamin-B-complex deficiency in producing a failure of the liver to inactivate oestrone seems to be due to the concomitant inanition."

If we may assume that cervical carcinoma is comparatively infrequent in the better-nourished members of a community, then there must be some factor or factors which lessen its occurrence in this group. Alternatively, in the undernourished group there must be some factor or factors which tend to cause this lesion. As cancer is an active condition it would seem more logical to suppose that poor economic conditions in some way produce this disease. Our present knowledge would suggest that cervical carcinoma may be produced in the poorer economic class by some unknown hormonal imbalance or by an unsatisfactory reaction, associated with poverty, to irritative lesions of the cervix.

Summary

Figures are given for the relative incidence of endometrial and cervical carcinoma as seen in a selected population.

These figures are at variance with the incidence usually accepted, and it is suggested that the incidence of the various forms of uterine cancer vary with the socio-economic group.

The possible implications of these findings are briefly discussed.

One of us (J. W. M.) acknowledges a grant from the Medical Research Council of Ireland, held for part of the time during which this work was carried out.

The National Research Development Corporation exists primarily to develop and exploit in the public interest inventions (including medical ones) resulting from public research. It also has other powers. In June this year the Corporation's borrowing powers come to an end, and if the Corporation is to continue its normal activities, new legislation will be necessary. The chance is therefore taken in the annual report for 1952-3, published recently, to review the results of the Corporation's first four years of trading. Starting in 1950 with costs of a little over £20,000 and a return by way of royalties of less than 1%, by 1953 the accounts showed 23% earnings on operating costs of £120,000. Several of the inventions being developed by the Corporation have a direct bearing on medicine. The pilot scale production of hecogenin from sisal juice in East Africa provides a starting material for the synthesis of cortisone. Prototypes of the Burns analgesic inhaler, designed for trilete and other volatile analgesics, have been prepared for clinical trial. The Corporation has underwritten the costs of the initial manufacture of an aural microscope and chick sexer. Other projects range from large electronic digital computers ("electronic brains") to a new machine for liquefying atmospheric gases.

DIABETES INSIPIDUS ASSOCIATED WITH PULMONARY DISEASE

BY

R. B. RAFFLE, M.D. M.R.C.P.

South Shields

Spillane (1952) described four cases in which diabetes insipidus was associated with pulmonary disease. The case here reported falls into the same category and exhibits diabetes insipidus and lung lesions as the only discoverable abnormalities.

Case Report

A housewife aged 57 was first seen in January, 1952, having been referred for further investigation after attending a mass x-ray session. She had suffered from increasing dyspnoea on exertion for about four years, with morning cough and the expectoration of a small amount of yellowish sputum. For several years she had passed large amounts of pale urine at frequent intervals during the day and night. She was also troubled by excessive thirst and said that she could drink a pint of soda-water at a time and still be thirsty. Her sleep rhythm was unchanged and there was no somnolence by day.

Before her present illness she had been healthy and had when younger often cycled 50 miles (80 km.) a day without distress. Until seven years previously she had worked as a waitress in addition to looking after her home, but she had had to discontinue this in order to look after her husband, who was becoming severely disabled owing to post-encephalitic Parkinsonism. She had had pneumonia on three occasions, at the ages of 23, 29, and 37; erysipelas at 14; and scarlet fever in childhood. There was no history of skin disease.

She was the second oldest of a family of 13 of whom five of six brothers had died in infancy, the other being killed in adult life. Of her six sisters, five were healthy and one had died 48 years previously, the cause of death being unknown. The patient had had two children, both of whom were healthy; her son was 34 and her daughter 28.

Examination revealed a rather pale middle-aged woman, weighing 134 lb. (60.8 kg.), an excellent witness, though inclined to make light of her complaints. Her skin was somewhat dry and wrinkled but otherwise showed no abnormality. No lymphatic glands were palpable and there was no enlargement of the salivary glands. Venous congestion, ankle oedema, and finger-clubbing were not present. She was somewhat dyspnoeic at rest, but no other clinical abnormalities were detected in the chest or heart. The blood pressure was 150/100. The abdomen showed no abnormality and the liver and spleen were not palpable. The optic disks were normal and neurological examination was negative.

Further investigation showed that she passed 12 to 16 pints (6.8 to 9.1 litres) of urine daily and drank roughly equal amounts. The specific gravity of the urine was in the neighbourhood of 1005; there was no glycosuria or albuminuria and no casts were present. X-ray films of the chest showed a mixture of reticulation and miliary mottling throughout both lung fields without enlargement of the hilar lymph nodes. No cysts were detected and there was no pneumothorax. X-ray films of the hands, feet, and skull showed no bony abnormalities. The pituitary fossa was radiologically normal.

Sputum tests for tubercle bacilli were repeatedly negative. The Mantoux test was positive to 1:1,000 O.T. Blood examination showed: Hb, 66% (9.8 g.); erythrocytes, 5,000,000. The E.S.R. was 12 mm. in the first hour (Wintrobe). The blood Wassermann and Kahn reactions were negative and the glucose-tolerance curve was normal. The

serum cholesterol was 305 mg. per 100 ml.; serum albumin 5 g. and globulin 3.5 g. per 100 ml.; albumin/globulin ratio 1.43:1. Liver-function tests showed serum colloidal gold reaction 3+, gamma globulin (zinc sulphate) 8 units, thymol turbidity 4 units, and thymol flocculation +.

Pituitary snuff immediately controlled her polyuria and allowed her to sleep well at nights. After starting this treatment, however, she stated that her breathlessness was somewhat increased. Because of the hypochromic anaemia she was given iron, which resulted in some amelioration of the dyspnoea.

A year later her condition was unaltered and a further x-ray film of the chest showed no substantial change.

Comment

The diagnosis of diabetes insipidus cannot be in doubt, there being adequate evidence to exclude other causes of polydipsia and polyuria—that is, diabetes mellitus, renal disease, and hysterical polydipsia. The only other discoverable lesions were those in the lung, manifested by exertional dyspnoea and radiographic changes.

Spillane (1952) summarized fully the literature relating to this combination of lesions. Following him the diagnoses to be considered are sarcoidosis, tuberculosis, xanthomatosis, tuberous sclerosis, syphilis, honeycomb lungs, and bronchogenic carcinoma.

The first of Spillane's four cases was an undoubted example of sarcoidosis, and this diagnosis could not be excluded in his Case 4. The other two cases were considered clinically to be examples of xanthomatosis. Necropsy in Case 3 later showed, in the hypothalamus and the lungs, the changes of eosinophilic granuloma which shares a morphogenesis in common with Hand-Schüller-Christian and Letterer-Siwe diseases, all three being secondary xanthomatoses associated with progressive reticular hyperplasia. It is therefore interesting to note that one of Cates and Garrod's (1951) cases of diabetes insipidus occurred in a patient with xanthomatosis and honeycomb lungs who also developed an eosinophilic granuloma of bone.

Dennis and Rosahn (1951) reported the case of a man aged 30 with diabetes insipidus and cystic lungs. They concluded from the necropsy findings that it represented a granulomatous disease involving the reticulo-endothelial system.

In the present case sarcoidosis does not appear to be the most likely diagnosis. Spillane (1952) collected from the literature 18 cases of sarcoidosis associated with diabetes insipidus. In none were the lesions confined to the pituitary region and the lungs. Similarly his own Case 1, which was an example of sarcoidosis, had an initial characteristic uveo-parotitis with facial palsy. His Case 4, in which no certain diagnosis was reached, and in which sarcoidosis could not be excluded, showed lesions in these two situations only. In this respect it is similar to the present case in which the Mantoux test (positive to 1:1,000 O.T.) is rather against the diagnosis of sarcoidosis. In addition, the dyspnoea was more intense than might be expected in a case of sarcoidosis with similar radiographical findings.

If we adopt a histological definition of sarcoidosis, as does Scadding (1950), diagnosis must await confirmation by biopsy. In the present case no superficial glands were available for biopsy and, owing to her commitments at home, the patient was unwilling to accept admission to hospital for liver biopsy.

Although, therefore, it is not possible definitely to exclude sarcoidosis, a granulomatous or xanthomatous process seems by exclusion to be a more likely diagnosis.

It is possible that when lung changes and diabetes insipidus occur together as the only discoverable disease they constitute a syndrome the pathological basis of which is a granuloma of some as yet undetermined and possibly variable type. The two conditions may, however, occur as a part of more widespread pathological processes such as those indicated in the papers cited.

Summary

The case is described of a woman aged 57 who had diabetes insipidus associated with a combination of reticulation and miliary mottling throughout both lung fields. A granulomatous or xanthomatous process is thought to be the most likely diagnosis, though sarcoidosis cannot be definitely excluded.

PULMONARY ACARIASIS IN SPAIN AN ILLUSTRATIVE CASE REPORT

BY

MARIANO DE FIGUEROA TABOADA, M.D.

Director, National Antituberculosis Institute, La Ventilla, Madrid; Professor, Medical Academy of the Spanish Air Force

Considerable interest has been created in many parts of the world by the association that has been postulated by workers in Ceylon between hypereosinophilic respiratory disorders and pulmonary acariasis. Carter Wedd, and D'Abrera (1944) were the first to detect mites (Acarina) in the sputum of asthmatic patients with high eosinophilia. This discovery was confirmed by Soysa and Jayawardena (1945), who also suspected that the syndrome might result after exposure to inhalation of airborne mites. Further investigations in Ceylon by Carter and D'Abrera (1946) and by Soysa (1949, 1952a) have verified the previous findings. The conclusions of the Ceylonese workers that pulmonary acariasis may be associated with respiratory symptoms and massive eosinophilic reaction have been supported by reports from England (Hall, 1946), the Netherlands West Indies (Van der Saar, 1946), East Africa (Wilson, 1947), etc.

Since 1946 my attention has been engaged by the occurrence of mites in the sputum of certain patients with respiratory disorders associated with eosinophilic leucocytosis, and cases have been reported in Spain (Figueroa Taboada, 1946). I have been able, in my studies of this curious syndrome, to verify the ideas that have been so carefully and clearly presented by Soysa, and the results of my investigations are in complete agreement with his views concerning the three-stage clinical course discernible in many cases; the remarkable eosinophilic leucocytosis that is the most prominent and constant pathological feature of this syndrome; the variability of the pulmonary radiological appearances; the presence of mites in the sputum; the possibility of bronchial infestation by airborne mites; the ambient air importance of environment in relation to the acquisition of the disease; and the dramatic response to arsenical therapy, which is often associated with a Herxheimer reaction.

As an example of our findings in Madrid I cite a typical case history.

Case Report

A male clerk in a food store, aged 39, was investigated for asthma of seven months' duration. His personal and family history revealed no indication of any allergic antecedents. A blood count showed a total leucocyte count of

TRICHLORETHYLENE POISONING WITH PARANOID PSYCHOSIS AND LILLIPUTIAN HALLUCINATION

BY

J. TODD, M.B., B.S., D.P.M.

Assistant Psychiatrist, Littlemore Mental Hospital

There are few published reports of psychosis resulting from poisoning with trichlorethylene ("trilene"). Eichert (1936) recorded two cases and Rickles (1945) one case. All three arose from the excessive use of trichlorethylene inhalations to assuage the pain of tic douloureux. The opportunity to study the effects of orally ingested trichlorethylene has rarely arisen. However, Stephens (1945), Naish (1945), and Kallenback (1947) have between them described the toxic manifestations of swallowed trichlorethylene in four cases. In general, the symptoms consisted of prolonged inebriation, with vomiting, dizziness, deafness, or numbness of the limbs. The following case has some unique features.

Case Report

An Irish labourer aged 40 was admitted to Littlemore Mental Hospital on April 11, 1953. On April 5 he had accidentally swallowed a quantity of trichlorethylene contained in a beer bottle. The precise quantity ingested could not be ascertained, but was described as a "good swig." Realizing his mistake, he succeeded in vomiting up some of the liquid by swallowing an emetic mixture of salt and water. Nevertheless, his breath reeked of trichlorethylene and he was grossly inebriated on arrival at the casualty department of the Radcliffe Infirmary less than an hour after the accident. Despite stomach washouts (and other treatment), he passed into a deep coma lasting 36 hours. At times he was frankly cyanosed. The pupils varied in size from pin-point to wide dilatation with brisk light reaction. The B.P. varied between 90/50 and 140/70. On April 8, consciousness having returned the previous day, he developed a system of paranoid ideas to the effect that he was going to be "beaten up" during the night by two patients in league with the nursing staff. That night he awoke in a state of delirium which he described as follows:

"The next thing I remembered was awakening to find myself soaked in sweat and strapped in a kind of long leather sack. I could hear the two patients who had spied on me during the day talking with the night nurses. One of them said, 'Let's give it to him now.' I opened my eyes, struggled free from the sack, and shouted for help. I then saw that the ward was its usual length, but only about 2 ft. high; the beds were about 18 in. long. In response to my cries a little nurse, 12 in. high, ran to my bed. I told her I was afraid, so she tried to reassure me, and went away to get a hot drink. While she was away, other nurses came to my bedside and were later followed by a doctor. They were all about 12 in. tall. I recognized all of them as the nurses and doctor I had seen before. The only other person besides myself who seemed the normal size was a patient in the bed next to mine. I thought he was a negro who was also being persecuted, but later found that he was white. I felt terribly afraid while all this was going on. They changed my shirt and gave me an injection. The next morning everything was back to its usual size."

During the next few days he continued to show evidence of a paranoid psychosis. For example, he complained that people were saying he had V.D., and that a nurse had "framed" him with a 10s. note introduced into his locker. His transfer to a mental hospital became necessary as a result of marked restlessness.

He was examined on his arrival at Littlemore Mental Hospital, with the following results. *Psychiatric condition:* During the first 48 hours he was unduly loquacious and

lacking in insight. He still harboured delusions of a persecutory nature. The family and personal psychiatric histories were negative. *Physical condition:* He showed no physical abnormality with the exception of a coarse tremor of his extended fingers and a few persistent sibili at both lung bases. He was discharged in excellent mental and physical condition on April 25.

Special Investigations at Radcliffe Infirmary.—April 5: Hb, 100%; white cells, 20,000 per c.mm.; a neutrophil leucocytosis was present. April 8: Normal plasma proteins. No abnormal constituents of any kind in the urine.

Special Investigations at Littlemore Mental Hospital.—April 15: Blood urea, 30 mg. per 100 ml.; blood bilirubin, 0.2 mg. per 100 ml.; prothrombin level, 100%; plasma proteins, 7.1 g. per 100 ml.; urine testing showed no abnormal constituents. April 16: Hb, 115%; white cells, 10,000 per c.mm. April 20: Blood urea, 27 mg. per 100 ml.; blood bilirubin, 0.3 mg. per 100 ml.; prothrombin level, 100%; plasma proteins, 6.5 g. per 100 ml.; the urine contained no abnormal constituents.

Discussion

A noteworthy feature of this case is the fact that at no time was there any evidence of hepato-renal damage, despite the ingestion of enough trichlorethylene to produce a coma lasting 36 hours. This demonstrates a highly selective action of the substance on the central nervous system. Hunter (1949) showed that trichlorethylene has no serious toxic effect on the kidneys or liver of healthy mice. Ostlere (1953), after reviewing the literature, arrived at the conclusion that "the evidence of animal experiments, industrial toxicology, laboratory tests, and clinical practice clearly indicates that the toxic effects of trichlorethylene on the liver are negligible." The sparing of the liver cells by trichlorethylene is surprising, as the chemically related chloroform, carbon tetrachloride, and tetrachlorethane are notorious hepatotoxins.

The adjective "Lilliputian" was first used by Leroy (1909) to describe a rare form of visual hallucination consisting in the perception of imaginary objects, persons, or animals of diminutive size. These tiny animals or personages are usually seen as brightly coloured mobile creatures strongly reminiscent of those described by Swift in *Gulliver's Travels*. The perception of the colourful midgits tends to produce in the subject an agreeable emotional reaction, whereas the more usual forms of visual hallucination often engender a feeling of terror. The real environment does not usually participate in the Lilliputian contraction. In the case described, the microptic hallucinations took an exceptional (if not unique) form in that they represented real personages, were not coloured, produced a feeling of fear in the patient, and the ward was involved in the Lilliputian effect. In his delirium, the patient would appear to have experienced microptic illusion in addition to hallucination. Lilliputian hallucinosis has been described as a result of intoxication from alcohol, chloral, ether, cholera, and typhoid (Leroy and Rogués de Fursac, 1920). It has also been reported in the course of scarlet fever (Hall, 1922) and cocaineism (Henderson and Gillespie, 1927). It is tempting to wonder if Dean Swift (or one of his friends) experienced the phenomenon at some time or another.

Summary

A case of accidental poisoning with trichlorethylene is described. An acute paranoid psychosis with Lilliputian hallucination followed a 36-hours coma. There was no evidence of hepato-renal damage at any time. In this case the microptic hallucination differed in many ways from the classical descriptions in the French literature.

My thanks are due to Dr. R. W. Armstrong, physician-superintendent of Littlemore Mental Hospital, Mr. W. A. McDougall, laboratory technician, and to the doctors of the Radcliffe

32,000 per c.mm., with 36% eosinophils. X-ray examination of the lungs showed fine linear striations superimposed upon the pathognomonic "ground-glass haze." Examination of the sputum by the special technique of Carter *et al.* revealed the presence of *Carpoglyphus* mites (Fig. 2).

FIG. 2.—*Carpoglyphus*.

to prevent cumulative effects. The patient developed status asthmaticus on the fourth and fifth days of arsenical treatment. Clinical control of the asthma was affected by the tenth day. The leucocytes gradually declined to 12,500, with eosinophils 11% on the twenty-second day, and to 10,000, with eosinophils 6%, on the thirtieth day after starting acetarsol therapy (Fig. 1). The patient has had no recurrence of asthma for fourteen months.

Comment

This case conforms in all its features to the typical cases recorded by Soysa and confirms his observations as regards the symptomatology, pathogeny, and therapy of this syndrome. I believe that pulmonary acariasis is a perfectly delimited pathological entity which should be separated from allied respiratory disorders.

Though generally regarded as a tropical disease, this syndrome may be much commoner than it may seem to be in temperate zones, such as Europe, where the causal Acarina are widely distributed—for instance, in stored food products. In England have been found the mites of the genera *Carpoglyphus*, *Glyciphagus*, *Cheyletus*, *Tarsonemus*,

and *Tyroglyphus* (Hughes, 1948). It seems possible, therefore, that careful examination of sputum in cases of eosinophilic respiratory disorders may disclose the presence of mites in countries that are not circumscribed within the tropical zone.

The laboratory procedure required for this purpose is long and laborious. Strict precautions have to be taken against accidental contamination of the specimens of sputum that have to be collected over a 24-hour period. The mass of material to be examined is so large that the work demands much patience and perseverance. The relatively small number of mites found in this quantity of sputum may appear insignificant, but it should be remembered that a few mites can cause disproportionate clinical disturbances in other acarine infestations, such as scabies. It may be argued that airborne mites may be prevalent in the respiratory passages without causing clinical or haematological manifestations. This objection has been met by the careful examinations made by Soysa (1949) of 44 control specimens of sputum taken from healthy persons and from patients suffering from non-eosinophilic respiratory diseases: not a single mite was found in any case, though 17 of these subjects were definitely exposed to the risk of inhaling airborne mites.

In a recent review of the aetiology and pathogeny of eosinophilic pneumonitis Soysa (1952b) discussed the various conditions that may present with somewhat similar clinical manifestations, and has suggested that, of the pathogenic agents that have been alleged to be responsible for eosinophilic pneumonitis, mites, metazoa, and fungi seem to come most under suspicion at the present time. He holds with the view that, despite the multiple aetiology and diverse pathological conditions that have been observed or suspected, the manifestations are linked by a common anaphylactoid pathogeny which is probably related to vascular allergy.

Medical Memorandum

Traumatic Retroperitoneal Rupture of Duodenum

In view of the rarity of traumatic retroperitoneal rupture of the duodenum the following case is worthy of record.

CASE REPORT

A window-cleaner aged 17 was admitted on October 16, 1951, at 4.30 p.m. with a history of having fallen from a window-sill, a height of 20 ft. (6 metres), one hour previously. No one had seen him fall and he had been picked up by his workmate a few minutes later. He was quite conscious, but had no memory of falling. He was complaining of severe pain in his abdomen and was bleeding from his nose.

On examination his temperature was 98° F. (36.7° C.), pulse 92, respirations 20, and blood pressure 110/70. He was bleeding from both nostrils and he had a 1-in. (2.5-cm.) laceration of the chin. There was no obvious fracture of the nose or mandible. He complained of severe abdominal pain, mostly in the umbilical and hypogastric regions. He vomited twice during examination, and blood-staining of the vomitus was noticed, but the possibility of blood swallowed from his epistaxis was considered. Abdominal examination revealed abrasions and some bruising in the right iliac fossa. He was very tender, with some guarding over the whole abdomen, especially in the left iliac fossa. There was no rigidity. Bowel sounds were not heard. Dullness was not elicited in the flanks, and rectal examination caused no undue discomfort. A soft rubber catheter was passed to exclude bladder injury. It passed easily and 6 oz. (170 ml.) of clear urine was obtained. A diagnosis of ruptured abdominal viscus was made, and laparotomy was performed by one of us (W.P.C.) two hours after admission.

Operation.—Under thiopentone, cyclopropane, curare, and oxygen anaesthesia the abdomen was opened through a long right paramedian incision. A small quantity of free blood was present in the peritoneal cavity. By palpation no tear was found in either spleen or liver. Further inspection revealed a large left-sided retroperitoneal haematoma behind the descending colon and extending forwards between the layers of the pelvic mesocolon. The haematoma extended upwards and towards the right, and was continuous with a haematoma behind the hepatic flexure and the duodenum. The right kidney felt normal. Blood and extensive bile-staining were present in the lesser omentum. A laceration of the biliary tract was considered. The gall-bladder was normal and contained bile. The lesser omentum was incised and no lesion was seen in the common bile duct. Bile-stained fluid was coming upwards from behind the first part of the duodenum. The peritoneum along the right border of the duodenum was divided and the

duodenum mobilized to the left. A 1-in. (2.5-cm.) linear tear was found on the posterior wall of the first part of the duodenum across the long axis of the bowel. Bile-stained contents were emerging. The tear was closed with two layers of continuous catgut. Examination of the whole bowel revealed no further lesion. Abdominal toilet was performed and the abdomen closed in layers with a stab drain to the duodenum. Extraperitoneal drainage of the left-sided retroperitoneal haematoma was carried out.

After operation 2 pints (1.1 litres) of blood was given by intravenous drip followed by alternating normal saline and 2½% dextrose. Gastric suction was instituted.

His progress was stormy. On the fourth post-operative day the stab drain to the duodenum discharged bile-stained fluid which digested the surrounding skin. Although not analysed, this was doubtless due to associated pancreatic trauma. It cleared up on the ninth day. The abdomen gradually distended and there were signs of paralytic ileus by the sixth post-operative day. Gastric suction and intravenous fluids were continued until the tenth day, when the bowel action returned. The drains were removed on the ninth day and the sutures on the eighteenth day, when the wound was soundly healed and the patient was eating normally.

He reported four weeks after discharge, and was symptom-free and on a full diet. A barium-meal examination on December 7 revealed a slight narrowing of the first part of the duodenum, probably as a result of the operation.

COMMENT

Closed traumatic retroperitoneal rupture of the duodenum is a rare injury. Johnson (1944) collected 52 cases from the literature between 1910 and 1943. The causative force may not necessarily be great, and the diagnosis of intestinal abdominal injury may therefore be delayed until signs of retroperitoneal sepsis or haemorrhage develop. When the parietal peritoneum of the abdomen is torn the signs of developing peritonitis may be the first indication of the diagnosis. In the case here reported the large retroperitoneal haematoma on the left side, associated with the free blood in the peritoneal cavity, no doubt explains the severe lower abdominal pain and tenderness in the left iliac fossa and probably accounted for so early a laparotomy.

The aetiology of retroperitoneal rupture of the duodenum is not clear. Cases of "burst injury" of the duodenum due to sudden compression of gastric contents with "blow out" of the duodenum have been described. This type of injury would be expected to cause a tear in the long axis of the gut. In the above case the tear was across the long axis and was most probably due to a sudden strain at the junction of the fixed and mobile parts of the first part of the duodenum associated with crushing against the vertebral column.

At operation, as pointed out by Simpson (1950), bile-staining of the retroperitoneal tissues should suggest a diagnosis and warrant inspection of this region. Simpson also recommends simple suture if possible, as was performed in this case.

Our thanks are due to Mr. G. H. Buckley for permission to publish this case.

Reviews

A NAVAL OCCASION

Our National Ill Health Service: An Essay on the Preservation of Health. By Surgeon Vice-Admiral Sir Sheldon F. Dudley, K.C.B., F.R.S., Hon.L.L.D.(Ed.), M.D., F.R.C.P., Hon.F.R.C.S.Ed., D.T.M., D.P.H. (Pp. 225. 15s.) London: Watts and Co. 1953.

Is this book meant to be taken seriously? One might regard it as a *jeu d'esprit* were it not that its distinguished author, who was Medical Director-General of the Royal Navy for the greater part of the war, is not the person to jest with sacred subjects. Its theme is that the N.H.S., which shows "appalling ineptitude after five years of brawling, obstruction and procrastination by all concerned," fails because it aims at cure rather than prevention; it should have been modelled on the medical services of the Forces, particularly the Royal Navy.

The thread of the argument, conspicuous enough in the first section, becomes less and less perceptible as the book proceeds until, before the middle is reached, it is irretrievably lost in a patchwork of bewildering variety and inconsequence—priority in medical discovery, anonymity in publication, unnecessary operations, the treatment of burns, the ethics of placebos and proprietary medicines, the inferior intelligence of Members of Parliament, and many other topics of lively interest but hardly to the point. For any evidence of consistent thought apposite to the subject one looks in vain. In the section on "The Preservation of Global Health," for instance, fulmination against the Civil Service and particularly the Treasury (whose staff should be trained not in the classics but in applied anthropology) leads straight to a discussion of world food production, the host-parasite relationship, and the damage done by the rabbit, moth, locust, rat, and prickly pear. Then follow field hygiene and its enforcement by health education and propaganda.

The author naturally gives great prominence to Lind, Blane, and Pringle, who, it will be generally admitted, from their Service experience taught civilian medicine the principles of prevention. But this happened in the eighteenth century. Sir Sheldon fails to mention that in both wars of the twentieth century the Royal Naval medical services had to be buttressed by the appointment of civilian consultants who were given the rank of admiral. He seems to forget, too, that naval personnel are highly selected for an age-to-period of maximum efficiency and discarded before degenerative and senile changes set in. Criticism of the Medical Man-Power Committee comes ill from a Service which might have been less wasteful of its own personnel.

The author admits the great advantage of naval discipline, but thinks its absence from civilian life can be remedied. The principles of health preservation are to be instilled into children at a tender age. He would like to see problem families put "into large establishments, under a firm but benevolent discipline such as that of the Services, whereby all sorts of bad or amoral, antisocial personalities become happy, self-respecting citizens." He admits, however, that this is impracticable until "fecklessness is made a punishable misdemeanour or certifiable as a dangerous form of mental deficiency." As if these remedies were not sufficiently draconian, a code of health morals would be laid down by a "panel of medical specialists assisted by experienced Law Lords." Among offenders would be those who sneeze in buses without covering their faces.

An epilogue deals with Utopias, uncongenial work, the harm which "meddlesome psychiatrists" might have done to Dr. Johnson, Charles Darwin, and Florence Nightingale, the use of leisure, and the obscure "as if" philosophy of Vaihinger. It ends with the strange belief that King Solomon was the most famous of all Freudians and that he was the author of *Ecclesiastes*:

Since this book was written the Government has appointed a commission to inquire into the medical services of the Forces. *Post hoc*, of course, but can anything be wrong? FRANKCON ROBERTS.

RESUSCITATION

Inhalation Therapy and Resuscitation. Meyer Saklad, M.D. American Lecture Series. (Pp. 338; 130 illustrations. £2 14s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1953.

Preventable anoxia as a direct cause of death is commoner than is generally believed. Not only in anaesthesia but in a wide range of diseases and circumstances this condition occurs, and its recognition, prevention, and treatment would undoubtedly save many lives every year. Dr. Saklad has cast his net wide to gather the material for his book. The physiology of respiration, the pathological effects of oxygen lack on every organ of the body, the treatment of a variety of conditions ranging from eclampsia to heat exhaustion and from intestinal distension to whooping-cough, the apparatus and technique of oxygen therapy, and the methods of artificial respiration and cardiac resuscitation—all these and many other topics too are to be found in some detail. The text does not make easy reading, for it is too often little more than a series of abstracts from the literature, but as a work of reference to the causes, results, and treatment of oxygen lack the book has no equivalent. It is well produced, the illustrations are clear and generally helpful, and an alphabetically arranged bibliography of some 402 papers and books is included.

This monograph is recommended to anaesthetists and others called upon to treat a patient suffering from oxygen lack. It is an invaluable book of reference to readers interested in the literature on anoxia.

W. W. MUSHIN.

SYNOVIAL FLUID

Synovial Fluid Changes in Joint Diseases. By Marian W. Ropes, M.D., and Walter Bauer, M.D. A Commonwealth Fund Book. (Pp. 150. £1 5s.) Harvard: University Press. London: Geoffrey Cumberlege. 1953.

Over a period of more than twenty years Dr. Marian Ropes and Dr. Walter Bauer, with others of their colleagues at the Massachusetts General Hospital and the Harvard Medical School, have become well known for a number of outstanding contributions—both clinical and pathological—to our knowledge of joint disease. One aspect of their studies is summarized in this interesting book, which includes a large amount of hitherto unpublished material. Not only are their findings of great practical importance to those who are concerned with the diagnosis of joint diseases, but they are of interest in connexion with many problems of the physiology of synovial fluid formation.

Joint disease is usually marked by some degree of effusion, and ever since the introduction of chemical methods as aids to clinical investigation it has been hoped that analysis of aspirated fluid would provide information of help in diagnosis. Study of the present volume makes it clear that, although this has proved to some extent to be so, there are serious limits to the diagnostic possibilities of synovial fluid analysis. No individual chemical constituent of synovial fluid shows any change which is specifically diagnostic for a particular disease, although the pattern of change in a number of constituents broadly reflects the type and the extent of pathological change in the synovium of the involved joint. Even so, on the basis of their tabulated findings for 1,500 fluids, the authors suggest that the following determinations are sometimes clinically rewarding: viscosity; pH; cell count (total and differential); protein content; albumin:globulin ratio; sugar content; mucin content; and the type of mucin precipitate obtained on addition of acetic acid. Values for non-protein nitrogen, uric acid, and electrolytes—such as calcium, inorganic phosphate, and chloride—were not found to have any diagnostic significance.

The main purpose of the work is to show that joint diseases may be divided into two main groups on the basis

of synovial fluid findings. The first of these groups includes conditions such as traumatic effusions, osteoarthritis, osteochondritis, neuroarthropathy, and osteochondromatosis, where the joint fluid is clear and viscous, forms little or no clot, contains few cells—mostly lymphocytes, and mononuclears—has a relatively low protein content with a high albumin:globulin ratio, has a sugar content approximately the same as that of the blood, and gives a conspicuous mucin precipitate. Contrasting with these is the second main group consisting of all infectious arthritides and rheumatoid arthritis, where the fluids are turbid and less viscous, form large clots, contain many cells, most of which are polymorphs, have a high protein content with a low albumin:globulin ratio, show a sugar content lower than that of the blood, and give a poor mucin precipitate. It is suggested that the joint effusions in the first group have a common "traumatic" origin, and that effusions can thus be regarded as "traumatic" or "inflammatory." The main diagnostic value of chemical study is that it aids materially in distinguishing between these two large groups, although in a few conditions—notably rheumatic fever, pigmented villonodular synovitis, and gout—the fluid changes resemble each of the two groups in some respects.

H. A. Sissons.

POLIOMYELITIS

Die Poliomyelitis. By Professor Stéphane Thieffry. (Pp. 328; 205 figures. 26.80 francs.) Bern and Stuttgart: Hans Huber, 1953.

This is a German edition of a French symposium published in 1950. It suffers from the unevenness of treatment characteristic of books formed from a collection of essays. The first essay, on epidemiology and immunology, has been brought up to date and is well documented in the text. It is as clear and balanced a short summary of the knowledge of to-day as I have yet read. After this the character of the book alters and the succeeding essays resemble more closely the chapters of a student's textbook and are devoid of references. The essays on the disturbances of respiration, muscle strength, and electrology are preceded by full discussion of the physiological basis of the respective subjects which at times is rather elementary. Their inclusion is useful for the student but swells the bulky volume unnecessarily. For example, the detailed description of the general chemical factors associated with muscular atrophy are not specific for poliomyelitis alone and could therefore have been compressed or omitted.

The book is illustrated by a series of line drawings which are most useful in the excellent section on testing muscle strength. Although the standard grading of muscle function is given, there are no comparative tables showing changes in muscle balance with convalescence. The orthopaedic section of the book is well illustrated and forms a sound résumé of the methods used with success. More important, it is dogmatic about what cannot be done with success.

While such a book, embracing as it does many specialties, cannot be expected to advance each one, it does give an overall picture of the disease and forms a sound student's manual. Many specialists would gain from it the advantage of a deeper insight into the problems of their co-workers on this distressing disease.

J. G. BONNIN.

EXAMINING THE PATIENT

Physical Examination of the Surgical Patient. By J. Englebert Dunphy, M.D., F.A.C.S., and Thomas W. Botsford, M.D., F.A.C.S. (Pp. 326; 188 figures. £1 17s. 6d.) Philadelphia and London: W. B. Saunders Company, 1953.

The tendency for the student to rely on laboratory tests and the x-ray examination in the diagnosis of surgical cases has often been deplored, but the only way to counteract it is to provide attractive books teaching him how to diagnose by his unaided senses. The authors quote Thayer: "Learn to see, hear, feel and smell and know that by practice alone can you become an expert," and in the preface they state that

"this book is designed to focus attention on the methods and importance of eliciting physical signs in surgical conditions." They have undoubtedly succeeded in their aim, and we can cordially recommend the book to every surgical student.

The changing problems in diagnosis are indicated by the caution given that in infections of the hand "systemic signs may be completely abolished by vigorous antibiotic therapy although the local process may be progressing." The same warning is given in diagnosis of peritonitis: "The liberal use of the antibiotics greatly alters the signs of peritonitis. There may be very little abdominal tenderness, rigidity, or distension." This is a book to welcome and not to criticize, but we should like to see a fuller description of the signs of coxa vara, and Figures 57 and 38 are not in our opinion distinctive enough. English students need not worry about distinguishing the bite of the black widow spider in diagnosing acute abdominal conditions.

ZACHARY COPE.

MEDICINE AS A WHOLE

Modern Concepts in Medicine. By Julius Jensen, Ph.D. (in Medicine), University of Minnesota; M.R.C.S., L.R.C.P. (Pp. 636; illustrated. £4 6s.) London: Henry Kimpton, 1953.

Successful textbooks may come about for at least two reasons. A book may represent material which the author has practised and perfected through years of teaching students and appreciating their difficulties. Or it may represent a new and stimulating approach to a subject, as when Osler gathered together the clinical investigations and pathological observations of the nineteenth century into a single vividly written volume, or when McCallum wrote of pathology in all its manifestations as a process and not as something static. Jensen has tried to write this second type of book, but good intentions are not the same as achievement, and this must be frankly described as a disappointing book. Jensen's thesis is that medicine can be regarded as a consistent whole, in harmony with a general unitary conception of man's life and his destiny. The keys to this holist conception are to be found in Selye's work on stress, the theory of cybernetics, and the writings of philosophers such as Gerald Heard. So far so good, but when we get to the body of the book we find nothing new or fresh in this sense. The introduction is on cellular activity and principles of adaptation. The second part is entitled the "Essential Processes of Adaptation" and is on the various mechanisms of homeostasis. Part III, "Structural Facilities in Support of Adaptive Processes," is internal medicine treated in the ordinary way. Part IV, "Cybernetics," deals with enzymes, vitamins, the endocrines, and the nervous system. The general impression is of material taken from standard textbooks of applied physiology and medicine which has been rearranged under new titles. The material is not illuminated with new ideas, and the book cannot be recommended for the ordinary medical reader.

L. J. WITTS.

PICTURES OF PARASITES

Synopsis of Medical Parasitology. By V. E. Brown, Ph.D. (Pp. 109; 103 figures. \$3.50.) Wisconsin, U.S.A.: V. E. Brown. No date.

Although most of the drawings in this book are beautifully executed, it is regrettable to find that in many instances they are inaccurate in detail. To take but a single page (p. 102), we find that in the drawing of the microfilaria of *Loa loa* no cephalic space is shown, and that in the figure of a *Mansonella ozzardi* microfilaria nuclei are shown extending to the tip of the tail. In both cases these details of structure are taxonomically of great importance. These are not the only mistakes on the page. Little can be expected of a text that deals with trypanosomes in less than a thousand words, but the book is hardly intended to be more than a collection of drawings.

FERGUS J. O'ROURKE.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY FEBRUARY 20 1954

TOXIC GOITRE

In October, 1863, Trousseau¹ was consulted by "a young married lady who habitually resides in Paris suffering from a subacute exophthalmic goitre." He was occupied with the idea that there would be some danger in giving iodine—and wrote iodine instead of digitalis on the prescription. When the patient returned in a fortnight her pulse rate had fallen from 150 to 90. Despite this fortunate accident Trousseau wrote in his subsequent comments that iodine generally does harm in Graves's disease. Not until 30 years ago did Plummer,² of the Mayo Clinic, re-introduce and popularize the use of iodine for hyperthyroidism, following it with thyroidectomy. Two other landmarks stand out in the treatment of thyrotoxicosis: the introduction of radioactive iodine, first recorded by Hertz,³ and the discovery of the antithyroid drug thiouracil by Astwood,⁴ also of Boston, in 1943. The clinician, who forty years ago had no effective therapy to offer in Graves's disease, is nowadays sometimes bewildered by finding that he has no fewer than three forms of treatment from which to choose. Like Bassanio in *The Merchant of Venice*, he is faced with a good deal of heart searching before he can decide in which of the three caskets he will find the right answer.

The cause of thyrotoxicosis remains unknown, though much evidence points to the anterior pituitary as the villain of the piece. Since this disease is subject to spontaneous remissions and occurs in widely varying degrees of severity, it may also present particular difficulties in diagnosis. For these reasons the introduction of techniques using radioactive iodine as a diagnostic tool is particularly valuable and is

rightly emphasized in the Bradshaw Lecture delivered by Professor E. J. Wayne which we publish in the opening pages of the *Journal* this week. He reviews in comprehensive fashion the clinical manifestations of thyrotoxicosis and concludes that, while most of the classical signs and symptoms are a reliable guide to the disease in men, the diagnosis may be much more uncertain in women, especially at the menopause. Increased appetite, loss of weight, preference for cold weather, hot and sweating hands, persistent tachycardia especially during sleep, and hyperkinesis prove the most helpful diagnostic features. But there remains a group of patients in whom the diagnosis cannot be made with certainty, and then laboratory tests are necessary.

So many tests of thyroid function are available that it is clear that none is completely satisfactory. Estimation of the basal metabolic rate still remains the most useful test which is generally applicable, and when carried out with the careful technique described by Robertson⁵ it is remarkably accurate. But the metabolic rate is raised in conditions other than thyrotoxicosis and may be difficult to determine accurately in the nervous woman; moreover, the test can be conducted satisfactorily only on the in-patient.

Serum protein-bound iodine estimations (P.B.I.) are exceedingly difficult to carry out and the technique is expensive and exasperating—except in the hands of such experts as Riggs.⁶ The serum P.B.I. is a direct measure of the level of circulating hormone and therefore an excellent guide to hyperthyroidism; it is a pity that no simple method of determining it has been discovered. Cholesterol estimations⁷ reflect indirectly the function of the thyroid gland and are of most value in assessing hypothyroid states.⁸ Creatine and galactose tolerance tests vary too much in other pathological states to be of specific use in assessing hyperthyroidism.

Radio-iodine offers a unique way of measuring thyroid action, and it has deservedly become popular in clinics where many patients with thyroid disease are seen. It is idle to argue whether the B.M.R. or the radio-iodine uptake is a more accurate test of hyperthyroidism, since the two measure different functions of the gland. In fact all thyroid tests measure some aspect of thyroid metabolism, and a combination of them is more reliable than any single one. Radio-iodine has been used in many ways for measuring thyroid function. The rate of uptake in the gland can be obtained by placing a Geiger-Müller counter over the neck⁹; the amount excreted in the urine can be estimated from samples,¹⁰ or the uptake in neck and blood stream can be compared. In addition radio-iodine offers an easy method of measuring the radioactive P.B.I. in the blood.¹¹

The treatment of thyrotoxicosis by long-term therapy with thiouracil compounds can now be fairly assessed after the first ten years of trial. If a patient is given thiouracil it is almost always possible to control the hyperthyroidism; later the disease can still be controlled with a much smaller dose. Poate¹² in Sydney and Himsworth¹³ and others in this country have reported series of patients treated in this way. In this issue of the *Journal* Dr. J. F. Goodwin and his co-workers report at p. 422 the results obtained at Sheffield on 126 patients who were treated initially with thiouracil and a large number of whom have been maintained symptom-free for periods up to four and a half years. Their final conclusions are that about two out of every three patients will eventually relapse after withdrawal of treatment no matter how long that treatment is carried out. In view of this, such therapy can be recommended only for patients who live fairly close to a medical centre, since thiouracil may at any time cause agranulocytosis, and this will require treatment in a hospital if a fatal issue is to be avoided. The other disadvantages of long-term thiouracil therapy are that the thyroid gland enlarges, especially if the dose is not reduced early enough, drug rashes are fairly common, and unpleasant side-effects may be seen in individual patients.

The treatment of hyperthyroidism with radio-iodine is fairly new; the first patients were treated ten years ago, but they were few in number and a short-lived isotope, I¹³⁰, was usually given. To-day I¹³¹, with a half-life of eight days, is in common usage, and many clinics have now been equipped to provide this kind of therapy. Speaking at the Royal College of Surgeons last month, Dr. George Crile, jun., of Cleveland,¹⁴ stated that in his clinic hyperthyroidism, when not associated with a nodular gland, was now treated exclusively with radio-iodine. Over 1,000 patients have been so treated in the last five years, with a recurrence rate of about 1%. One disadvantage of this kind of therapy is that it is impossible to estimate the dose accurately, since this depends on the size of the gland. But the treatment has many advantages: the patient is spared an anaesthetic and operation and has only a short stay in hospital, and there is no risk of damage to the recurrent nerves or parathyroids. However, there remains the possibility that this therapy may lead to thyroid cancer. In the experimental animal there is quite good evidence that radio-iodine has a carcinogenic effect. Because of these findings many are unwilling to prescribe it for a patient under 40 years of age,¹⁵ remembering that in the past the irradiation of skin led to malignant changes after a long latent period,

often of the order of twenty years. At present the number of patients treated is too small and the time elapsed since treatment too short for a firm opinion to be given, but it appears unreasonable to give young patients this therapy.¹⁶

The surgical treatment of thyrotoxicosis has been greatly improved by preparing patients with the thiouracil drugs, so that now the mortality rate is negligible.¹⁷ In addition the practice of removing at least seven-eighths of a toxic gland has reduced the recurrence rate of thyrotoxicosis to about 2%. There is no doubt that surgery offers the best form of treatment for toxic nodular goitre, for this is resistant to all kinds of medical therapy. If the patient with Graves's disease is prepared with methylthiouracil or neo-mercazole, and iodine is given in the immediate pre-operative period, the results of operation are good. In this week's *Journal* Dr. H.-J. B. Galbraith and his colleagues describe at page 420 the pre-operative use of iodothiouracil, which is a thiouracil compound containing iodine in its chemical structure. This drug has been in use for about five years now, and McClintock,¹⁸ in Albany, and Catz and Starr,¹⁹ in Los Angeles, have described large series of patients treated with it. The claim of the latter workers that this compound is more effective in hyperthyroidism than the administration of thiouracil and iodine separately has not been confirmed by other workers, and Doniach has shown histologically in the rat that iodothiouracil is less effective than either thiouracil or iodine alone. It seems, however, that if iodine and thiouracil are given concurrently or in combination, as described by Galbraith, excellent preparation is obtained for the surgeon.

The number of operations for hyperthyroidism fell precipitously with the introduction of the thiourea compounds, but it is now seen that they are climbing again as it becomes apparent that these anti-thyroid drugs when used for long-term therapy do not offer a very good chance of producing a remission. Radio-iodine is being used increasingly for this disease, but until another ten years has elapsed it is unlikely that many clinicians will be happy in using it extensively because of the risk of causing cancer.

The old observation, confirmed by Campbell²⁰ in 1927, that hyperthyroidism is commoner where there is endemic goitre seems to have been overlooked in Britain. There are many parts of this land where there is a relative iodine deficiency and simple goitre occurs, as shown by the Medical Research Council's report.²¹ Despite the recommendation that salt should be iodized in this country, probably not more than 2% of salt consumed at present has this addition.

LUNG CANCER AND SMOKING

'That there is a "strong presumption" of a causal relationship between smoking and cancer of the lung was conceded in Parliament by the Minister of Health¹ last week. The evidence on which this opinion is based came to a head with the publication in this *Journal* of the paper² by Doll and Bradford Hill in 1950, and was reinforced by their second paper³ in 1952. The data have now been carefully assessed by a special panel under the chairmanship of the Government actuary (Sir George Maddex)⁴ on behalf of the Standing Advisory Committee on Cancer and Radiotherapy, which in turn advised the Minister. As readers who followed the cautious and close-knit arguments of Doll and Bradford Hill might expect, these writers' conclusions from their own and others' researches⁵ find ample confirmation in the statement that the Minister gave to Parliament. The evidence of some connexion between smoking and lung cancer may have received some additional support recently from the discovery by Wynder, Graham, and Croninger⁶ that the experimental painting of mice with tobacco tar causes carcinoma of their skin. Moreover, some earlier experiments, also in the U.S.A., had shown that mice of a strain liable to develop lung cancer were more likely to develop it when exposed for a year to tobacco smoke than other mice of the same strain not so exposed.⁷ The validity of these smoke experiments needs confirmation, and a series of somewhat similar experiments begun by the Medical Research Council 18 months ago will test the point. The strength of the evidence so far gathered together moved the tobacco manufacturers in the U.S.A. a month ago to set up a committee for research into lung cancer and smoking, and now British manufacturers have followed with the offer of a donation of £250,000 to the Medical Research Council, to be used at the Council's discretion.

Though so much evidence has been provided in Britain and the U.S.A. showing that some connexion exists between smoking and lung cancer, relatively much more is needed before a clear understanding of the connexion is obtained. No substance known to be carcinogenic to man, for instance, has yet been identified in tobacco, and this is one of the problems on which research is concentrated. The mouse carcinogen discovered by Wynder and his colleagues could prove to be misleading, a hazard to mice but not to

men. Again, it is well known that some patients with lung cancer are non-smokers. Nor is tobacco smoke the only agent or condition associated with the causation of lung cancer, for Stocks⁸ has shown that there is also a close association between urban residence and incidence of the disease. The possibility that townsmen smoke more than countrymen would seem to be insufficient to account for the disparity. On the other hand the principal and more positive facts known about lung cancer and smoking are broadly two: first, there is some kind of causal connexion; secondly, the risk increases with the amount smoked. In addition, cigarettes seem to carry a greater risk than pipes and cigars, and the risk attached to cigarettes may possibly be diminished by the use of filter tips or cigarette holders.

At a press conference held last week the Minister of Health wisely pointed out that it is not his duty or his Ministry's to speculate on the significance of the published reports, and he emphasized that research must be pursued with all vigour and speed. He considered the time had not yet come when the Ministry should issue public warnings against smoking, but, as his advisers pointed out, "It is desirable that young people should be warned of the risks apparently attendant on excessive smoking." The evidence perhaps allows medical men individually to go rather further than this and tell patients that there is probably an increased risk, to greater or less degree, associated with any amount of smoking, especially of cigarettes.

CHEMICALS IN FOOD

Agricultural chemicals used as insecticides, fungicides, and weed-killers have been in the medical news for the last few years. The dangers of some of these materials have been described, discussed, and, unfortunately, illustrated by cases of poisoning. In 1951 a working party under Professor S. Zuckerman reported¹ on the situation and made recommendations which have now been incorporated in legislation designed to reduce these hazards. No fatal or serious cases of poisoning were reported in this country during the past season. This satisfactory situation may be due not so much to the regulations as to the general alertness of the manufacturers and users, backed up by the watchfulness of the Government departments concerned.

Some of the chemicals used as pesticides may persist in crops and find their way in very small quantities into food. This possible danger is discussed in the second report² of the working party, which was reconstituted under the same chairman after finishing

¹ See *Journal*, p. 465.

⁸ *Brit. J. Cancer*, 1952, 6, 99.

its first task in 1951. It is not open to doubt that some of these chemicals are dangerous to those who use them. The doses received by men accidentally poisoned in this way are probably comparable in size to those causing signs of poisoning in experimental animals. The risks of consuming the very small quantities that could find their way into food are difficult, if not impossible, to measure. The dose likely to be taken in this way would probably be far below that capable of producing unequivocal changes in experimental animals.

Discussions on food are said to rank high on the list of subjects "having curious powers of robbing the speaker of his powers of logic,"¹ and members of the working party making this report have done well to retain their sense of proportion. The report gives an excellent survey of the situation as it exists to-day, and on the whole is reassuring. It contains an impressive list of materials that are used in pest control, including rodenticides. Incidentally, many will regret that the working party has not followed the lead of some other countries in condemning outright the use of bacterial cultures as rat poisons when there are other effective and safer rodenticides now freely available. In general the report states the facts or points out where ascertainable information is deficient and suggests how it may be amassed in the future. It wisely avoids adding more speculation to the question of possible health hazards arising from small quantities of chemicals in food, and begins by stating that no evidence has been presented "of any specific instances of illness which have resulted from eating such [treated] food. The position does not appear to have been established as one of immediate danger." Evidence and not mere opinion is needed before this assessment of the situation can be upset.

The working party then sought facts about the extent of the use of toxic chemicals in agriculture and the amounts that are actually present in food. These chemicals are not widely used in this country, but their use may become commoner as agricultural methods are modernized and efforts intensified. As to imported food, little information is available, and there is no control of the chemical treatment received during production, storage, and transit. Though some details might be obtained from analyses of food reaching this country, a much more satisfactory solution would be to organize some international

exchange of information about the practices current in each food-producing country. The routine analysis of food is a widespread practice, but the search at present is mainly for the older and better-known poisons, such as lead and arsenic. The range of analytical control will have to be extended before we can obtain information about the quantities of the new chemicals in our food.

The working party recommends that a committee should be set up "to advise departments on problems relating to the risks to the consumer arising from the use of toxic substances in agricultural products and in the storage of food," and this recommendation has been accepted by the Government. If it fulfils the functions suggested for it, the advisory committee will gradually accumulate factual data on which future action may be based. When it has acquired some of these facts, it is to be hoped that it will be able to speak with authority on these new agricultural practices, so that a fully documented case can be made out for or against the use of any particular toxic material. Such authority is in fact badly needed in the whole field where chemicals are deliberately or accidentally added to food. Seevers,⁴ for instance, has pointed to the impossibility of proving anything to be harmless and shown how scientific data have been distorted in attempts to make a case for or against the addition of this or that chemical to food. He writes:

"It is almost axiomatic that areas of activity such as these in which *opinion* may substitute for lack of factual data may become the province of the crack-pot, self-styled scientist, and the well-meaning but misinformed reformer, [who] may exert a powerful influence on the general public by posing as a champion of the individual safety and protector of the public welfare."

It is doubtful if the influence of any such reformer would ever equal or exceed that of a powerful commercial interest anxious to introduce a new material or technique into food production.

Several experts have suggested that decisions about the permissible chemical additions to food should be within the province of the medical profession, which, they think, is losing control of the situation. This presupposes that there are formulae that can be applied which will enable the doctor to decide whether or not a chemical will be harmful in given doses. But much still remains a matter of opinion. Mellanby⁵ has suggested that some of the diseases of our modern civilization may be attributable to the effects of eating sophisticated food. Dodds,⁶ taking an opposing stand, is apparently prepared to put his faith in animal tests to determine whether or

not a substance is likely to be harmless. But it is difficult to interpret the findings of animal tests. Some would allow a large safety factor and expect a substance to be harmless to animals in doses exceeding by 10- or 100-fold those likely to be consumed by man. The results of some recent experiments in which sodium chloride was fed to rats⁴ would lead, if such a formula was applied, to the condemnation of salt as a flavouring agent. In times of food shortage, rather than go hungry most people would cheerfully accept wheat contaminated with D.D.T. which had been added to prevent the depredation of insects. In other words, we must know the facts—be they political, economic, chemical, or biological—before we can assess what advantages will accrue from accepting an uncertain risk entailed by eating food containing foreign chemicals.

When an advisory committee such as that suggested by the working party has collected enough facts it may eventually frame a policy in which the use of chemicals in agriculture and food storage will come to represent a balance between productivity, cost, quality, keeping properties, nutritional value (for example, vitamin content) of the food and any possible risk of injury to health from chemicals persisting in the food. At least there is little question of the value of these chemicals in improving production and the quality of crops, whereas the benefits of some chemicals added to food during processing may be much more questionable.

BUCCAL CANCER

"Gentlemen," Sir Henry Butlin is supposed to have said to his students at St. Bartholomew's Hospital, "I shall not get cancer of the tongue. I neither smoke nor drink, my teeth have been removed, and I have never had syphilis." What is true for the aetiology of carcinoma of the tongue is also broadly true for the rest of the mouth. To these causes Butlin could have added leucoplakia, the importance of which as a precancerous lesion has long been recognized but the exact significance of which is still a matter for dispute. Two, at any rate, of these factors are less common now than they were at the beginning of the century, and it is therefore not so surprising that buccal cancer is one of the few types of malignant disease which appear to be on the wane. Certainly dental sepsis and patchy leucoplakia are found in the majority of patients with this disease, but it is equally true that it can occur in the cleanest of mouths. Squamous-celled carcinoma of the floor

of the mouth is a rare condition (the term is made to include by some the inferior aspect of the tongue and by others the mucosal surface of the lower alveolus). Only 83 deaths were recorded from this cause in 1952 in England and Wales.¹ *The British Journal of Surgery* has now published the symposium on this subject read before the Association of Surgeons of Great Britain and Ireland in 1952 by Sir Stanford Cade,² Professor Brian Windeyer,³ Mr. A. J. Gardham,⁴ and Dr. J. L. Dobbie.⁵ This valuable contribution puts on record the methods and results of treatment of a large number of patients from five of the hospitals which are justly renowned for their experience in the treatment of cancer. Cade reports on his patients at the Westminster and Mount Vernon Hospitals (97 patients in 25 years); Windeyer on the Middlesex Hospital group (131 patients in 20 years); Gardham on University College Hospital patients (72 patients in 27 years), and Dobbie on those from the Christie Hospital and Holt Radium Institute (427 patients in 12 years). If to these are added the figures published in 1950 by Ledlie and Harmer⁶ on behalf of the Royal Cancer Hospital (190 patients in 10 years) an excellent survey of the subject may be obtained. But for the best interpretation of survival rates, as Miss Marion H. Russell discusses in an article at page 430 of the *Journal* this week, men and women should be considered separately, for women have higher survival rates than do men.

It is generally agreed that the early lesion is best treated by radiotherapy and the late primary lesion by surgical excision, particularly when the mandible is invaded by growth. Secondary nodes are dealt with on the same principles that govern their treatment when arising from primary growths in the tongue. Gardham calls attention to the fact, which is evident not only in the University College Hospital series but in the others as well, that the most diverse methods of treatment produce very much the same proportion of "cures." Thus, interstitial radium needling, double radium mould, and radium applicator-cum-teleradium all result in about 45% five-year survivals for the early cases with no nodes and 15% five-year survivals for the late cases with nodes. Some surgeons and radiotherapists are still willing and even anxious to argue the merits of their own particular choice of treatment. A more rewarding debate might decide which procedure gives the patient least tribulation. In any case the moral is clear: to get patients earlier and treat them effectively.

MILK AND MALARIA

Two years ago Maegraith and his colleagues¹ at the Liverpool School of Tropical Medicine were studying the metabolism of malaria pigment in rats kept on a special diet. Much to their annoyance they found that few of the malaria infections progressed normally: infections were either completely suppressed or of a low intensity, and this line of research had to be abandoned. These workers, however, quickly realized the peculiar significance of their results, and were able to demonstrate that a diet consisting of milk plus certain vitamins inhibited infections of *Plasmodium berghei* in rats. Not

⁶ Ledlie, E. M., and Harmer, M. H., *Brit. J. Cancer*, 1950, 4, 6.

long afterwards Dr. F. Hawking² attributed the phenomenon to deficiency of *p*-aminobenzoic acid in the diet. This substance (or some derivative) was found to be necessary for the growth of the parasite, and when it was added to the milk diet normal infections followed. Elsewhere in this issue Hawking has analysed the process in greater detail, and has shown that it is not quite so simple as he originally thought. The parasite is affected at the intracorporeal stage when its nuclei are dividing—when it is metabolizing the haemoglobin. Rodhain³ has found that piroplasms—which also live in red blood cells but do not require haemoglobin—are unaffected by deficiency of P.A.B. Likewise, Bray and Garnham⁴ have shown that the pre-erythrocytic stage of mammalian plasmodia in the parenchyma cells of the liver is unaltered by a milk diet, possibly because the chemical processes accompanying nuclear multiplication at this stage do not involve haemoglobin. The malaria parasite is obviously very sensitive to slight changes in the constitution of haemoglobin: even minor alteration of the "sickling" type apparently inhibits growth of the parasite.⁵ Incidentally, it is probable that a milk diet would fail to influence *P. elongatum* infections in birds because this malaria parasite lives principally in cells containing no haemoglobin: such an experiment might provide useful confirmation of the theory.

Hawking now points out that suppression of malaria by milk is a marginal phenomenon. Maegraith⁶ had already reported that at certain seasons of the year the effect is not apparent, presumably because at these times the milk contains an extra amount of P.A.B. or derivative; and Hawking has found that the addition of P.A.B. to a nursing monkey's diet will permit the evolution of a normal infection of *P. cynomolgi* in the baby. On the other hand, he showed that the infection could be completely suppressed in a baby monkey whose mother was on a P.A.B.-deficient diet. The effect of a milk diet is discernible also in human malaria. The relative insusceptibility of African infants to this disease had been noticed for a long time, and Hackett⁷ originally thought that it was due to possession by the child of an inherited immunity; but now a milk diet seems likely to be as important a factor. The effects in breast-fed infants are, however, inconstant and incomplete. Experiments in India⁸ have recently shown that adults can be protected against *P. vivax* infections by living on milk alone.

The metabolic requirements of the malaria parasites are still so incompletely understood that the exact mechanism involved in this phenomenon remains unknown. Hawking points out that folic acid is as effective as P.A.B. in promoting the growth of *P. berghei*, and Fulton⁹ has recently shown that cortisone also brings on a normal parasitaemia in rats on a milk diet. All those working on this subject have realized its

importance to the chemotherapy of malaria, and Hawking reminds us of the way that drugs like sulphoamides or proguanil act in this disease by combining with or taking the place of the P.A.B. (or derivative) and thus depriving the parasite of an essential catalyst for its nuclear growth. This reaction can take place only when the parasite is in the blood; parasites living in liver cells are bathed in such a rich nutrient medium that such drugs cannot cope with the excess of catalyst and are therefore largely incapable of dealing with the tissue stages.

ASCITIC FLUID CIRCULATION

The peritoneal cavity normally contains only a few millilitres of free fluid, but in cases of hepatic cirrhosis or carcinomatous peritonei the volume of peritoneal fluid often exceeds 5 and sometimes even 10 litres. This excessive accumulation is generally attributed to gross over-filtration of fluid in the splanchnic area. When in any given case the volume of the ascites remains stationary the reabsorptive mechanisms are keeping pace with production. It is only recently, however, that studies in both man and experimental animals have shown that ascitic fluid is far from being a stagnant pool, but, like so many other constituents of the body, is in a constant state of flux. The production of ascites in experimental animals by partial ligation of the inferior vena cava above the diaphragm has been closely studied by Whipple and his colleagues¹ with special reference to the protein constituents of ascitic fluid. Using plasma protein labelled by lysine containing C¹⁴, they found that equilibrium between the ascitic fluid and the circulating blood was reached in one to two days in the case of albumin, and in something over two days in the case of globulin. Even more striking were the figures obtained by Prentice, Siri, and Joiner² for the turnover rate of the aqueous component of ascitic fluid. They gave intravenous or intraperitoneal injections of water labelled with tritium (radioactive hydrogen) to six patients with ascites, and recorded the passage of the radioactive water from the plasma to the peritoneal cavity and vice versa. Equilibrium was reached in about 10 hours, and from the slopes of the equilibration curves it was calculated that between 40 and 80% of the ascitic fluid present in any given case was exchanged every hour. Thus in a patient with 6 litres of ascitic fluid the daily turnover lies between 58 and 115 litres.

It has long been known that both fluid and particulate matter can be absorbed from the peritoneal cavity, but its capacity in this respect, demonstrated by the above experiments, is surprising. The results show that ascites can and does develop in the face of an absorptive mechanism capable of dealing with more than 100 litres a day. Figures for the turnover of peritoneal fluid in normal subjects are not at present available, but in view of those obtained by Prentice and his colleagues it is reasonable to attribute ascites to over-production rather than impaired removal of fluid. It is also apparent that only a slight displacement of the equilibrium can lead to rapid accumulation or equally rapid removal of the ascitic fluid.

CLINICAL PATHOLOGY IN GENERAL PRACTICE

THE CEREBROSPINAL FLUID IN DIAGNOSIS

BY

J. N. CUMINGS, M.D., F.R.C.P.

Clinical Pathologist, the National Hospital, Queen Square, London, W.C.1

The examination of the cerebrospinal fluid (C.S.F.) constitutes a very valuable method in the investigation of many diseases of the nervous system, and even in some general disorders. It often enables a firm diagnosis to be made, even while the patient is still at home, and this cannot but be of immense satisfaction to both practitioner and patient. The process of recovery in diseases hitherto fatal, but now yielding to treatment by antibiotics, can be followed with a fair degree of scientific accuracy by means of the examination of frequent samples of C.S.F.

The C.S.F. is nearly always obtained by lumbar puncture. It can also be collected from the lateral ventricles of the brain and from the cisterna magna, but these two sites should be punctured only when the patient is in hospital, where such facilities as an x-ray department and operating theatre are readily available. Discussion of such procedures has accordingly been omitted from this article.

The technique of lumbar puncture,* while relatively simple, does require practice and should be performed only after due consideration has been given to the benefits likely to accrue from this method of examination. Should the specimen be collected by the patient's own doctor it should be dispatched to the pathologist at once, as examination of the fluid should always be made without any undue delay. This is particularly important in a suspected case of meningitis, for both the cell count and the sugar content of the fluid will fall after a few hours. The C.S.F. pressure, the result of the Queckenstedt test, and the suspected clinical diagnosis should in such cases always accompany the specimen. This will help the pathologist to decide what examinations will yield the most satisfactory answers to the problem concerned.

Normal Cerebrospinal Fluid

It is necessary to know, first of all, exactly what constitutes a normal fluid. Table I shows the range of figures that can

Pressure	125 mm. of water
Appearance	Clear and colourless
Cells	Up to 4 lymphocytes per c.mm.
Protein	Up to 30 mg. per 100 ml.
Globulin (e.g., Nonne-Apert reaction)	Negative
Chlorides	700–760 mg. per 100 ml.
Sugar	50–70 mg. per 100 ml.
Lange test	No change
Wassermann reaction	Negative

be regarded as normal for an adult. A few additional comments may be made. The cells are always lymphocytes in a fluid uncontaminated by blood, but if contamination has occurred one can assume that one polymorph may be present for every 500 red cells per c.mm.; never more than 4 and usually fewer than 4 cells per c.mm. are found. The level of the protein content—which is composed almost entirely of albumin and with only a trace of globulin—varies with age. A child should have 10 to 15 mg. of protein per 100 ml., while in an elderly adult a figure of 50–60 mg. per

*See the article on this subject by Dr. William Gooddy earlier in this series (*British Medical Journal*, November 7, 1953, p. 1040).

100 ml. can still be regarded as normal. Similarly, prolonged immobility in bed will tend to raise the protein level. The chloride content may vary a little with the blood chloride, but the sugar level is fairly constant throughout the day, and it is not necessary therefore to collect the specimen while the patient is fasting.

The Lange colloidal gold test is empirical, and normally colour changes do not occur in any of the 10 tubes containing dilutions of C.S.F. Varying degrees of precipitation of the colloidal gold may occur, resulting in changes of colour, and these are recorded numerically from 1 to 5, the latter figure representing a complete loss of all colour in the supernatant fluid. There are two main types of abnormal curve: (1) the paretic, in which the maximum degree of colour change occurs in the first tubes—that is, in those of the strongest concentration of C.S.F.; and (2) the mid-zone or luetic curve, which shows a maximum change in the middle of the curve. Examples of each of these are described below. The C.S.F. pressure is normally about 125 mm. of water when the patient is in the recumbent position, and an increase takes place in cases of infection and when there is some space-occupying lesion inside the cranium. When the jugular veins are compressed in a healthy subject there is a rapid rise in C.S.F. pressure as recorded in the manometer, followed on release of the jugular pressure by a drop to the initial figure. This is known as the Queckenstedt phenomenon or test.

The clinical diagnosis and the results of the pathological examinations have always to be correlated, so that it would seem to be easiest to describe the results of the examinations under the headings of various disease processes.

Meningitis

There are three main types of meningitis—pyogenic, tuberculous, and virus. Table II shows the types of results that can be expected in each group. Naturally, the actual figures depend upon the stage of the disease reached when lumbar puncture is performed.

TABLE II.—The C.S.F. in Meningitis

	Pyogenic	Tuberculous	Virus
Pressure	Raised ++	Raised ++	Slight increase
Appearance	Turbid in varying degree	Clear or slightly opalescent	Usually clear
Cells	Hundreds or thousands	Tens or hundreds	4–200/c.mm.
Type of cell	Polymorphs	Usually more lymphocytes than polymorphs (2 or 3 to 1)	Lymphocytes
Protein	100+ mg./100 ml.	100+ mg./100 ml.	Up to 150 mg./100 ml.
Globulin	Positive	Positive	Positive
Chlorides	Decreased to about 600 mg./100 ml.	600 to 650 mg./100 ml.	Slight decrease—680 mg./100 ml.
Sugar	Absent	Decreased to 20 to 35 mg./100 ml.	Normal or only very slightly reduced
Direct smear	Causal organism	T.B. present	None
Culture	" "	" "	Sterile

In pyogenic infections, such as meningococcal or pneumococcal meningitis, the fluid which is turbid shows a considerable increase of cells, all of which are polymorphs. The chloride content is often reduced, although not to such a low level as in tuberculous meningitis, but this must not be regarded as a diagnostic feature. The reduction in the sugar content is of the utmost importance, and an accurate estima-

tion should always be obtained. The fluid from cases of pyogenic meningitis shows a great reduction and often a complete absence of sugar. Effective treatment will always be reflected by a rise in sugar content, in fact this may precede the clinical improvement. The finding of the causal organism is vital, for it will indicate which antibiotic should be used. Prompt treatment is essential in all cases and is of special importance in pneumococcal meningitis.

The C.S.F. is less turbid in tuberculous meningitis than in the pyogenic group. There is an increase in cells, which are largely lymphocytes, although a small number of polymorphs are present in most cases. The chloride level is reduced in well-established cases, but may be almost normal in the early stages. The sugar content is early reduced, but this decrease never becomes a complete loss. Tubercle bacilli in the smears confirm the diagnosis. There is little doubt that they can be found in practically every case given enough care and time by the pathologist. Cultures or animal inoculation will confirm the smear findings after four or more weeks, but this delay is not permissible before initiating treatment. Again, a rise in the sugar level is the best guide to effective treatment, as intrathecal streptomycin will cause an increase in the cells and protein in the fluid, but does not affect the sugar level.

There are numerous viruses that are now known to affect the central nervous system, but all yield a somewhat similar C.S.F. picture. It is often difficult to distinguish between tuberculous meningitis, poliomyelitis, and lymphocytic meningitis in the early stages, but, by paying particular attention to the sugar and the results of the smear examinations, diagnosis should be possible. There are a few other conditions, such as sarcoidosis of the meninges and torulosis, both of which are very rare, that give rise to great difficulty in diagnosis.

Poliomyelitis

The C.S.F. varies with the stage of the disease, and in Table III are given the findings at the three most important stages. The noticeable feature in the pre-paralytic period is

TABLE III.—The C.S.F. in Poliomyelitis

	Before Paralysis	1st Week of Paralysis	Subsequent Weeks
Appearance	Clear and colourless	Clear and colourless	Clear and colourless, or with a coagulum
Cells	Can be up to 2,000/c.mm. (May be 25% polymorphs)	5-10 lymphocytes/c.mm.	Up to 4 per c.mm.
Protein	Normal or only slightly raised	Raised about 100 mg./100 ml.	Up to 300 mg./100 ml.
Globulin	Negative	Positive (+)	Positive (+)
Chlorides and sugar	Normal	Normal	Normal
Lange test	No change	0011210000	Normal or slightly mid-zone

the resemblance of the fluid, especially as regards the pleocytosis, to that found in tuberculous meningitis, except that the chlorides and sugar are normal. When paralysis occurs the cells decrease but the protein increases, and this increase may persist for some months. A fluid with a protein level of 150 mg. per 100 ml. or more may show a fibrin clot of the "spider web" type seen in tuberculous meningitis. Another point of importance is that, while polymorphs are commonly found in poliomyelitis, they are not seen in encephalitis.

Cerebral Abscess

The most characteristic features are to find a raised pressure, a pleocytosis of both lymphocytes and polymorphs, with normal sugar and perhaps normal or slightly reduced chloride levels, in a patient with infection of ear, frontal sinus, or lung. However, a deep-seated abscess may yield a C.S.F. similar to that found in a cerebral tumour in a similar site.

Encephalitis

The C.S.F. in the acute stage is under pressure, it is clear, and there is never a coagulum. A small lymphocytic pleocytosis with a slightly raised protein and a normal chloride content are found. The sugar level may be somewhat raised.

Syphilis

Primary.—A small proportion of patients with primary syphilis show a slight increase in the number of lymphocytes, together with a positive Wassermann reaction in the fluid before treatment. Few cases continue to give these findings after a normal course of treatment, but if these changes persist treatment should be continued, as in most instances the fluid will return to normal.

Secondary.—The C.S.F. shows an increase of cells up to about 50 per c.mm. composed almost entirely of lymphocytes, a slight increase in protein content, and a positive Wassermann reaction. The Lange test shows a mid-zone curve of the type 0012332100, but it is of no special significance. Rarely a spinal block caused by an inflammation of the meninges—an arachnoiditis—may be found, and give results similar to those seen in a spinal tumour, together with a pleocytosis and a positive Wassermann.

Tertiary.—There are three common types of disorder—namely, meningo-vascular syphilis, tabes, and general paralysis of the insane (G.P.I.). Table IV shows the results that

TABLE IV.—The C.S.F. in Syphilis

	Meningo-vascular	Tabes	G.P.I.
Pressure	Normal or slightly raised	Normal or slightly raised	Normal or slightly raised
Appearance	Clear and colourless	Clear and colourless	Clear and colourless
Cells	20-150/c.mm.	10-50/c.mm.	10-50/c.mm.
Type of cell	Mostly lymphocytes, few large mononuclears	Lymphocytes, a few large mononuclears	Usually lymphocytes and large mononuclears
Protein	Usually up to 100 mg./100 ml.	Usually up to 100 mg./100 ml.	50-150 mg./100 ml.
Globulin	Positive (+)	Positive (++)	Positive (++)
Lange test	Variable but usually mid-zone	Leutic, i.e., mid-zone (0012332100)	Paretic, i.e., 1st stage (5544322110)
Wassermann reaction: C.S.F.	+	++ (in 70%)	+++ (in 100%)
Blood	+++	+++ (in 65%)	+++

may be found in each of these conditions. It must be remembered that it is not always possible to place a patient in one of these categories with absolute accuracy following the first lumbar puncture, and it may be only after treatment or after a period of time that the correct diagnosis can be determined. The Lange test in particular does not always conform to pattern, and paretic curves such as 5544322110 may be found in meningo-vascular disease. Should, however, such a curve persist despite treatment a revision of the original diagnosis may be advisable. It is also noteworthy that a positive Lange curve of any pattern will change much more readily as a result of treatment in a patient with meningo-vascular syphilis than in either of the other two forms of this disease. The strength of the Wassermann reaction is indicated by the number of positive signs. Here again, treatment in meningo-vascular disease will reduce the strength of the Wassermann reaction faster in the C.S.F. than in the blood, and both will respond much more quickly in this type of disorder than in tabes or G.P.I. Fluids from these last two types of case may retain a positive Wassermann reaction in the blood or in blood and fluid, and an abnormal Lange test long after the patient improves clinically. The Wassermann reaction in the C.S.F. is positive in syphilitic conditions only, but a negative test does not exclude syphilis except for G.P.I. The other abnormal findings in the fluid in syphilis may be seen in some other conditions such as disseminated sclerosis, meningial spread of a secondary carcinoma, sarcoidosis, and torulosis.

Congenital.—No alterations from the normal may be found in the fluid from some patients. Cases of clinical

tabes or G.P.I. will often show findings comparable to those found in acquired syphilis. Treatment only results in slow improvement in the pathological findings.

Disseminated Sclerosis

Characteristic changes may be found in this condition, one of which is a raised cell count of up to about 50 per c.mm. While lymphocytes largely predominate, a few fluids will also contain polymorphs in small numbers. The protein is rarely raised above 100 mg. per 100 ml., but the globulin test (Nonne-Apel reaction) is almost always positive. The Lange test is abnormal in some 40-50% of cases and shows either a mid-zone or a paretic curve, the former occurring twice as often as the latter. The Wassermann reaction is always negative.

A paretic curve in the absence of a positive Wassermann reaction occurs only in disseminated sclerosis, inclusion-body encephalitis, and a few cases of encephalitis lethargica.

Cerebral Tumour

Lumbar puncture in cases of cerebral tumour is open to certain obvious dangers. Before removing C.S.F. it is essential to measure the fluid pressure, and to ensure by jugular compression, with a consequent rapid rise in pressure, that there is no herniation of the cerebellum into the foramen magnum. Great care must always be exercised in performing lumbar puncture in patients with a suspected cerebral tumour, and in general it is probably wiser to delay making this examination until the patient is in hospital, where operation can follow lumbar puncture should the need arise. Frequently the fluid pressure is raised, and any pressure above 200 mm. can be regarded as pathological. Examination of the fluid may show it to be quite normal. There is a raised cell count in some 5% of cases, which may be due to polymorphs as well as lymphocytes, and in a few cases even tumour cells may be found. The protein content is raised in some 75% of cases. On the whole the more innocent tumours tend to show a lower protein level, but there are exceptions to this rule. A glioma of the pons gives rise to a low protein, whereas a neurofibroma of the eighth cranial nerve is always associated with a raised protein content. Fluids from cases of tumours near the lateral ventricle have a higher protein content than do those associated with tumours above the tentorium and near the surface of the brain.

Spinal Tumour

The measurement of the C.S.F. pressure and the result of the Queckenstedt test are very important in this condition. There is no rise in pressure after jugular compression in a complete spinal block, while should the block be partial the rise will be slow, and the fall to the original level will also be slow. The initial pressure may, in fact, be low, figures of 40 mm. being not uncommon. The fluid, while it may be clear and colourless, is on some occasions straw-coloured and may clot spontaneously. Cells are not increased except in such conditions as meningial sarcomatosis. The protein content is always raised in complete block, with figures even as high as 2,000 mg. per 100 ml. In partial block the protein content is raised, but rarely above 300-400 mg. per 100 ml. The Wassermann reaction is always negative, except in cases of syphilitic spinal arachnoiditis.

Other Conditions

There are numerous other disorders in which the examination of the C.S.F. may yield instructive results. For instance, in subarachnoid haemorrhage a fluid intimately mixed with blood will be obtained and, should the bleeding have occurred three days or more prior to lumbar puncture, the fluid after centrifugation will show a yellow coloration and a positive indirect van den Bergh reaction.

The examination of the C.S.F. for barbiturates in cases of poisoning by these drugs, and for urea and sugar in cases of coma from uraemia or diabetes, may also be mentioned as examples of some of the less common investigations that can be carried out.

The pathologist, provided he is aware of the possible clinical diagnosis, should be able, as a result of his examination of the C.S.F., to express a reasonably confident opinion on the nature of the disease process. There are, however, some neurological conditions which may still baffle both the practitioner and the pathologist, but these will probably be seen only at very infrequent intervals by any one practitioner.

Next article on Clinical Pathology.—"Simple Skin Pathology," by Dr. John O. Oliver.

Refresher Course Book.—The first collection of articles in the Refresher Course for General Practitioners (fully revised) are available as a book containing 55 chapters, price 25s. Copies can be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

APPROVED NAMES

The General Medical Council has authorized the following "approved names" of drugs, selected by the British Pharmacopoeia Commission. The last supplementary list was published in the *Journal* of December 12, 1953 (p. 1321).

Approved Name	Other Names
Aminopterin sodium	Sodium 4-aminopteroylglutamate.
Bacitracin	An antibiotic produced by a strain of <i>Bacillus subtilis</i> .
Benzathine penicillin	NN'-dibenzylethylenediamine di-benzylpenicillin. "Dibencil," "Neolin," "Penidural," "Permapen."
Benzethonium chloride	Benzyltrimethyl-p-(1:1:3:3-tetra-methylbutyl)phenoxyethoxyethyl-ammonium chloride. "Phemeride," "Phemerol chloride."
Dehydrocholic acid	3:7:12-Trioxocholanic acid. "Decholin," "Dehydrocholin."
Dichloroxylenol	2:4-Dichloro-3:5-xyleneol.
Dihydrotachysterol	"A.T. 10."
Dyfos	Diisopropyl fluorophosphonate "DFP."
Erythromycin	An antibiotic produced by a strain of <i>Streptomyces erythreus</i> "Erythrocin," "Ilotycin."
Fumagillin	An antibiotic produced by certain strains of <i>Aspergillus fumigatus</i>
Nicotinyl alcohol	3-Pyridylmethanol. "Ronicol" is the tartrate.
Pentolinium tartrate	Pentamethylene-1:5-bis-(1-methylpyrrolidinium tartrate). "Anso-lysen."
Primaquine	8-(4-Amino-1-methylbutylamino)-6-methoxyquinoline.
Reserpine	An alkaloid obtained from <i>Rauwolfia serpentina</i> Benth. "Serpasil."
Sodium acetizoate	Sodium 3-acetamido-2:4:6-triiodobenzoate. "Diaginol."
Tetracycline	4-Dimethylamino-1:4:4a:5:5a:6:11:12a-octahydro-3:6:10:12:12a-pentahydroxy-6-methyl-1:11-dioxonaphthacene-2-carboxamide. "Achromycin."
Tretamine	2:4:6-Tri(ethyleneimino)-s-triazine. "Triethanmelamine," "Triethylene melamine," "TEM."

Reports of Societies

DENTAL ANAESTHETICS

At a meeting of the Section of Anaesthetics at the Royal Society of Medicine on February 5, with Professor R. R. Macintosh presiding, Dr. J. G. BOURNE challenged the present custom of regarding nitrous oxide as the mainstay of anaesthesia for out-patients. In his opinion the time had come for a fresh clinical assessment of this low-potency anaesthetic. He had therefore devised a method by which the reactions of patients could be observed after nitrous oxide had developed its maximum effect (after 10 or more minutes). Only 1 in 4 out of 60 unselected adult patients investigated in this way reached surgical anaesthesia. In a further 1 in 4 patients Dr. Bourne was not even convinced that unconsciousness was present, though these patients remembered nothing. More than half the patients retained reflexes that were too brisk to allow even minor operations.

Saturation of the brain with nitrous oxide took time (periods varying from 7 to 15 minutes had been suggested). But the majority of out-patient dental operations, including induction of anaesthesia with nitrous oxide, were completed within two minutes. Armstrong, in his book on aviation medicine, had given the explanation why this method worked. He had written: "A man at rest can hold his breath for 1 to 1½ minutes. But if the oxygen in the lungs and blood is washed out by breathing any inert gas such as nitrogen, sudden and complete loss of consciousness will occur in about 50 seconds." Armstrong had recorded the times taken for pilots to lose consciousness when cut off from their oxygen supply at high altitudes and left breathing air, and his figures had led Dr. Bourne to the conclusion that "the expert with nitrous oxide, knowing the trick, induces 'anaesthesia' rapidly by taking his patients straight to 30,000 or 40,000 ft.* From there he allows them to descend only so long as they behave themselves and then only at a rate that is compensated by the accumulation in the central nervous system of increasing quantities of nitrous oxide."

Anoxia Plus Nitrous Oxide

In some patients not resistant to nitrous oxide a light plane of anaesthesia could be reached by the summation of two effects—anoxia plus nitrous oxide. As nitrous oxide accumulated in the brain more and more oxygen could be added and anoxia was gradually relieved. But with the large group of patients who were semi-resistant the position was not so happy. As several authorities had noted, anaesthesia demanded a restriction of oxygen supply (according to Kaye a "gross" restriction). Clement had written: "Control of anaesthesia is synonymous with control of the oxygen."

True resistance was seen in patients who were barely unconscious even when saturated with 80% or 90% nitrous oxide. It seemed to come from habituation to narcotic drugs, and was commonest in middle-aged and elderly patients—those in whom deprivation of oxygen would seem most unwise. Anoxia of the severity required to produce unconsciousness in these patients did not leave much room for bungling. Courville had shown that the anoxic decerebration of nitrous oxide anaesthesia could be irreversible. Some degree of damage to the brain might pass unnoticed in many cases. Though anoxia was recognized as harmful and was avoided in in-patient anaesthesia, in out-patient practice it was still employed by all and sundry as a supplementary, or perhaps even a main, agent of anaesthesia.

After asking whether nitrous oxide, as commonly used in out-patients, was a suitable introduction to anaesthesia for

*9,000 or 12,000 metres.

undergraduate medical and dental students, Dr. Bourne then described (with the help of an admirable film) the advantages of a method of out-patient anaesthesia with cyclopropane. Using a large reservoir bag (1.3 gallons—4.6 litres), with 50% cyclopropane in oxygen, he had anaesthetized 1,918 patients of all ages without mishap. Induction was very quick: all patients lost consciousness in 3 to 6 breaths, and after a few more breaths were ready for operation. By this means a maximum effect was produced with a minimum amount of drug.

The possible disadvantages of cyclopropane as an out-patient anaesthetic were threefold: first, salivation might occur, but was easily prevented by giving 1/75 gr. (0.86 mg.) of hyoscine hydrobromide, or half that dose to children, 40 minutes before operation; secondly, recovery might be delayed; and, thirdly, post-anaesthetic nausea and vomiting might occur.

Nausea and vomiting delayed recovery, but they could largely be avoided if the mixture of cyclopropane was breathed for only one minute. This gave satisfactory operating conditions for about 2½ minutes; if necessary the period of anaesthesia could in most cases be extended by administering nitrous oxide (80%) and oxygen after induction with cyclopropane. In Dr. Bourne's series of patients recovery was rapid, and 4 out of 5 of those who had previously had "gas" expressed a decided preference for cyclopropane. He claimed that, provided the duration of cyclopropane inhalation and its concentration were controlled as he had indicated, this technique might be safer in the hands of a novice than nitrous oxide. Nevertheless, nitrous oxide anaesthesia carried a very low mortality, and any method recommended as an alternative must be given a thorough clinical trial and no danger overlooked. The time had now come when the whole subject of anaesthesia for the out-patient should be reviewed.

Discussion

In the discussion that followed Mr. ROBSON said that from a dental surgeon's viewpoint the cyclopropane mixture was far preferable to the usual dental "gas." Bleeding was less and, most important of all, the patient was motionless. In short, the dentist received ideal conditions, and it was to be hoped that the day would come when nitrous oxide would be discontinued—the sooner the better.

Dr. VICTOR GOLDMAN pointed out the danger of attaching too much importance to the weak anaesthetic properties of nitrous oxide if the patient had previously been breathing a high percentage of oxygen. The nitrous oxide-oxygen mixture must be defended. He recalled that Clement claimed that the majority of "gases" were ruined by giving too much oxygen at the start, and yet even more were spoiled by not giving enough oxygen once the patient had lost consciousness.

Dr. G. S. W. ORGANE stressed the importance of the danger of an explosion with cyclopropane. He thought it might be possible for a spark between the dental forceps and a filling in the patient's mouth to ignite the anaesthetic mixture.

Dr. J. D. LAYCOCK felt that more thought should be given to the use of trichlorethylene in out-patient anaesthesia. In his experience trichlorethylene was capable of producing suitable anaesthesia even when used with "a rag and bottle."

Dr. R. BLAIR GOULD claimed that the dangers of nitrous oxide as a dental anaesthetic were exaggerated. Very few people could not be given nitrous oxide and still be kept "pink" during the two or three minutes of a dental operation. Resistant patients should be given a little pre-medication.

In a brief reply Dr. BOURNE countered any criticism of cyclopropane as an out-patient anaesthetic by saying, "The patients prefer it, the surgeons prefer it—so why use anything else?"

Correspondence

Early Treatment of Cleft-lip and Cleft-palate

SIR,—I do not agree with Mr. W. G. Holdsworth (*Journal*, February 6, p. 304) that in double clefts of the lip there is usually "a serious deficiency of tissue." I know this belief is widely held, and it has led to some surgeons advocating what is to me the horrifying procedure of a "primary Abbé" operation—that is to say, transplanting a part of the normal lower lip into the alleged deficiency of the upper.

In my opinion the meagre, tight, and immobile upper lips which result from the classical operations are due to fundamental faults of principle and technique. These are: (1) Not correcting the displacement of the premaxilla, if this is present. To do this it is necessary to understand what pushes it forward—the prevomerine bone—and to remove this alone. (2) Not getting junction of the premaxilla with the rest of the alveolar ridge. If this is not done it will atrophy. (3) Not forming the labio-gingival sulcus at the start. If this is not done the lip is tethered down and immobile, and the muscles cannot develop. (4) Not obeying the primary orthopaedic principle of joining the actual ends of divided muscle. All classical procedures join one end of the orbicularis oris to one side of an inert central piece of tissue, and the other end to the other side. Imagine what would happen were a ruptured quadriceps to be treated in the same way. (5) Not understanding the embryology of the lip. Embryologists have not noticed that there is an interesting minor problem to be solved in how the mouldings of the normal lip are produced by the fusion of its various primary parts. I think it is possible to work this embryology out, to translate the process into a geometrical formula, and finally to interpret this in a surgical proceeding.

I have published large-size unretouched photographs, without lipstick and without smiles, showing the results of treating double hare-lip with displaced premaxilla in two operations.¹ If those who use other methods would do the same we would be able to judge how we stand.—I am, etc.,

DENIS BROWNE.

London, W.1.

REFERENCE

¹ *Ann. roy. Coll. Surg. Engl.*, 1949, 5, 169.

SIR,—Mr. W. G. Holdsworth, in his article on the "Early Treatment of Cleft-lip and Cleft-palate" (*Journal*, February 6, p. 304), states: "Little is known of the effects of operation on the development of the facial skeleton, and these may be serious enough to prohibit procedures otherwise commendable." The essential problem which requires solution is whether the deviation from the normal growth pattern seen in the adult patient who has undergone surgical closure of a cleft lip and/or palate in infancy represents the mature development of an intrauterine defect, or the end result, which in some cases almost amounts to a mutilation, of surgical interference with growth centres, either directly from the operative procedures, or indirectly from restriction of the normal downward, forward, and lateral projection of the middle third of the facial skeleton by its enclosure in a vice of scar tissue.

Contrary to Mr. Holdsworth's statement, the whole question of the effects of operation for closure of cleft lip and/or palate defects on the development of the facial skeleton has been carefully and comprehensively studied since 1931 in the United States. The investigations carried out have not been confined merely to the dental arches, but have embraced the entire facial skeleton. The technique utilized was that of cephalometric roentgenology by means of the Broadbent-Bolton cephalometer, a method which employs a series of antero-posterior and lateral radiographs of the skull exposed and positioned under standardized conditions so that accurate determinations of the growth pattern may be carried out by anthropometric and cephalometric measurements.

Foremost among the conclusions derived from these investigations is the fact that five-sixths of the total palatal breadth have been accomplished by the end of the fourth year in normal individuals, with total width increments by the end of the tenth year. The other major points of interest can best be summarized by

reference to the observations of Slaughter and Brodie,¹ whose deductions are based upon a study of 1,349 cases. They state: "The evidence is already at hand that surgery can and does inhibit normal growth. This interference is directly proportional to the amount of injury to growth centres and to diminution of blood supply to the parts concerned. Other evidence is available to show that congenitally deformed parts, unless permanently damaged, grow at normal rates. These two findings alone should cause us to examine our concepts and procedures very carefully. Together they indicate that surgery, poorly executed or poorly timed, can do more damage than good in the long run."

The only advantage claimed for operation on the palate before the age of 9 months is that the child will ultimately have a much better chance of achieving normal speech later. Mr. Holdsworth refers to "the inadequacy of any classification based upon personal appraisal of cases," and this sense of inadequacy would appear to be particularly pronounced when it comes to the assessment of what constitutes apparently faultless speech. The evidence that better speech results from closure of the palatal defect before the age of 5 is largely based upon the auditory impressions of the operators themselves rather than upon impersonal scientific facts, which latter observations have at least established beyond reasonable doubt the price which must be paid when the debt of early operation is redeemed in adult life. A rough translation of the words of Veau and Borel quoted by Mr. Holdsworth would be: "The minor details of the lip which often attract all our attention, have not the same importance as the general appearance of the face which occupies us less." To which I would like to add the suggestion that the minor details of the differences in clarity of enunciation between cleft-palate patients operated upon at different ages have not the same importance as the major differences in the ultimate appearance of the face and jaws which ensue from surgical interference during the period of maximum growth of the maxillae—that is to say, the first four years of life.

The results which may be anticipated from the careful and meticulous technique employed by Mr. Holdsworth may ultimately be very much better than those hitherto performed by less delicate operators, but any attempt to advance the age of operation upon a cleft-palate must be deplored by those who have studied or carried out careful investigations into the ultimate sequelae of such a procedure.—I am, etc.,

Basingstoke.

A Cosmetic Amputation

SIR,—It was a pleasure to see the letter of my friend and former teacher, Hamilton Bailey, on this subject (*Journal*, January 30, p. 275). From my experience I can support what he said. He taught me this amputation over 20 years ago, and since then I have practised it. It has always been pleasing to see these patients afterwards—they have had good functional and cosmetic results. Amputations where the head of the metacarpal has not been removed have always seemed to me unsightly, and for several patients I have re-operated to remove the "odd" prominence.—I am, etc.,

London, W.1.

HAROLD DODD.

Mucocele of the Appendix

SIR,—Mr. J. H. Johnston's article (*Journal*, January 16, p. 135) stimulates me to report a case of mucocele of the appendix with pseudomyxoma peritonei.

The patient was a para one, aged 30, whose only complaint was of a mucous vaginal discharge which appeared to be due to an excessive cervical secretion. The uterus was in fixed retroversion and there was a small cyst of the left ovary. Further questioning revealed some discomfort recently in the lower abdomen and back a few days before her periods. A diagnosis of pelvic endometriosis with a chocolate cyst of the ovary was made, and the discharge considered to be due to pelvic congestion.

At laparotomy about 10 oz. (284 ml.) of "mucin" was found lying free in the peritoneal cavity. The uterus was bound down in retroversion by extensive pelvic endometriosis, and there was a small chocolate cyst of the left ovary. The right ovary appeared normal. The appendix was grossly thickened throughout its length, and surrounded by myxomatous tissue which appeared to be coming from a perforation in the appendix which was neither constricted nor kinked, and I removed it with a small cuff of caecum. The ovarian cyst was enucleated, and the uterus anteverted by means of a Gilliam suspension.

I am grateful to Dr. Whitelaw for the following histological report. "Ovarian tissue shows a follicular cyst filled with blood clot. Section of appendix is cyst-like in character with diameter of lumen 1.0 cm. In the specimen there is no occluding stricture. The wall is composed of a lining of high mucus-secreting columnar cells. There are no remains of cysts, and lumen is filled with mucin material with a few scattered cells. The submucosa is narrowed, fibrous, and has a few scattered lymphoid follicles. The muscular coat is of considerable thickness (1.7 mm.) and in two places is ruptured or deficient, and the mucous contents pour through and infiltrate the peritoneal coat. The cells associated with the 'mucin' are plasma cells and round cells and a few foreign body giant cells. There are no cells of epithelial origin in this over-spill."

The patient had an uneventful convalescence, and subsequent questioning failed to elicit any history that could have been construed as appendicitis. The muscle hypertrophy and the perforation would conform with Wilson's theory of appendiceal diverticula,¹ which in the absence of a constriction must represent the continuous efforts of the appendix to expel its unusually profuse and viscous secretions.

I have called this case a pseudomyxoma peritonei, but if we accept Woodruff and Macdonald's classification of benign and malignant mucocoele this is really only a *pseudo* pseudomyxoma peritonei. We are so little conversant with the real mechanism of this condition that I do not agree with Mr. Johnston's suggestion of post-operative radiotherapy for these cases, particularly if the patient happens to be a young woman, unless the pseudomyxoma is seen to recur. Pseudomyxoma due to cystadenoma of the ovary requires separate consideration, which space does not permit.

I saw this patient recently, four months after the operation. There is no evidence of recurrence. She is now free of all discomfort at her period times, but her mucous vaginal discharge persists, and I shall now try a small "office procedure" which includes the use of a silver-nitrate stick.—I am, etc.,

EDWARD COPE.

Immunization Against Tetanus

SIR,—I was interested to read in your leading article entitled "Combined Prophylactics" (*Journal*, December 12, 1953, p. 1313) a suggestion that active immunization against tetanus should be offered to schoolchildren. It is not generally realized that all Service recruits receive on enlistment full active immunization with three doses of tetanus toxoid. The Services laboratories consider that this confers a safe level of immunity for about four years, when a further boosting dose is necessary. After completing their National Service a high percentage of young men who meet with accidents will already have a reasonable level of immunity. Before giving an injured man anti-tetanus serum I think it is always worth while to ask about previous Service inoculations. No Serviceman will have missed having his doses of tetanus toxoid unless he has deliberately "refused" them, and this fact he will certainly remember. Within ten years of active immunization one boosting dose of tetanus toxoid should then be adequate. I have recently encountered several examples when Servicemen in uniform were given "3,000 A.T.S." by casualty officers.—I am, etc.,

Sunning-on-Thames.

G. M. BAILEY.

Ulcerative Colitis

SIR,—Just a few lines in reply to Dr. Norman P. Henderson (*Journal*, January 30, p. 277). All my patients were examined by the sigmoidoscope and opaque enema before operation, but I thought these elementary precautions so obvious as not to require mention. The conditions which may be mistaken for true ulcerative colitis and to which Dr. Henderson rightly draws attention were, therefore, as far as possible excluded.

I was flabbergasted to read that Dr. Henderson regards ileostomy as only a preliminary to colectomy. I have seen some of the results of the latter operation, not that I was ever guilty of recommending it myself, but a good many

years ago it was rather a favourite procedure of the late Sir Arbuthnot Lane, who regarded the colon as a sort of cesspool and the fons et origo of a mythical condition "auto-intoxication"—then almost as popular a diagnosis as "allergy," "endocrine-imbalance" (odious term), or "disk lesion" is now. (Odd, by the way, how every generation of our profession has its favourite diagnoses. Looking back over the past 60 years I can recall many such, each of which has had its little day and ceased to be, and if I might venture to give the young doctors of to-day a piece of fatherly advice I would say: Beware of the fashionable diagnosis.) Well, I often saw the end results of Lane's activities, and, apart from any question of immediate operative mortality, they were sometimes, in the idiom of to-day, "pretty grim." Dr. Henderson had best be careful, therefore, lest the last state of his patients be worse than the first, even if he does prevent an occasional one from developing cancer later on.—I am, etc.,

Streatley, Berks.

ROBERT HUTCHISON.

Fatal Bronchial Asthma

SIR,—The most important fact brought out again by Drs. C. K. Robertson and K. Sinclair (*Journal*, January 23, p. 187) is the necropsy finding of bronchi blocked by mucous plugs in all cases. The practical conclusion from this is that the mucus must be removed by treatment. The effect of a trypsin aerosol as reported in two American papers quoted by your annotator (p. 203)¹ scarcely justifies his optimism. One of the authors has not treated asthmatics, and the other stresses that the treatment was ineffective in chronic asthma. Neither has made any attempt to assess objectively the effect of trypsin on expectoration.

Nor do I agree with Mr. A. M. Zamora (*Journal*, February 6, p. 333) that treatment should be suction through the bronchoscope. This rather drastic method might give partial relief for a short time, but not all bronchi, and particularly not the smaller ones, are cleared by it. Moreover, the treatment cannot be repeated every few days. The aim of treatment for patients who continue to produce large amounts of sticky mucus must be to liquefy the mucus. This can be done efficiently by iodine, given either in the form of Lugol's iodine, as Drs. Robertson and Sinclair suggest, or as potassium iodide 15 gr. (1 g.) three times a day or more. Iodine sensitivity is infrequent in asthmatics and can be overcome by drastic reduction of dosage. Myxoedema² is rare and can be countered by thyroxine. Treatment with iodine is indeed so efficient that neither Pines³ nor I⁴ have had to resort to bronchoscopy in any case of asthma.—I am, etc.,

Chronic Bronchitis

SIR,—I read Mr. John Fry's article on chronic bronchitis (*Journal*, January 23, p. 190) with great interest. That the death rate in Great Britain should be so much higher than any other country certainly suggests that the subject requires further investigation.

It seems possible that the distribution of the disease and the morphology of the bacteria and/or virus involved might prove a useful angle of approach to the problem. In America (New England) the incidence of chronic bronchitis is higher in rural districts than industrial areas, and in England, if we exclude pneumoconiosis, we may find that rural districts have a high incidence, and I think this has been established in the Thames Valley. Is there a factor in the environment of bacteria and/or virus which increases their virulence? How is it that scarlet fever is commoner in late summer and autumn, that measles is prevalent in the winter and spring, that influenza has periodic pandemic waves, and that smallpox apparently spreads sometimes by convection? What is the factor that determines a harmless saprophyte such as *B. coli* becoming a virulent germ?

Sterilization of Ampoules

SIR,—It is inevitable that words of wisdom must fall on stony ground, for Dr. G. C. Steel (*Journal*, February 6, p. 335), alas, has missed the point, not only of correspondence which litters the literature, but also of the inferences to be drawn from Professor L. P. Garrod's excellent letter (*Journal*, December 5, 1953, p. 1269).

As the subject of "sterilizing ampoules" is fast becoming tedious, may I just ask Dr. Steel at least to examine his opened ampoules, preferably before intrathecal injection? Even if he does not believe that bacterial contamination of an intact ampoule can occur, the fragments of unsterile glass occasionally reposing in the bottom of his unsterile opened ampoule will doubtless be an object lesson to him.—I am, etc.,

Edgware.

D. RECKLESS.

Sedimentation Rate in Active Tuberculosis

SIR,—In his article on "The Laboratory Diagnosis of Pulmonary Tuberculosis" (*Journal*, January 30, p. 267) Dr. J. W. Clegg includes the sentence: "The sedimentation rate is always raised in active tuberculosis and falls as healing takes place." The article is one of a series giving excellent advice or instruction, and maintains the high standard which has been set. Consequently many who have read it will be likely to place great reliance on the statements made, and there is a danger that it will be assumed that the absence of a raised sedimentation rate excludes a diagnosis of activity of a tuberculous lesion. While it is true that the sedimentation rate is usually raised in active tuberculosis, active disease can exist in its absence. In 287 cases of active pulmonary tuberculosis which I analysed,¹ 107 (37%) had a B.S.R. of under 8 mm. in 1 hour. Of the 65 cases with a positive sputum smear stained by the Ziehl-Neelsen method, 17 (26%) had a normal B.S.R.—I am, etc.,

Harrow.

H. J. TRENCHARD.

Treatment of Tuberculous Meningitis

SIR,—With reference to Dr. J. Lorber's criticism (*Journal*, December 26, 1953, p. 1433) of my article (*Journal*, November 21, 1953, p. 1127), I would like to state that this article was intended to be an interim report. The apparent discrepancy between Dr. Lorber's and our analysis of mortality rates is due to the fact that several of the cases who were reported to have died did not die of tuberculous meningitis (see Table III of the article). Of all cases who were reported in the second series, one has since died of tuberculous meningitis, No. 60 remains the same, No. 50 is still paraplegic, and all the others now have a normal C.S.F. and are clinically well, except for two who have a residual weakness of one leg following a hemiplegia. With the exception of case 60, all children of a suitable age are now at school or at nursery school.—I am, etc.,

Durban.

WINIFRED C. M. BULKELEY.

The African in Industry

SIR,—The medical needs of the miners in Southern Africa are by no means as "fearful" as Mr. R. Schram (*Journal*, February 6, p. 334) would have us believe. Both the mines and the recruiting organizations provide free medical services to the Africans which are second to none. The health of most Africans is greatly improved during their period of service, since they receive a proper diet with a surfeit of proteins and vitamins which are sadly lacking from their diet at home. In addition, the South African Government provides free medical attention for the Africans and is giving the mission hospitals active financial support in their fight against tuberculosis and other diseases such as malaria, typhoid, bilharzia, drugs for the treatment of which are supplied free. Some areas have already been freed of malaria for several years.

Modern entomological books provide distribution maps of insects, and, although their pabulum may be widespread, the insects are found in more or less restricted areas. May not the flora of the bronchial tree be also restricted by certain unknown laws? Some years ago it was found in a large town that cases of rheumatism in children were largely restricted to the areas around the submerged rivers of the city. No doubt immunity and heredity play their part in resistance to infection, but is there not a case for the factors that increase the virulence of the germs?—I am, etc.,

Tarrington.

H. G. LANGDALE-SMITH.

The Normal Blood Count

SIR,—In his excellent article under the heading "Clinical Pathology in General Practice" (*Journal*, February 6, p. 326) Dr. George Discombe states that the mean corpuscular haemoglobin concentration is obtained by dividing the haemoglobin concentration in grammes per litre by the packed cell volume. I suggest that this should be calculated by dividing the haemoglobin concentration in grammes per 100 ml. by the packed cell volume and multiplying by 100.—I am, etc.,

Haywards Heath.

R. W. P. JOHNSON.

SIR,—Dr. George Discombe's article on "The Normal Blood Count" (*Journal*, February 6, p. 326) was helpful and stimulating. He rightly emphasizes the value of inspection of the stained film in the study of red cell abnormalities, and he says that the film should be "so thin that the cells are separate." This does not go far enough, for it does not exclude parts of the film which are too thin, notably the very last part spread. Here the cells are separate, but they are mechanically distorted and so flattened that the normal central pallor is not seen.

Red cells should be studied in parts of the film which are a little thicker than the thickness of a red cell. In such a place a few of the cells in a field will be slightly overlapped by other cells, but most will be uncovered. Such parts of a film are excellent for studying the morphology of both red and white cells (but are not suitable for white cell differential counts).—I am, etc.,

London, W.2.

R. R. WILSON.

Controlled Hypothermia

SIR,—We were relieved to see from his comments on the letter from Drs. J. W. Dundee and T. Cecil Gray (*Journal*, January 30, p. 272) that the writer of the annotation on "Chlorpromazine for Hypothermia" (*Journal*, January 9, p. 89) realized his error in assuming that we believed the drug to be a ganglion-blocking agent. It is clear, however, from his further remarks on regulation of body temperature and the autonomic system that we differ in our conceptions of what structures constitute this system. While it is quite true that from a strictly anatomical point of view the autonomic nervous system is simply an efferent outflow with two groups of peripheral pathways, sympathetic and parasympathetic, it has not seemed unreasonable to us to take a broader view of it. Physiologically it may be regarded as the system which effects those adjustments necessary to maintain constant the internal milieu in the face of a changing external environment.

Holding this view, we feel that it is quite logical to include in our conception of the autonomic system these centres in the hypothalamus and elsewhere which co-ordinate and integrate the functions of this system. Ample evidence exists that heat-regulating centres are present in the hypothalamus.¹ It is here as well as on other centres that we have supposed chlorpromazine to act, and in using the term autonomic block we intended to refer as much to this action of the drug as to its adrenolytic effect.—We are, etc.,

I have had extensive experience in these fields of work, and would suggest to the critics that they bear in mind the vast areas involved and the extremely primitive conditions of African tribal life. The cost of these services has to be borne by a few million Europeans in a country several times the size of England.—I am, etc.,

London, W.C.1.

C. C. GRUNBERGER.

The Uvula and East African Negroes

SIR,—I do not think there is any record of the importance which the East African negroes attach to the uvula regarding disease and magic. It is considered by them to be the seat and cause of all diseases affecting the throat and to be the source of all coughs. Therefore they will go to any length and travel enormous distances to find a doctor who will cut their uvula.

My father, during his more than 50 years of practice in Nairobi, 1898–1951, must have cut altogether over 40,000 uvulas. I remember seeing him when I was a boy in the 1920's cut as many as 20 or more a day. He used to do this by the simple method of steadying the patient's head against the wall, catching the uvula with a forceps and snipping it in one stroke with sharp curved scissors. Then he gave the patient some dry ginger to take home and chew. The patient invariably reported that he was cured from his cough and from his sore throat.

The African, particularly of the Jajuo (Lake Victoria area) and the Kikuyu tribe from the Kenya Highlands, is absolutely certain that if his "kilimi" (Swahili word for the uvula) is not cut he will die from his sore throat. He is also convinced that all cough is produced by the "kilimi" and will not hear of any other treatment other than having it cut. The fear of death if "the kilimi is not cut" is probably due to some cases of diphtheria which died and which were diagnosed by the local witch doctor as "kilimi" and helped to establish this cult with the fear of the "kilimi" as the source of all evil to be removed at once. The Kikuyu, particularly the ignorant women from the bush, will insist that the "kilimi" is the sole cause of their child's illness and will refuse to treat the child for bronchopneumonia from which it is really suffering.

Such is the strange belief and cult of the "kilimi" among them, and it is worth putting it on record now, because it will probably disappear with education within the next 25 or 30 years.—I am, etc.,

Nairobi.

A. L. RIBEIRO.

Rheumatic Heart Disease Complicating Pregnancy

SIR,—We are grateful to your annotator (*Journal*, January 9, p. 87) and to Drs. Denny and Ryle (*Journal*, January 23, p. 215) for their interest in our article entitled "Rheumatic Heart Disease Complicating Pregnancy" (*Journal*, January 9, p. 70). The suggestion that pregnancy did not contribute to the deaths which occurred later than one year after confinement has been criticized. The relevant facts are these. The average age at death of these women was 38 years. Paul Wood¹ states that the average age at death of cases of mitral stenosis is 35 years. The average age of those who died from heart failure during, or within one year, of pregnancy was 25.4 years. Do these figures suggest that we have indulged in "wishful rather than logical thinking"?

The rejection of therapeutic abortion and sterilization and the references to contraception have also been questioned. Yet the text showed that each patient who died during or within one year of pregnancy was, when first seen, completely unsuitable for artificial termination both by virtue of the stage of pregnancy and of the cardiac condition. Thus no one died because therapeutic abortion was not employed. Since no patient who received antenatal care succumbed, it seems eminently reasonable to argue that antenatal care is preferable to abortion. Four of the women who died from heart failure were primigravidae and the other a gravida 2. If these deaths be used as arguments in favour

of sterilization and contraception it would seem to follow that women with heart disease should not be allowed to conceive at all.

Brief reference to the literature shows that we are not alone in believing that pregnancy, if survived, does not contribute to an early demise. Bunim and Rubricius² state that "data collected under well controlled conditions" indicate that pregnancy does not alter the course of rheumatic heart disease. Boyer and Hadas³ found that women who had four or more pregnancies did not die at a younger age than those who had none. Morgan Jones⁴ states that "there is no evidence that repeated pregnancies appreciably shorten life." We presume that women who have borne children generally must care for them.

We have seen fatalities result from operative intervention in other centres. Such fatalities frequently escape the obstetrical records, as these procedures are often carried out in gynaecological departments. Scientific analysis of our own cases and of published reports has convinced us that conservative management is the ideal at all stages in all cases of rheumatic heart disease complicating pregnancy. Contrary facts have not been published.—We are, etc.,

M. I. DRURY.

M. K. O'DRISCOLL.

"Antidotarie Chyrurgical"

SIR,—I was interested to read your note on Banester's *Antidotarie Chyrurgical* (*Journal*, February 6, p. 329). I have always been puzzled as to the methods by which booksellers and others arrive at their estimate of a book's rarity. It is quite certain that there are more than two other copies of this book in existence, if one is in the Wellcome Museum and the other appeared at a book auction within the last 50 years. There has been a copy in the library of the Royal College of Physicians, Edinburgh, since 1846, which I have before me as I write and which corresponds exactly to the copy you describe.

It is a curious fact, which still awaits explanation, that the Tweed appears to present an insuperable barrier to medical bibliographers. It would take very little time to produce quite an impressive list of medical books of which it has been said that only one or two copies are preserved, and of which another six copies can be found in Scottish libraries. I would add that Banester's book is included in the printed catalogue of this Library, published in 1898.—I am, etc.,

Edinburgh, 2.

L. JOLLEY.

SIR,—Your interesting Nova et Vetera "An Extremely Rare Treatise" (*Journal*, February 6, p. 329) assumes too readily that all known copies of John Banester's *Antidotarie Chyrurgical* of 1589 are recorded in the *Short-Title Catalogue*. The Royal College of Surgeons of England has been fortunate to own a copy of this book since 1818, when it was bequeathed to the College library by William Long, surgeon to St. Bartholomew's Hospital and second Master (President) of the College.—I am, etc.,

London, W.C.2.

W. R. LE FANU.

Rh-Hr Nomenclature

SIR,—For some time there has been need for another conference on Rh-Hr nomenclature in order to clarify the confusion which exists among workers in the field. With the appearance of two new books dealing with the Rh-Hr types^{1,2} the facts regarding this problem become easily available to anyone. Clearly there is room for only a single nomenclature as in the other blood group systems—namely, the international Rh-Hr nomenclature. It may be, how-

ever, that the people still using the C-D-E notations feel that they should be given a final opportunity to defend their position. In that event they might decide to hold a conference either at the next meeting of the International Society of Haematology in Paris or at the International Congress of Clinical Pathology in Washington. Should it be felt desirable to hold such a meeting, I, for one, would not object, but would instead welcome the opportunity to explain this complex subject again.—I am, etc.,

Brooklyn, N.Y.

Rh Antibodies and Domiciliary Midwifery

SIR,—With the establishment of the College of General Practitioners and the re-emergence of the general practitioner I would like to ask for the views of fellow G.P.s about the problem of Rh antibodies in domiciliary midwifery. I would particularly ask those who believe that domiciliary midwifery has distinct advantages over hospital midwifery and those who practise midwifery, not merely to fill in a claim form and pass the buck at any conceivable excuse. With the great strides in the treatment of haemolytic disease, such mental stress caused by the investigation alone is overlooked. The anxiety that can be caused by an "uncomplicated" green card is known only to the woman's G.P. The explanation is often misunderstood and comfort not accepted.

But to come to the specific problem. One is instructed by the local blood transfusion laboratory, and I use the word instructed deliberately, that should a woman have Rh antibodies then she must be confined in hospital. The reason for the instruction is set out with the letter of instruction. I feel that G.P.s are entitled to kick very hard at being instructed, but even if we are to assume that the laboratory's letter is one of advice one has to consider whether their advice is indeed correct and sound.

In the course of the last four years I have had some 300 confinements. All mothers had their blood grouped and there were five cases with Rh antibodies. Of these five, two infants were Rh -ve Coombs -ve, and were of course no problem. Two infants had haemoglobins of 120% approximately, and were very little problem. One infant had a Hb of a little under 100% and required a small transfusion for anaemia on the 8th and 20th day of life. Four of the confinements took place at home and the fifth I reluctantly advised to go into hospital—the advice was even more reluctantly accepted.

Provided one practises within easy reach of a laboratory with 24-hour facilities, and there is a hospital with proper facilities within easy reach, the problem as it appears to me is as follows. The mother has antibodies—the child may or may not have haemolytic disease. Provided one is prepared to be present at the confinement—for clinical assessment of the infant—and provided that one will send a sample of blood to the laboratory for estimation of Hb and Coombs test, what risks are run by a home confinement? Within an hour or two of the child's birth the practitioner will be able to report to the mother. In the great majority of cases this report will be entirely satisfactory. In the small minority of cases it will have been decided that replacement transfusion is required and arrangements will have been made, certainly well within four hours of birth. The case that may possibly require a small transfusion in the second week of life should, of course, not present any immediate problem.

It leaves one with the final small group—which I understand requires immediate transfusion—how extremely rare this group is I do not know. But I am pretty sure that the chances of an individual practitioner meeting a case are small to the extreme. In the past I have allowed my patients with antibodies to be confined at home—I have taken the precautions detailed—and I am very reluctant to give up this practice.

I am sure that many other G.P.s have given this problem thought, and one would be very grateful for their views. For myself, I feel that absolute safety is non-existent. (What about haemolytic disease due to other factors?) And to have given the mother peace of mind and happiness is a very great thing.—I am, etc.,

Gatehead, 8.

M. CHALK.

Mongolian Blue Spots

SIR,—Holt¹ describes these spots as follows: "In the skin of the lumbosacral region of the newborn infant one not infrequently finds irregular areas of pale brown or bluish pigmentation, several centimetres in diameter; they may also involve the buttocks and the posterior thoracic wall. These 'Mongolian spots' are quite regularly found in infants of Mongolian race, are fairly frequent in Negroes, but are not uncommon in infants of Caucasian stock. In Negroes they occasionally take the form of decreased, rather than increased, pigmentation. They usually disappear in later infancy or early childhood."

In this country these spots are usually considered to be rare. However, the proportion of foreign blood is steadily increasing, and investigation shows that they are becoming rather more common. During the year 1953 in the maternity wards of a large hospital 778 children were born. Four of them were observed to have Mongolian blue spots (0.51%). These four all had white British fathers. The mother of the first was a Negress and of the second an Indian. The mother of the third was of unknown race as she had herself been adopted in infancy. The parents of the fourth were both English, but the mother's mother was a Jewess from Odessa. An attempt was made to obtain a photograph of one of the spots with panchromatic and infra-red film, but it could not be seen in the prints. A colour photograph was successful.

This experience is recorded, as others may meet with the spots and be puzzled as to their nature. It is important to note that there is no connexion between these spots and Mongoloid idiocy.—I am, etc.,

Bath.

Medicinal Teaspoons

SIR,—Dr. L. Carlyle Lyon's letter (*Journal*, January 23, p. 217) is a timely warning of the possible dangers of inaccurate measuring of medicines. Until comparatively recently most of the medicines supplied to patients for use in their own homes were relatively innocuous even in considerable excess of the correct dose. Now, however, very potent drugs such as methadone, the barbiturates, anti-histamines, and sulphonamides are issued as flavoured liquid preparations, especially for administration to children. With these drugs the margin of safety is small, and already at least one child has been poisoned by methadone because of inaccurate measurement of the dose.¹

There is even greater confusion about the value of a teaspoonful than Dr. Lyon has indicated. In 1947 the British Standards Institute issued a specification for a standard kitchen teaspoonful which holds approximately 49 minims (3 ml.). After protests from the pharmaceutical profession a standard for medicinal teaspoons was introduced in 1949 (B.S.S. 1348, 1949). The requirement for the capacity of this spoon is 60 minims (3.6 ml.) (±5%). In spite of the fact that a fluid drachm has been accepted by the medical, pharmaceutical, and nursing professions for many years as the volume of a teaspoon, at least three values are now in common use by manufacturers. For example, the dose of elixir of piperazine ("antepar") is given as 1 teaspoonful (3.5 ml.), that of chloramphenicol palmitate suspension as 1 teaspoonful (4 ml.), and of benzathine penicillin ("penidural") suspension 1 large teaspoonful (5 ml.).

Marston² quotes an example of two preparations of a similar compound being in one case labelled with 3.5 ml. as a teaspoonful and in the other 5 ml. He also mentions another preparation where the following is stated on the same label: "One teaspoonful (5 ml.) three times a day" and then "one drachm (4 ml.) contains x grains, etc." Spalton³ requested 20 clerical workers in a Leicestershire factory to bring from their homes "one tablespoon and one teaspoon such as you would use to administer medicine." He investigated the capacities of these and found that the teaspoons varied from 2.4 to 7.0 ml. and the tablespoons from 13.4

to 27.2 ml. It is probable that the majority of the public are unaware of the existence of the standard medicinal teaspoon, and the number of homes in which they are to be found must be very small. Surely the time has come to abandon the use of these inaccurate so-called "domestic equivalents" and to advise patients to measure medicines exactly. If drugs were prescribed and dispensed on the metric system it would be quite simple for patients to measure the dose as 4, 5, 10, or 30 ml., etc. Even on the old system it would be better for medicines to be labelled in fluid drachms and ounces and for measures to be supplied.

With modern drugs it is so important that the patient takes the correct dose that accurate medicine measures should be allowed to be prescribed on Health Service prescriptions. Diabetic patients can easily be taught to administer insulin in doses of 1 or 2 ml., and it should not take long to teach others to measure liquid medicines if the appropriate measures are readily available. Finally, it is obviously the duty of doctors and pharmacists to impress on their patients the need for accuracy in measuring medicines and the dangers of overdosage.—I am, etc.,

Ophthalmic Waiting-lists

SIR.—The City Surveyor of Birmingham in a recent speech gave a most apt description of a statistician: "A statistician is a man who can draw a straight line from an unfounded assumption to a questionable conclusion." Professor Sorsby in his report on the causes of blindness in England¹ has stated that each year about 2,500 to 3,000 patients are certified blind with cataracts and that some 80% have not had any treatment. Also, some 1,200 to 1,500 are registered blind from glaucoma. The statisticians have therefore jumped to the conclusion that these patients go blind while they are on ophthalmic waiting-lists.

I see, and certify as blind in each year, at least three patients with cataracts who decline operation because of fear (I wonder how many cases our general surgical colleagues see of malignant disease which has advanced to an inoperable stage for the same reason). I see at my hospital clinic at least two patients in each year who present themselves for the first time with grossly constricted visual fields and with optic disks that one could almost "take a bath in." I have no reason to suppose that I am in a different position to any of my colleagues, and I believe the membership roll of the Faculty of Ophthalmologists has 700 or 800 names on it. I have no difficulty, therefore, in accepting these figures. I do not think that any ophthalmic surgeon puts a case of bilateral mature cataracts on a routine waiting-list. I am convinced "glaucoma classes" for opticians would prove more beneficial than "glaucoma clinics" for patients, although the latter seems to me an excellent idea.—I am, etc.,

Dudley.

Doctors' Handwriting

SIR.—May I express my utmost sympathy with the views expressed by Dr. Frewen Moor on doctors' handwriting (*Journal*, February 6, p. 334)? Some of my professional friends seem to specialize in forming a totally illegible signature, which seems to me to be almost the worst sin of all, though this is not specifically mentioned by Dr. Moor. It is true that some of them try to mitigate the effect on their correspondents by having a secretary type out the name below the signature, since this by itself affords no clue to identity.

Whatever the reason for execrable writing among doctors, it has to be admitted that it is no recent phenomenon. Dr. Moor's distinguished predecessor in Norwich, Sir Thomas Browne, wrote a terrible hand, and I must admit,

as an editor of Browne's *Works*, that I could not have compassed the task without the assistance of a British Museum expert, who first transcribed the MSS. for me so that I might then verify them for myself. Dr. William Harvey is another lamentable example. His writing was so bad that his friend, Sir George Ent, apologized for it in his dedication to the President and Fellows of the College prefixed to Harvey's *De Generatione Animalium*, and explained that he had taken much trouble over the MS. himself, as no one else would have been able to read it. A similar problem now faces the President and Fellows of the College over the transcription of Harvey's remaining unpublished MS.

Some years ago the Marquis of Cholmondeley, aided and abetted by Sir Sydney Cockerell, instituted prizes for handwriting at Eton, Harrow, and Winchester, with the most gratifying results. A generous patron of this kind is perhaps needed for our larger medical schools, though it may be that the prizes should really be awarded among fellows, members, and licentiates of the royal colleges. Indeed, I know several young men recently graduated from my own hospital who have trained themselves as students to write beautiful and legible hands. Perhaps this resolution may falter when they find themselves faced with the exigencies of medical practice—though this does not always happen. The late Sir Norman Moore and his son, Sir Alan Moore, were both famous at St. Bartholomew's for their beautiful handwriting, though it will be urged that neither was afterwards in general practice.

There is one further point. It is not generally realized how many inaccuracies may be traced to the modern demand for everything in typescript. As the author of several bibliographies, books which are useless if inaccurate, I have always written out my material in such a way that it could go straight to the printer without any typewritten intermediary. Typist's errors are thus eliminated, and no printer has yet complained of any difficulty.—I am, etc.,

London, W.1.

GEOFFREY KEYNES.

Hospitals and the Visiting Public

SIR.—We shall be sharing Dr. Doris Odium's deep concern (*Journal*, February 6, p. 334) over her discovery of the lack of waiting amenities in our hospitals for the relatives of dangerously ill patients. It is our clear duty to ask for conditions calculated to enhearten and comfort rather than accentuate the depression of spirits naturally sorrowful and racked with anxiety. Nothing short of simple consideration in entertaining them is thinkable; and, fortunately, the occasion is likely to evoke sympathetic action by the administrative authorities.—I am, etc.,

Bristol, 8.

A. WILFRID ADAMS.

Cortisone and Manipulation of Knee-joint

SIR.—There are several aspects of the report of the joint committee of the Medical Research Council and the Nuffield Foundation entitled "A Comparison of Cortisone and Codeine Medication as an Adjuvant to Manipulation in Rheumatoid Arthritis" (*Journal*, January 30, p. 233) which invite comment.

(1) The title: this has been wisely rehearsed on other pages by you, Sir, as "Cortisone and Manipulation of Knee-joint," as the scope of the investigation was restricted to the knee-joint. The negative result of the knee-joint does not alter the possibility of the value of cortisone cover in manipulating other joints, such as the elbow- and finger-joints where local reactions are marked following manipulation. (2) The opening sentences specify that the essential problem was the flexion deformity of the knees. There are no figures given to indicate whether or not this flexion deformity was improved, and, if so, if there was any difference between the two series. (3) It would appear from the text that no clear distinction was made between manipulations to reduce flexion deformity and manipulations to improve range of movement. The aim influences the technique of manipulation and its after-treatment, and of course the post-manipulative

gain in range. Again, there is no indication as to whether the range of movement recorded is that obtained passively by an observer or that under voluntary control—surely not an unimportant technical point when drugs which might influence performance are being used. (4) It would be interesting to know how the cases were shared between the centres, and whether or not differences were noticed between the results obtained at different centres. (5) As mean values of such a small series of numbers are given then there should be some advantage in including the range of findings or the standard deviations.

I intend no criticism of the actual participants in this trial, but cannot help expressing my surprise at so woolly a report from so eminent a source.—I am, etc.,

Buxton.

R. HARRIS.

Displaced Intervertebral Disk

SIR.—Much of the discrepancy of opinion with regard to displaced intervertebral disks has arisen owing to a misunderstanding. There is no evidence that a displaced disk can ever be replaced by means of manipulation. Even when exposed at operation, there are no records of cases in which the surgeon has found it feasible to reduce the prolapsed tissues into their original position. On the other hand, it is undoubtedly true that instances of pain in the back may sometimes be relieved by means of manipulation, but in such cases the symptoms are to be attributed to rheumatic or fibrositic changes in the soft tissues, and not to a displaced disk as is sometimes supposed.

There are thus two distinct conditions of everyday occurrence, the symptoms of which bear a general resemblance to one another but which are of different origin and require different treatment. In cases of displacement of a disk manipulation aggravates the symptoms, whereas immobilization is of benefit. On the other hand, in rheumatic or fibrositic conditions manipulation may be of value, whereas immobilization delays recovery. Fortunately it is not difficult to distinguish between these two conditions, provided that they are approached with an open mind; and it is also fortunate that in both conditions there is a strong tendency for the symptoms to subside, a process aided or impeded according to the treatment employed.—I am, etc.,

Sheffield.

R. G. ABERCROMBIE.

Persistent Adult Bed-wetting

SIR.—Even the most Oedipus-ridden of us will welcome Mr. C. Jennings Marshall's paper (*Journal*, February 6, p. 308) not only for its clear statement of the unsolved anatomic and physiological problems of bladder behaviour but for the hope it holds out for those frustrating and intractable adult cases one sees, many of whom are remarkably free from emotional disturbance considering what they have been through. Certain things should be remembered, however, if this paper is not to start, quite unintentionally, a surgical pursuit of enuretics-as zealous as that which for a time attached to patients with "disks."

Essential nocturnal enuresis is certainly not a clearly defined entity. In the first place I doubt very much whether even the majority of cases show diurnal precipitancy or frequency. Many patients state that they can sit through cinema performances quite comfortably, and can empty their bladders in as leisurely a way as other people. Secondly, there are children in whom enuresis is one of a number of behaviour disturbances—temper, destructiveness, spitefulness to a sibling, and so on; and in whom the enuresis disappears with the other things under the impact of a little play therapy. Oedipus or no Oedipus, this just happens to be true. Thirdly, there are deep sleepers, both children and adults, in whom the loss of cortical inhibition seems to be the factor. The history is so often striking in that it is related that the patient "dies" when he goes to sleep. If such a patient spends a restful night after 30 mg. of amphetamine, which is what sometimes occurs, there cannot be much doubt about the matter. Lastly, it should be

remembered that spontaneous cures occur not only at puberty. There is a continuous falling off in incidence throughout childhood and adolescence.

This leaves a nucleus of cases, which from Mr. Marshall's case reports may be those with "great diurnal precipitancy," in which his theory of the mechanism of enuresis is convincing and his results encouraging. It is good to have Mr. Marshall's reassurance about the nervi erigentes. The stirrings of Nature have a biological function of some importance, and this has usually nothing to do with the Oedipus.—I am, etc.,

London, S.W.1.

GERALD GARMANY.

Thiopentone Injection into an Aberrant Artery

SIR.—Dr. M. Swerdlow's presence of mind in leaving the supposedly intravenous needle *in situ* in the aberrant artery until procaine solution had been injected may have saved his patient from serious complications (*Journal*, January 30, p. 258). To avoid this accident two simple precautions are recommended. Careful palpation will reveal pulsation, and the colour of the blood withdrawn will be seen to be bright red if from an artery. It has been stated, however, that blood withdrawn into a syringe containing thiopentone will darken and so nullify this test.

In some experiments carried out for me by Messrs. Abbott Laboratories Ltd. it was found that venous blood drawn into 5% thiopentone solution did darken a little temporarily, but blood taken from an artery into the solution remained bright red. It would appear, therefore, that thiopentone mixed with blood from an artery will not spoil the redness by which entry of an artery might be recognized. In spite of precautions it is possible to enter an artery, and it would be wise always to pause after injecting a little to see if anything untoward is happening.—I am, etc.,

Enfield, Middlesex.

C. ALLAN BIRCH.

Galactosaemia

SIR.—The two articles on galactosaemia that appeared in the *Journal* of January 30 (pp. 242 and 245) describing the full investigations done were an admirable contribution to our knowledge of this fascinating disease—probably the only authentic cause of "me milk don't agree with me baby." However, should not a note of caution be sounded, Sir, regarding these blood investigations? These babies are very liable to bleed. We have in hospital now, under the care of Dr. John Apley, a baby with proved galactosaemia who at the age of 14 days was admitted on account of profuse bleeding from the umbilicus that was very difficult to stop. Such haemorrhages are fairly common in this disease. Hence, since the diagnosis of galactosaemia can be confirmed by investigation of the urine alone, venepunctures are better avoided in the early stages of the disease. Should such venepunctures be considered necessary, they should be done with care and confined to the peripheral veins. It seems worth stressing that particularly an internal jugular puncture, or even a femoral puncture, might well prove disastrous.—I am, etc.,

Bristol, 2.

BERNARD LAURANCE.

Human Lactation

SIR.—Dr. F. E. Hytten has described (*Journal*, January 23, p. 175) his investigations of milk yield and the content of fat over periods of one day. Although he acknowledges the importance of the draught reflex he has not, it seems, appreciated that the effectiveness of the reflex is not strictly proportional to the fullness of the breast. If the breasts are very full the draught reflex may be exhausted before the breast is emptied and the residual milk be unobtainable. This then doubtless contributes to the available milk at the next feed. Probably, therefore, the diurnal variation in quantity of milk obtained in Dr. Hytten's investigation was produced by the preceding long night interval. Some of the 06.00 hours' unobtainable milk went to increase the 10.00 hours' yield. Dr. Stainer and I, when studying the diurnal

variation in the fat content of milk, took the precaution of emptying the breast at constant intervals and of emptying the breast at the same interval before the outset of each investigation. Under these conditions we found the rate of secretion of milk throughout 24 or even 52 hours to be almost steady. The consistent emptying of the breast gave a clearer picture of the diurnal variation of the fat content because residual milk had been reduced to a minimum.

Although there is reason to believe that milk is modified after leaving the alveolar cell—the passage of globulin direct from plasma,³ the variation of salt content with fullness of the breast,⁴ the nature of regression milk and the thinness of the duct epithelium all suggest it—the concept of constant secretion is an important one. Irregular yields indicate difficulties in obtaining milk, failure of draught or failure of suckling technique. They give warning of milk retention and its attendant risk of mastitis. In the management of human lactation they should be viewed as failure of emptying first, because this is common and can so often be remedied.—I am, etc.,

London, W.C.1.

Piperazine in the Treatment of Threadworms

SIR.—Professor T. Gordonoff (*Journal*, February 13, p. 394) "once gave piperazine by mouth to rats and . . . found it quite toxic. At 4 to 5 g. per kg. there was laboured breathing and twitchings, and some of the animals died." This is a reasonably accurate though not an original observation and agrees in a general way with more detailed tests carried out elsewhere, which were carefully considered before we undertook the trials recorded in our paper (*Journal*, October 3, 1953, p. 755). However, 4 to 5 g. per kg. is more than 60 times the maximum dose we recommend. Many drugs which are freely available to the public would be highly toxic, if not lethal, if given in equivalent quantities—e.g. (in terms of adult dosage), aspirin 2 oz. (62 g.) (180 5-grain (0.32 g.) tablets), santonin or gentian violet 180 gr. (12 g.), quinine 1½ oz. (41 g.), castor oil 1½ pints (0.9 l.). It is perhaps wise to exercise a certain sense of perspective.

Piperazine was commonly used for gout at the beginning of the century, in doses similar to those now recommended for threadworm, without noticeable ill effects. In the last few months it has been widely used in this country as an anthelmintic, with excellent results. The few side-effects which have been reported provide no sound reason for muzzling this very successful treatment.—We are, etc.,

R. H. R. WHITE.

POINTS FROM LETTERS

Press Publicity

Mr. N. C. WILKINSON (London, W.14) writes: As a journalist who has for some years reported medical news, both as a freelance and a staff writer, I may say that if doctors are treated with courtesy, their scruples regarding medical professional ethics carefully regarded, and if they are given the chance of verifying that they have been correctly reported before an article or news item is published, then they almost always help the journalist to the fullest extent in their power. This co-operation is a powerful factor in public health education.

Site for Vaccination

Dr. E. P. RIGBY (Nairobi) writes: I am intrigued by the suggestions of Dr. J. Cantor (*Journal*, November 7, 1953, p. 1050) and Dr. Dorothy M. Roels (*Journal*, December 5, 1953, p. 1272). Having at one time had to examine the vaccination scars of landing passengers, I can assure both these doctors that the examination of scars in the sites mentioned by them would cause considerable delay in the clearance of a ship. The most convenient site for this purpose is the volar aspect of the forearm, which, while not being absolutely ideal for cosmetic reasons, is, however, reasonably inconspicuous.

Obituary

WILLIAM DOW, M.D.

Dr. William Dow, formerly medical superintendent of Knightswood Hospital, Glasgow, died on January 31 in his 79th year. Of Highland stock, he was born in Glasgow and received his schooling and medical education in his native city. He graduated M.B., Ch.B. in 1903 and became house-physician to Dr. Finlayson in the Western Infirmary. After a voyage to India he joined the staff of Belvidere Infectious Diseases Hospital, Glasgow, under Dr. John Brownlie—one of the greatest epidemiologists of the day—and at the same time became a member of a coterie of medical men who were all to win distinction in their various fields of medical endeavour. During his stay at Belvidere he wrote a thesis on cerebrospinal meningitis, and for this work was awarded his M.D. degree, with high commendation, in 1908. He was troubled by ill health at this time, and spent the next ten years as medical officer to several extensive sheep ranches in Tierra del Fuego and Patagonia. A wonderful raconteur, he had many interesting stories to tell of his experiences there—of long journeys on horseback, and of meeting and attending to the author and many of the people mentioned in Lucas Bridges's book *Uttermost Part of the Earth*.

In 1919 he returned to Glasgow and after a year in Robroyston Hospital was appointed physician superintendent of Knightswood Infectious Diseases Hospital, where he remained until his retirement in 1940. After only a few months he was recalled to become superintendent of Peel Emergency Hospital, Galashiels, and this post he held till 1947. He then lived quietly in retirement, but maintained an intensive interest in all things medical, and, although greatly crippled by his last illness, was present at a meeting of the Glasgow Medico-Chirurgical Society only a few weeks before his death.

Dow was a kindly and genial man, and was truly beloved by all his residents, whom he affectionately spoke of as his "boys." A clinician of the older school, he had a deep knowledge of infectious diseases and an intuitive and sound clinical judgment. Medically he was rather self-effacing and had a remarkable gift of stimulating the younger members of his staff to original work. In many ways he was the ideal type of physician superintendent, taking a fatherly interest in all his staff—medical and nursing—but also being a firm disciplinarian when occasion demanded it. He was very proud of Knightswood Hospital, and on leaving he provided funds to have a gold medal presented annually to the most proficient nurse. He was a bachelor and is survived by his sister.—P. McK.

We are indebted to Sir ALEXANDER MACGREGOR for the following appreciation: Dr. William Dow was an intimate friend as well as a colleague of mine during most of our professional lives. He was for 20 years physician superintendent of Knightswood Fever Hospital—a hospital which under him and his successor, Dr. Thomas Anderson, acquired a high reputation for clinical and scientific research, which was continuously pursued there throughout the years. Indeed, a post as resident there was much sought after by young graduates in medicine. Dr. Dow had an inquiring mind, and the pursuit of knowledge was one of his main interests in life; above all, he had a gift for communicating

his enthusiasm to his junior staff. It will be a sufficient indication of his qualities and early promise to mention that after graduation he was invited simultaneously by two of the chiefs at the Western Infirmary, including the late Sir William Macewen, to become their resident. His clinical judgment and skill in the diagnosis and treatment of his patients were universally admired and often commented upon. But apart from these qualities he had a flare for administration, so that his hospital was always kept in a state of high efficiency.

Perhaps his most outstanding quality was his genius for friendship. He was by nature warm and friendly; he was that rare person who loves to mingle with young people, and to discuss with them their work and their prospects, and to stimulate them to high endeavour. I know that his memory is revered by almost a generation of former residents, as well as by the nursing and other staff of Knightswood Hospital. When he retired some years ago he was appointed by the Government as medical superintendent of the new War Emergency Hospital at Peel in the Lowlands of Scotland, and it was his duty to organize the hospital from the beginning so as to serve the large area of the border counties—a duty which he performed with the utmost success.

Dr. R. D. SMEDLEY, for 27 years county medical officer of health for West Sussex, died, after a long illness, on January 19 at his home in Goring-by-Sea. He was 77 years of age. Ralph Davies Smedley was born on March 15, 1876, at Pembroke Dock. From Shrewsbury School he went on to Pembroke College, Cambridge, with an exhibition. He completed his medical training at Guy's Hospital, qualifying M.R.C.S., L.R.C.P. in 1902 and graduating M.B. two years later. He took the D.P.H. in 1904 and proceeded to the M.D. degree in 1908. After graduation he returned to Cambridge to undertake research work. Later he became bacteriologist to the City of Leeds, and for five years he was demonstrator of pathology in Sheffield University. His first post in the public health service was in the county of Durham, where he remained until 1913, when he was appointed county medical officer of health for West Sussex. In 1908 he married Dr. Florence Erin Gubb, daughter of Dr. Alfred E. Gubb, who was for long the editor of the *Medical Press and Circular*. His widow and a son and daughter survive him.

Dr. WILLIAM TEMPLETON writes: Dr. R. D. Smedley was virtually the first county medical officer of health for West Sussex, and he at once seized the opportunity of instituting a comprehensive service. He found only two part-time medical officers in the service, doing mainly school work, and within six months he added two whole-time medical officers for tuberculosis and school work, of whom I was one, and three whole-time nurses for staffing school and tuberculosis clinics. Progress was halted by the outbreak of the 1914-18 war, when Dr. Smedley himself, both his whole-time officers, and one of his part-time officers departed on war service. He was fortunate, however, in his wife, who was medically qualified and able to carry on the county health service under war conditions of great difficulty, with the assistance of several part-time temporary officers, though she had her own two young children to look after. In addition, she was appointed inspector of midwives for the county in 1918, and she inaugurated the midwifery and child welfare work under the Maternity and Child Welfare Act of 1918. Early in 1919, on the return of Dr. Smedley and of all his assistants from war service, a new chapter of public health endeavour began. The maternity and child welfare service was extended rapidly, and in 1920 the tuberculosis service became the whole responsibility of the county, and a county sanatorium was essential. After prolonged effort a suitable building was acquired, and Aldingbourne Sanatorium was opened in 1921. Dr. Smedley was from the first the moving spirit in adapting the building and providing equipment, and for many years he was responsible for the administrative work in the institution and grounds. Much of the sana-

torium's success was due to his foresight and care. The school medical service also demanded much of Dr. Smedley's time, and the development of treatment, dental, and orthopaedic clinics, and other departments gave full scope to his genius for visualizing the county's needs. He was closely associated with the local voluntary nursing services, which under his guidance became the efficient county nursing service of to-day. Another of his interests was the welfare of the blind. In 1921 he was largely responsible for the formation of the West Sussex Association for the Blind, and was its honorary secretary for many years. The provision of a new county hospital in Chichester was a project with which he was closely concerned, and, with the county architect, he was responsible for much of the planning of a new building opened in 1939. It was put into use immediately as a war hospital and is now the efficient modern general hospital, St. Richard's, Chichester. After a life of exacting responsibility, which from 1920 necessitated almost daily travelling between his home in Worthing and his office in Chichester, he retired in March, 1940. He immediately took an active part in the Home Guard, and served as battalion medical officer. He was a man of great charm and of sound judgment, considerate and thoughtful for all who worked for him, and a real "father" to all his numerous office staff. To his colleagues, not only in his own department but throughout the county, he was always approachable and willing to help and advise.

It was with great sorrow that the Colony of Aden learned of the death on January 7 of Dr. N. R. GUPTA at the Civil Hospital, where he had been in charge of the skin and V.D. departments. Born in Calcutta in 1902, Nirod Ranjan Gupta was the son of the late Dr. Dakshina Ranjan Gupta and Indu Bala das Gupta. He was educated at the Victoria Institution at Singapore, where he won high honours both in scholastic and in athletic fields. He studied medicine at Edinburgh, where he qualified in 1931. On his return to India Dr. Gupta served the Government of Bengal as surgeon-in-charge of the V.D. and skin departments of the Campbell Medical School and Hospital, Calcutta. During the war he served in the Indian Army, attaining the rank of major. In 1945 he joined the staff of the 13th Indian General Hospital at Aden, where he soon found friends at the Civil Hospital, little knowing that later he would become a member of its staff. His last post in India was officer commanding the Indian wing, Combined Military Hospitals, Peshawar. In 1947 he joined the Colonial Medical Service and was posted to the Civil Hospital, Aden, where he soon showed his therapeutic skill in the skin and V.D. departments. He returned to Edinburgh for a year in 1949 in order to take a postgraduate course in his specialty. Dr. Gupta was a loyal and conscientious physician, carrying out his work with exemplary skill. A deeply religious man, he was simple in his habits and charming in manner, and was admired and respected throughout the colony, where he will be sorely missed. He is survived by his wife and three children, to whom we extend our deepest sympathy.—N. H. S.-B.

The death of Surgeon Lieutenant-Commander BASIL GEOGHEGAN, at the early age of 34, is not only a personal tragedy to his many friends, it is a serious loss to the field of research in which he was engaged. His father was the late Dr. Joseph Geoghegan, who practised in Wimpole Street until his death in 1948. Basil Geoghegan was educated at Epsom College and the Middlesex Hospital Medical School, qualifying in 1945. After completing some house appointments, he joined the R.N.V.R. and was transferred to the permanent list of the Royal Navy in November, 1946. For two years he served in H.M.S. *Swift*, and here he was described as an officer of considerable professional ability, and capable and zealous in all his duties. In 1953 he was promoted to the rank of surgeon lieutenant-commander. In December, 1948, Geoghegan was seconded for duty to the Medical Research Council unit for climate and working efficiency in the department of anatomy at Oxford. He was an invaluable member of this unit, for he

combined a flair for sound and accurate research with a quite unusual insight into statistical methods and their practical application. He went on two Arctic cruises in order to carry out investigations on the effect of exposure to cold on naval personnel, and collected a great quantity of valuable data. Much of the latter has still to be analysed (for his illness unfortunately prevented him from preparing all his material for publication), but he established a most interesting relationship between the cholinesterase and vitamin-C content of blood plasma and the environmental temperature, which he communicated in 1952 to the International Congress of Biochemistry in Paris. In a Medical Research Council Report he presented an ingenious mathematical analysis of the cyclical diurnal variations of temperature conditions on board ship. The other data which Geoghegan accumulated on the Arctic cruises have particular reference to the nutritional effects of exposure to cold. In addition to these important observations he made a special study of the determination of body measurements, surface area, and body volume by a photographic technique (published last year in the *American Journal of Physical Anthropology*), and there can be little doubt that this method, from the point of view of its practical application, has many advantages over the traditional methods of anthropometry. Apart from his scientific activities, Geoghegan was a man who knew how to appreciate the good and simple things of life; he was a prodigious reader, and because of his wide interests he was a most engaging conversationalist. He also had a high reputation as a first-class swimmer and frequently took part in inter-university swimming contests. It is a remarkable tribute to his tenacity and loyalty that after his first severe illness in 1951 Geoghegan returned to work and continued to pursue his research with the greatest fortitude until at last, in September last year, the recurrence of the illness finally forced him to give it up.—W. E. Le G. C.

Dr. A. E. ROBERTS, county medical officer of health for Flintshire, died at his home at Rhyl on January 1 at the age of 65. His friends and colleagues will miss him greatly, for his influence permeated well beyond the responsibilities of his post. Aneurin Evan Roberts, who was born in Denbighshire on May 22, 1888, received his medical training at the London Hospital, and graduated M.B., B.S. from London University in 1913. During the first world war he served in the R.A.M.C., and on demobilization in 1919 he was appointed assistant county medical officer in Flintshire. On the death of his predecessor, Dr. A. E. Williams, during the last war, he took over the duties of county medical officer. After the war he attended the D.P.H. course at Liverpool University and obtained the diploma in 1946. In the following year he was appointed county medical officer of Flintshire.

We are indebted to Dr. M. T. ISLWYN JONES for the following appreciation: Having an intimate and detailed knowledge of the county he served, gained over many years, Dr. A. E. Roberts assessed accurately the needs of the community, and his shrewd advice and sound wisdom were greatly appreciated by his colleagues. Youthful in appearance and outlook, he kept abreast of recent developments and trends, while his congenial, energetic, and mature personality powerfully supported new advances. Blessed with the rare gift of true friendship and innate charm, he won the affection and loyalty of all those with whom he came in contact. His fortitude and unwavering acceptance of his illness reflected truly the philosophy which had guided him through life. He continued to work up to within a few days of his death, and received the unstinting support and sympathy of all his staff. He was denied the brief respite which his long years of service had earned, but those who knew him intimately realized that whether in office or not he would have continued to contribute to the betterment of humanity. On January 5 he was buried in the peaceful serenity of Llanrhudd church, near Ruthin, in his native county of Denbigh. Many colleagues and the staff of the Flintshire health department wish to be associated with this tribute

to an honoured, valued, and beloved friend. Dr. Roberts leaves a widow, a son, and a daughter, to whom we extend our deepest sympathy.

Dr. LL. S. H. GLANVILLE died at Emsworth, Hampshire, where he had been in practice for over forty years, on January 15 at the age of 75. Llewellyn Stanley Howard Glanville was born on July 25, 1878, and received his medical training at Guy's Hospital, graduating M.B. from London University in 1903. Two years later he obtained the B.S. degree and in 1906 he proceeded to the M.D. He held house appointments at Guy's Hospital, the East London Hospital for Children, and the Samaritan Free Hospital for Women before settling in practice at Emsworth in 1908. Except for the period of his service with the R.A.M.C. in the first world war, he continued in practice at Emsworth until shortly before his death. From 1915 to 1918 he served in Gallipoli, Egypt, and France, and was taken prisoner at St. Quentin in 1918. On return to civilian life he quickly settled down again to his work as a general practitioner, work in which his integrity, acute mind, and keen judgment combined to endear him to his patients and friends. A man of simple tastes and of rather diffident nature, he was nevertheless often asked for help and advice by those in difficulty. His good humour and his friendly chuckle made him a delightful companion. All thoughts of relaxation from work were dispelled in 1939, when retirement or semi-retirement was in his mind, by the outbreak of the second world war, and he remained in full-time practice until 1946, shouldering the burdens left behind by his partners on service in addition to his own duties. After the war his life became quieter and easier, although by no means idle, and he gave valuable assistance as chairman of the house committee of the Victoria Cottage Hospital at Emsworth, to which he was also consulting physician. An example of the very best type of general practitioner, he kept himself abreast of the many advances in medical treatment. He was happy in his work and never spared himself; he had, therefore, the affection of all his patients, to whom he was both kind and generous. For recreation he would take walks over the South Downs, or sail in Chichester harbour, or tend his beautiful garden. His life was saddened in 1951 by the death of his wife, whom he had nursed devotedly during her last illness.

Dr. C. D. EDWARDS died on January 15 at Kington, Herefordshire, at the age of 84. The son of the late Edwin Evans Edwards, Charles Derwent Edwards was born at Rugeley, Staffs, in 1870, and was educated at Hereford Cathedral School, St. John's College, Cambridge, and Guy's Hospital. After graduating M.B., B.Ch. in 1896, he held resident posts at his teaching hospital, and then went into practice, first at Woodford, Essex, and later at Chalford, Gloucestershire. In 1910 he proceeded to the degree of M.D., and in the following year he took the D.P.H. During the first world war he served in the R.A.M.C. with the rank of captain, and he was sanitary specialist to the 34th Division and medical officer of the 102nd Field Ambulance. He was awarded the Military Cross for his services. After his retirement he lived at Kington, and took an important part in the life of the district, as can be seen from the following description of his interests and activities. He was particularly devoted to the parish church, of which he was churchwarden, and he did a great deal for the maintenance of the church itself, and was largely responsible for the building of the Huntington Parish Hall. He was in fact a generous supporter of many charities. Chairman of the Huntington Parish Council for many years, he was also for some time a member of the Kington Rural District Council. He was always concerned in the assistance of disabled men, and worked unceasingly for the British Legion, being chairman of the Kington Branch from 1927 to 1953. A vice-president of the North Hereford Conservative Association and chairman of the Huntington Branch, he was also chairman of the Leominster Division of the Junior Imperial League. One of his appointments was that of Commissioner of In-

come Tax. As a member of the committee and a trustee of the Victoria Cottage Hospital, Kington, he was a considerable benefactor, and he was chairman of the Kington District Nursing Association, as well as being a member of the executive committee of the County Nursing Association. Interested as he was in helping young people, he was a keen supporter of the Boy Scouts Association, of which he was a district commissioner, a governor of the Lady Hawkins Grammar School, and chairman and correspondent of the managers of Mahollam School. Local agriculture also benefited by his enthusiasm: he was a member of the National Farmers' Union and of the Kington Local Committee of the Herefordshire War Agricultural Committee, and president of the Kington Young Farmers' Club since its foundation. For many years chairman of the Kington Horse Show and Agricultural Society, he helped greatly to build it up. He was particularly successful as a rose grower, and was also a keen bee-keeper, winning many prizes for his honey. A fine sportsman, he played Rugby football while at Cambridge and represented the university in athletics. He greatly enjoyed hunting and shooting, and was an ardent fisherman, being chairman and later president of the Kington Fishing Club. Another of his interests was first-aid work, and he was associated with both the British Red Cross Society and the St. John Ambulance Brigade, being president of the Kington Division of the latter. In 1898 he married Janet Louise Paterson, at one time a sister at Guy's Hospital: she died in 1949. Dr. Edwards will be missed by everyone with whom he came in contact.—W. L. J.

Dr. CHARLES HERBERT GOULDSMITH PRANCE died at Woodford Green on January 21 at the age of 84. He was a medical student at St. Bartholomew's Hospital and qualified in 1897. He practised in turn at Polyphant, near Launceston, at Plympton, South Devon, and then in Cornwall again, this time at St. Austell. During the first world war he served in the R.A.M.C. and was present at the Gallipoli landings. He attained the rank of major and was mentioned in dispatches for his services. After demobilization he settled at Ashted, in Surrey, where he was in practice until he retired in 1940. He then became chairman of a medical board. At Ashted he served on the welfare committee of the local branch of the British Legion for many years, being chairman of the branch in 1936. In 1945 he went to live at Mentone, in the South of France, but he returned to England shortly before his death. In the days when Dr. Prance first entered general practice great demands were made on the family doctor, who, besides being physician, general surgeon, and accoucheur, might be called upon to act as dental surgeon, dental mechanic, or veterinary surgeon: with his resourcefulness and versatility, however, Dr. Prance was capable of dealing with any emergency. His unbounded energy and his great love and understanding of his fellow-men endeared him to all who knew him.—S. F. H.

Dr. NOEL KEMM died suddenly at Bristol on January 23 at the age of 60. Noel Edward Ifarnewell Kemm, who was born on November 24, 1893, came of a medical family, both his grandfather and father having been in practice in the West Country, and his brother being in practice at Cheddar. He was educated at Blundells School, and from there went on to Bristol University as a medical student. Immediately after qualification, in 1918, he entered the R.A.M.C. and saw active service in Palestine as medical officer to the Queen's Bays. After demobilization he held a number of appointments at Bristol Royal Infirmary and then went to the Richard Murray Hospital, Blackhill, County Durham, as resident medical officer for three years. Returning to Bristol as surgical registrar at the Royal Infirmary, he obtained the London degrees of M.B., B.S. and the F.R.C.S.Ed. in 1925. Eventually he settled in practice at Clifton, but after a time he became interested in occupational health, and for the last 10 years had acted as whole-time industrial medical officer. During the last war he served as a combatant officer in a Bristol Home Guard

infantry battalion. Dr. Kemm had many interests outside his profession, and his tall, spare figure was well known and welcomed at meetings of local medical societies and at social functions. His bluff manner could never conceal his great kindness of heart, and he was a staunch friend to many. He continued to work, as he wished, to the end. He is survived by a widow and stepdaughter, to whom our deepest sympathy is extended.—R. B. B.

Dr. C. P. DONNISON, consulting physician to the children's department of the Cheltenham General Hospital, died at his home at Cheltenham on January 23 after a short illness. Cyril Percy Donnison served as a pilot in the Royal Flying Corps during the first world war, and then began the study of medicine at the London Hospital, qualifying M.R.C.S., L.R.C.P. in 1924. Having joined the Colonial Medical Service, he worked for the next three years in Kenya. The results of his careful observations of the health of Africans were incorporated in his book *Civilization and Disease*, published in 1937. On returning to England, he entered general practice and took the London degrees of M.B., B.S. in 1928. Two years later he proceeded to the M.D., and in 1934 took the M.R.C.P. He practised at first at Benfleet and later moved to Cheltenham, where his interest in children led to his appointment as paediatrician to the Cheltenham and County Child Guidance Clinic and afterwards as consulting physician to the children's department of Cheltenham General Hospital. He was also a member of the medical staff of the two well-known public schools in Cheltenham. With the advent of the National Health Service he gave up general practice and worked purely as a consulting paediatrician. When he was in general practice he maintained a very high standard of work, himself carrying out such clinical pathology as was required, and he brought to consulting practice the same painstaking care over every detail. This, supported by an extensive knowledge of the literature of his specialty, gave his opinion a value which was greatly appreciated by doctors who sought his help. His other great interest, apart from his work, was sailing, and it was characteristic of him that he should bring to his hobby the same scrupulous care that he brought to his work. His death, at the comparatively early age of 55, has removed a friend and a colleague who was greatly loved and respected. He leaves a widow and two daughters, both of whom are working in hospitals—one as a house-physician and the other as an almoner.—R. G. A.

Dr. H. S. GABB, a member of a well-known Hastings family and consulting surgeon to the Royal East Sussex Hospital, died suddenly at his home at Hastings on January 24 at the age of 76. Harry Secretan Gabb was born at Framlingham, Suffolk, on November 16, 1877, and was educated at Walsall Grammar School, Wellington College, Shropshire, and Shrewsbury School. Entering Downing College, Cambridge, in 1895 with an open scholarship in natural science and a scholarship from the Shropshire County Council, he obtained the B.A. degree with a first class in the Natural Sciences Tripos in 1898. He then went to Charing Cross Hospital Medical School with a university scholarship and took the M.B., B.Chir. degrees in 1901. At hospital he won the Llewellyn scholarship, and, after holding house appointments there and at the Central London Ophthalmic Hospital, he became senior house-surgeon at the South Devon and East Cornwall Hospital, Plymouth. In 1904 he joined his cousin, the late Dr. C. B. Gabb, in practice at Hastings, where he soon gained the affection of his patients, who regarded him as family physician and friend, and of his professional colleagues. He combined the work of his private practice with the duties of a surgeon at the Royal East Sussex Hospital, and in 1948 he became consulting surgeon to the hospital. During the first world war he was in the R.A.M.C. and saw service in France. He represented the Hastings Division of the British Medical Association at the Annual Representative Meetings in 1944, when the proposals for a National Health Service were debated, and in 1945. Dr. Gabb held decided views about the Service, which he never entered. He was president of

need for any statutory requirement of notification. The Government was considering, in consultation with the interests concerned, the suggestion that the use of bacterial rodenticides should be discontinued in view of possible risks to public health. These preparations, which were not on sale to the general public, had been in use on a considerable scale for many years. The companies using them had agreed to adopt, with minor modifications, the precautions recommended in the report, the chief of which were already part of their current practice. They had also offered to collaborate with the appropriate Departments, who would keep the matter under close review.

Disability in the Ageing

Dr. HORACE KING, pressing the case for a speedy revision of the supplementary allowances for disabled ex-Service men, said in the House of Commons on February 8 that not only had the real value of the basic pension declined but disability got worse with old age. A group of M.P.s had been urging the Minister to give extra pensions for the ageing limbless. He hoped the Minister would not say that they must wait until the Rock Carling Committee's report had been received and fully considered. It did not need a medical report to tell them that physical handicaps were more burdensome in old age.

The Ministry had always been advised by medical men, and properly so. But medical men must give a medical opinion; if a disabled man's condition deteriorated the medical men must state what was the scientific truth—that if one lost one leg the other did not tend to degenerate. If a doctor gave false medical testimony he would cause much greater general anxiety than the extra pension would give relief to a particular man. But this was a human problem, not a medical one, and a man who had lost a leg in the war and then lost another ought to receive 100% disability pension, whatever the doctors said.

Brigadier J. G. SMYTH, Parliamentary Secretary, Ministry of Pensions, said the work of the Rock Carling Committee had taken longer than had been expected, but it must be done with the greatest thoroughness, because its findings would be of supreme importance. They would all hope that the result of the committee's work would indicate that amputees were not more liable to cardiovascular disorders than other people, and that their expectation of life was in no way reduced. But if the evidence was to the contrary they would have to re-examine the whole problem. On present medical evidence there was no reason to regard the disabled amputee as being any different from all the other classes of disabled. Dr. King had suggested that the Minister should disregard his medical experts in certain cases. In accordance with the royal warrant the Minister must abide by the decision of his medical advisers in purely medical cases, except where some serious medical doubt was disclosed by the evidence, when the Minister could appoint an independent medical expert; and in addition to that there were the tribunals.

Anaesthesia on Animals

The Protection of Animals (Anaesthetics) Bill was given a second reading in the House of Commons on February 12. Its purpose is to bring up to date the law on the use of anaesthetics in animal operations, and Viscountess DAVIDSON, who introduced the Bill, said there had been no legislation on the subject since the original Act of 1919, which the veterinary profession considered now to be too limited and rigid. The Bill made the use of anaesthetics compulsory for all except minor operations on animals, but not on birds, fish, or reptiles. It would give the veterinary profession a better opportunity in the application of modern scientific developments in anaesthesia. The motion was seconded by Mr. SOMERVILLE HASTINGS, who said the object of operations on animals was for the benefit of human beings. For that reason it behoved them to carry out operative treatment with as little discomfort to the animals as could be managed. That was the aim of the Bill. Surgery in animals and in humans had much in common, and had changed materially since 1919.

The Bill received Government support from Mr. G. R. H. NUGENT, Parliamentary Secretary to the Ministry of Agriculture. Sir THOMAS MOORE described it as a half-way house between those who believed that vivisection was a necessity and the antivivisectionists.

Fees for Inquest Work

The Coroners Bill, which enables the Home Secretary to prescribe the fees and allowances payable to witnesses at coroners' inquests and to medical practitioners who make post-mortem examinations for coroners, was given a second reading in the House of Commons on February 12. Sir HUGH LUCAS-TOOTH, Under Secretary, Home Office, promised Government assistance in the further stages of the Bill. During the short debate Dr. A. D. D. BROUGHTON said that the Bill was long overdue. He had conducted many post-mortem examinations; they occupied much time, and the fees were inadequate.

New Abortion Bill.—Lord Amulree introduced in the House of Lords on January 26 a private Member's Bill to amend s. 58 of the Offences against the Person Act, 1861.

Medico-Legal

PRINCIPLES OF CRIMINAL LAW

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

Textbooks on the criminal law are inclined to approach the subject as a series of rules relating to particular crimes and groups of crimes. In *Criminal Law* Professor Glanville Williams approaches the subject by analysing and expounding the principles which underlie the rules and are common to most if not all crimes. Later, the author says in his preface, he hopes to follow it with a companion volume on specific crimes.

Anyone seriously interested in the criminal law will find the book of great interest. It is not a practitioner's textbook but a penetrating exploration of the foundations, the superstructure of which is to be seen in the everyday administration of justice. Those concerned in the administration of criminal justice will, if they approach the argument with the concentration it deserves, find much to stimulate their thought.

Doctors in particular will find in the chapter on mental abnormality a profound and comprehensive examination not only of the M'Naghten Rules but of the machinery for dealing with the mentally abnormal in the courts of summary jurisdiction. Though this attracts less popular attention, it is of no less importance to the community. When the next Straffen shocks doctors and lawyers into argument on the M'Naghten Rules, they would do well to read this chapter before taking up their pens to write to the press. Anyone interested in the why of the criminal law as well as in the how and the what will find their work repaid if they read this book.

Criminal Law: The General Part. By Glanville L. Williams. LL.D. (Pp. 736. £3 3s.) London: Stevens and Sons Ltd. 1953.

Universities and Colleges

UNIVERSITY OF OXFORD

In a Congregation held on December 12, 1953, the following degrees were conferred:

M.B.—N. L. Gittleston, T. H. Hughes-Davies, R. T. Wood, R. H. O. Parker, C. A. S. Wink, J. D. Craven, M. G. Gelder, J. Mould, I. Hadfield, R. C. Ilbert, B. E. Juell-Jensen, S. Solomons, C. E. Strode, J. E. Cooper, C. T. Howe, J. D. Wigdahl, R. F. N. Duke, V. D. Pippett, S. E. Smith, G. H. Bush, C. R. Tribe, J. Bradshaw, M. C. French-Constant, J. M. Jones, G. L. Asherson, G. St. John-Ives, D. K. Croll, G. Bennett, Barbara H. MacGibbon, Mrs. Hassia Orgel, Brenda L. Radford, Muriel K. Quick, Eileen B. B. Young, Mrs. Ann G. Parker, and (in absence) M. C. Brain.

UNIVERSITY OF CAMBRIDGE

Drs. B. Towers and A. D. Dickson have been appointed University Demonstrators in the Department of Anatomy with tenure for three years from April 1, 1954, and October 1, 1954, respectively.

In Congregation on December 12, 1953, the degree of M.B. was conferred, by proxy, on John Hughes.

UNIVERSITY OF DURHAM

The following medical degrees were conferred in Congregation on December 19, 1953:

M.B., B.S.—C. R. B. Bamford, R. W. Barker, J. A. Bewick, R. Brown, A. R. Buchan, B. Colville, J. P. Dawson, W. I. Hay, D. W. B. Hogg, Margaret R. Hutton, R. Jackson, R. F. Laverick, C. M. Leon, T. M. McKenzie, C. Madhoo, J. N. O'Neill, S. D. Pagden, A. Petterson, Madeleine A. Sharp, S. G. Shaw, Jane Sherman, A. J. Talbutt, A. A. Walker, *P. L. Campbell, *W. B. Chambers.

*In absentia.

UNIVERSITY OF WALES

The following candidates at the Welsh National School of Medicine have satisfied the examiners at the examination indicated:

D.P.H.—R. B. Davies, R. G. Evans, Anita J. Thomas.

UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examinations indicated:

M.D.—June P. Arnold, L. Mandel.
M.Ch.Orth.—J. C. Anderson, M. Anwer, J. M. Gold, J. Harari, T. J. Mills, R. Owen, F. W. Shea, G. A. Wetherell.
Ch.M.—P. A. P. Joseph, J. K. M. Rawlinson, J. T. Rowling, and S. E. Wijetilaka have satisfied the examiners in the clinical and oral sections of the examination.

M.B., Ch.B.—Margaret J. Alltree, S. J. Alltree, D. R. Cole, T. R. W. Cowell, R. H. Cranmer-Gordon, B. E. Dalton, L. M. Ellis, M. A. R. Eslick, C. D. Fisher, Pamela M. Frazer, D. N. Guest, F. Hewitt, C. D. James, I. V. Lishman, D. R. Morris, S. Naylor, N. N. Nehra, D. F. Rice, A. M. Stewart. *Passed in separate subjects:* N. McKie (surgery and obstetrics and gynaecology), Pear Ramkallop (medicine and obstetrics and gynaecology), A. Swithinbank (medicine and surgery). *Part III:* T. R. Evans, T. R. T. Hughes, J. B. Middleton, B. J. O'Dowd.

DIPLOMA IN PUBLIC HEALTH.—Part I: Ursula M. Anderson, G. T. Crook, Jeannette Diamond, A. W. Iljon, Joan Knowles, P. Lorigan, H. P. P. Morris, D. S. Parken, J. L. Patterson, Joyce K. Watkin.

CERTIFICATE IN PUBLIC HEALTH.—Margaret Hughes, Eira Thomas.

DIPLOMA IN RADIOLOGY (RADIO-DIAGNOSIS).—J. G. Kay.

UNIVERSITY OF SHEFFIELD

The following appointments were made on December 18, 1953: Dr. J. D. S. Hammond, Full-time Research Assistant in Medicine; Dr. C. C. Bowley, Part-time Honorary Lecturer in Pathology; Dr. H. L. J. Wilson, Part-time Instructor in Anaesthetics.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

The following candidates have been awarded the Diploma in Obstetrics: C. A. C. Abraham, R. D. Allen, J. P. Alvey, A. G. Amias, J. A. D. Anderson, J. R. Angwin, J. H. Armstrong, R. Bain, D. A. Baird, Doreen S. Ball, G. V. Balmforth, J. A. C. Bamford, A. A. Bapty, A. P. Barclay, N. H. Barley, H. C. Barr, A. C. Beatty, H. R. C. Benny, W. G. Benson, J. S. Berkeley, Margaret S. Beverland, J. R. Billingham, Dorothy G. Blackett, Ord, R. C. Bloomfield, D. G. Bluett, Audrey A. Boutwood, Iona M. Brereton, R. W. Brotherhood, B. J. Brown, C. T. Brown, G. L. Brown, J. D. Bruce, C. V. Bullen, A. K. Burt, Seonaid C. Cameron, Patricia E. Campbell, R. W. Campbell, R. Carr, Sumathi R. Chandy, Sin Giap Chua, B. W. Cole, P. F. A. Crawshaw, Barbara M. St. J. Coventry, H. J. E. Cox, G. E. Crawford, P. M. Crawford, Flora M. Dale, G. M. Davidson, I. F. Digby, Josephine Dolan, K. C. Easton, Barbara C. Edwards, B. D. Ellis, Doreen A. Ellis, L. Elton, H. A. Evans, Margaret G. Fairman, D. C. Faull, L. C. Fernandez, F. I. Firth, J. A. Fleming, Marjorie H. E. Flowerday, D. S. Foster, I. H. Gardner, W. A. Gentle, W. J. Glover, M. Goodman, Leonora H. Goult, C. W. Grant, Monica C. Grant, C. C. Griffiths, Jean M. Halliwell, Elinor C. Hamlin, J. L. Hanington, Maureen E. Hardeman, J. G. Hayes, Margaret A. Hayes, J. Hennigan, J. R. Hewett, A. N. Horwitz, M. Howett, J. D. Jackson, R. J. Jameson, A.

Jervis, D. D. Johnstone, G. M. Johnstone, Zohra B. Kazi, T. W. Kidd, F. F. Kinnaird, W. A. Kirkpatrick, T. P. Kissack, R. I. Kleinman, Mukulika Konar, Yu Shing Lam, Sheila M. Lane, A. S. Liddell, Ruth Lister, Mary I. Lloyd, Anne E. T. Lodge, W. H. McBay, T. D. McCarthy, Jessie Macdonald, Morag S. Macdonald, J. MacIntosh, M. J. McKenna, A. Mackinnon, J. H. Marks, Helen F. Martin, J. B. H. Martin, P. L. Martin, D. G. May, Prabha Mehra, A. H. Mendoza, B. R. Middleton, N. A. Miles, R. H. D. Miles, A. P. Millar, A. P. Miller, D. D. Moir, Marjorie Monk, J. L. Montagnon, R. D. Morbey, D. F. Morley, J. D. Morris, E. A. Murray, Joan M. Nabarro, Shirley E. Nathan, R. W. A. Nel, P. A. Normandale, R. C. Norton, K. C. Nyman, Irene M. F. Ondatje, Heather M. Panton, E. R. Parry, Mary C. W. Paterson, D. C. Pattison, P. Pau, Barbara M. Philpott, A. C. C. Pinion, G. H. G. Poole, Gertrude M. Pullan, T. A. I. Rees, J. G. Rider, K. J. Roberts, C. Rooney, J. J. O'C. Rorke, A. D. Rose, L. Rose, D. P. Rough, P. C. Roy, F. C. Rutter, P. E. H. Rutter, R. G. Seagar-Thomas, Noel P. Shannon, J. Sharp, Mary E. T. Sheridan, H. A. D. Shirlaw, J. Li. Skinner, A. I. Smith, D. P. Q. Smith, L. Smith, R. C. Smith, A. G. Stephens, Monnica C. Stewart, A. M. Stobie, G. F. Stone, H. L. Symon, G. W. Taylor, Mary T. Taylor, J. C. Turner, Barbara V. Tyman, Lilian S. Underhill, T. W. West, I. J. Waite, Mary J. Watson, J. N. Wattie, H. B. G. Webb, A. L. Wells, W. G. Wenley, Constance M. Wilkinson, F. C. Wilkinson, R. Williams, E. A. Wilson, Janet W. Worling, Margaret E. Wort, V. Zuck.

ROYAL COLLEGE OF PHYSICIANS OF CANADA

At a recent examination the Fellowship of the College was awarded to W. F. T. Tatlow, M.D., M.R.C.P.

Vital Statistics

Week Ending February 6

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,015, whooping-cough 1,984, diphtheria 19, measles 1,487, dysentery 624, acute poliomyelitis 21, paratyphoid fever 4, and typhoid fever 0.

Infectious Diseases

The largest variations in the trends of infectious diseases in England and Wales during the week ending January 30 were decreases of 117 for whooping-cough, from 2,357 to 2,240, and 80 for scarlet fever, from 1,138 to 1,058, and increases of 84 for measles, from 1,106 to 1,190, and 82 for dysentery, from 490 to 572.

The largest falls in the trends of whooping-cough were 67 in Southampton, from 117 to 50, 38 in Lincolnshire, from 63 to 25, and 34 in Staffordshire, from 113 to 79. Only small variations occurred in the local trends of scarlet fever. The largest variations in the returns for measles were a decrease of 131 in Cumberland, from 196 to 65, and increases of 92 in Staffordshire, from 128 to 220, and 54 in Norfolk, from 166 to 220. The chief centres of infection in the last two counties were Stoke-on-Trent C.B. 148 and Norwich C.B. 104. 16 cases of diphtheria were notified, being 2 fewer than in the preceding week. The chief features of the returns for diphtheria were a decrease in Lancashire from 9 to 1 and a rise in Staffordshire from 1 to 5 (Coseley U.D. 3).

22 cases of acute poliomyelitis were notified. These were 14 fewer for paralytic and 1 fewer for non-paralytic cases than in the preceding week. The only areas with multiple cases were Gloucestershire, Mangotsfield U.D. 3, and Wiltshire, Calne and Chippenham R.D. 2.

The largest returns for dysentery were London 115 (Islington 40, Finsbury 11), Yorkshire West Riding 113 (Bradford C.B. 47, Leeds C.B. 28), Lancashire 76 (Bolton C.B. 16, Swinton and Pendlebury M.B. 16), Middlesex 53 (Enfield U.D. 14, Willesden M.B. 14), Nottinghamshire 30 (Worksop M.B. 27), Southampton 16 (Christchurch M.B. 10), Norfolk 15 (Norwich C.B. 15), Gloucestershire 15 (Bristol C.B. 15), and Warwickshire 15 (Birmingham C.B. 15).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus -----, the figures for 1953-4 thus ————. Except for the curves showing notifications in 1953-4, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending January 30 (No. 4) and corresponding week 1953.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Medical News

Diphtheria Prophylaxis.—The number of babies under 1 year receiving diphtheria immunization in England and Wales is disturbingly low. Instead of the 75% regarded as the desirable immunization target, in 1952 only 31% were immunized and the figure for the first half of 1953 is hardly any better. The Ministry of Health is therefore calling for renewed efforts on the part of all local authorities to improve the rate (Circular 5/54). The figures for diphtheria deaths and notifications during the last 10 years show a remarkable change: in 1944 there were 934 deaths and over 23,000 notifications; in 1953 the provisional figures are 24 deaths and 240 notifications, but, in the words of the Ministry circular, "if parents leave their children unprotected there may be a return of diphtheria outbreaks."

Hunterian Society.—The annual dinner of the Hunterian Society was held on February 11 with the president, Sir Heneage Ogilvie, in the chair. In proposing the toast of the Hunterian Society Sir Alan Herbert said that when he recalled all the stories he had read about medical students he was astonished to see how impressive was this gathering of beautifully dressed and decorated doctors. After a characteristic tribute to John Hunter—"a pioneer in all my favourite things, like the placental circulation"—Sir Alan praised the Society, saying he was pleased to find it was not composed of "ugly little groups discussing diseases of the bladder." In reply Sir Heneage Ogilvie said that John Hunter had established scientific surgery. He paid a special tribute to Mr. Mortimer Wolff for his great efforts in past years in bringing the Society up to its present strength. Mr. R. H. Metcalfe proposed the toast of the Lord Mayor and Corporation of the City of London, and Sir Noel Bowater replied. Sir Allen Daley proposed the toast of the guests and kindred societies, and responses were made by Miss Pat Hornsby-Smith, M.P., and Mr. E. W. Riches.

World Health Organization.—The executive board of W.H.O., under the chairmanship of Dr. Melville Mackenzie, has concluded its preparatory work for the seventh World Health Assembly in May. For 1955 a budget of \$10,300,000 is proposed, a 21% rise on this year's sum. The executive board warns the Assembly that any significant cut in the budget would have serious effects on W.H.O.'s programme. During its recent session the board also decided to look into two important public health problems, the chemical adulteration of food and the protection of workers and the general public against irradiation hazards.

World Medical Journal.—The World Medical Association has for the past few years published each quarter the *World Medical Association Bulletin*. This has now been renamed the *World Medical Journal*, and is, as was the *Bulletin*, the official journal of the W.M.A. The *Bulletin* was edited by Dr. Morris Fishbein, who has now been succeeded by Dr. Austin Smith, Editor of the *Journal of the American Medical Association*, and he is assisted by a small editorial committee. Dr. Louis H. Bauer, Secretary-General of the W.M.A., is business manager of the new journal, which now appears with a new look in the shape of a well-designed cover and an attractive lay-out of the text. The *World Medical Journal* is to appear bimonthly instead of quarterly, is published in the three official languages of the W.M.A.—English, French, and Spanish—and contains articles of information that should be of much interest to members of the 46 national medical associations which make up the membership of the W.M.A. The journal is widely circulated throughout the world, and the annual subscription to it for British readers is £1 15s. Anyone wishing to subscribe should write to Dr. Louis H. Bauer, World Medical Association, 345, East 46th Street, New York, 17, N.Y., U.S.A. The January number opens with an article entitled "Relations between the Medical and Non-medical Press," by Mr. John Pringle, public relations officer to the B.M.A. This article is based on a paper read by Mr. Pringle at the Medical Journalism meeting of the W.M.A. at The Hague

last September. Other communications include one on "The Medical Aspects of Social Security," by Dr. Gunnar Gundersen, "Conditions for Practising Medicine in Canada," by Dr. L. Gerin-Lajoie, and "On the Retirement of Doctors," by Dr. P. Cibré, of Paris.

Bicentenary Celebrations at Madras.—At the Government General Hospital, Madras, on December 19 celebrations were held to commemorate the bicentenary of its founding by the East India Company, the golden jubilee of the discovery of the causative organism of kala-azar by Lieutenant-Colonel Charles Donovan, I.M.S., and the opening of the cancer pavilion, which had been given by the Madras Cancer Association. Mr. Sri Prakasa, inaugurating the celebrations, paid tribute to the East India Company, which had done so much in building up institutions such as the hospital in Madras for the good of the community. The residence of the first agent of the Company had been used for housing the hospital. Dr. D. V. S. Reddy, professor of physiology in the Madras Medical College, introduced Sir A. Lakshmanaswami Mudaliar, Vice-Chancellor of Madras University, who unveiled a tablet to commemorate Colonel Donovan's discovery in 1903. Dr. S. Muthulakshmi Reddy opened the cancer pavilion.

Health Information Digest.—The Central Council for Health Education has published the first issue of a new half-yearly journal, *Health Information Digest*. The journal provides summarized information on important health problems. It is intended for those who are unable to search the literature for themselves. The first issue deals with the fluoridation of water supplies, mental deficiency, and the future of the child welfare centre. The journal is edited by Dr. A. J. Dalzell-Ward and Mrs. Priscilla Milton. It may be obtained from the Central Council for Health Education, Tavistock House North, Tavistock Square, London, W.C.1, or from leading booksellers, price 2s. 6d. a copy or 5s. annually, post free.

Journals for Chemists.—Two additions to the literature on chemistry have just made their appearance. *Current Chemical Papers* is a monthly classified world list of new papers in pure chemistry. It is published by the Chemical Society, Burlington House, London, W.1, price £2 10s. per annum (£4 10s. by air mail). *Analytical Abstracts* deals with all branches of analytical chemistry and is published monthly by the Society for Analytical Chemistry, 7-8, Idol Lane, London, E.C.3, price 50s. per annum.

Doctors with New Zealand Himalayan Expedition.—Sir Edmund Hillary's expedition to the Barun Glacier includes two British doctors. Dr. Michael Ball is the expedition's medical officer, and in addition there is Mr. R. C. Evans, F.R.C.S., who reached the south summit of Everest last year.

A Rare Treatise.—John Banester's *Antidotarie Chyrurgical*, which was recently the subject of a note in the *Journal* (February 6, p. 329), was sold for £400 on February 8.

Mr. Norman Hodgson, lecturer in surgery at Durham University and surgeon to the Royal Victoria Infirmary, Newcastle-upon-Tyne, has been appointed to a University professorship of surgery personal to himself. Professor A. G. R. Lowdon, who last year succeeded Professor F. H. Bentley in the chair of surgery at Durham University, continues as head of the department.

Dr. Donald McL. Johnson, a former member of the Liberal Party's national council, has been adopted by the local Conservative Party Council as Conservative candidate for Carlisle.

Dr. J. N. Loring has been appointed Apothecary to the Queen Mother's Household. Dr. Loring is also Apothecary to the Queen's Household and held the same appointment to the late Queen Mary's Household.

Journal Index.—The half-yearly indexes to Volume II of the *Journal* and the *Supplement* for 1953 are now being sent to members who receive them regularly and to subscribers. Members who have not previously asked for the indexes can obtain copies, post free, on application to the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

COMING EVENTS

Irish Medical Association.—The annual meeting will be held at Killarney from July 7 to 10. Opening speakers include Mr. Terence Millin, on "Urological Emergencies in General Practice"; Dr. William O'Donovan, on "Drug Eruptions, Old and New"; and Sir James Spence, on "Recent Advances in Paediatrics." There will also be clinical demonstrations at the Mental Hospital, Killarney. Further information from the medical secretary, 10, Fitzwilliam Place, Dublin.

Third International Congress of Nutrition.—The congress is to be held, under the auspices of the International Union of Nutritional Sciences, in Amsterdam from September 13 to 18. The programme will include sessions on the following topics: "Overnutrition and Disease," "Nutrition and Liver Disease," "Parenteral Nutrition," "Nutrition and Psyche," "Non-nutrient Foreign Chemical Substances in Foods (Intentional and Non-intentional Additives)." Nutrition workers in Britain who would like to participate in the discussions are invited to submit a title and a short synopsis (not exceeding 200 words) to Dr. G. H. Bourne, honorary secretary of the Nutrition Society, London Hospital Medical College, Turner Street, London, E.1, by February 28.

Dr. Paul Wood will deliver the Joseph Strickland Goodall Memorial Lecture at Apothecaries' Hall, Black Friars Lane, Queen Victoria Street, London, E.C.4, on March 24 at 5 p.m. His subject is "An Appreciation of Mitral Valve Disease."

National Association for Mental Health.—The annual conference will be held on March 25 and 26 at Friends House, Euston Road, London, N.W.1. The conference will be opened by Sir Walter Monckton, and the theme will be "Strain and Stress in Modern Living: Special Opportunities and Responsibilities of Public Authorities." Further particulars may be obtained from the conference secretary, National Association for Mental Health, 39, Queen Anne Street, London, W.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Monday, February 22

HUNTERIAN SOCIETY.—At the Mansion House, 8.30 p.m., Hunterian Oration by Sir Gordon Gordon-Taylor: A Famous Hunterian—Sir Charles Bell.

INSTITUTE OF PSYCHIATRY.—5.30 p.m., lecture-demonstration by Dr. E. Sengel.

MANCHESTER MEDICAL SOCIETY: SECTION OF GENERAL PRACTICE.—At Medical School, Manchester University, 9 p.m., Dr. W. H. Patterson: Convulsions in Infancy and Early Childhood.

Tuesday, February 23

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. R. R. Race, F.R.S.: Blood Groups.

KEATS-SHELLEY MEMORIAL ASSOCIATION.—At Anatomy Theatre, Guy's Hospital, 5 p.m., Mr. F. N. Doubleday: Portraits of John Keats.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Goulstonian Lecture by Dr. A. W. Woodruff: Natural History of Anaemia Associated with Protein Malnutrition.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Mr. Bryan Williams and Mr. J. D. Martin: Deep Transverse Atelectasis.

WEST END HOSPITAL FOR NERVOUS DISEASES.—5.30 p.m., Dr. C. Worster-Drought: Blood-vessel Tumours of the Brain. Demonstration illustrated by lantern slides.

Wednesday, February 24

BIRMINGHAM MEDICAL INSTITUTE: SECTION OF PSYCHIATRY.—8 p.m., Dr. Jeannie E. Sturt: Dynamics and Preventive Mental Health.

EDINBURGH CLINICAL CLUB.—At Albyn Rooms, Edinburgh, annual dinner.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Foreign Body Granulomas.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. A. R. C. Higham: Diminished Fertility in the Male.

LONDON UNIVERSITY: DEPARTMENT OF EXTRA-MURAL STUDIES AND ATOMIC SCIENTISTS' ASSOCIATION.—At Beveridge Hall, Senate House, 7 p.m., Professor Kathleen Lonsdale, F.R.S.: Atomic Energy and Moral Issues.

MANCHESTER MEDICAL SOCIETY: SECTION OF MEDICINE.—At Medical School, Manchester University, 4.30 p.m., Professor R. V. Christie: Dyspnoea.

MEDICAL SOCIETY OF LONDON.—8.30 p.m., Lettsomian Lecture by Mr. Norman C. Tanner: Surgery of Peptic Ulcers and its Complications.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., James Watson Lecture by Dr. A. S. Douglas: Modern Concepts of Blood Coagulation and its Disorders.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. J. D. W. Pearce: Lecture-demonstration in psychiatry.

SOCIETY FOR ENDOCRINOLOGY.—At Royal Society of Medicine, 10 a.m., joint meeting with Endocrinological Section of Royal Society of Medicine.

Symposium: Technique and Significance of Oestrogen Determinations.

Thursday, February 25

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Lord Stamp: Action of Bacterial Enzymes on Immunizing Antigens.

GLASGOW UNIVERSITY MEDICO-CHIRURGICAL SOCIETY.—At Glasgow University Union, 7.30 p.m., B.M.A. Lecture by Dr. D. A. Williams: Problem of Asthma.

INSTITUTE OF CHILD HEALTH.—5.30 p.m., Dr. D. Stafford-Clark: Prevention of Delinquency.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. O. Oliver: Pathology of Lupus Erythematosus.

LEEDS UNIVERSITY.—At Littlewood Hall, General Infirmary at Leeds, 4.15 p.m., Professor Dorothy S. Russell: Methods of Growth and Spread in Primary Intracranial Tumours.

LIVERPOOL MEDICAL INSTITUTION.—8 p.m., Symposium: Mitral Disease. Openers, Dr. G. R. Ellis, Dr. R. J. Keating, and Mr. F. R. Edwards.

NUFFIELD ORTHOPAEDIC CENTRE.—At Wingfield-Morris Orthopaedic Hospital, Headington, Oxford, 8.30 p.m., Mr. Geoffrey Platt: Recurrent Dislocation of the Elbow and its Treatment; Mr. M. H. M. Harrison: Recurrent Dislocation of the Patella and its Treatment.

OXFORD UNIVERSITY.—At Southfield School, Glanville Road, Cowley Road, Oxford, 8 p.m., Dr. A. G. M. Weddell: Science and Medicine.

ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Dr. R. H. Mole: Fission Products.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Goulstonian Lecture by Dr. A. W. Woodruff: Natural History of Anaemia Associated with Protein Malnutrition.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Professor J. M. Yoffey: Bone Marrow.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., neurology demonstration by Dr. D. Williams.

SURREY INTER-HOSPITAL PSYCHIATRIC ASSOCIATION.—At Banstead Hospital, Sutton, 8 p.m., clinical meeting. Papers by Dr. I. F. Collie, Dr. T. Grygier, and Dr. R. Wheeler.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—At South Kensington Hotel, 7.30 for 7.45 p.m., dinner meeting. 8.30 p.m., Dr. A. E. Martin: Smog.

Friday, February 26

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. D. I. Williams: Alopecia.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—3.30 p.m., clinical meeting for general practitioners. Mr. G. H. Howells: Modern Trends in Treatment of Cancer of the Ear, Nose, and Throat.

LIVERPOOL SOCIETY OF ANAESTHETISTS.—At Liverpool Medical Institution, 8 p.m., discussion to be opened by Dr. M. M. Burrows: Anaesthesia in Obstetrics.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.—7.30 p.m., Dr. W. V. Macfarlane and Miss Johns (Almoner): Medico-Social Background of Congenital Syphilis. A discussion will follow.

OSLER CLUB OF LONDON.—At 26, Portland Place, W., 7.45 p.m., Sir Philip Manson-Bahr: Life and Work of Sir Patrick Manson. Discussion to be opened by Professor P. C. C. Garnham.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Professor W. A. Machy: Splenectomy.

ROYAL INSTITUTION.—9 p.m., Dr. C. H. Andrews, F.R.S.: The Common Cold.

ROYAL MEDICAL SOCIETY, Edinburgh.—8 p.m., Sir V. Zachary Cope: How Medicine Helped to Win the War of 1939-45.

APPOINTMENTS

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—W. A. Heaton-Ward, M.B., Ch.B., D.P.M., Medical Superintendent to Stoke Park Colony Group, Bristol; C. T. Vincent, M.B., B.S., Assistant Clinical Pathologist to North Gloucestershire Clinical Area; Margaret A. Lakeman, M.B., B.S., D.Obst.R.C.O.G., Registrar in Obstetrics and Gynaecology, Camborne, Redruth, Miners' and General Hospital, Redruth; Elizabeth P. Champion, M.B., B.S., D.A., Anaesthetic Registrar, Southmead Hospital, Bristol; Kathleen C. Iles, M.B., Ch.B., Registrar in Diseases of the Chest, Bristol Clinical Area; T. C. Gibson, M.B., B.Chir., Medical Registrar, Royal United Hospital and Royal National Hospital for Rheumatic Diseases, Bath; C. E. C. Wells, M.B., B.S., M.R.C.P., Senior Medical Registrar, Bath Clinical Area.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Grant.—On February 7, 1954, at Derby, to Patricia, wife of Dr. P. W. Grant, of Wayside, Duffield, Derby, a son—James Walker.

Meek.—On January 27, 1954, at Bristol Maternity Hospital, to Eileen, wife of Edward S. Meek, M.B., Ch.B., a daughter.

Nicholas.—On January 28, 1954, at Woodmount, Linden Road, Clevedon, Somerset, to Eileen (formerly Moore), M.B., Ch.B., wife of John C. Nicholas, L.D.S., a sister for Jennifer and John—Margaret.

Perry.—On February 7, 1954, at the Cardiff Royal Infirmary, to Dr. M. Elizabeth R. Perry (formerly Thomas), wife of Dr. C. Lynn Perry, a son.

GOLDEN WEDDING

Vartan-Hepworth.—On February 16, 1904, at Augustine Church, Edinburgh, Charles Samuel Vartan, M.B., Ch.B., to Florence Ethel Hepworth. Present address: Flat 4, 10, The Paragon, Blackheath, London, S.E.

DEATHS

Allan.—On January 20, 1954, in hospital, the result of an accident, Alexander William Allan, M.D., of 3, East Heath Road, Hampstead, London, N.W., late of Skegness, Lincs, aged 85.

Angus.—On January 24, 1954, at 6, Church Street, Epsom, Surrey, Dorothy Graham Angus, M.R.C.S., L.R.C.P.

Brady.—On January 22, 1954, in a nursing-home, Dublin, Michael Richard Brady, M.D., of 150, Harley Street, London, W.

Brown.—On January 20, 1954, at 2, Reddings Road, Moseley, Birmingham, James Duncan Brown, M.B., Ch.B., D.M.R.C., late of Mukden, Manchuria.

Fisher.—On January 20, 1954, at his home, Wells Road, Fakenham, Norfolk, William Henry Fisher, M.B., B.Ch., aged 87.

Steward.—On January 10, 1954, at Ellery Bank, Windermere, Edward Simmons Steward, F.R.C.S., aged 83.

Wrench.—On January 8, 1954, at his home, 5, Victoria Road, Karachi, Pakistan, Guy Theodore Wrench, M.D., formerly of London, W., and Reading, Berks.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Smoking Cures

Q.—Please tell me what you think about the various smoking cures one hears about. Are they any good?

A.—"Cures" for smoking, as for other forms of addiction, fall into three classes. In the first are those which aim at making the act of indulgence so unpleasant that it is soon renounced. The most impressive example of this class is the use of "antabuse" (tetraethylthiuram disulphide) in alcoholism. In the case of tobacco, however, no such effective agent exists: most of the methods suggested make the mouth dry or impart an unpleasant taste to tobacco smoke. Stramonium has been used for the first purpose; the second can be accomplished by a mouth wash of 0.25% silver nitrate or 0.01% copper sulphate or by a pill containing ferrous sulphate and alum. The psychotherapeutic approach has not been neglected and it has been recommended that unpleasant associations with the act of smoking should be established by suggestion.

The second method is by gradual withdrawal; this is, of course, familiar in the treatment of narcotic drug addiction. In its simplest form it would consist in gradual reduction in the number of cigarettes smoked, advice often tendered but seldom followed. In its more radical form smoking is forbidden and nicotine administered in gradually reducing doses, either by subcutaneous injection or in the form of pastilles. This method makes the assumption that the desire to smoke and nicotine addiction can be equated. Although addiction is certainly of importance, the causes of the habit are undoubtedly more complex. Smoking has become something of a social observance and the act has acquired a ritualistic significance.

The third class of "cures" attempt to abolish the desire to smoke. Their shortcomings are due to our ignorance of the origins of this desire. It has been claimed that the administration of lobeline sulphate by mouth reduces the desire to smoke. Lobeline is derived from a plant the leaves of which have long been smoked by some Indian tribes, and its pharmacological effects are similar to those of nicotine. The recommended dose of 8 mg. may cause a metallic taste, heartburn, epigastric pain, fainting, vomiting, salivation, lethargy, inability to concentrate, and fullness of the head. These symptoms may last for as long as four hours, and it will occasion no surprise that the subject experiences no desire to smoke while they endure. Other attempts to abolish the desire to smoke include hypnosis, simple exhortation, and admonition aimed at implanting in the smoker's mind notions of guilt, uncleanness, and pusillanimity.

It is difficult to assess the efficacy of these various cures. Patients seldom ask the doctor's advice on how to give up smoking; *per contra*, doctors frequently issue a bland injunction to abstain from tobacco without suggesting any means by which the renunciation can be made easier. It is a matter of common observation that a heavy smoker can stop smoking at no greater cost than a few days' shortness of temper. Determination is the only quality required; but it seems probable that one who lacks sufficient to give up smoking without a cure will certainly not possess enough to persevere with the various cures recommended. The very desire for a smoking "cure" shows that the smoker is not prepared to take full responsibility for his addiction and is anxious to be able to attribute his failure to abstain from it to the inefficacy of the cure rather than to the weakness of his will.

The Serum-sensitive Recruit

Q.—A boy, aged 13, was discovered to be serum sensitive about five years ago. An injection of A.T.S. (1 min—0.6 ml.—intradermally) produced a violent local reaction and a temperature of 103° F. (39.4° C.). He has never had any serum injections since. The boy wants to join the Navy. Would it be safe to give him T.A.B. injections? If not, can he be desensitized to horse serum generally?

A.—The degree of sensitivity of this boy to various allergens might be investigated in the first instance, partly by cross-examination about his history, including reactions to previous inoculations of all types, and partly by attempting active immunization against diphtheria and tetanus if this has not been done already. The reaction to the Schick control injection might also give useful information. Most subjects who are allergic to serum can be immunized actively with diphtheria or tetanus toxoid without much trouble from reactions. (Diphtheria prophylactic T.A.F. should be avoided as it contains a small amount of serum.) Active immunization is indicated where possible, because it should obviate the emergency use of diphtheria or tetanus antitoxic serum.

It should not be assumed that this youth is very sensitive to horse serum on the basis of what happened five years ago after an intradermal injection. If he should require serum again, a small "trial dose" given subcutaneously is much the best procedure.

With regard to T.A.B. injections, it is altogether exceptional for reactions to be so severe that immunization has to be discontinued. With this possibility in mind, however, it would obviously be wise to make a preliminary sensitivity test using a 1:100 dilution of vaccine subcutaneously. There is no horse serum in T.A.B. vaccine, the reactions to which are unrelated to sensitivity to serum. In any case it is probably impossible to desensitize a patient to horse serum.

Pharaoh's Ants

Q.—My small hospital has had a plague of minute ants, reddish in colour and about 3 mm. long, called Pharaoh's ants by the pest officer. They are found in kitchens, dining rooms, passages, and in the patients' beds, and have resisted all attempts at eradication. Is there a cure? The state of mind of a patient in a plaster jacket with numbers of ants crawling about in his bed is becoming manic.

A.—Pharaoh's ant (*Monomorium pharaonis* L.) is a fairly common and very troublesome pest of hospitals and other large steam-heated buildings. Although it has been with us for over 100 years it does not live out of doors in Britain, but forms nests in crevices inside the walls and floors of buildings. It probably travels from one site to another in packing cases and similar goods.

The most effective treatment seems to be spraying with chlordane dissolved in kerosene. The trails of ants should be traced back to the nest or-nests (there may be more than one). Then the walls and ceilings in the neighbourhood should be thoroughly sprayed. It may be advisable to employ a reliable pest control firm for this purpose. One good treatment may effect a cure, but a watch should be maintained for survivors.

As a temporary measure to protect the beds of individual patients, the legs should be stood in tins containing oil or strong carbolic acid.

Phenylbutazone and Pulmonary Tuberculosis

Q.—Is phenylbutazone contraindicated in the presence of pulmonary tuberculosis?

A.—There is no special reason why phenylbutazone should not be given in the presence of pulmonary tuberculosis except that it occasionally has unpleasant and dangerous side-effects such as agranulocytosis, peptic ulceration, exfoliative dermatitis, and salt retention.

Acid-forming Foods

Q.—Which articles of food are acid forming and which alkali forming? Many patients complain of "acidity" and seek advice about diet, and we doctors give them conflicting advice. Some patients are told, for example, that oranges and grapefruit are acid forming and they avoid them permanently. But are not the organic acids such fruits contain broken down in the body to carbonates and therefore alkali forming?

A.—The acidogenic value of a food is expressed as the volume of 0.1 N acid which would be produced if all the phosphorus, sulphur, and chloride in the food were fully oxidized to phosphoric, sulphuric, and hydrochloric acid respectively. The alkalogenic value of a food is expressed as the volume of 0.1 N alkali which would be produced if all the sodium, potassium, calcium, and magnesium in the food were converted into their respective hydroxides. Tables of these values are readily available (e.g., *Medical Research Council Special Report Series No. 235, "The Chemical Composition of Foods,"* by R. A. McCance and E. M. Widdowson), where the excess of acidogenic or alkalogenic components in a large variety of foods is given. As examples, predominantly acidogenic foods are eggs, lean meat, fish, and cereals, whilst potatoes, vegetables, fruit, and leguminous foods are predominantly alkalogenic.

It will be seen from the above that the organic acids contribute neither to the acidogenic nor to the alkalogenic value of a diet, and do not appreciably alter the acid-base equilibrium of the body when taken in food, because they are completely oxidized to carbon dioxide and water, which are rapidly eliminated. If, however, these acids are present as their salts, the metals so combined would contribute to the alkalogenic value of the diet.

Selection for Work in Compression Chambers

Q.—In examining men for fitness for working in compression chambers, are there any special points to bear in mind?

A.—The routine examination should be very thorough, especially of the heart and lungs. It is also advisable to test the locomotor system and ask about previous injury, especially fractures, as such people are prone to "bends" at the site of the injuries. If enough candidates are available, then any history of serious lung disease (pneumothorax, complicated pneumonia, minimal tuberculosis) should mean exclusion, even though the present condition is satisfactory. It is now considered that, with even a minor lung lesion, breathing from a closed apparatus during severe pressure changes may cause serious accidents, such as pneumothorax and perhaps even aero-embolism. If no breathing apparatus is used under pressure this risk is not present. Men with even mild bronchitis or bronchospasm should also be excluded. For all these reasons a routine x-ray picture of the lungs is highly desirable.

Any nose or throat abnormality or disease, unless easily remediable, should also mean exclusion. The ears should be examined carefully and patency of the eustachian tubes checked by "ear clicking." Middle-ear disease of any degree contraindicates exposure to pressures. All selected candidates should be tested for easy pressure equalization in the middle ear by actual compression in a chamber. Those who can clear their ears but with some difficulty will finally suffer ear damage due to repeated congestion and oedema of the middle ear over long periods and are therefore best excluded.

Surprisingly enough, men with claustrophobia may volunteer for this work, and all candidates should be watched carefully during the compression tests. The behaviour of each man when breathing in a closed circuit is also a useful indication of suitability for this type of work. Finally, if possible, men of stable and moderate temperament should be selected.

Hypertension and Nocturnal Frequency

Q.—Is active treatment (for instance with hypotensive drugs) indicated in a middle-aged man with essential hypertension (B.P. 260/130) whose only symptom is nocturnal frequency of micturition (3-5 times)? Fluid restriction, barbiturates, and belladonna have failed to relieve the nocturnal frequency.

A.—Although this degree of hypertension suggests a serious prognosis in a male patient I do not think this is simply a problem of high blood pressure. There is no reason why hypertension should cause nocturnal frequency of micturition unless it is complicated by either renal failure or an enlarged prostate (or, of course, some other independent cause of nocturnal frequency). I do not think one can discuss treatment without an investigation of renal function and prostatic condition. There is no reason to expect that treatment directed solely to the hypertension will cure the frequency.

Ferrous Gluconate

Q.—Has ferrous gluconate any advantages over other iron preparations in the treatment of an iron-deficiency anaemia?

A.—Ferrous sulphate in tablet form in a dose of 3 to 5 gr. (0.2 to 0.32 g.) three times a day is a cheap and effective form of iron therapy, and it is seldom that any other preparation need be employed. Nevertheless ferrous sulphate is a gastric irritant, and in really big doses always gives rise to vomiting. A very few patients are peculiarly susceptible to its nauseating effect, and in them even ordinary doses may produce vomiting. There seems little doubt that ferrous gluconate does not have this disadvantage, and it is a perfectly effective form of iron therapy.

Ocular Side-effects of Streptomycin

Q.—Does streptomycin give rise to any subjective ocular symptoms? For instance, does it make patients with refractive errors more liable to complain of their eyes?

A.—Streptomycin is not known to give rise to any subjective ocular symptoms, nor does it aggravate existing symptoms. Some years ago, when the drug was not available in as pure a form as it is to-day, serious toxic effects, including optic atrophy, were reputed to occur. Such complications are no longer to be feared.

Are Cases of Disseminated Sclerosis Spared Other Diseases?

Q.—Does disseminated sclerosis show a negative correlation with any other diseases, e.g., diabetes?

A.—There is no recognized negative correlation between disseminated sclerosis and other diseases.

"Any Questions?" Book.—The second book of selected "Any Questions?" is available, price 7s. 6d. (postage 6d.). Copies may be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

LONDON SATURDAY FEBRUARY 27 1954

THE NATURE OF DISEASE*

BY

A. E. CLARK-KENNEDY, M.D., F.R.C.P.

Physician to the London Hospital; Fellow of Corpus Christi College in the University of Cambridge

Doctors are apt to evade the question of the real nature of disease by giving certain states of body and mind names, as if these had an independent existence apart from their patients who suffer from them. Some we call after their primary causes (for example, fractures and cases of poisoning); others after the reactions of the body (for example, fever and reticulosis); some after the functional disturbance manifest during life (for example, diabetes, heart failure, and schizophrenia); others after the structural changes found in the body after death (for example, tuberculosis and cancer); some after the most arresting symptom or sign with which they are associated (for example, measles and mumps); others even after the clinicians who first described them (for example, Cushing's syndrome and Addison's disease). This, I admit, is clearly necessary for practical purposes. No system of nomenclature could, however, be more chaotic, and it is not surprising that we all get into the habit of thinking of diseases as if they had a real existence independent of our patients. And yet, a moment's thought, and we realize that diseases are not to be found in books or bottles, not even in post-mortem rooms or laboratories, but only in our individual patients who suffer from them and come to us for help. In fact, there can be no disease without a patient to suffer from it, any more than there can be a mind (in our ordinary experience) without a body and a brain to maintain it.

Before we can even start to discuss the question, therefore, we must form some idea of the nature of the potential patient who at any moment may develop his disease, and, on the evidence before us, is it really very difficult to arrive at a working concept on which we can all more or less agree as a common frame into which to fit our individual special interests? For must not every man be in part, at least, the product of three sets of factors: his genetic origin, his environment (physical, biological, and mental), and the use which he has made of his own free will? And to anticipate for one moment, just to give you an inkling of what I am aiming at, are not these three factors in his genesis in the last analysis also the only three possible factors in the pathogenesis of his diseases?

Body and Mind

But to return to the nature of the potential patient before we embark on a discussion of the nature of his

*A lecture delivered in the Medical Faculties of the Universities of Madrid and Granada in May, 1953.

disease. Everyone naturally thinks of himself as two separate things—a body and a mind—and yet how can two separate things be so intimately related? It does not make philosophical sense. Further, it is contrary to our own experience. The mind can upset the working of the body. It is well known that ill-health of the body can profoundly influence the mind. What, therefore, is the body? What in fact is the mind? Whence do both come? What is the relationship which exists between them? These questions must be answered, at least we must attempt to answer them, or how can we hope to understand the nature of disease of the body, or of the mind, or, more difficult still, of, as we see it, the body-mind relationship?

Nature and Origin of the Body

We will start with the body. First, what is it? From the point of thermodynamics it is a physico-chemical machine, made of compounds of carbon, hydrogen, oxygen, nitrogen, and sulphur, which converts the energy in the food we eat (derived originally from the light of the sun) into heat and kinetic energy which enable us to live and move and have our being. In that respect, in fact, it differs from a man-made machine only in that it is constructed of rather different stuff and works at rather lower temperature. Nevertheless, it exhibits the criteria of life. It is self-adapting, self-maintaining, self-repairing, and, if it mates, self-reproducing, reproduction of fixed form and structure being the main characteristic of living things.

Next, whence does it come? On evidence before us (and there would appear to be no escape from the conclusion) a man's body is the product of a plan laid at his conception when the genes in the chromosomes of his two parents were reshuffled in the fertilization of an ovum in much the same way, to give a rough analogy, as a house is the product of an architect's plan; and it is through this plan that he inherits all the ordinary characteristics of the human race, many of the particular characteristics of his ancestors, and some characteristics peculiarly his own. The motive force responsible for the execution of the plan remains one of the mysteries of life, but the right physical conditions are normally provided by the body of the potential mother, while the necessary building materials are supplied at first from her food through her blood and after birth direct from the environment into which the child is born. Its execution is not, however, finally

finished for over twenty years, and the original plan may be modified in the process of development and growth or actually spoilt at an early stage or in later life. No two men, therefore, can be the same in body, because (identical twins excepted) all are derived from different genetic plans, and all (identical twins included) are ultimately subject to different experience, mental and physical, in their environment.

Nature and Origin of the Mind

So much for the body. Now what about the mind?—and it helps us to understand its nature if we ask ourselves where it comes from, rather than what it is, first. For, as I see it, the body alone permits the development of the mind. (In ordinary human experience there can be no mind without a body, any more than there can be a disease without a patient.) It would, in fact, appear that the higher development of the nervous system in animals permits the development of consciousness, and that experience, writing on consciousness through the sensory machinery of the human body, leads to the development of the human mind. Thus the individual mind depends in part on the brain which a man possesses (as a result of his genetic origin and his physical environment) and in part on the conscious experience through which he has passed; and no two men can be the same in mind, because their brains are different and they have passed through different experience. Nevertheless, I do not think that on the evidence before us (scientific observation and experiment and human experience down the ages) the human mind can be explained *entirely* in terms of the brain, which a man has been given, and the experience through which he has passed. There is more to the human mind than that. The mystery of consciousness which permits of pleasure and pain, so unnecessary if we are but machines operated by conditioned reflexes (as the philosophy of behaviourism will have us believe), remains. We are all convinced that within limits we possess free will. Aesthetic sense cannot be explained on this basis. A strong case can be made out for the existence of intuitive as opposed to empirical knowledge. Faith in the real existence of the human soul is deeply rooted in human experience down the ages. Nevertheless, within factors capable of analysis at present, it is clear that the individual mind depends in part on the brain and in part on experience, and both of these are coming more and more under our power to control.

Psychosomatic Development

The development of the body in general and of the brain in particular therefore conditions the development of the mind under the stimulus of experience in the same way, to give a rough analogy, as the surface of a slate conditions the form of the writing on it. For example, the male body conditions the mind in such a way that it comes to exhibit the characteristics which we associate with a man, and the female body in such a way that it comes to exhibit those which we associate with a woman. And is there not reason to suppose that the mind so developed influences in some way which we do not yet understand the further development and maintenance of the body? We all know that a man's character is reflected in his face, and we must admit that psychological experience can have a profound effect on physical health. Therefore, not only are no two men the same either in body or in mind, but no two men are the same in their body-mind relationship. In fact, every man has his own particular psychosomatic constitution, because mind and body are mutually interdependent in their

development (although, of necessity, there are average types), which determines his reactions to physical and mental experience.

Adverse Action on Body and Mind

Now there may be a fault in the genetic plan whence a man is derived. Those which are hereditary are easily recognized, but those produced *de novo* by unfortunate combinations of genes are difficult to distinguish from those produced by adverse influences acting during the early months of intrauterine development. (The wrong environment can spoil the execution of a perfect plan.) For both during intrauterine development and throughout life the body is exposed to risk. At any stage it may suffer from lack of one or more of those substances on which its development and maintenance depend—food, water, salt, oxygen, iron, calcium, and vitamins. It may be damaged by physical trauma, excess of heat or cold, or by over-exposure to some form of radiation. It may succumb to some chemical poison taken by accident, used in industry, indulged in for pleasure, or swallowed, injected, or inhaled with suicidal intent. It may be infected by one of the larger parasites or by pathogenic protozoa, spirochaetes, bacteria, or viruses. It also runs risk because it is the basis of an individual human mind. Emotion can interfere with the physical health of the body through the nervous system or lead to maladaptation to social living. Free will enables a man within limits to choose his environment and his way of life.

Reactions of Body and Mind

In fact, the body would not survive long in the environment in which we live were it not endowed (presumably through the genetic plan whence it is derived) with the potentiality to react in such a way as to protect it from many of the risks to which it is exposed and often maintain its life when it does succumb. Now many of these reactions are part of everyday experience—for example, functional adaptation to exercise, change of temperature and altitude, intake of food and drink—and are therefore classed as physiological. Others are evoked only under unusual circumstances and are therefore regarded as pathological—for example, reactions to injury, chemical poisons, and infection. Similarly the mind would not maintain its balance long were it not endowed (presumably through the structure of the brain) with the capacity of adaptation to ordinary conscious experience. Now, most men react to experience in much the same way. Their behaviour is predictable. Reactions of this kind are therefore classed as psycho-physiological. Others, however, as a result of genetic predisposition due to the structure of their brains on which their minds are based, and/or as a result of previous experience, react abnormally. Their behaviour is not predictable. Reactions of this kind are classed as psycho-pathological.

Pathological Processes

Thus we arrive at the concept of primary pathological processes. A primary pathological process of the body is abnormal action on it evoking normal reaction by it. A primary pathological process of the mind is normal action on it evoking abnormal reaction by it. While, however, a pathological process of the body can run its course independently of the mind, a primary pathological process of the mind depends on the body, for the simple reason that the mind depends in part at least on the body. Therefore no absolute distinction can be maintained between primary pathological processes of the mind and primary pathological processes of the body, which often lead to secondary disturbance of the mind. In fact, the psychoneuroses—namely, anxiety states, obsessional states, and hysteria—merge into the organic psychoses, due to primary pathological processes of the body affecting the brain, through the so-called “functional” psychoses—namely, mental deficiency, schizophrenia, mania, endogenous depression, and involution melancholia.

Symptoms and Signs

Symptoms and signs due to physiological and normal psychological reactions to change of internal and external environment are a matter of everyday experience, but pathological processes, as above defined, lead to symptoms and signs which cannot be explained on this basis, although they can be identical with them. Primary pathological processes of the body lead directly—that is, through the body—to alteration of structure and disturbance of function of the body, with the result that the patient complains of physical symptoms and physical signs are often discovered on examination, but, if his brain (or any function of the body on which it depends) is affected, a primary pathological process of the body may lead to a secondary disturbance of the function of the mind and therefore to mental symptoms and mental signs. Primary pathological processes of the mind lead directly—that is, through the mind—to mental symptoms and signs, but they may also lead to a secondary disturbance of the structure or the functions of body and therefore to physical symptoms and signs, either through emotion and the autonomic nervous system, as in anxiety neuroses, or through conscious and unconscious thought and the skeleto-motor nervous system, as in malingering and hysteria. Some of the symptoms in any one case (in view of the nature of pathological processes) are due to action on the body or the mind and others to reaction by the body or the mind. The clinical picture produced by a pathological process is, however, often so complex that exact analysis on these lines is impossible.

Definition of Disease

A disease, therefore, so far as definition is possible, is that condition of a man, woman, or child of a certain psychosomatic constitution, and at a certain stage of his or her life, when a pathological process of body or mind is leading to alteration of structure or disturbance of function, with the result that he or she sooner or later starts to complain of symptoms, or signs are discovered on examination, most diseases being due to complicated interactions between genetic weakness, the adverse factors to which a man is exposed in his environment, and the psychosomatic machinery of his individual constitution. No two cases, therefore, are ever quite the same, although certain types of reaction are common, justifying the abstract conception of the real existence of diseases, apart from the individual patients who actually suffer from them.

Classification of Disease

Can we, however, classify the different manifestations of disease in order to help us in our understanding of it? For the human mind craves for classification and would impose discontinuity into the obvious continuum of the phenomenon of disease if it could. It is certainly very difficult. In the first instance there is no absolute dividing line between normality, that which is most common, and abnormality, that which is unusual, the extreme limit of generally accepted normality merging in one direction into the superathlete and the genius and in the other into disease of the functional variety in which body or mind is insufficiently strong (for obscure genetic or acquired reasons) to stand up to the demands on function which ordinary life in an average environment imposes on the psychosomatic machinery of the individual man. In the second place, although functional disease, weakness of body or mind as thus defined, is not a progressive process and is not, therefore, usually regarded as disease, it sometimes renders body and mind more liable to succumb to adverse factors in environment and therefore merges into disease proper, as I have attempted to define it. In the third place, no absolute dividing lines can be drawn between somatic, psychoneurotic, and the psychosomatic disease for the simple reason that body and mind are mutually interdependent in their development. Nevertheless we must make some attempt to classify disease.

Somatic Disease.—Somatic disease, as I see it, is alteration of structure and disturbance of function of the body

due to a primary pathological process of the body—that is to say, abnormal direct action on the body evoking potential reactions by it. If the brain or any function of the body on which it depends is affected, somatic disease as thus defined may lead to disturbances of the mind. Its recognized causes are genetic defects, any form of physical trauma, deficiency of any substance on which the development and maintenance of the body depends, chemical poisoning of any variety, and infections of all kinds. All somatic disease is organic in the sense that it is associated with structural or more or less permanent functional change, but all organic disease—that is, disease associated with structural change—is not necessarily somatic in the sense in which it has been defined in this paragraph.

Psychoneurotic Disease.—Psychoneurotic disease is alteration of structure or disturbance of function of the mind due to a primary pathological process of the mind—that is to say, to normal direct action on the mind and abnormal reaction by the mind. It may interfere with the functions of the body through the nervous system. The predisposition of the mind to react abnormally depends on unfortunate previous experience and/or genetic predisposition. Psychoneurotic disease therefore links up, as I have already pointed out, through defective personality, mental deficiency, and the functional psychoses with disorder of mind due to primary pathological processes of the body (the organic psychoses).

Psychosomatic Disease.—Psychosomatic disease is that to which a man succumbs under circumstances of stress in his environment on account of his own individual peculiar psychosomatic constitution. For, as I have already pointed out, no two men are the same in body or mind, or in the relationship which exists between body and mind. As thus defined, psychosomatic disease falls into two groups. In one group some peculiarity of body, as evidenced sometimes by hereditary tendency and association with physical characteristics, seems to have predisposed the mind to succumb to adverse factors in conscious experience. I am thinking of the people who fail to adapt to widening experience (the schizophrenics) or to dwindling experience (the involutional melancholics), or those who fail to control their emotions and lapse into uncontrolled excitement or unjustified depression. In the other group some peculiarity of the way in which the body has conditioned the development of the mind, and the mind the subsequent development of the body, seems to have predisposed the body to react to emotional experience in a way in which the average body does not react. I am thinking of people who develop asthma or thyrotoxicosis under circumstances of emotional stress. And I am sure that disease of this kind “piles up.” For instance, emotional stimulation of the bronchi renders them more sensitive to physical stimulation, and physical stimulation more sensitive to emotional stimulation, with the result that asthma or thyrotoxicosis, emotional in origin in the first instance, can actually lead to death.

Unclassifiable Disease

Nevertheless, there are many diseases normally regarded as organic, in the sense that they are associated with structural change in the body, which cannot be classified at present as psychoneurotic, somatic, or psychosomatic. They must, however, be due to some combination of the only three possible causes of disease which we can envisage—namely, genetic predisposition and adverse factors in environment, and the influence of the conscious mind on the physical state of the body. That cancer and old age are due to some complex interaction between genetic predisposition and adverse environmental factors seems likely. But can anxiety, stress, and disappointment lead to structural and functional change, such as hypertension, atherosclerosis, and cardiac infarction? For instance, can a person die of a broken heart, as is popularly supposed? Can the news of Napoleon's victory at Austerlitz have killed, as has been said, our great Prime Minister, the younger Pitt? Now, there is no theoretical reason why states of mind should not lead to structural change in the

body. For the will to execute the simplest movement leads to physico-chemical change in the nerves and muscles taking part, and chemical change, the body being basically a physico-chemical machine, is structural change. Further, we now know of three physiological mechanisms through which mental states can exert an influence on the body: the autonomic nervous system, the pituitary-thyroid mechanism, and the pituitary-adrenal mechanism. And it would be unscientific to expect consistency. All experience suggests that one man's psychosomatic constitution is such that his body can stand up to mental stress, while another man's is such that under the same circumstances he inevitably succumbs. One is like a castle built on sand and another like a house built on rock.

There remain, therefore, a group of diseases associated with structural change in the body for which at present no certain cause can be found, and in which the part played by the mind cannot as yet be assessed. It may well be very important. True that some of these—disseminated sclerosis and diabetes, for instance—may prove to be somatic only; that is, due to some combination of genetic predisposition and adverse factors acting on the body. Others—for example, duodenal ulcer and malignant hypertension—may well prove to be in part psychogenic in the sense that the psychosomatic constitution of the individual was such that he was predestined to succumb in this way when exposed to mental stress of that type or of that degree of intensity, while another person of different constitution under similar circumstances would have stood the strain.

The Future

What, therefore, of the future? For modern medicine, with its emphasis on the prevention of disease rather than on the treatment of the established condition, now that the age of materialistic optimism is past, can no longer ignore the psychosomatic concept or the part played by mental states in the pathogenesis of structural disease. Short of eugenic control of human mating we have no power (and one can hardly see how we could ever gain it) to alter the plan whence the individual is derived, and, although we should theoretically be able to modify its execution by controlling the environment in which it is carried out, the plan laid at the conception is hidden, so that, even if we could modify it in its execution, indications for the attempt are always wanting. We can, however, by controlling environment minimize the risks to which body and mind are exposed. But how is environment controlled? That depends on teaching the patient how to live, the doctor how to work, and the State its responsibilities (and the limits of its responsibilities) in this direction.

Lastly, will it ever be possible to alter the psychosomatic constitution of the individual so as to reduce the risks to which he is peculiarly exposed in one direction without increasing them in another? To give one example to indicate my meaning. Maleness is one form of psychosomatic development, as I have already pointed out, and femaleness another, while it is well known that men are predisposed to certain diseases and women to others by virtue of their constitution. If the female constitution could be converted into the male, and vice versa, it seems reasonable to suppose one would alter the diseases to which that person was liable to succumb by virtue of his or her sex. Whether in the future this will become possible is one question. Whether, if it ever does become possible, it will be wise or justifiable to do it, is, however, another.

Conclusion

One thing is certain. Our power over body and mind has increased, is increasing, and is likely to increase still further, and, as our power increases, it becomes more and more important that it should be used in the right way in the interests of society. This depends on a proper understanding of the nature of disease and on establishing the right relationship between the potential patient, the doctor, and the State.

IMMUNIZATION OF YOUNG BABIES AGAINST DIPHTHERIA

BY

N. R. BUTLER, M.D., M.R.C.P., D.C.H.

MOLLIE BARR, M.Sc., A.R.I.C.

AND

A. T. GLENNY, B.Sc., F.R.S.

(From the Obstetric Hospital of University College Hospital, London; the L.C.C. Infant Welfare Clinic of University College Hospital Medical School; and the Wellcome Research Laboratories (Biological Division), Beckenham, Kent)

This paper records some of the first results obtained with one prophylactic in an investigation of the methods of immunizing young babies against diphtheria. The whole work includes a comparison between the efficiency of different prophylactics, and a consideration of the effect of age at the time of the first injection and of the interval between injections on the levels of immunity produced.

Immunization against diphtheria is usually started during the second half of the first year of life. It is now generally recognized that immunization can be carried out successfully in the great majority of babies if the first dose of prophylactic is given earlier than this. Immunization against diphtheria has not the same appeal to mothers as protection against whooping-cough. Their eagerness for immunization against whooping-cough, however, can be used to include early immunization also against diphtheria: work on early protection against whooping-cough is being carried out by one of us (N. R. B.) in conjunction with other workers.

Although diphtheria is not at present a danger to young babies there are several advantages in early immunization. Large doses of prophylactic can be given without fear of undue reaction, and injections can be made at the same time as those of *H. pertussis* vaccine, which should be given as early in life as possible. The chief disadvantage lies in the possibility that inherited passive immunity may interfere with active response by neutralizing some or all of the injected prophylactic. The extent to which such interference may occur may increase as the proportion of immunized mothers increases. It is therefore important to employ methods of immunization that are effective in the presence of considerable passively acquired antitoxin. At all times there is also the question of post-inoculation poliomyelitis, and it would seem that the incidence of poliomyelitis in very young babies is not so low as had been supposed (Wright and Owen, 1952).

Barr, Glenny, and Randall (1950) found that babies in whom the maternally conferred antitoxin had fallen below 0.04 unit per ml. at the time of the first injection could be successfully immunized by two doses, each of 0.5 ml. (25 Lf) of A.P.T. When, however, the passive antitoxin was in higher concentration, immunization was unsatisfactory as judged by antitoxic response two months after the second injection. Barr *et al.* (1952) have shown that babies with low maternally conferred antitoxin titres can be successfully immunized by two doses of 0.5 ml. of A.P.T. even when the first dose is injected at the age of 6–10 days. They also found, however, that a high proportion of failures could be

expected if, instead of two doses of A.P.T., three doses of purified toxoid were injected at monthly intervals, the first dose at the age of 6–10 days. They suggested that very young babies might not respond well to unprecipitated prophylactics, or that the intervals between the injections might have been ill-chosen.

Bousfield (1951) used a mixture of P.T.A.P. with additional fluid toxoid for the immunization of older babies. He thought it possible that the free toxoid in this preparation, which he named F.P.T., might neutralize circulating passive antitoxin, so that interference with the action of the P.T.A.P. would be reduced or abolished. He employed a mixture containing 100 Lf toxoid plus 25 Lf of P.T.A.P. per ml. and stated that a "reasonable proportion" of the toxoid remained unadsorbed on the phosphate: no figures were given.

Present Investigation

The results here recorded have been obtained with a preparation of F.P.T. This material contained a total dose of 145 Lf of purified diphtheria toxoid per ml., of which 75 Lf was unadsorbed a few days after preparation. This prophylactic was made for us by Dr. F. V. Linggood, who kindly retested the flocculation values after three months' storage at 4° C., and found that a further 15 Lf had been adsorbed during this time. The composition at the beginning of the work on babies was 60 Lf free plus 85 Lf adsorbed per ml. of prophylactic: 11 months later the composition was 52 Lf free plus 93 Lf adsorbed. The dose injected into babies on each occasion was 0.5 ml. (72.5 Lf), and the schemes used in this work are shown in Table I.

TABLE I.—Schemes of Injection of Babies with F.P.T.

Age	Scheme		
	A	B	A and B
1 week	F.P.T.	F.P.T.	<i>H. pertussis</i> vaccine
6 weeks	"	"	" " "
14 "	"	"	" " "

Of the babies in scheme A 96% received the first injection when between 6 and 9 days old (72% of the total were within the narrow limits of 7 or 8 days) and the remainder when from 9 to 15 days old. The variation in the length of time between the two injections in individual babies can be seen in Table VII; for practical administrative reasons few babies were injected at the exact ages shown in Table I. Blood samples were taken from the babies by jugular venepuncture, the first being taken eight to nine weeks after the second injection of F.P.T. in 90% of cases.

The children were consecutive babies born in the obstetric department of University College Hospital. Samples of cord blood were collected in every case for estimation of the diphtheria antitoxin content. The nature of the immunization scheme was explained to each mother personally or by pamphlet on or about the fifth day of the baby's life, and it was pointed out that most of the injections would be given at the time of routine hospital attendance. Premature babies weighing less than 5½ lb. (2.5 kg.) at birth were excluded, as were babies suffering at the end of the first week from congenital malformations, effects of birth trauma, or infections; a few others were excluded because their homes were so far from the hospital as to preclude further attendance. The parental response was excellent, for out of the first 250 births of all weights 209 (83%) received a first injection in hospital and 195 completed the primary course of diphtheria and whooping-cough immunization.

An autoclaved all-glass syringe was used for each injection; after the prophylactic had been drawn up, the needle was changed to a No. 20 for the injection. The route and site of the injection were varied, and included subcuticular

or deep subcutaneous in the leg and deep subcutaneous in the deltoid area: this route gave the lowest reaction rate to injections either of diphtheria prophylactic or of *H. pertussis* vaccine. Both local and general reactions to the first injection of F.P.T. were very slight, and no reaction was complained of after the second injection, given at either 6 or 14 weeks. Table II shows the incidence of local reactions

TABLE II.—Incidence of Local Reactions to First Injection of F.P.T. Given at Age of About 1 Week

Group	Site	Route	No. Showing Erythema				No. Showing Induration				Total
			0	1–25	26–50	>50 mm.	0	1–25	26–50	>50 mm.	
1	Thigh	Subcuticular	11	70	12	1	94	41	46	2	89
2	"	Deep subcutaneous	38	41	4	1	84	59	24	0	83
3	Deltoid	"	50	47	1	0	98	85	12	0	97
All groups			99	158	17	2	276	185	82	2	269
Percentage			35.9	57.2	6.2	0.7	68.8	30.5	0.7		

in 305 consecutive babies given the first injection of F.P.T. in the hospital nursery during the first two weeks of life: 99 (35.9% of the 276 examined) showed no erythema, and 185 (68.8% of 269) had no induration at the site of injection 24 hours after the first injection. Only 19 babies (6.9%) showed areas of erythema or induration of more than 2.5 cm. diameter, and none of these progressed to local abscess formation. There were 14 babies showing small nodules five weeks after the first injection, but none of these was still present at the age of 3 months.

We are indebted to Mr. P. A. Young, of the Wellcome Research Laboratories, for making a statistical analysis of the figures given in Table II. From this analysis he has drawn the following conclusions.

Erythema is significantly more frequent and more extensive after subcuticular injection than when it occurs after subcutaneous injection.

Erythema occurs with equal frequency on thigh and deltoid after deep subcutaneous injection, but when it does occur it tends to be more extensive on the thigh.

After deep subcutaneous injection induration is significantly more frequent on the thigh than on the deltoid.

Induration on the thigh is significantly more frequent after subcuticular injection than after deep subcutaneous injection.

Determination of Antitoxin Titres

The antitoxin titres of sera from cord blood and from the babies after immunization were determined by a modification of the Römer and Sames (1909) guinea-pig intracutaneous method (Glenny and Llewellyn-Jones, 1931). Tests were made at approximately twofold differences; the lowest level tested was 0.001 unit per ml. Since only small amounts of serum were available from some of the babies, a dilution 1 in 5 was made, and the lowest titre measured, in terms of undilute serum, was therefore raised to 0.005 unit. When serum was plentiful tests were made at lower levels, but for the purpose of analysis of results such low titres were included as under 0.005 unit: this figure corresponds roughly to the Schick level. Diluted sera were tested at the same levels as the undilute cord sera, but the multiplication of the titre by five brings some recorded values to slightly different figures. For example, cord blood titres are recorded as 0.004 (above 0.004 and below 0.01), 0.01, 0.02, and 0.04 unit per ml., but tests on diluted material at the same levels represent titres of 0.02, 0.05, and 0.1, etc., after correcting for dilution. The form of the histograms in Figs. I, II, and III shows the limiting values for all the recorded titres; The geometric means in the tables are calculated from the geometric means of the limiting titres; thus a recorded titre of 0.01 is regarded as 0.014 for the purpose of such calculations. Values recorded as under 0.005 are taken to be 0.002.

Antitoxin Titres of Babies in Scheme A

Fig. 1 shows the distribution of antitoxin titres of babies at the age of 3 months, about eight weeks after the second injection of F.P.T. The results have been arranged

Fig. 1.—Distribution of diphtheria antitoxin titres in the serum of babies when 3 months old after immunization under scheme A.

(1) 110 babies with cord blood titre of 0.01 unit per ml. or less
(2) 21 " " " " " " 0.02 or 0.04 unit per ml.
(3) 34 " " " " " " 0.1, 0.2, or 0.5 unit
(4) 12 " " " " " " 1, 2, or 10 units
Broken lines show the distribution of residual passive antitoxin titres.

into four groups according to cord blood titre. In diagram 1, which shows the titres of babies for whom the cord blood had contained 0.01 unit or less, the great majority were between 0.1 and 1 unit per ml. Only four babies had titres below 0.05 unit.

In diagram 2 (cord blood titres between 0.01 and 0.1), there is a suggestion of two, possibly three, populations. Two babies out of 21, both with the higher cord blood titre of 0.04 unit, failed to produce 0.005 unit per ml.; 12 babies produced over 0.01 but under 0.1 unit; and only five reached 0.2 or 0.5 unit per ml. There is thus a clear dividing line at 0.02 unit between the cord blood titre which seldom interfered with and that which often reduced active response to injection. With lower cord blood titres (diagram 1) only 10 among 110 babies failed to produce 0.1 unit, compared with 14 of 21 shown in diagram 2.

Diagram 3 deals with babies whose cord blood titres were between 0.1 and 1 unit per ml. Such babies would have measurable amounts of residual passive antitoxin at the age of 3 months. Calculations from the formula of Barr, Glenny, and Randall (1949) show that slightly less than one-tenth (7.8%) of the cord blood titre would still be present in the serum of babies 3 months old. Babies with cord blood titres recorded as 0.1 unit per ml.—that is, between 0.1 and 0.2 unit—would thus be expected still to have titres between 0.0078 and 0.0156 unit. Such titres would be recorded as either 0.005 or 0.01. By assuming an even distribution of titres between the various limits, it is possible to work out the distribution of passive titres to be expected at 3 months (and also at 6 months as shown in Fig. II)

if no active antitoxin production had occurred as a result of the injections of F.P.T. This distribution is shown in Fig. I as a broken line, and corresponds fairly closely to the distribution actually found. There was thus little active response in these babies, though there is a suggestion from both diagrams 3 and 4 (babies whose cord blood titres were 1 unit or more) that a few babies may have produced some antitoxin actively. In diagram 4 the agreement between the distribution of calculated passive titres and those found is not so good as that in diagram 3, but the figures for both diagrams seem to provide confirmation of the formula of Barr, Glenny, and Randall.

Fig. II shows the distribution of antitoxin titres of the babies when 6 months old. The titres of those with low cord blood initially had mostly fallen to about one-half the titre found at 14 weeks (diagrams 1 and 5). A comparison of the titres in diagrams 2 and 6 shows that a few of the higher titres at 14 weeks had fallen, but that there was an increase in some of the lower ones. Diagram 7 shows that the passive titres of babies with cord blood values over 0.1 and under 1 were almost negligible at the age of 6 months, and that nearly all the babies had responded actively by this time. A number of the babies in the highest cord blood group (diagram 8) had also shown an active response by this time. Thus a delayed response, the "intermediate response" of Glenny and Südmersen (1921), may occur in babies with a high level of circulating passive antitoxin at the time of injection of prophylactic. Barr, Glenny, and Howie (1953) found a close inverse correlation between passive titre and response to the first and to the second injection of A.P.T. in lambs that had acquired diphtheria antitoxin from the colostrum of their actively immunized mothers. Even very high passive titres that

(5) 38 babies with cord blood titre of 0.01 unit per ml. or less
(6) 17 " " " " " " 0.02 or 0.04 unit per ml.
(7) 30 " " " " " " 0.1, 0.2, or 0.5 unit
(8) 8 " " " " " " 1, 2, or 10 units
Broken lines show the distribution of residual passive antitoxin titres.

prevented any detectable antitoxin production after two injections of A.P.T. did not prevent the development of basal immunity, so that considerable antitoxin production occurred after a third injection. It is therefore possible that some antitoxin would be actively produced by all babies if given a third injection at the age of 6 months.

TABLE III.—Changes in Antitoxin Titres in Serum of Babies Injected under Scheme A and Bled when 3 Months and 6 Months Old

Cord Blood Titres		No. of Babies Whose Titres			Total
Over	Under	Increased	Remained the Same	Decreased	
—	0.004	1	4	25	30
0.004	0.1	6	10	5	21
0.1	0.2	9	2	1	12
0.2	1.0	4	3	8	15
1.0	—	0	0	8	8
Total		20	19	47	86

Table III shows the changes in antitoxin titres of all babies injected under scheme A and bled when 3 months and 6 months old: the responses are divided according to cord blood titre, but in different groups from those in Figs. I and II. Twenty-five of the 30 babies whose cord blood titres were below 0.004 unit showed a fall in antitoxin between the third and sixth months, and only one increased. This suggests that nearly all the babies in the second group had given a secondary response to the second injection of F.P.T. Only two out of six with cord blood titres of 0.004 or 0.01 decreased in titre during the third to sixth months of life; these results are therefore included in the second group in Table III. Those with initial titres of 0.1 unit per ml. formed the only group in which more than half the titres increased during the third to sixth months; this group is therefore recorded separately. Those babies with higher cord blood titres—0.2 and 0.5—were almost equally divided between those who decreased in titre and those who either increased or remained the same. All with an original value of 1 or more decreased in titre during the third to sixth months.

Table IV gives a comparison of the distribution of antitoxin titres of those babies who were bled on two occasions, together with the average passive titre expected to be present in the higher groups at the time the blood samples were taken. These figures were calculated from the formula of Barr *et al.* (1949), and, by subtraction from the total titre found, the average active titre for each group has been calculated. Babies in the first group must have reached their maximum antitoxin titre at or before the time of their first bleeding when 3 months old, and their titres had fallen considerably when bleedings were taken three months later. The second group consisted of two populations irrespective of the cord blood titres within the recorded limits; 10

babies had responded by three months as well as those in the first group, and those had mostly fallen in value by 6 months, although the reduction in titre was not so great as that in the first group. The other population had responded badly by 3 months and mostly increased in titre by 6 months. As a result of this delay in reaching the maximum titre the average titre at 6 months of the second group was higher than that of the first group. The third group, consisting of those babies whose cord blood titre was 0.1 unit, included only one whose titre at 6 months was lower than that at 3 months. As this baby reached 0.2 unit at 3 months it can be concluded that all had been actively immunized.

It can be concluded, therefore, that all babies with cord blood titres of 0.1 unit or less per ml. were actively immunized by scheme A. This would apply to 766 of the first 1,000 at U.C.H. whose cord blood titres were tested.

The results given in the last two groups in Table IV are not so definite. In the fourth group the geometric mean of the titres found at 3 months is almost identical with the expected passive contribution, but at 6 months the mean titre found was 3.7 times the expected passive titre; some at least of the babies must have responded actively. It seems reasonable, therefore, to accept as actively immunized the 7 out of 15 recorded in Table III as at least maintaining their level of total antitoxin content from the third to the sixth month, although their passive antitoxin content fell by 0.03 unit per ml. This would bring the estimated number of babies immunizable under scheme A to at least 84%. The figures given for the fifth group in Table IV suggest that at least one of the seven babies was actively immunized, although the cord blood titre was 1–2 units per ml.

TABLE V.—Comparison Between Titres at 3, 6, and 9 Months of Babies Injected under Scheme A. Cord Blood Titres were all 0.01 Unit or Less per ml.

Antitoxin Titre (Unit/ml.)	No. of Babies Possessing the Stated Antitoxin Titre when Aged		
	3 Months	6 Months	9 Months
Under 0.005	1	1	1
0.005	1	0	1
0.01	2	3	3

Active production	0.327	0.133	0.117	0.147	0.012	0.044	Nil	0.016	0.045	0.055

A and bled at 3 months and at 6 or 9 months. The figures come from a dwindling and mixed population, and few of those bled at 9 months had been bled at 6 months, but it is important to note that, whereas the geometric mean titre of those bled at 6 months was about half that at 3 months, the mean titre at 9 months was only 10% lower than that at 6 months. This suggests that babies in whom the maternal antitoxin was insufficient to interfere with active immunization gave secondary responses, and that the flattening out of the curve of loss, typical of such responses, occurred at about 6 months.

TABLE VI.—Comparison Between Antitoxin Titres of Babies about 8 Weeks After the Second of Two Injections of F.P.T. under Scheme A Divided According to Route of Injection. Cord Blood Titres were all 0.01 Unit or Less per ml.

Route	No. of Babies with Antitoxin Titres (Units/ml.)							No.	G. Mean Titre
	0.01	0.02	0.05	0.1	0.2	0.5	1.0		
Subcutaneous	1	3	20	11	13	2	50	0.262	
Deep subcutaneous (arm and thigh)	2	1	1	7	22	23	0	56	0.377

It is perhaps of interest to record the antitoxin titres in babies immunized by subcutaneous and by deep subcutaneous injections of F.P.T. A comparison is given in Table VI, relating to babies injected in scheme A whose cord blood titres were 0.01 unit per ml. or lower. Although there is

FIG. III.—Distribution of diphtheria antitoxin titres in the serum of babies when 6 months old after immunization under scheme B.

- (9) 43 babies with cord blood titres of 0.01 unit per ml. or less
 (10) 18 " " " " " " 0.02 or 0.04 unit per ml.
 (11) 26 " " " " " " 0.1, 0.2, or 0.5 unit
 (12) 7 " " " " " " 1 or 2 units

Broken lines show the calculated distribution of residual passive antitoxin titres.

a suggestion of better results with deep subcutaneous injections, the differences between the means of the logarithms of the two sets of titres is not significant.

Antitoxin Titres of Babies in Scheme B

Babies injected under scheme B were bled for the first time at the age of 6 months. Antitoxin titrations were therefore made about 12 weeks after the second injection, compared with eight to nine weeks in scheme A.

The distribution of antitoxin titres of these babies at 6 months is shown in Fig. III. The results are grouped according to cord blood titre as in Fig. 1, so that diagrams 1 and 9, 2 and 10, 3 and 11, and 4 and 12 show titres of babies with the same ranges of cord blood values. It is at once evident on comparing diagrams 1 and 9 that babies born with little maternally conferred antitoxin were better immunized under scheme B than under scheme A. There is a very small scatter of titres in diagram 9, in contrast to the wide scatter and the poor titres of some babies in diagram 1. We are of the opinion that a small scatter provides evidence of satisfactory immunity in a population as a whole (see Barr, Glenny, and Randall, 1950). The same improved response is shown in all groups under scheme B except those with cord blood titres of 1 unit or higher. The improved response of babies receiving the second injection at the longer interval after the first, recalls the finding of Barr *et al.* (1950) that young babies immunized with two doses, each 0.5 ml. of A.P.T., responded better if the interval between the injections was 10–18 weeks than if it was 6–9 weeks.

It is probable that, when a potent prophylactic such as F.P.T. is used, intervals between injections could be extended even further in babies with low passive titres at the time of the first injection. It is, however, of interest that those with high cord blood titres responded less well when the interval between injections was 13 weeks than when it was five weeks. This result suggests that the potential immunity conferred by the first dose of F.P.T., injected at a time when the circulating passive antitoxin was considerable, had been largely lost by the 13th week. The presence of considerable passively conferred antitoxin reduces the amount of effective prophylactic available to act as a stimulus. When very small dosage is used the degree of potential immunity established by the first injection is insufficient to provoke a good antitoxic response if the second injection is delayed unduly (Barr and Glenny, 1945). Although the babies whose titres are shown in diagram 12 may subsequently show delayed production of antitoxin, they seem to be less effectively immunized than those in diagram 4.

The effect of interval between injections upon response is shown in Table VII. The titres are those of babies for whom the cord blood titre was 0.01 unit or less per ml., and babies who received the second injection after eight

TABLE VII.—Distribution of Antitoxin Titres in Serum of Babies Taken about 8 Weeks After Second of Two Injections of F.P.T. under Schemes A and B Divided According to Interval Between Injections. Cord Blood Titres were all 0.01 Unit or Less per ml.

Interval Between Injections (Weeks)	No. of Babies with Antitoxin Titres (Unit ml.) of							Total	G.M. (Unit ml.)
	0.01	0.02	0.05	0.1	0.2	0.5	1.0		
4 to 5 ..	2	1	1	19	14	12	1	50	0.24
5 " 6 ..	0	1	4	7	17	17	0	46	0.31
6 " 8 ..	0	0	0	1	3	7	0	13	0.58
12 " 15 ..	0	0	0	0	3	21	2	35	0.86

weeks or less (scheme A) were bled and tested eight to nine weeks later, while those in scheme B (12–15 weeks interval) were bled about 12 weeks after the second injection. It is clear from the distribution of titres, the smaller scatter, and the geometric mean values that the response of these groups was improved as the interval between injections was increased.

Table VIII compares the distribution of titres of babies with higher cord blood values immunized under schemes A, and B. This table shows in addition the average passive titre to be expected in each group at the time the blood samples were taken. It is clear that much greater active antitoxin production occurred in babies immunized under scheme B than scheme A, except those with cord blood titres of 1 unit or more.

It is perhaps of interest to consider these results in relation to the distribution of 1,000 cord blood titres from this particular population. Only 7.4% of this large sample had cord antitoxin titres of 1 unit or more per ml., and it would therefore appear that over 90% of the babies would be immunized more satisfactorily by two doses of F.P.T. given at the ages of 1 and 14 weeks than by two similar doses given at the ages of 1 and 6 weeks. There was, however, one other point of difference between the injection procedures in schemes A and B. Whereas group A received

suitable, not necessarily optimal, interval for P.T.A.P., but a much longer interval, such as that in scheme B, was necessary for uniformly good results when F.P.T. was used.

Summary

Further evidence is given that active production of diphtheria antitoxin in babies is greatest in those with little or no antitoxin in their cord blood. The interference with active production caused by higher passive titres does not appear to be reduced by the use of F.P.T.—that is, P.T.A.P. to which additional unprecipitated purified toxoid has been added.

Babies whose cord blood titres were below 1 unit per ml. and who were immunized with two doses of F.P.T., each of about 70 Lf, gave better antitoxic responses if injected at the ages of about 8 days and 14 weeks than

two injections each of F.P.T. and of *H. pertussis* vaccine given at the same times but in a different site, group B received an injection of *H. pertussis* vaccine alone between the injections of F.P.T. and vaccine. The effect of the introduction of injections of one antigen alone in a course of combined prophylaxis has not received much investigation. It has been recently shown by Barr and Llewellyn-Jones (1953a) that a preliminary injection of typhoid-paratyphoid vaccine before the first of two injections of this vaccine in combination with tetanus toxoid may bring about interference with the response to the tetanus toxoid in guinea-pigs. The same workers (1953b) have found that in certain circumstances an injection of a vaccine in between two injections of a combined prophylactic containing the same vaccine and a toxoid may improve the response to the toxoid. It is possible that the injection of *H. pertussis* vaccine given to the babies of scheme B between the two injections of the same vaccine and of F.P.T. contributed in some measure to the better response of the majority of this group. We are, however, of the opinion that the superiority of results in scheme B to those in scheme A was due chiefly to the longer interval between the injections of F.P.T.

P.T.A.P.—A few babies, including 25 with cord blood titres of 0.01 unit or less per ml., were injected with 0.5 ml. of P.T.A.P., given at the same time as in scheme A. The responses of this group were far better than those injected with F.P.T. in scheme A, and approached the results of scheme B. The total antigen content in the dose of F.P.T. was slightly more than double that in the dose of P.T.A.P. Thus, babies with no circulating passive antitoxin at the time of the first injection of F.P.T. received twice as much total antigen as similar babies injected with P.T.A.P. In babies who had maternally conferred antitoxin the free toxoid in F.P.T., though it might neutralize this antitoxin, would be expected also to have an antigenic effect if gradual dissociation of the toxoid-antitoxin complex took place. It is therefore to be expected that the optimum interval between the two injections of this potent prophylactic would be longer than that for the weaker preparation, P.T.A.P. It is probable that five weeks between two injections was a

if injected at the ages of about 8 days and 6 weeks. When the cord blood titre was 1 unit or more, responses were poorer in the group receiving injections at the longer interval.

In the short-interval group, comparison of the antitoxin levels of babies at the ages of 3 and 6 months suggested that many with cord blood titres above 0.004 unit per ml. had given an intermediate, not a secondary, response to the second injection of prophylactic. This was shown as a delayed production of antitoxin, due to reduction in the effective first dose of F.P.T. because of neutralization by passively conferred antitoxin. A few babies with low cord blood titres gave better responses to two doses, each of about 25 Lf of P.T.A.P., given at the ages of 8 days and 6 weeks, than similar babies receiving two doses of F.P.T. at the same ages.

The general reaction rate was negligible after injections of F.P.T.: local reactions were also very slight, and were less after deep subcutaneous than after subcutaneous injection.

We are greatly indebted to the staff of the Obstetric Hospital and the Infant Welfare and Children's Department of University College Hospital. We also wish to thank Mrs. F. Blackman for considerable technical assistance.

THE HERPES SIMPLEX VIRUS IN INFANTILE ECZEMA

BY

GEORGE I. BARROW, M.B., Ch.B.

Registrar, Department of Dermatology, Royal Infirmary,
Bradford

Infantile eczema is perhaps one of the most distressing afflictions of early life, frequently more so to the parents than to the victim. Treatment is always a problem; at home improvement is often slow, and in hospital other conditions, occasionally serious, are readily contracted. The damaged skin is frequently infected by bacterial "opportunists," and less often, though with apparently increasing frequency, by viruses, which may produce an acute vesicular eruption not unlike smallpox, with a high mortality rate. This complication of atopic eczema was first recorded by Kaposi in 1887, and there is little to add to his vivid description:

"... an acute outbreak of numerous vesicles, partly scattered, partly arranged in groups. The vesicles are as large as a lentil, filled with clear serum, and the majority are umbilicated. They look like varicella lesions, but undoubtedly do not belong to this class. The integument which has been attacked in this manner now appears still more swollen, even tense. The little patients have a high fever and are very restless. The vesicles develop very acutely (sometimes overnight), in large numbers, and often continue to appear, in successive crops, for three or four days, or even a week. Those which appear first undergo desiccation, rupture, and expose the corium, or they become encrusted and fall off. The largest number of these varicella-like vesicles are found upon the already eczematous skin, but smaller groups appear upon the previously intact skin of the neighbourhood, upon the forehead, ears, neck, and even the shoulders and arms."

Kaposi originally suggested the title "eczema herpetiforme," but he suspected a fungus as the cause. The syndrome was first identified with the virus diseases by Juliusberg (1898), who, although confusing the issue himself, drew attention to the close resemblance of the individual lesions to vaccination pustules. Although the precise aetiology was subsequently disputed, by common consent the term "Kaposi's varicelliform eruption" became firmly established. The numerous reports during recent years have clearly demonstrated that this condition is a distinct entity, is commonly produced by the virus of either herpes simplex or vaccinia, and that, although rare, it may well be seen by many during their practising career (Whittle *et al.*, 1950). When due to vaccinia there is usually a history of recent vaccination or contact with recently vaccinated persons. In the absence of such contact it is likely to be due to herpes simplex, when a history of herpetic infection in a close contact is often obtained.

Several examples of both types have been seen recently. The object of this paper is to describe three typical cases and to review the published literature on the subject.

Case 1

A female infant aged 6 months, who had been immunized against diphtheria but not vaccinated, had suffered from infantile eczema in moderate form affecting both legs and face since the age of 3 months. Three days before admission she became listless and developed "blisters" be-

hind both knees. She was admitted to the ward on April 13, 1953. When seen on April 15 she showed groups of umbilicated vesicles and pustules superimposed on the eczematous skin of the neck and both legs, some areas being extensively traumatized. There was considerable inguinal lymphadenopathy. Her temperature was 101.4° F. (38.6° C.), pulse 146, and respirations 36. No abnormality was detected in any system. She was transferred to the fever hospital on April 15. The child's father and grandmother had recently suffered from colds associated with "cold spots." In fact, the father's labial herpetic infection was still present.

Treatment consisted of aureomycin lotion locally, soluble penicillin, and, later, "distaquaine" systemically (Fig. 1). The child was acutely ill during the pyrexial phase. Crops of fresh umbilicated vesicles appeared daily, even on the gums. Recovery ensued without pitting or scarring. The basic eczema remains unchanged.

Investigations.—Blood: Hb, 85%; white cells, 8,000 per c.mm. (polymorphs 76%, lymphocytes 20%, monocytes 4%; no eosinophils or basophils). Films showed anisocytosis of red cells. Swab from vesicle: films showed Gram-positive cocci; culture showed *Staph. aureus*. Egg culture: positive for herpes simplex. Serum for herpes-neutralization tests: increase in herpes-neutralizing antibody titre between first and second specimens.

Fig. 1.—Chart of Case 1.

Case 2

A female infant aged 11 months, who had not been immunized or vaccinated, had suffered since the age of 3 months from moderately severe infantile eczema affecting the face and neck, for which she was in hospital when Case 1 was admitted (April 13, 1953). In the course of a routine ward round on April 20 comment was passed on this child's good luck in having escaped Kaposi's varicelliform eruption. Careful examination revealed nothing apart from her basic eczema. During the same evening she became listless and developed a temperature of 104° F. (40° C.), pulse 140, and respirations 40. One hour later crops of small clear vesicles were seen on the left shoulder and chest. The next day typical umbilicated vesicles and pustules were present. At first there was no lymphadenopathy, though this later became marked in the left axilla. The child was transferred to the fever hospital on April 21.

Treatment consisted of aureomycin lotion locally and penicillin and, later, aureomycin systemically (Fig. 2). The child was gravely ill during the pyrexial phase, fresh umbilicated vesicles appearing daily. Recovery ensued, but the basic eczema was unchanged. There are no pitted scars.

Fig. 2.—Chart of Case 2.

Investigations.—Blood: Hb, 80%; white cells, 20,000 per c.mm. (polymorphs 62%, lymphocytes 25%, monocytes 13%; no eosinophils or basophils). Films showed anisocytosis and microcytosis of red cells. Swab from vesicles: films showed Gram-positive cocci; culture showed *Staph. albus*. Urine: N.A.D. Portable x-ray film of chest showed no lesion. Egg culture: positive for herpes simplex. Complement-fixation test negative for vaccinia-variola group. Serum for herpes-neutralization tests: increase in herpes-neutralizing-antibody titre between first and second specimens.

Case 3

A male infant aged 8 months, who had not been immunized or vaccinated, had suffered from xeroderma since birth and had developed scattered patches of eczema, for which he had received treatment at hospital. Both parents were vaccinated on May 14, 1953, but this was not attempted on the child because of the skin condition. Four days before admission—that is, on May 27—the child suddenly became listless, developed a high temperature, and later had "vaccination blisters" on the left arm. When admitted to the fever hospital on May 31 the left arm showed groups of umbilicated vesicles and pustules, with marked inflammatory reaction, and occasional vesicles on the right arm and legs. There was moderate axillary lymphadenopathy. His temperature was 101° F. (38.3° C.), pulse 138, and respirations 34. No abnormality was detected in any system. Treatment consisted of systemic penicillin and local aureomycin cream. Recovery was rapid and uneventful. The basic xeroderma was unaltered. There is some residual scarring.

Investigations.—Blood: white cells, 13,600 per c.mm. (polymorphs 61%, lymphocytes 28%, monocytes 4%, eosinophils 7%; no basophils). Swab from vesicles: haemolytic streptococci present. Egg culture: positive for vaccinia; complement-fixation test positive for vaccinia-variola group. Serum for vaccinia-neutralization tests: increase in vaccinia-neutralizing-antibody titre between first and second specimens.

Diagnosis

The clinical diagnosis of virus eruptions in their typical form usually presents little difficulty. Confusion may arise because of pre-existing skin disease, particularly atopic eczema. Atypical forms of virus disease create further difficulties in diagnosis, especially during an outbreak of smallpox. In susceptible persons varicella, variola, and vaccinia, as well as herpes simplex and herpes zoster, should be considered, and, if excluded, some other virus sought.

The clinical diagnosis of eczema herpeticum in infants depends upon the sudden appearance of profound toxæmia, high temperature, and a pock-like eruption on eczematous skin. A history of recent herpetic infection in close contacts is often obtained. Cases are undoubtedly unrecognized or misdiagnosed, and the condition is probably commoner than reports indicate. In eczema vaccinatum the nature of the eruption and a history of recent vaccination or contact should suggest the diagnosis. The possibility of confusion with chickenpox is slight, but the resemblance to smallpox may be striking, especially if the face is affected. If possible, laboratory confirmation should be obtained.

The laboratory diagnosis of virus eruptions, although not easy, depends upon identification of the virus concerned after culture on the chorioallantoic membrane of fertile hens' eggs, or demonstration of its presence by complement-fixation tests. For both tests papule scrapings or vesicle fluid and crusts are required. Alternatively, the patient's serum may be used against known virus antigen. The complement-fixation tests are rapid; egg culture is precise, but

requires more time. Microscopical examination of smears of vesicle scrapings for elementary and inclusion bodies is rapid and, if positive, of considerable value. Biopsy and the demonstration of virus-neutralizing antibodies in the serum are of little value except in retrospect (Anderson, 1952).

For the laboratory, six to twelve "fresh" vesicle tops or scabs should be placed in a small sterile bottle. Vesicle fluid should be obtained in two or three capillary tubes (similar to those for vaccination lymph), which are sealed by flaming the ends, and then placed in a dry bottle. Smears may be made by scraping the bases of four to six lesions. The greater the quantity of material collected the better the interpretation of the results (MacCallum, 1952). If possible, two samples of clotted blood should be obtained—one during the first few days of illness and the other during the second to third week—in order to show a rise in serum antibody titre.

Treatment

There is as yet no effective form of antiviral treatment. Gamma globulin or transfusion of immune serum may be tried. Moccasin venom is mentioned by Barker and Hallinger (1947), but no other reports have been seen. Extensive cases should be watched for signs of fluid depletion, and corrected if necessary.

Despite varying reports, the recent antibiotics are probably equally effective, although differing from one case to another, in controlling secondary infection. The cases recorded here were given penicillin because the earlier cases had failed to respond to aureomycin. Sulphonamides should not be used, because there may be an actual or a relative leucopenia (Lane and Herold, 1944; Miller *et al.*, 1950). The value of A.C.T.H. and cortisone is still undecided, although one of the earlier cases developed eczema herpeticum whilst on small doses of A.C.T.H.

Locally, potassium permanganate soaks (1:100,000) are viricidal against vaccinia and variola (Gordon, 1941), and may be tried against herpes simplex. The viricidal action is inhibited by glycerin. Antibiotic creams or lotions should be used; all of the present series appeared to benefit from local aureomycin.

The basic eczema, although temporarily improved, usually remains unaltered.

Prognosis

The prognosis of eczema herpeticum depends upon virus virulence, susceptibility of host, nature and extent of previous skin trauma, and secondary infection with its ensuing complications. All grades of severity occur, from mild abortive to extensive fatal cases (Lynch and Steves, 1947). Death may occur during the primary toxæmia, or later because of extensive secondary infection. Most of the deaths reported in eczema vaccinatum have been due to encephalitis or general sepsis (Perry and Martineau, 1949).

The mortality rate is variable. Blattner *et al.* (1945) state that the disease is self-limiting and in general the prognosis is good. O'Leary (1944) thinks that its seriousness should not be minimized, as the literature indicates that probably one out of every three children with eczema herpeticum dies, whereas in adults it is not so serious; Sims and French (1948) report six deaths out of nine cases. None of the present series died, but at various times three (of six) cases were dangerously ill.

Communicability

All the pock viruses, including herpes simplex, are highly infectious, especially in the presence of eczema or other skin damage, when the reaction to primary infection may be unusually severe. The occasional epidemic outbreaks of eczema herpeticum are possibly due to an increase in virus virulence (Unger, 1947). In the presence of virus-neutralizing antibodies, recurrent lesions of herpes simplex may be due to local lowering of resistance (Varley and Kletz, 1949). The development of sore throats, vesico-pustules, and herpetic lesions in the attendant staff has been reported

(McLachlan and Gillespie, 1936; Barton and Brunsting, 1944). In the present series three nurses developed vesicopustules, which remained limited in extent on the hands and fingers and responded rapidly to local aureomycin. Virus studies were not made.

It is suggested that eczema herpeticum should be classed as a notifiable disease to ensure future epidemiological investigation.

Vaccination

As routine for public protection, vaccination is preferably performed by the multiple pressure method on the upper arm during the first six months of life. Despite cosmetic considerations the leg should be avoided, for it is almost impossible to keep an infant dry in this region, and the consequent skin damage predisposes to dangerous reactions.

There are certain contraindications to vaccination: it should not be attempted, on adult or child, in the presence of eczematous or otherwise damaged skin. The desirability of vaccinating the parents of children thus afflicted should be considered, and if attempted the vaccination site should be carefully occluded (Jeffs, 1952). Women should not be vaccinated during the first three months of pregnancy because of the significant increase in foetal mortality. There is virtually no risk during the later months of pregnancy (MacArthur, 1952).

Prevention

In view of their high infectivity to susceptible persons, cases of extensive eczema herpeticum and eczema vaccinatum should be isolated. Sufferers from atopic eczema should be warned of the danger of exposure, and safeguarded, if possible, from persons with active herpetic or vaccinia lesions, including, if infected, members of the medical and nursing staffs. Somerville *et al.* (1951) suggest that recently vaccinated persons should not be admitted to hospital, especially to a skin ward, without adequate precautions being taken. They suggest that during times of widespread vaccination it might be wise to discharge persons, especially children, suffering from allergic eczematous conditions. Normally, maternal antibodies in human milk protect infants up to the age of about 12 months: it may be that lack of this protection allows "ward" epidemics to occur. Mothers of infants in hospital should therefore be encouraged to continue breast-feeding.

Discussion

The cases described constitute a little-known clinical syndrome of which the main features are a sudden general disturbance and a pock-like eruption occurring on previously damaged skin. Hitherto the inclusive term "Kaposi's varicelliform eruption" has been used without qualification regarding the causative virus. Since there is little resemblance to chickenpox, it has been suggested that the term "Kaposi's varicelliform eruption" should be discarded in favour of "systemic herpes simplex" (Barker and Hallinger, 1947), "disseminated herpes simplex" (Sulzberger and Baer, 1948), or "eczema herpeticum" (Lynch, 1945) when due to the herpes simplex virus. Anderson (1949) has suggested the inclusive term "virus pyoderma."

The term "vaccinia" is used to denote the course of the eruption at the site of inoculation with the virus of vaccinia and the concurrent reaction of the body. Normally, the vesicular eruption is limited to that site, but rarely it may appear extensively over the body, for which the term "generalized vaccinia" has long been used (Jubb, 1943). About two-thirds of these cases have suffered from pre-existing skin disease, when the special title "eczema vaccinatum" is applied. There is no evidence to suggest that the remainder are due to "a latent unhealthy state of the skin" (Jubb, 1943).

Although not entirely satisfactory, but in order to obtain some degree of uniformity and to denote the association between damaged skin and inoculation with the virus of herpes simplex and vaccinia respectively, the terms "eczema herpeticum" and "eczema vaccinatum" are suggested.

The incidence of eczema herpeticum and eczema vaccinatum is higher among children, but adults are occasionally affected. In a review of the literature, Ruchman *et al.* (1947) state that of 96 reported cases 75 occurred in children, of whom 24 were under 1 year of age. The mortality rate was 23% in children and 9% in adults. Cases are normally sporadic, although epidemics occur in dermatological wards (McLachlan and Gillespie, 1936; Esser, 1941), and have been reported in paediatric and burns units (Nimpfer, 1936; Sims and French, 1948), indicating high infectivity to susceptible persons. Eczema herpeticum may be suspected in the absence of vaccination or known contacts.

A rise in the incidence of generalized vaccinia and eczema vaccinatum occurs when large numbers of people are vaccinated—for instance, following an outbreak of smallpox. Estimates have placed the incidence of generalized vaccinia at one in 20,000 to one in 96,000, and the mortality rate at 12% to 30% (Ross, 1940; Jubb, 1943).

During the course of approximately 50,000 recent vaccinations in the Bradford area at least five known cases of eczema vaccinatum have occurred, one being fatal (McDonagh, personal communication). Three were seen personally, one of which is described.

Since November, 1952, one case of eczema vaccinatum and six cases of eczema herpeticum, including the two reported, have occurred. There were no fatalities, but all the cases of eczema herpeticum were gravely ill, three of them, at one point, being considered moribund.

The lesions of eczema herpeticum were greater in number, more uniform in size, and of more widespread distribution than those of eczema vaccinatum, which showed close grouping of larger, firm, almost indurated vesicles of varying sizes with marked local inflammatory reaction. Crusts from herpetic vesicles were easily removable whole, whereas the vaccinia crusts were adherent, and when removed left frank bleeding surfaces. Lymphadenopathy was more pronounced in eczema herpeticum than eczema vaccinatum. In both types the eruption was maximal on eczematous areas, but occasional scattered lesions on apparently normal skin were seen. All the herpetic cases developed "cheeks" which gave rise to some concern. No corneal lesions occurred. Secondary infection was milder in eczema herpeticum, although it became severe in the later stages of the four earlier cases. It should be possible in the majority of cases to distinguish clinically between the herpetic and the vaccinia types (Lane and Herold, 1944; Lynch, 1945; Lynch and Steves, 1947), although other viruses may occasionally be causative (Anderson, 1949; Leverton and Whitlock, 1949; Brain *et al.*, 1950; Miller *et al.*, 1950; Whittle *et al.*, 1950; Leider, 1951).

The damaged skin is an ideal site for chance inoculation, not only because it presents a large raw surface but because the virus is thus afforded a wider choice of cells suitable for its continued existence. There is probably no immediate tissue response, as occurs with the pyogenic bacteria. This is possibly because the virus, depending upon an intracellular environment for growth and multiplication, allows cell metabolism to proceed normally until ultimate interference with enzyme mechanisms causes complete cellular disintegration, thus liberating the viruses into the tissue fluids. Subsequent haematogenous dissemination occurs, with localization of the viruses at sites of previous injury. This may account for the apparent lack of virus-neutralizing antibodies initially, with a rise in titre during convalescence (Ruchman *et al.*, 1947). This is illustrated by Case 2, in which there was a presumed maximum possible "incubation" period of seven days, during which the child was apparently quite well. When the first toxic sign appeared no eruption was visible, but almost within the hour herpeticiform vesicles were uniformly distributed throughout the eczematous areas. All the present cases show a rise in virus-neutralizing-antibody titre, suggesting primary infections.

The association between previous injury and localization of lesions is well known—occurring, for example, in warts, lichen planus, and psoriasis, along the line of a scratch (Koebner's phenomenon).

Eczema herpeticum—and in parallel eczema vaccinatum and the vaccinia virus—represents one of the primary manifestations of herpes simplex infection (Kipping and Downie, 1948; Blank, 1949; Brain *et al.*, 1950) occurring in persons subject to a cutaneous allergic diathesis. It may well be regarded as a specific infectious disease with a short incubation period (Burnet and Williams, 1939). This infection normally occurs during childhood, and is not usually accompanied by severe reactions, though these sometimes occur (Kipping and Downie, 1948). The severity of these reactions may be due to anaphylaxis (Barker and Hallinger, 1947), although virus virulence, susceptibility of host, secondary infection, and the nature and extent of the preceding eruption are probably contributory factors (Lynch, 1945). There is probably synergic action between virus and bacteria (Lack, 1948), and the prognosis may ultimately depend upon this (Brain *et al.*, 1950). In the two cases of eczema herpeticum reported, secondary infection was comparatively mild, possibly because of early diagnosis and administration of antibiotics.

Lane and Herold (1944) suggest that eczema herpeticum occurs predominantly in persons who suffer from a definite and particular disease—for instance, atopic eczema. By contrast, eczema vaccinatum may be superimposed on many different primary diseases, inoculation occurring at a point of lowered resistance or altered epidermis. This is illustrated by Case 3, in which, despite the presence of xeroderma, there was no immediate history of preceding epidermal breach at the site of the eruption.

Although infantile eczema is a common disease, and the virus of herpes simplex widely distributed, eczema herpeticum remains a relatively rare condition. After primary infection the virus is thought to become latent and exist symbiotically with its host, being stimulated to fresh activity by other exciting agents—for example, trauma, infections, or even vaccination. Although the primary attack of herpes simplex often passes without notice, other manifestations occur, since more organs than the skin are affected (Wenner, 1944; Evans *et al.*, 1945; Lancet, 1952). These are many and varied, including all grades of severity from keratoconjunctivitis and mild stomatitis to fatal hepatic disease and encephalitis (Dodd *et al.*, 1938; Quilligan and Wilson, 1951; Florman and Mindlin, 1952). Many cases are probably unrecognized or misdiagnosed. It is feasible that, because the virus of herpes simplex prefers ectodermal tissue, infection may occur with equal frequency in the skin and the central nervous system, thus accounting for several of the otherwise unexplained "temperatures" and mild toxic reactions which so commonly occur in children. Perhaps the well-known patch of "recurrent herpes simplex" which so consistently occupies its chosen site in the skin has its counterpart within the central nervous system.

Boake *et al.* (1951), reporting an adult case of recurrent eczema herpeticum, point out that, once infected, people are liable to recurrent attacks of herpes simplex, which vary in severity, frequency, and the stimulus required to produce them. Sulzberger (1945) suggested that some of the vesicular diseases of which little is at present known may be due to the virus of herpes simplex. Other forms of infection include herpetic paronychia, bullous herpes simplex of the fingers, and follicular and sycosiform herpes simplex of the beard area.

Miller *et al.* (1950) report a patient who contracted eczema herpeticum during the second to third month of pregnancy, and was subsequently delivered of an apparently normal infant. They discuss the possible role of the herpes simplex virus in the aetiology of congenital abnormalities. It is established that German measles contracted during the first three months of pregnancy is associated with a high incidence of foetal abnormalities (Gregg, 1941; Swan *et al.*, 1946). Wesselhoeft (1947) cites mumps, herpes

zoster, scarlet fever, varicella, influenza, hepatitis, and poliomyelitis as causative factors in congenital abnormalities. The actual way they produce this effect is uncertain. It is significant that the diseases are mostly viral, and that the viruses of smallpox, chickenpox, and vaccinia may pass the placental barrier, causing death or giving rise to active foetal disease *in utero* (MacArthur, 1952). The virus of measles probably affects the foetal tissue directly, and it is reasonable to expect other viruses, including herpes simplex, to act similarly. This view is supported by France and Wilmers (1953), who report premature twin boys dying a few days after birth showing pathological features of herpetic hepatitis, and in one case encephalitis. Since no obvious portal of entry was found, they consider that infection was probably transplacental.

It is apparent that the manifestations of infection with the virus of herpes simplex vary immensely in degree and character. One of the severe types constitutes the syndrome described here as eczema herpeticum.

Summary and Conclusions

Primary infection with the virus of herpes simplex, complicating infantile eczema, is probably often unrecognized although clinical diagnosis is possible. Two infants so affected are described, and attention is drawn to the characteristic features. Vaccination, and its bearing upon eczema vaccinatum, are commented upon. One case of eczema vaccinatum is reported. Despite the Lilliputian proportion of the present series, but in conjunction with the observations of others, the following conclusions suggest themselves:

The term "Kaposi's varicelliform eruption" should be discarded. Eczema herpeticum is suggested for extensive herpes simplex complicating eczema. It represents an exaggerated response to primary infection, and is highly infectious to susceptible persons. The primary inoculation of the virus may be via the damaged skin. Subsequent dissemination is haematogenous, with localization in the damaged areas. The prognosis is variable, but may be influenced by prompt diagnosis and prevention of secondary infection. Patients affected should be rigidly isolated. Persons afflicted with atopic eczema should be safeguarded from herpetic and vaccinia contacts, including members of the medical and nursing staffs if affected. Vaccination should never be performed in the presence of any skin damage, especially atopic eczema. It is doubtful whether the parents of children so afflicted should be vaccinated. If so, the vaccination site should be carefully occluded. Finally, both eczema herpeticum and eczema vaccinatum should be regarded as notifiable diseases.

I am grateful to Dr. Allan Bigham for constant encouragement and for permission to report the cases; to Dr. H. L. W. Beach, of the Leeds Road Hospital, Bradford, and Dr. H. G. Smith, of the Public Health Laboratory, Bradford, for their assistance; and to the staff of the department of dermatology for their co-operation.

THE ADRENAL RESPONSE TO CORTICOTROPHIN EFFECT OF A.C.T.H. ON PLASMA ADRENAL STEROID LEVELS

BY

R. I. S. BAYLISS, M.D., M.R.C.P.
Physician

AND

A. W. STEINBECK,* M.D., M.R.C.P.
Research Assistant
Postgraduate Medical School, London, W.12

In certain diseases corticotrophin (A.C.T.H.) is used as a therapeutic agent with the object of reversing or modifying the underlying pathological process by increasing the secretion of adrenocortical steroids. The hormone is injected intramuscularly or intravenously, the amount given being increased or reduced according to the clinical response, which varies widely in different patients. For example, Kellgren *et al.* (1952) observed that, whereas in one patient intramuscular A.C.T.H. might relieve the symptoms and signs of rheumatoid arthritis and induce metabolic changes indicating hypercorticism, in another patient presenting a somewhat similar clinical picture the same treatment failed to produce any clinical improvement or metabolic changes. They noted that some patients showed excellent clinical improvement when given cortisone by mouth but derived little benefit from intramuscular A.C.T.H. All the cases which responded to either A.C.T.H. or cortisone showed an eosinopenia, which suggests that in these a significant increase in circulating adrenocortical hormones had been achieved.

*Postgraduate Fellow in Medicine, University of Sydney, N.S.W., and Tweddle Research Scholar, Royal Australasian College of Physicians.

In the present investigation the effectiveness of A.C.T.H. as an adrenal stimulus has been assessed by estimating the concentration of adrenocortical steroids in peripheral blood.

Materials and Methods

Adrenocortical hormones were estimated by a method which is relatively specific for 17:21-dihydroxy-20-ketosteroids such as hydrocortisone, cortisone, and their metabolic reduction products (Nelson and Samuels, 1952; Bayliss and Steinbeck, 1953). The volume of plasma required for each estimation has limited the number of determinations made in each patient. The mean value for isolated determinations in normal subjects by our method is 9.5 μ g. of 17-hydroxycorticosteroids per 100 ml. plasma with 95% fiducial limits of 3 to 16 μ g. The accuracy of the method is such that a difference of 3.3 μ g. per 100 ml. between samples is significant.

Ordinary A.C.T.H. (Armour) and a long-acting preparation of A.C.T.H. in gelatin and propylene glycol ("acthar gel") were used in this investigation.

Results with Intravenous A.C.T.H. (Table I)

A.C.T.H. dissolved in saline was infused intravenously at a constant rate as possible, the concentration being arranged so that the amount given per hour was contained in 100 ml. of saline. When the response to different doses or different batches of A.C.T.H. was determined in the same patient, an interval of at least three days was allowed to elapse between each infusion to avoid producing adrenal hypertrophy. When the response to repeated stimulation with A.C.T.H. was investigated the infusions were given daily.

Of the twelve patients only two were not clinically ill at the time of study, Case 7 being a normal control and Case 8 being referred as a case of Addison's disease, a diagnosis which was not confirmed. Of the ill patients, No. 6 had been in status asthmaticus for five days when given his first infusion, but was asymptomatic when given the second a week later.

A slight increase in the plasma level of 17-hydroxycorticosteroids was detected within 15 to 30 minutes of starting the infusion, and a definite increase had occurred within an hour (Cases 1 to 5). The levels after two hours were not very different from those at one hour, and thereafter remained constant for six hours in Case 1, but rose still higher in Case 4. When the infusion was continued for six or eight hours there was no consistent rise after the fourth hour (Cases 7 to 9). On stopping the infusion the steroid level remained high for an hour and then fell, returning towards the control value within three hours (Case 4).

The effect of different doses of A.C.T.H. given at intervals of at least three days was studied in Cases 8 to 11. In Case 8 there was little difference in the degree of steroid elevation induced by 0.25 and 2.5 units per hour for eight hours, and in Case 9 after eight hours the effect of 2.5 and 5 units per hour was the same, but 0.25 unit produced a smaller rise. Cases 10 and 11 were given repeated six-hour infusions of A.C.T.H. in doses ranging from 0 to 3.3 units per hour. The results for Case 10 (Fig. 1) suggest that a dose of about 1 unit per hour caused maximum adrenal stimulation. (The poor response when 1.8 units was infused was probably related to difficulties in maintaining the drip at a constant rate during this particular infusion.) In Case 11 maximum stimulation was obtained with a dose of about 0.7 unit per hour.

Infusions of A.C.T.H., repeated daily, produced after six or eight hours a progressive rise in the steroid level, suggesting that repeated daily stimulation increased the hormonal output from the adrenal glands (Cases 3B, 3C, 12A, and 12B).

No significant difference was observed in the response to different batches of A.C.T.H. in Cases 6 and 7. The dosage

used, however, was probably greater than the maximum stimulating dose and too large to indicate minor differences in the potency of the various batches given.

There was no apparent correlation between either the clinical state of the patient or the control level of plasma 17-hydroxycorticosteroids on the one hand and the height to which the steroid concentration rose during the infusion on the other. With two exceptions, a dose of A.C.T.H. ex-

FIG. 1.—Case 10. The response to repeated six-hour infusions of A.C.T.H. given at intervals of at least three days in doses ranging from 0 to 3.3 units an hour. The results are plotted as the rise in plasma 17-hydroxycorticosteroids at the end of the infusion above the control value obtained just before each infusion was started.

ceeding 1 unit per hour raised the steroid level to a range varying from 24 to 36 µg. per 100 ml. in all patients receiving their first infusion. The two exceptions were Case 10E, in which there was difficulty in maintaining a constant drip rate, and Case 3B, in which the steroid level rose to the unusually high value of 67 µg. per 100 ml.

Results with Acthar Gel (Table II)

A single intramuscular injection of 4 ml. of acthar gel containing 80 units of A.C.T.H. was given to 17 patients (Cases 13 to 29), all of whom were comfortable at the time of study, except three with asthma (Cases 26 to 28). Injections into the gluteal muscles did not hurt, but a few into the lateral aspect of the thigh caused some pain. A significant increase in the plasma steroid level was found after two hours, and the maximum concentration was reached in four to eight hours. Thereafter the steroid level usually fell. In Cases 13 to 16 the concentration had returned to or below the control value in 12 to 14 hours; in Cases 17 to 19 it was still elevated at 12 to 14 hours, but was at or near the control value in 24 hours; in Cases 20 to 23 it was at or near the control value in 24 hours, but few intermediate estimations were made; and in only Cases 26 to 29 was the level still raised significantly 24 hours after the injection. As a control the same volume of gelatin menstruum containing no A.C.T.H. was injected in Cases 30 and 31 and caused no significant rise in the plasma steroid level.

A single injection of 20 units of acthar gel was given to Cases 37 to 42. In five the steroid level reached a maximum within two to four hours and had returned to or below the control value by eight hours. In Case 38 absorption was apparently delayed and the maximum level observed was at eight hours.

No correlation was detected between the clinical state of the patient and the height to which the plasma steroid level rose. In several the maximum level after 80 units of acthar gel was not significantly higher than after 20 units in other patients.

Repeated Injections. Five patients were given repeated injections of acthar gel every 12 or 24 hours (Cases 32 to 36). The steroid concentration four hours after the injections rose progressively to high levels in Cases 32 and 35 (Fig. 2), but in Cases 33 and 36 the results were variable and inconsistent. The differences in individual response were considerable (compare Cases 33 and 35). No consistent elevation of the plasma steroid level was found 24 hours after the daily injections, neither did an injection every 12 hours produce a consistent elevation up to the time of the next injection.

FIG. 2.—Case 35. The progressive increase in plasma 17-hydroxycorticosteroids following repeated daily injections of 25 units of acthar gel.

Results with Ordinary A.C.T.H. (Table III)

Single Injection.—A single intramuscular injection of 20 to 50 units dissolved in 4 ml. of saline was given to 16 subjects, of whom eight were clinically ill at the time of study (Cases 45, 46, 49, 50, 51, 52, 54, and 56). The maximum increase in circulating adrenocortical steroids occurred after one to two hours. Thereafter the concentration fell, returning towards the control value in four to six hours. The height to which the steroid level rose varied widely in different patients. Cases 49 and 56A showed the greatest response of the ill patients, but the levels induced in the others were not consistently different from those found in the normal and convalescent subjects. Cases 44A and 50 showed no apparent response. The variability of the response in different individuals was so great that no significant difference in the effect of 20, 30, 40, or 50 units of A.C.T.H. could be detected.

Repeated injections of 20 to 25 units of A.C.T.H. in 4 ml. of saline were given six-hourly to Cases 45, 46, 52, and 56. The height to which the steroid level rose after two hours did not increase with successive injections, nor was the elevation of steroid concentration persistently prolonged into the sixth hour.

Discussion

At any given time the plasma concentration of adrenocortical steroids depends upon the amount being secreted by the adrenal glands and the amount being excreted in the urine and faeces, utilized in the tissues, and metabolized to compounds not estimated by the analytical method used. When the plasma level is changing rapidly too much emphasis cannot be placed on the exact concentration at a particular time. Although some degree of individual variation in responsiveness to hormones is to be expected, the differences after A.C.T.H. are marked, and may be related to differences in the responsiveness of the patient's adrenals, and also in the rate of absorption and destruction of the administered A.C.T.H., in the potency of different batches of A.C.T.H., and in the rate of utilization and elimination of the adrenocortical steroids secreted. It has been suggested

* The figure 1 indicates the first injection of A.C.T.H. or an interval of at least three days since the previous injection. Other figures indicate the number of the injection following which blood samples were taken. All injections were given six-hourly.

that the differing response of individual patients may be partly a reflection of the level of endogenous hormone production. "If the administered dose of hormone greatly exceeds endogenous production it causes some degree of hypercorticism . . . but if the administered dose is less than the amount produced endogenously the pituitary-adrenal system merely adjusts itself to a lower level of production and the net result is no change" (Kellgren *et al.*, 1952).

Duration of Response

There are striking differences in the duration of the adrenal response when A.C.T.H. is given by intravenous infusion, and when it is injected intramuscularly in saline or in gelatin. The duration of the response depends upon the length of time that the stimulating action of A.C.T.H. is applied. By intravenous infusion A.C.T.H. causes a rapid rise in the plasma steroid level, and thereafter the concentration remains constant during the remainder of a six- or eight-hour infusion. When the infusion is stopped the steroid level quickly falls, in keeping with the evidence that A.C.T.H. is rapidly destroyed in the blood stream (Sayers *et al.*, 1949; Greenspan *et al.*, 1950; Reiss *et al.*, 1951; Pincus *et al.*, 1952). Intramuscular injections of A.C.T.H. in saline usually cause a rapid rise in the plasma steroid level, reaching a maximum in one or two hours. Thereafter the concentration falls, returning in most instances to the control value in four to six hours. Two patients showed no apparent response to 20 to 25 units, and the one little response to 40 units, although A.C.T.H. of the same batch given by the same route was effective in other patients.

This lack of response to intramuscular A.C.T.H. in saline has been observed by other workers, and Thorn and his associates (Renold *et al.*, 1952) ascribe it to destruction of the hormone at the site of injection because patients unresponsive to intramuscular A.C.T.H. respond when the hormone is infused intravenously. When A.C.T.H. is incorporated in a gelatin menstruum its effect is prolonged. After large doses of 80 units the plasma steroid concentration rises within one to two hours, but does not reach a maximum until four to eight hours. Thereafter the level usually falls, returning to the control value in 12 to 24 hours. After 20 units of acthar gel the maximum level is usually reached in two to four hours and returns to the control value within eight hours. The action of gelatin is to retard absorption and perhaps also to prevent local destruction of A.C.T.H., so that the maximum plasma steroid concentration is delayed and the adrenal response more prolonged.

Degree of Plasma Steroid Increase

The degree of steroid elevation produced by A.C.T.H. infused intravenously over a constant time depends upon the rate of hormone infusion up to an optimum beyond which no further increase occurs. Our data suggest that over a six- or eight-hour period as little as 1 unit an hour will cause maximum adrenal stimulation. This dosage is similar to that suggested by Thorn and his colleagues (Renold *et al.*, 1952), who found that, whereas the urinary excretion of 17-ketosteroids increased with 0.12, 0.3, and 0.75 unit an hour for eight hours, no further increase occurred with 1.2, 2.5, or 5 units an hour. In all but two of our patients receiving their first infusion, a dose of A.C.T.H. exceeding 1 unit an hour raised the steroid level into the range of 24 to 36 µg. per 100 ml. This comparatively narrow range suggests that in these patients the degree of steroidogenesis achieved in response to maximum stimulation over six or eight hours was not greatly different from one patient to another, or, alternatively, the rate of elimination of the steroids secreted was similar. Too much significance cannot be attached to the height of the steroid levels obtained after a single intramuscular injection of A.C.T.H. in saline or gelatin because of the rapidly changing plasma concentration, but in many instances the values were comparable to those obtained after maximum stimulating doses of A.C.T.H. given intravenously. In the dosage used clinically A.C.T.H. by intramuscular injection in saline or gelatin may cause maximum adrenal stimulation, but because of variations in the rate of absorption and destruction of the A.C.T.H. the duration of the response may be so brief and short-lived that it appears submaximal.

The different responses to 20 units of A.C.T.H. infused intravenously over eight hours or injected intramuscularly in saline or gelatin are compared diagrammatically in Fig. 3.

Increasing the duration of the infusion or repeating the infusion at frequent intervals would be expected to produce a greater secretory response, and this has been achieved by the second method. In some patients repeated injections of acthar gel have induced progressively higher steroid levels, but in others this effect was not apparent, nor was it found in patients given repeated intramuscular injections of A.C.T.H. in saline, although other workers studying the urinary excretion of 17-ketosteroids have shown that this may increase adrenal secretion progressively (Sprague *et al.*, 1950). In a few instances intravenous and intramuscular A.C.T.H. produced a greater response than the level of 24 to 36 µg. usually encountered. It is not possible to relate these unusually marked responses to the control level of

circulating adrenocortical steroids, nor is it possible from our data to tell whether they are the response of adrenal glands previously hypertrophied by increased secretion of endogenous A.C.T.H. or are due to decreased excretion, utilization, or metabolism of the adrenal hormones secreted.

No striking differences in the potency of various batches of A.C.T.H. have been observed in the few observations made in this study, and further investigation of this by

FIG. 3.—The responses to 20 units of A.C.T.H. given by intravenous infusion over eight hours and by intramuscular injection dissolved in saline and suspended in a gelatin menstrium.

biological assay in human subjects would not be practicable by our method. The clinical variations in the response to intramuscular A.C.T.H. in saline observed by Kellgren *et al.* (1952) are probably related to differences in the rate of absorption and destruction of the administered hormone, although in some instances, such as the case reported by Kersley *et al.* (1952), the disease process may not be influenced by increased levels of circulating adrenocortical steroids. The clinical dosage of A.C.T.H. appears so much larger than the amount secreted endogenously that it is unlikely that the pituitary-adrenal system can adjust itself so that there is no change in the steroid output from the adrenal glands.

If therapeutic effect depends upon the duration of the elevation of adrenocortical steroids in the blood stream, A.C.T.H. in gelatin or by intravenous infusion—or cortisone or hydrocortisone—is the agent of choice. Despite the theoretical objections to infusing a foreign protein intravenously no untoward effects have been observed by us, using Armour's A.C.T.H., nor by Thorn (Renold *et al.*, 1951), whose experience is much greater than ours. It must be determined for how long and at what intervals the infusions should be given to obtain the best therapeutic benefit, but there is ample clinical evidence of the greater efficiency of this method over intramuscular injections of A.C.T.H. in saline (Gordon *et al.*, 1951; Mandel *et al.*, 1951; Renold *et al.*, 1951). Not only is this method more effective and more reliable in raising the steroid level, it is much more economical in material.

Summary

The adrenocortical response, as reflected by changes in the plasma level of 17-hydroxycorticosteroids, has been determined after intravenous infusions of A.C.T.H. and after single and repeated intramuscular injections of A.C.T.H. in saline and in gelatin.

Infused intravenously A.C.T.H. causes a rapid rise in the plasma steroid level, which remains elevated during the rest of the infusion. Over a period of six to eight hours 1 unit an hour seems to cause a maximum response.

By intramuscular injection A.C.T.H. in saline usually causes a rapid rise in the plasma steroid level, which reaches its maximum in one to two hours. Thereafter the concentration falls, returning to the control value in four to six hours. Considerable individual variations in response were observed, and are largely attributable to differences in the rate of absorption and destruction of the administered hormone.

The incorporation of A.C.T.H. in a gelatin menstrium delays its absorption and prolongs its effects to a variable extent depending upon the rate of destruction of the injected hormone.

Factors influencing the adrenal response to A.C.T.H. are discussed.

We are grateful to Miss Pamela Griffin, Miss Eunice Burton, and Mr. Clive MacKenzie, who at various times have given technical assistance. Dr. H. Robinson, Merck Institute, Rahway, N.J., kindly provided steroids used in the 17-hydroxycorticosteroid estimations, and Dr. E. E. Hays, Armour Laboratories, Chicago, the gelatin menstrium for control observations.

USE OF PHENYLBUTAZONE IN RHEUMATOID ARTHRITIS

BY

M. PEMBERTON, M.B., Ch.B.

Registrar, Rheumatology Department, Withington Hospital, Manchester

When phenylbutazone ("butazolidin") was first introduced to this country the report on its effects by Currie (1952) caused it to be hailed as a new "wonder drug" and likened to the corticosteroid hormones. Then the high incidence of toxic effects began to be discovered, and the pendulum of opinion has swung to the other extreme; at present many practitioners refuse to give the drug even to patients who have had it for long periods with no ill effects.

I hope to demonstrate that this view is pessimistic; given adequate management the drug has a definite place in the treatment of some forms of arthritis.

Present Series

Phenylbutazone was given to 210 patients (53 male, 157 female) (Table I). In 186 the condition was a polyarthritis of the rheumatoid type. The remaining 24 had a degenerative arthritis of one or both hip-joints. In most patients with rheumatoid arthritis the disease was in a chronic phase (either static or of low-grade activity), and they were attending the out-patient department. They continued to have

TABLE I.—General Classification

3 months	210	109	24	23	54
6 "	89	72	3	6	8

N.B.—All patients treated for six months are also included among those treated for three months.

various other forms of treatment as required, including gold in 37 cases. Five patients with considerable activity of the rheumatoid process were treated initially in hospital; in assessing the result the effect of rest in bed was discounted. Any patient with dyspepsia or a history of congestive heart failure was not given the drug.

The dosage used varied from 200 to 1,200 mg. daily, averaging 600 mg. Occasionally the dose was gradually reduced, but this often resulted in a lessening of the effect. Some patients were given 800 mg. daily for five days out of every seven to investigate the effect of interrupted dosage on the incidence of reactions.

At the beginning of treatment each patient received a printed sheet, warning against the principal side-effects, with instructions to report to the hospital or family doctor any untoward event. Routine blood counts were not performed.

Patients were examined before treatment, after three months' treatment, and after six months' treatment. Subjectively, improvement was measured by the patient's capacity for and comfort during normal activity at these times, compared with his or her condition before treatment; objectively, the patient was assessed by the method of Janus (1950), including erythrocyte sedimentation rate (Westergren) and joint chart. Based on subjective evidence, the results were graded as follows: ++, indicating considerable remission of symptoms, with complete absence of pain; +, moderate improvement; and 0, absence of response or even deterioration.

Results

A total of 156 patients were reviewed at three months (see Table II); 36 found the drug to be of little or no value; 104 found it to be of moderate value; and 16 had considerable benefit, often amounting to complete remission. Many

TABLE II.—Degree of Improvement After Three Months' Treatment with Phenylbutazone

Disease	Rheumatoid				Degenerative Arthritis			
	Inactive	Active	++	+	Inactive	Active	++	+
Grade Number (156)	6	47	14	10	43	20	—	14

patients thought there was less stiffness, and there seems to be no doubt that the drug has a more powerful analgesic action than aspirin in full dosage, an effect which is not objectively demonstrable.

This decreased stiffness was never convincingly demonstrated, and its method of production is obscure; it is a definite entity, and occurs in about 70% of cases.

The E.S.R. was unaltered in 60% of the cases; in the remainder there was a rise or fall of more than 10 mm. in approximately equal numbers. In a few cases an improvement in the mobility of the joints occurred, but in each case this could be ascribed to natural remission of the disease; this is felt to have occurred in many of the patients showing a ++ response. It was noteworthy that the best effects were seen in patients with a relatively small number of involved joints, though the length of history did not appear to affect the response.

Reactions

A reaction of one form or another occurred in 81 cases; a further eight had two separate reactions; and three had reactions but had not completed the first three months' treatment. The total number of reactions listed is thus 100. The total assessed (89 patients) is 42.4% of the whole series. This figure is higher than that obtained by Leonard (1953), who found an average incidence of 22% in figures obtained from the literature; it agrees with figures obtained by Hart (1953) and by Freeland *et al.* (1953); 25% of my cases have been forced to stop taking the drug owing to side-effects. The strikingly low figure of 4.7% (Currie *et al.*, 1953) may be the result of the very low dosage they recommend, which in my experience is of doubtful therapeutic value. Table III

TABLE III.—Relation of Reaction-incidence to Dosage

	Daily Dose (mg.)						Stopped Within 2/12 (No Value)
	200	400	600	800	800*	1,200

		19	31	20	18	12	
		36.54	55.36	66.6	38.3	75	

* Interrupted dosage, the drug being given for five days out of every seven. N.B.—These figures include three reactions not included in Table I, and each reaction in patients having two reactions.

shows that there is a definite increase in the incidence of reactions as the dosage is increased, and that, as has been generally agreed, 1,200 mg. daily is a dangerous dosage; at this level 75% of patients have a reaction.

The relationship between dosage and the incidence of reactions is statistically significant; using the χ^2 test, P is much less than 0.01 ($n=5$, $\chi^2=21.56$). Further, a definite reduction in the incidence occurs when using 800 mg. for five days of every seven compared with continuous administration of 800 mg. daily; in this case P is less than 0.02 ($n=1$, $\chi^2=5.68$). The difference between the former dose and 600 mg. daily is not significant, P being 0.09 approximately.

It has been suggested recently that tolerance to phenylbutazone is greatly reduced in the older patient; this is shown in Table IV; while statistically the significance is not proved, P being less than 0.07 ($n=5$, $\chi^2=10.25$), the

TABLE IV.—Relation of Reaction Incidence to Age

	Age in Years					
	21-30	31-40	41-50	51-60	61-70	71+
Total (210) Reactions (89) % reactions	13	26	46	79	40	6
	3	8	19	31	24	4
	23.08	30.77	41.3	39.24	60.0	66.6

difference in incidence between the age group 61-70 and that of the decade earlier is significant, the value of P for these two groups being approximately 0.03.

For no obvious reason males appear to be less liable to side-effects than females, the incidences being 28.3% and 47.13% respectively; this difference again is significant, P being less than 0.01 ($n=1$, $\chi^2=7.32$). That this difference is not due to unequal age distribution between the two sexes is shown by the average ages of the two groups, these being 53.57 years for males and 51.19 years for females.

It is striking that 89% of all reactions occur in the first three months of treatment; 75% occur before the end of the first month. In the second three-months period of therapy only 8.99% of patients had to stop the drug because of a side-effect.

Table V shows the relative frequency of reactions occurring during the first and the second three months. Under

TABLE V.—Type and Onset of All Reactions

	General		Dyspepsia		Rash		Oedema		Sore Mouth		Miscell.		Total

In second 3 months	—	—	2	1	—	—	1	6	1	—	—	—	8	3

S=Stopped. C=Continued.

the heading "general" are included patients having two or more reactions at the same time; this usually means the combination of a rash with oedema, with or without dyspepsia, and often with fever and considerable malaise. In these cases, and in patients having a rash alone, no significant alteration in the white-cell count, apart from an occasional eosinophilia, has been found. The rash is usually urticarial or morbilliform in type, and is often intensely pruritic, though this may be relieved by the use of antihistamines. Many of these patients have been able to return to the drug later, with no ill-effect.

Under the heading "dyspepsia" is included any gastrointestinal upset, ranging from flatulence to frank haemorrhage in one patient, who was thought to have had an acute gastric ulcer, a barium-meal examination at a later date being negative. Several patients were found to have previously unsuspected peptic ulcers, proved on x-ray examination after typical exacerbations had occurred within a few days of beginning treatment.

There is no doubt that phenylbutazone is extremely dangerous to any patient with proved or suspected peptic ulceration; several of the deaths already reported have been due to haemorrhage from such ulceration. In a few cases the "dyspepsia" merely consists of flatulence, and the patient is able to continue taking the drug in safety. Occasionally the pain is a typical colic, and has been known to mimic appendicitis; the reverse mistake could be tragic, but it almost occurred in one case in which the characteristic signs were late in appearing.

Sodium retention occurs in most patients, as has been demonstrated by regular weighing (Kidd *et al.*, 1953), but in few cases was it troublesome as overt oedema, and then was often controlled by dietary salt restriction.

The most common reaction during the second three months of treatment is soreness of the mouth, frequently accompanied by excessive salivation. Of patients who had to stop treatment at this period 75% did so because of this reaction, which recurs if the drug is given again at a later date. Usually little is to be found on examination, and the trouble is slow to pass away. No treatment has yet been found to produce any benefit.

The cases with miscellaneous reactions were as follows: (1) One patient who suddenly developed auricular fibrillation; she was hypertensive, but showed no evidence of sodium retention, and it is doubtful if this was a true toxic effect. (2) One patient who developed palpitation, and another who suffered from malaise; several patients had these symptoms in very mild form, and only as transitory effects. (3) In one patient a headache of migrainous type recurred each time after phenylbutazone had been given for three or four days; it was not relieved by salt restriction. (4) One patient who developed a febrile illness of uncertain aetiology. On the tenth day of treatment (800 mg. daily) she became febrile, but had no specific complaint or any abnormal physical signs apart from splenomegaly. Her white-cell count was 1,950 per c.mm. (polymorphs 62%, lymphocytes 33%, monocytes 5%). Three days later her total count was 4,800 per c.mm., the differential being unchanged. Her temperature settled spontaneously, and it was felt that she had a virus infection, the normal differential count making the possibility of drug-induced agranulocytosis unlikely. This is undoubtedly a reaction to be feared, but its incidence seems to be extremely low, and much less common with phenylbutazone than with amido-

pyrine. I would like to stress the futility of repeated blood counts as a precautionary measure; the alteration in the blood picture usually occurs with dramatic suddenness.

It will be seen that dyspepsia is by far the most troublesome reaction; its incidence does not appear to have been reduced by the use of thick enteric-coated tablets recently introduced. The mode of production of gastric irritation is obscure, as phenylbutazone is insoluble in an acid medium, and only slight benefit follows administration after meals.

Serum Concentration of Phenylbutazone

The drug, when given by mouth in the thinly coated tablets originally available, is rapidly absorbed, and levels of 6 to 8 mg. per 100 ml. are obtainable six hours after 800 mg. has been given. Pulver's (1950) method of estimation has been modified in the laboratories of the hospital (Moss, to be published) (see Appendix). By the new method it is claimed that 86 to 95% of the drug can be recovered, as compared with 60% by the original process. A good standard of accuracy is obtained, the mean difference of the mean of each pair of duplicate results being ± 0.3 mg. per 100 ml.

A series of readings have been obtained from blood samples taken six hours after the last dose of phenylbutazone had been given in patients who had received the drug

TABLE VI.—Serum Phenylbutazone Levels

Daily Dose	Average Level (mg./100 ml.)	No. of Readings	Range (mg./100 ml.)
200 mg.	7.4	10	3.5-12
400 "	13.7	33	6.1-19.5
600 "	14.76	17	8.5-23.5
800 "	16.3	11	4.5-20.5
800 "	15.22	17	6.6-21.8
1,200 "	19.55	9	18.8-24.3

* Interrupted dosage, the drug being given for five days out of every seven.

for at least two weeks (Table VI). It will be seen that there is no linear relationship between the concentration and the dosage. The effect of interrupted dosage is also seen. These levels are higher than those obtained by Currie *et al.* (1953) owing to the different method of estimation; in Pulver's original method whole blood is analysed, while Moss uses serum. I consider the therapeutic range to be 12 to 16 mg. per 100 ml., and to maintain this level the dose must remain steady; I was not able to confirm Currie's findings that such levels could be maintained with a dose as low as 200 mg. daily.

The blood level drops slowly after administration of the drug is stopped; appreciable levels remain after two weeks, and it appears that about 15% of the circulating level is metabolized daily. This agrees with the figures of Burns *et al.* (1952). There has, as yet, been no evidence of cumulation, and if concentrations are measured at long intervals a level at, say, three months is often lower than one obtained early in the administration. There is thus nothing to confirm the unexpected finding of a lower reaction incidence obtained with interrupted dosage: the incidence for a comparable blood level—that is, 600 mg. daily—is still much higher than for 800 mg. given for five days out of every seven. No correlation was observed between the blood level and the incidence of reactions.

In patients whose response to therapy is doubtful it is useful to obtain a blood concentration; this is at times found to be unusually low, and if raised to the "therapeutic range" the desired effect may be obtained.

Discussion

It would seem that an average incidence of reactions of 30 to 40% is to be expected from the use of phenylbutazone. In view of this high level of toxicity, should the drug be used? It is undoubtedly of benefit as an analgesic: it

seems to be the most powerful (after the corticosteroid hormones) in arthritis; and, in fact, Mason (1953), comparing the effect of phenylbutazone with that of A.C.T.H., found little difference in analgesic properties. Currie's original view that the drug has an anti-inflammatory effect was supported by the early experimental work on animals but has not been substantiated clinically (Hart, 1953; Cudkowicz and Jacobs, 1953). Is its value as an analgesic outweighed by its dangers? I consider that, given adequate medical supervision, the toxic effects should be sufficiently minimized. Agranulocytosis is the most dangerous reaction, but it is a remote chance in any given patient, who is often willing to take some risk to obtain relief from a painful and crippling disability.

To minimize reactions the following conditions must be observed.

Selection of Cases.—There must be a reasonably sure diagnosis of arthritis, either degenerative or of the rheumatoid type, including ankylosing spondylitis. It is not the treatment for rheumatic fever, in view of its lack of anti-inflammatory effect. Any patient with a history of dyspepsia, and especially in the presence of peptic ulceration, or having congestive heart failure, should not be given the drug, and older patients should be given small doses only. The most suitable type of case seems to be the patient in a "chronic" phase who has to undergo a fair amount of effort, either bread-winning or housework, often with a considerable amount of pain. It must be emphasized that this treatment has no curative value, and that accepted forms of treatment, including gold, must be used also as indicated.

Management.—The patient must be warned of possible dangers before beginning treatment, and instructed both to stop the drug and to report to the doctor immediately should any untoward effect occur.

Dosage. The optimum safe dose is still a matter for debate; Lawrence (1953) advocates using single doses of 400 mg. at prolonged intervals, of up to ten days, while Currie uses 200 mg. daily or on alternate days. These doses seem to be too low to be of therapeutic value. Hart (1953) uses 400 mg. daily, and Freeland *et al.* (1953) 600 mg. daily. This latter appears to be a commonly accepted level. My figures (Table III) show a lower incidence rate using 800 mg. daily for five days out of every seven, and this is now the dose that I use most commonly.

If these conditions are observed there seems to be no reason why the drug should not be used by the family practitioner, who must, however, be on the alert for possible cases of agranulocytosis. The patient's symptoms are of far greater value in early diagnosis than repeated leucocyte counts, which overtax pathological departments and may engender a false sense of security.

Summary

A series of 210 patients who have been treated with phenylbutazone is reviewed. The incidence of reactions is analysed. The use of the drug is discussed.

My thanks are due to Dr. H. Stuart Barber for encouragement and advice in the preparation of this paper; to Dr. R. Ellis for permission to include several of his patients in this investigation; to Mr. Moss for estimation of serum phenylbutazone levels; and to Miss Abberley for secretarial assistance.

APPENDIX

Estimation of phenylbutazone in blood has been carried out by Pulver (1950), who hydrolysed the substance, with formation of hydrazobenzene, which then rearranged to benzidine. This latter substance was estimated colorimetrically by a diazo reaction. The method used in the present investigation was based on the same series of reactions, but differs in the method of hydrolysis and the reagent used for the final colour reaction.

Reagents

(1) A.R. acetone. (2) N sulphuric acid. (3) 0.5% sodium nitrite: store at 0° C. (4) 1.8% N-sulphatoethyl-m-toluidine in water. Stored at 0° C, this solution keeps for several weeks, but should be discarded if a brown tint appears. (5) Standard phenylbutazone solution. 3 mg. per 100 ml. in A.R. acetone. Store in a tightly stoppered bottle.

Procedure

One ml. of serum is added to 4 ml. of acetone in a glass-stoppered centrifuge tube of 8-ml. capacity. After shaking well the mixture is stood for 30 minutes, and is then centrifuged, the stopper being retained in the tube during this procedure. Duplicate portions of 1 ml. of supernatant solution are removed and transferred to conical "pyrex" centrifuge tubes of 15-ml. capacity, graduated to tenths of a millilitre. A duplicate standard is set up simultaneously by taking two portions of 1 ml. of the standard phenylbutazone solution, in similar graduated centrifuge tubes.

The bulk of the acetone is now cautiously evaporated off in a hot-water bath, the tubes being agitated gently to prevent loss by spurring or bumping.

One ml. of N sulphuric acid is added to each tube, and the tubes are placed in a boiling-water bath for four hours. At half-hourly intervals the volumes in the tubes are restored to 1 ml. by addition of distilled water. The final volume is 1 ml. After hydrolysis the tubes are chilled in ice-water, and 0.5 ml. of ice-cold sodium nitrite solution is added, followed by 2 ml. of ice-cold N-sulphatoethyl-m-toluidine, the solution being mixed well after each addition. The purple colours are allowed to develop for 30 minutes at room temperature.

The serum tubes have a slight turbidity at this stage, owing to the presence of unsaponified lipid material. This turbidity is removed by the addition of 0.25 ml. of 40 to 60° light petroleum, shaking briefly, and centrifuging. Three ml. of the aqueous phase is then removed. The standards are similarly treated with light petroleum.

The coloured solutions are read in a spectrophotometer at 525 mg. or in a colorimeter with appropriate filter. The standards correspond to a serum level of 15 ml. per 100 ml.

A linear relationship was found between colour intensity and concentration of phenylbutazone. Normal serum gives a negligible colour by this method. Recoveries of phenylbutazone added to normal sera were 86 to 95%. In a series of 50 estimations the duplicate serum phenylbutazone levels differed from their mean by amounts varying from ± 0.0 to ± 0.8 mg. per 100 ml. The mean difference from the mean was ± 0.3 mg. per 100 ml.

The N-sulphatoethyl-m-toluidine was supplied by Imperial Chemicals (Pharmaceuticals) Ltd., Manchester. I am grateful to Geigy Ltd. for a gift of purified butazolidin.

The *British Journal of Anaesthesia* enters its second quarter-century of publication with a modernized format and an increase in size. In future it will appear six times a year instead of quarterly. The January issue, which includes a historical note on gas cylinders, a short biography of Dr. Z. Mennell, and papers on current techniques and modern anaesthetic agents, reflects the important part which British workers have played and continue to play in the development of anaesthesia.

APHONIA AND DEAFNESS IN
HYPERPARATHYROIDISM

BY

J. A. SIMPSON, M.B., F.R.F.P.S., M.R.C.P.

Lecturer in Medicine

(From the Gardiner Institute of Medicine, University
of Glasgow)

The role of calcium in variations of the excitability of nervous tissue is generally accepted. A relatively small decrease in the serum ionized calcium causes hyperexcitability of sensory and motor nerve fibres, and spontaneous activity may be sufficient to cause paraesthesiae and muscular spasm, which is the basis of tetany. Conversely, increased ionized calcium in the blood might be expected to decrease nerve excitability. The muscular weakness commonly found in cases of hyperparathyroidism has been so explained (Albright and Reifstein, 1948), but surprisingly few sensory symptoms have been reported. Aphonia and deafness were noted by a patient (Case 1) at a time when hypoexcitability of nerves was certainly present. Cases 2 and 3 were seen two years after operation, so data are not complete. It is suggested, however, that they closely resemble Case 1 in the type of symptoms exhibited, and in the prompt and permanent relief after removal of a parathyroid adenoma. They are reported by courtesy of Mr. J. Hinton Robertson.

Case 1

A married woman aged 58 was admitted to the Western Infirmary, Glasgow, under Mr. R. Barnes in October, 1952. In 1947 she had complained of weakness of the right leg sufficient to prevent her lifting the foot. This gradually improved, but once again deteriorated in March, 1951. She then became easily tired and both legs felt "slow and stiff," so that she was bedridden. In February, 1952, vomiting, associated with eating greasy food, and right subcostal pain were attributed to cholecystitis. Thereafter she complained of increasing weakness, pains in the legs, headache, anorexia, thirst, polyuria, and severe constipation. About the same time her voice became almost inaudible, she noted difficulty in opening her eyes and she had severe deafness, associated with sensations of being cut off from people—"as if my ears were blocked" and "as if the whole head was shutting

FIG. 1.—Case 1. Audiogram. O—O Rt. ear. X—X Lt. ear. Inset, bone conduction.

in." Deafness was severe for about a month, then gradually cleared. It was absent when she was examined at the orthopaedic clinic by Mr. T. Gardner, who diagnosed hyperparathyroidism as the cause of her limb pains.

Mr. Barnes kindly allowed me to investigate the case in the Gardiner Institute. There was generalized weakness with hypotonia but normal reflexes, the serum calcium was 15.0 mg. per 100 ml., serum inorganic phosphate 2.8 mg. per 100 ml., and serum alkaline phosphatase 145 K.-A. units. The serum calcium level slowly dropped to 13.6 mg. per 100 ml. Hearing was good and the ears were apparently normal. Dr. J. C. McKinley found the drum-heads normal, Rinne test positive, and bone conduction good in each ear. Whispered voice was heard at 6 ft. (1.8 m.) from each ear, and conversational voice at 18 ft. (5.5 m.). An audiogram was within the normal range in relation to the patient's age (Fig. 1). The response of

FIG. 2.—Case 1. Accommodation curve of right ulnar nerve. The slope is 31; the time-constant of accommodation (reciprocal of slope) is 32.3 msec. The shaded area shows the normal range for women (Solandt, 1936).

the right ulnar nerve to exponentially rising electric currents of variable time-constant was tested, as described by Solandt (1936), with Andrew's (1952) stimulator to estimate its time-constant of accommodation (λ) (Hill, 1936). It was found to be 32.3 msec. (Fig. 2).

A large parathyroid adenoma was removed from the upper mediastinum by Professor C. F. W. Illingworth on November 27, 1952. Symptoms and signs of latent tetany developed and were controlled by calcium gluconate injections, with calcium lactate and calciferol orally. A normal biochemical picture has been maintained. Strength was rapidly increasing, the patient was able to walk unsupported, and the bones were recalcifying. There has been no recurrence of aphonia or of deafness.

Case 2

A married woman aged 49 was admitted to the Victoria Infirmary, Glasgow, with spontaneous fracture of the femoral neck in April, 1950. A radiological diagnosis of hyperparathyroidism was confirmed by the biochemical findings. The serum calcium content was 15.8 mg. per 100 ml., serum inorganic phosphate 2.85 mg. per 100 ml., and serum alkaline phosphatase 59 K.-A. units. For one year previously she had complained of spells of deafness and tinnitus in the left ear. She was discharged from hospital after a negative exploration of the neck, but was readmitted in May, 1951. Her symptoms were as before, with the addition of dyspnoea on slight exertion, tiredness, mental depression, spells of tingling of the hands, and marked huskiness of speech. Serum calcium was now

12.2 mg. per 100 ml., serum inorganic phosphate 3.05 mg. per 100 ml., serum alkaline phosphatase 31 K.-A. units. A parathyroid adenoma was removed from the mediastinum by Mr. J. Hinton Robertson; signs of latent tetany developed, but spasm was prevented by injection of calcium gluconate. Fatigue, deafness, and tinnitus disappeared after operation, and had not returned when I examined the patient in March, 1953, and found no evidence of aural abnormality.

Case 3

A spinster aged 49 years was admitted to the Victoria Infirmary in December, 1950, with cardio-renal failure due to hypertension and with auricular fibrillation. She complained also of pains in many parts of the body, present for several years, and of weakness of the muscles. She had very bowed legs, kyphoscoliosis, and early lenticular cataract. Radiology suggested a diagnosis of hyperparathyroidism, which was confirmed by the biochemical findings (serum calcium 14.5 mg. per 100 ml.; serum inorganic phosphate 2.18 mg. per 100 ml.; serum alkaline phosphatase 62.8 K.-A. units). The reflexes were recorded as "physiological." A parathyroid adenoma was removed by Mr. J. Hinton Robertson in February, 1951, transient post-operative tetany being readily controlled. The patient was well when I examined her in March, 1953. In response to questioning she stated that she had noticed attacks of singing in the ears when muscle weakness was present before the operation, but had had no auditory disturbance since (without any specific treatment). In March, 1953, hearing was normal.

Discussion

Since 1937 five cases of hyperparathyroidism have been investigated in the Gardiner Institute, including Case 1 above. Of the other four, deafness was recorded in two. Unfortunately the deafness was not further investigated, and the case notes do not record the post-operative hearing state. The two patients who were admitted in 1937 and 1942 cannot now be traced.

The three cases presented exhibit the classical symptoms of hyperparathyroidism, including muscular weakness and hypotonia, which are attributed to diminished nerve excitability caused by hypercalcaemia (Albright and Reifstein, 1948). Though the husky voice of Case 2 is no doubt due to previous trauma, the aphonia described by Case 1 is thought to be due to muscle weakness of the same type. Gutman, Swenson, and Parsons (1934) report the case of a patient who was "almost aphonic," with a serum calcium content of 13.9 mg. per 100 ml. On laryngoscopy no abnormality was noted, except oedema of the mucous membrane.

Motor symptoms are alarming enough to a patient to be reported, but sensory symptoms other than pain tend to be ignored if thought irrelevant by both patient and examining physician. At any rate, a review of the literature on hyperparathyroidism reveals few references to disturbances of function of afferent nerves. Vertigo and dizziness are common complaints which are too indefinite to analyse. Gutman, Swenson, and Parsons (1934) also report a case in which the patient complained of occasional numbness of the extremities and pruritus, and the case records sometimes mention deafness without giving details—for example, Werner, 1942. Nevertheless, Cantarow (1947) finds that in late cases of hyperparathyroidism complaint of muscle weakness is made in 15%, paraesthesiae in 2%, and deafness in 1%. Reifstein (1950) states that decrease in auditory acuity occurs in hyperparathyroid patients, and Albright and Reifstein (1948) suggest that nerve deafness should be expected, but the case they quote as evidence was believed by Hunter and Turnbull (1931), who report it, to have otosclerotic deafness. It is common to find increased auditory acuity in tetany (Ucko, 1951), but this is always of short duration.

Bellin and Gershwin (1935) report severe deafness and decrease of muscle tone in a patient with hyperparathyroidism. "She was absolutely definite in stating that her hearing was markedly impaired since all these peculiar

things were happening to her." The serum calcium was 19.5 mg. per 100 ml., rising to 22 mg. before operation, and the serum inorganic phosphate was 6.8 mg. per 100 ml. The authors state that both eardrums showed calcification—more on the right side, "where almost complete deafness existed." Unfortunately they included no tests of bone conduction. After parathyroidectomy the serum calcium levelled out at about 11.6 mg. per 100 ml., muscle tone increased to normal, and hearing returned completely in the left ear and partially in the right. At the same time they observed disappearance of the calcific deposits in the eardrums. One hesitates to deny the possibility that metastatic calcification of the eardrums could be responsible for deafness in this case, yet it should be noticed that the authors found no other evidence of metastatic calcification and no renal calculi. Metastatic calcification most commonly affects those tissues in which acid secretion takes place (kidneys, stomach, lungs), or in scar tissue (Cantarow, 1947), so that it would be surprising to find that both eardrums were the only sites of metastatic calcification in hyperparathyroidism. Further, after removal of a parathyroid adenoma there is no tendency for resorption of metastatic deposits of calcium—indeed, they may increase—especially when the serum calcium level remains abnormally high.

On the other hand, the symptoms are strikingly like those of Case 1 of the present report, and comparison with Cases 2 and 3 suggests that auditory disturbance is greater when muscular weakness is severe, and so may have the same cause. The serum calcium level fluctuates considerably in untreated hyperparathyroidism (Cope, 1948) and may even return temporarily to a normal level (cf. Case 2), and symptoms are correspondingly variable. The serum calcium level was falling and muscle power improving when Case 1 was admitted to hospital. It may be presumed that the serum calcium had been higher than the recorded level at the time of maximum weakness, vomiting, aphonia, and deafness, yet even when the serum calcium was 15 mg. per 100 ml. and there was no deafness (Fig. 1), the accommodation of the motor fibres of the right ulnar nerve was greatly increased, with a time-constant of 32.3 msec. (Fig. 2), the lower limit in normal women being 50 msec. (Solandt, 1936).

The "time-constant of accommodation" (λ) of a nerve (Hill, 1936) is an index of its excitability by an electrical stimulus. It is lowered by increasing the calcium in the nerve's environment (Solandt, 1936). Increased accommodation (decreased λ) reduces the frequency of response of a nerve to a stimulus. Galambos and Davis (1943) have shown that alteration of loudness of a sound at the ear is signalled by the auditory nerve as variation in impulse-frequency so that the effect of increasing accommodation would be to decrease the apparent intensity of sound.

The possibility that deafness is determined by the bone changes rather than the biochemical changes must be examined, as at one time otosclerosis was widely believed to be due to hyperparathyroidism (Mayer, 1917), and deafness is also associated with other bone diseases. In osteitis deformans (Paget's disease) it is often attributed to nerve compression in the auditory canal, but otosclerosis is said to be common in advanced cases (Hunter, 1944), though Lindsay and Perlman (1936) and Wilson and Anson (1936) found no conclusive evidence for a close relationship. Anson and Wilson (1937) found that the deafness was usually due to damage of the inner ear from involvement of the petrous temporal bone. Otosclerosis also occurs in 60% of cases of osteogenesis imperfecta (Hunter, 1944), apparently as an associated genetic abnormality, and van der Hoeve and de Kleyn (1918) described degeneration of the labyrinth in this condition. It might seem, then, that deafness in hyperparathyroidism was of the same nature, but in these bone diseases, which are unaccompanied by hypercalcaemia, the deafness shows no tendency to spontaneous remission. It is inconceivable that otosclerosis can explain the loss of hearing in the cases of hyperparathyroidism in which deafness closely follows excessively high blood calcium levels, and is promptly and permanently relieved after parathyroidectomy.

The evidence cited cannot be regarded as conclusive, as the cases were all seen after recovery from deafness, but it is highly suggestive of a close relationship between reversible deafness, aphonia, muscular weakness, increased nerve accommodation, and hypercalcaemia. It is perhaps relevant to note that other causes of "chemical deafness" are quinine, which is well known to block nerve conduction (Cooper, 1924), and analgesics such as salicylates and acetanilid (Macht, Greenberg, and Isaacs, 1919). The latter drug at least has been shown to depress muscle-nerve excitability (Macht, 1919). Hyperparathyroidism is rare and is usually diagnosed at orthopaedic clinics. It is hoped that this paper will stimulate interest so that the occurrence of deafness can be fully investigated before and after operation.

Summary

Disturbances of hearing are reported in five cases of hyperparathyroidism, and aphonia in one case.

In three cases these symptoms disappeared after removal of a parathyroid adenoma, and examination showed no defect of hearing.

Increased nerve accommodation, demonstrated in one case, is suggested as a possible cause of these symptoms.

The cases are reported so as to draw attention to an unusual cause of nerve deafness.

I wish to thank Professor Sir John McNee, Mr. Roland Barnes, and Mr. J. Hinton Robertson for permission to study their cases; Mr. A. M. Andrew, of the department of physiology, for the use of his stimulator; and Dr. J. C. McKinley for the audiogram in Case 1.

The National Multiple Sclerosis Society has published a 32-page booklet on *Psychological Factors in the Care of Patients with Multiple Sclerosis*, written by M. P. Harrower and R. Herrmann. A brief summary of facts on the nature of the disease and its management in the U.S.A. is followed by a discussion on the personality of the patient, the psychological aspects of his relations with the doctor, and the psychological difficulties peculiar to those with disseminated sclerosis. The use of psychological testing in diagnosis and as an adjunct to therapy is described. Group therapy for patients and relatives is advocated; occupational therapy in the home is important, and rehabilitation centres are also of value. The booklet may be had free of charge from the Society at 270, Park Avenue, New York, 17, U.S.A.

SKIN LESIONS AND DEAFNESS IN DISSEMINATED TUBERCULOSIS

BY

ANDREW W. LEES, M.D., F.R.F.P.S.
M.R.C.P.Ed., D.P.H.

AND

I. B. MUNRO, M.B., Ch.B.

(From Ruchill Hospital, Glasgow)

Skin lesions which form part of a clinical complex produced by the dissemination of active foci of tuberculosis in various organs of the body are comparatively infrequent, so that when they are encountered their significance may be overlooked. Early recognition of these lesions is desirable when the tuberculous disease is chronic. When it is acute, skin involvement may provide the earliest means of identifying the nature of a disease in which prompt administration of appropriate treatment is of vital importance.

In the first four cases of disseminated tuberculosis reported below cutaneous lesions were either prominent presenting features of the disease or were or might have been of diagnostic assistance; and it is interesting that deafness was recorded in two of them. In Cases 5-8 abnormalities of the skin produced by subcutaneous tuberculous lesions were important clinical features, and increasing deafness was a presenting symptom in the only one in which the disease was of an overwhelming nature.

Case 1

A man aged 50 was admitted to Ruchill Hospital on March 21, 1951, with a diagnosis of erysipelas. He had been in another hospital from December 15, 1950, to January 29, 1951, with a left lower lobe pneumonia which had failed to respond to penicillin, but showed complete resolution clinically and radiologically after treatment with aureomycin. Subsequently he remained well until March 18, when he developed what he thought was a sty on the left upper eyelid; on the 19th the inflammation involved the periorbital skin, and later other cutaneous lesions developed on the back of the neck.

On admission to Ruchill Hospital he was moderately ill. His pulse was 80 and respirations 16. His temperature was normal on admission but rose a few hours later to 103° F. (39.4° C.) and continued swinging to 103-104° F. (39.4-40° C.) until death. He had a purplish swelling round the left eye, with numerous small papules and pustules in the affected skin. On the back and right side of the neck were several infiltrated bluish plaques with surrounding erythema and scaling and also numerous small papules and pustules. A linear, infiltrated purplish lesion on the right malar region and several small crusted papules on the front and back of the chest were seen. The tip of the spleen was just palpable. The urine contained a trace of albumin. Blood examination showed: leucocytes, 6,000 per c.mm. (polymorphs 44%, lymphocytes 46%). A chest x-ray film on March 28 showed marked right hilar enlargement; the lung fields were clear except for a calcified primary focus in the right upper lobe with associated calcification in the right paratracheal glands. Sputum examinations were negative for *Mycobacterium tuberculosis*. Penicillin was given on admission, followed by aureomycin, and, from April 4, streptomycin, 1 g. daily, but there was no response.

Repeated blood examinations during the illness showed a steady decline in the leucocyte count from 6,000 on admission to 1,000 per c.mm. a few days before death; the erythrocytes declined in that period from 3,200,000 to 2,100,000 per c.mm. The patient died on April 11.

Post-mortem examination revealed grossly enlarged, caseous, and necrotic right paratracheal glands. The adjacent right main bronchus was the site of extensive tuberculous caseation in which many tubercle bacilli were demonstrated. The left lower lobe showed only some post-pneumonic fibrosis. Sections of the liver, spleen, and sternal bone marrow showed numerous miliary necrotic foci, round a proportion of which was a feeble cellular response. The kidneys were apparently healthy. By mischance the affected skin of the neck was not histologically examined.

Case 2

A man aged 20 was admitted to Ruchill Hospital on April 13, 1952. About a month previously he had begun to feel lethargic, and for the past five days he had suffered from rigors, headaches, pains in the limbs, and nausea. Three days before admission a rash appeared. On examination he appeared seriously ill. His temperature was 101° F. (38.3° C.), pulse 100, respirations 20, and B.P. 120/75. Scattered over the distal parts of the upper limbs, buttocks, trunk, and back of the left ear were little papules about 10-20 mm. in diameter, surrounded by an area of erythema and topped by a crust. There were also a few bright-red petechiae on the forehead and behind the ears. The urine contained a trace of albumin. A blood count showed: erythrocytes, 4,300,000 per c.mm.; Hb, 12.6 g. per 100 ml.; leucocytes 8,400 per c.mm. (polymorphs 53%, lymphocytes 35%).

On April 14 penicillin treatment was begun, but the patient's condition began to deteriorate, and next day he became moderately deaf and little areas of faucial ulceration were noted; there was also a post-nasal discharge tinged with blood. He became irrational and incontinent on the 16th, and next day a fresh crop of petechiae appeared on the distal part of the limbs and a few on the trunk and face. It was observed that in a day or two the "petechiae" developed into little crusted papules of the type noted on admission. His temperature swung between 104 and 105° F. (40 and 40.6° C.). Streptomycin, 1.5 g. daily, plus P.A.S. was begun on April 17.

Histological examination of a skin-biopsy specimen taken on April 19 showed necrosis of surface epithelium and the upper part of the corium in ulcerated areas, but staining with Ziehl-Neelsen's method did not demonstrate acid-fast bacilli. The patient continued to improve somewhat, although the pyrexia continued, and by April 22 he was rational and no longer incontinent, and no more skin lesions had developed.

On April 17 a chest radiograph showed a circular lesion about 1.5 cm. in diameter in the right upper lobe and a similar lesion in the left upper lobe; the appearances suggested fibro-calcific quiescent pulmonary tuberculosis. Liver-function tests showed no abnormality, and the liver was not enlarged, but the biopsy of this organ on May 19 showed several granulomatous follicles with giant-cell systems, the appearances corresponding with tuberculosis. Pyrexia continued, the patient's condition deteriorated, and by June 2 he was semi-moribund; isoniazid, 8 mg. per kg. was then substituted for streptomycin. The improvement was dramatic: his temperature finally settled on July 16, he made a steady recovery, and has remained well.

During his stay in hospital attempts to culture *M. tuberculosis* from sputum, gastric washings, urine, and faeces were unsuccessful.

Case 3

A man aged 69 was admitted to Ruchill Hospital on April 19, 1951. For some time before admission he had lost weight and more recently had complained of anorexia. Three weeks before admission a slightly productive cough had developed, together with pain under the sternum. On admission his temperature was 101° F. (38.3° C.), pulse 80, and respirations 20. On the front and back of the chest

were a few dark-red macules and nine dull-red papules, some of which were surmounted by a crust. The lesions closely resembled acne vulgaris, but had appeared only about six weeks before admission. Physical examination was otherwise negative. Blood examinations showed: erythrocytes, 4,000,000 per c.mm.; Hb, 11 g. per 100 ml.; leucocytes, 4,600 per c.mm. (polymorphs 55%, lymphocytes 42%). Pyrexia continued, the temperature swinging between 101 and 102° F. (38.3 and 38.9° C.). A chest-film report on April 24 stated: "The right root is enlarged, but there is no intrapulmonary lesion. There is a healed primary focus at the right apex."

On April 27 a right pleural effusion developed. A chest-film report on May 4 stated: "There is now considerable thickening of the right pleura and some loss of volume of the right lower lobe. The right root remains enlarged. The appearance is now strongly suggestive of bronchial carcinoma." A biopsy of a skin lesion taken on May 4 showed giant-cell systems suggestive of tuberculosis. Streptomycin, 1 g. daily, and P.A.S., 20 g. daily, were started on May 13. On May 29 it was reported that *M. tuberculosis* had been cultured from pleural fluid received on April 27. Direct examinations and culture of sputum, bone marrow, urine, gastric washings, bronchial secretions, and materials from a skin lesion were negative for *M. tuberculosis*. The temperature settled on May 29, and no further skin lesions appeared. Streptomycin and P.A.S. therapy was stopped on July 13 after 67 g. of streptomycin had been given.

The patient left hospital against advice on August 11 and was readmitted in poor general condition on September 21. Apart from slow deterioration in his general condition, and extension of the disease in the right lung in spite of further streptomycin and P.A.S. therapy, there were no additional significant clinical features. He died on March 15, 1952.

Post-mortem examination revealed bronchopneumonic tuberculosis in the right lower lobe with a few areas of more chronic disease here and at the right apex. Areas of recent tuberculous caseation were scattered in the left lung. The right paratracheal glands were enlarged and caseous. Tuberculous pericarditis was noted, and the peritoneum was studded with numerous tuberculous foci. The liver was of normal size, but was riddled with large and small tuberculous abscesses; the spleen was similarly affected. The mesenteric glands were caseous. The kidneys were apparently healthy. Section of the bone marrow showed no abnormality.

Case 4

A woman aged 71 was admitted to Ruchill Hospital on December 21, 1952. She had been in excellent health until five months before that date, when dysphagia had occurred. Examination of the throat and a barium swallow in a general hospital had revealed no abnormality. Subsequently she complained of weakness, loss of weight, hoarseness, pain in the throat, and slight productive cough. About two months before admission her hearing, which had previously been good, steadily deteriorated until she became almost totally deaf. Dusky-red papules appeared in the skin and continued to do so in spite of penicillin.

On admission her temperature was 98.4° F. (36.9° C.), pulse 78, respirations 18, and B.P. 110/70. She was well built but had obviously lost a good deal of weight. She was intelligent, and, apart from almost total deafness, no abnormality was detected in the nervous system. The tongue, uvula, and pharynx were inflamed and ulcerated; the larynx could not be properly examined. The right cervical glands were enlarged. Nine dull-red papulo-necrotic lesions about 0.5-1 cm. in diameter were noted on the forearms, chest, and face. The tip of the spleen was palpable. Physical examination of the chest was negative, but radiography showed small areas of consolidation scattered in both lung fields. Blood examination showed: erythrocytes, 4,600,000 per c.mm.; Hb, 9.8 g. per 100 ml.; leucocytes, 7,600 per c.mm. *M. tuberculosis* was not detected on repeated direct microscopical examination of the sputum.

Biopsy of a skin lesion on December 22 was reported on as follows: "The ulcer base is composed of tuberculous granulation tissue with giant-cell systems, early caseation, and superadded acute pyogenic inflammatory change. Acid-fast bacilli are present." The patient died suddenly on January 4, 1953.

Post-mortem examination revealed numerous small areas of tuberculous disease in both lungs, especially numerous in the upper lobes and left lower lobe. The tracheo-bronchial glands were enlarged, but not caseous. No disease was apparent in the stomach, intestines, or liver, but the mesenteric glands were caseous. The spleen was studded with caseous foci, and miliary lesions were present in the left kidney. The right kidney was healthy.

Case 5

A man aged 57 was admitted to Ruchill Hospital on February 20, 1951. He had been in good health until about three weeks before admission, when he began to suffer from weakness, loss of appetite, and a cough which later produced a little sputum. About a week before admission he became deaf.

On admission he was seriously ill. The pulse was 80, and the respirations 20. His temperature was 98.4° F. (36.9° C.), rising in the evening to 102° F. (38.9° C.), and continued to swing until his death. Examination of the chest revealed slight impairment of the percussion note and fine crepitations over the right lower lobe. The liver edge was palpable two fingerbreadths below the costal margin. The patient was moderately deaf. Physical examination was otherwise negative. The urine contained some albumin and a few leucocytes; Fouchet's test for bile pigments was positive. A blood count showed: erythrocytes, 4,500,000 per c.mm.; Hb., 11.8 g. per 100 ml.; leucocytes, 4,000 per c.mm. (polymorphs 87%, lymphocytes 7%). Blood urea was 85 mg. per 100 ml., and a van den Bergh test gave a delayed direct reaction. X-ray examination on February 22 showed extensive consolidation throughout the right lung and in the left upper and mid-zones; the affected areas had a hazy rather than a solid appearance. Repeated sputum examinations were negative for *M. tuberculosis*.

On February 27 10 painless nodules about 20 mm. in diameter were felt in the subcutaneous tissues of the anterior abdominal wall, and two were noted on the anterior chest wall. A nodule was excised and sent for pathological examination; the report was as follows: "Histological examination shows skin in which there is much congestion of the arterioles in all layers, but no other abnormality."

Slight jaundice was noted on March 1. On March 6 the leucocytes numbered 7,000 per c.mm. (polymorphs 82%, lymphocytes 13%). The patient died on March 7.

Only a limited post-mortem examination was allowed. A nodule on the abdomen was opened; pus flowed out and many acid-fast bacilli were demonstrated on direct microscopical examination; *M. tuberculosis* was grown on culture of the pus. A portion of liver was removed; histological examination showed lesions which were mainly necrotic, though some showed a slight surrounding cellular reaction; numerous acid-fast bacilli were noted in the lesions.

Case 6

A boy aged 16 was admitted to Ruchill Hospital on March 27, 1950. Eight weeks before admission two swellings had appeared simultaneously—one over the dorsum of the right foot and one in the left mastoid region. He was admitted to a surgical ward in a general hospital. The swellings became fluctuant; penicillin was given, and both abscesses were incised. Bacteriological examination of pus revealed *M. tuberculosis*, and a subsequent chest radiograph showed mottling of a coarse miliary character in the right upper lobe.

On admission to Ruchill Hospital his temperature was normal, and subsequently remained normal except for an

occasional rise to 99° F. (37.2° C.). Pus was draining from the wounds in the abscesses, and *M. tuberculosis* was grown on culture. Chest radiography showed the features previously described, and a radiograph of the mastoid processes showed no evidence of bone involvement. Culture and guinea-pig inoculation of gastric washings, and a 24-hour specimen of urine did not reveal the presence of *M. tuberculosis*. Treatment with streptomycin and P.A.S. was instituted on April 3, and the patient was discharged well on September 27.

Case 7

A youth aged 18 was admitted to Ruchill Hospital on August 10, 1950. About two years before admission a swelling had developed on the dorsum of his right hand. Two months before admission a subcutaneous nodule had appeared under the nail of his third right finger, another on his left wrist, and several on the right forearm; some of these nodules subsequently became fluctuant. A chest film at that time showed an enlarged left root with infiltration into the lung field.

On admission his general condition was good, his temperature was normal, and he felt well. X-ray examination of the chest now showed miliary opacities throughout both lungs. Treatment with streptomycin and P.A.S. was begun on August 17 with a dosage of 1 g. of streptomycin and 20 g. of P.A.S. daily; a total of 100 g. of streptomycin was given. The lung fields cleared by January 18, 1951, and, although several further abscesses appeared on the left forearm soon after admission, most had resolved in a further month; one or two continued to discharge pus from time to time, but all had healed by June, 1951. Several samples of pus aspirated from different abscesses were cultured, but *M. tuberculosis* was grown on only one occasion.

Case 8

A man aged 21 was admitted to Ruchill Hospital on December 4, 1949. He complained that for some months he had not felt well, had developed a productive cough, and had lost weight. Six weeks before admission he noted the appearance of a lump on the left foot, another on the right forearm, and one month before admission a painful swelling of the right testicle.

On examination his temperature was 99° F. (37.2° C.). Fluctuant, tender subcutaneous swellings were present on the dorsum of the left foot, the right forearm, and the anterior surface and left side of the neck; there were more fluctuant, tender subcutaneous swellings on the left forearm, left wrist, dorsum of the left hand, left knee, and right and left thighs; the lower pole of the right testicle was painful, tender, and swollen.

The liver was palpable two fingerbreadths below the costal margin, and examination of the chest revealed rales and diminished air entry in the left lower lobe. *M. tuberculosis* was cultured from sputum and from pus aspirated from a fluctuant swelling. A chest radiograph showed fibro-caseous tuberculosis in the left upper lobe and also miliary opacities, apparently of more recent origin, in the same area. The left lower lobe was emphysematous. Blood examination showed: erythrocytes, 4,400,000 per c.mm.; Hb., 14.4 g. per 100 ml.; leucocytes, 17,200 per c.mm. (polymorphs 53%, lymphocytes 33%).

With streptomycin and P.A.S. therapy the miliary opacities in the left upper lobe cleared, but fresh subcutaneous lesions continued to appear every few weeks despite repeated courses of these drugs until isoniazid therapy (8 mg. per kg. daily) was instituted on April 24, 1952. After left pneumonectomy and thoracoplasty on December 1, 1952, the patient improved and is now well.

Discussion

These case reports indicate that early recognition of the nature of skin lesions appearing in the course of the graver forms of disseminated tuberculosis may be of great value,

because there may be no other definite lead to the correct diagnosis, and appropriate treatment must be prompt to have a chance of achieving success.

Some of the lesions described as involving the skin were really subcutaneous, consisting of nodules which in some instances developed into abscesses of various dimensions. When the lesions arose in the dermis itself they varied greatly in appearance: in Case 1 they were multiform, consisting of papules and pustules in purplish-red skin, and violaceous infiltrated lesions; in Case 2 "petechiae" developed into tiny papules surmounted by a vesicle and later crust; in Case 3 innocuous-looking papules resembled the lesions of acne vulgaris; and in Case 4 the lesions looked like small indolent furuncles.

Biopsy specimens were histologically examined in Cases 2, 3, 4, and 5. The one from Case 2 showed only areas of necrosis, but giant-cell systems and areas of caseation were noted in those from Cases 3 and 4, and acid-fast bacilli were also demonstrated in that from Case 4. The specimen from Case 5 was of a small subcutaneous nodule, and the only abnormality noted was dilatation of capillaries and arterioles; when another nodule was examined *post mortem* eight days later its centre contained pus in which there were many tubercle bacilli.

In fulminating cases of disseminated tuberculosis histological examination of affected tissue may show areas of necrosis swarming with tubercle bacilli rather than characteristic tubercle formation. Necrosis was the prominent histological feature in Cases 1 and 5. In such instances involvement of the bone marrow may give rise to abnormalities of the peripheral blood: Ball *et al.* (1951) reported three cases with leucopenia and reviewed similar cases; Leibowitz (1938) recorded a case with a leukaemoid blood picture and reviewed similar cases; and Rennen (1922) reported a case with polycythaemia. Leucopenia, amounting by the time of death to a virtual agranulocytosis, was noted in Case 1. Histological examination of the bone marrow supported the suggestion of Ball *et al.* that sternal marrow examination may be diagnostically helpful in cases of disseminated tuberculosis, especially when there is an abnormal blood picture; and Horowitz and Gorelick (1951) have described a suitable technique for culture.

Rich and McCordock (1929) found that miliary tuberculosis occurred four times as often in white persons over the age of 60 as it did in those aged between 20 and 60, and Spain (1947) noted a similar age distribution in adults with haematogenous tuberculosis.

The relatively high proportion of older persons among those suffering from disseminated tuberculosis suggests that in later years there is a waning of immunity in some people, so that tuberculous disease takes in them the form it is apt to assume in children.

Ball *et al.* considered that in their three cases the source of the bacilli was either a recent primary complex or a lesion of the same nature as a primary complex which had occurred because previous tuberculous infection had completely healed. In our Case 1, however, there was a calcified primary complex in the right upper lobe, and it seems possible that products of the initial pyogenic infection of the left lower lobe, which would drain to the calcified right paratracheal glands (Rouvière, 1932), activated a latent focus there.

The deafness which occurred in three out of the five more acutely ill patients is worthy of attention, because further experience may prove it to be of some diagnostic importance in certain cases of acute tuberculosis. Interest in this symptom was aroused by the study of two patients encountered in the hospital. One was a woman of 20 who presented with a pyrexial illness, increasing and eventually severe deafness, and consolidation of the right lower lobe; after some weeks without antituberculous drugs the temperature settled, the general condition improved, the deafness gradually disappeared, and when the right lung was later removed the right lower lobe was found to be almost replaced by tuberculous caseation. The other patient was a woman of

20 who became deaf soon after the onset of very acute, widespread bilateral pulmonary tuberculosis; the temperature eventually settled and the deafness actually disappeared during the period of administration of streptomycin and P.A.S.

By the time the last patient was encountered, an alert old lady of 71, the recent onset of severe deafness did not appear to be contrary to but rather consistent with a clinical diagnosis of disseminated tuberculosis based on loss of weight, painful throat, and the appearance of suspicious skin lesions.

Deafness cannot be common in cases of acute tuberculosis or the fact of its occurrence would be better known, though at the same time it is obvious that its presence could easily be ignored in seriously ill patients. It is interesting, however, that Pagel and Woolf (1949) record the symptom of increasing deafness in a case of fulminating tuberculous septicaemia. In the five cases of deafness seen by us there was no evidence of tuberculous meningitis or of middle-ear disease, and it seems likely that the deafness was the result of toxæmia. Deafness occurs in the course of other communicable diseases, presumably for the same reason; it is common in rickettsial diseases such as typhus, and in the later stages of typhoid fever.

In conclusion, the cases described above illustrate the variety of clinical features which may be present in disseminated tuberculosis—pyrexia, skin lesions, deafness, mental confusion, leucopenia, buccal ulceration, laryngitis, respiratory symptoms and signs, splenic enlargement, and jaundice. It may be difficult to make an early diagnosis, but if suspicion is aroused confirmatory evidence may be obtained from biopsy of any skin lesions which may be present, biopsy of sternal marrow, or aspiration biopsy of the liver.

Summary

Attention is drawn to the diagnostic importance of skin involvement in disseminated tuberculosis. Eight cases of the latter condition, four with cutaneous and four with subcutaneous lesions, are described. The occurrence of deafness was recorded in three of five cases in which toxæmia was severe. The clinical features of disseminated tuberculosis are discussed.

Our thanks are due to Dr. T. Anderson, reader in infectious diseases, University of Glasgow, for his helpful criticism and advice in the preparation of this paper, and to Dr. J. H. Lawson, physician-superintendent, Ruchill Hospital, for his interest and his kindness in allowing us access to case records of patients who were under his care.

The only population group whose diets in 1951 gave some cause for concern was large families with several children or adolescents, according to the National Food Survey Committee's second annual report on "Domestic Food Consumption and Expenditure." The report gives estimates of household expenditure on all kinds of foods and of the quantities of these foods consumed by families of different social class and different composition. Analyses of the energy value and nutrient content of the diets of the various groups are also given. During the period under review, food prices bore the full impact of the inflation caused by the Korean war; but, in general, food expenditure and consumption kept pace with rising prices, and the level of the diet was maintained. There was some further narrowing of the dietary gap between social classes, but the diets of large families revealed certain inadequacies, notably in protein and calcium.

BACTERIOSTATIC AGENTS IN THE TREATMENT OF SUBACUTE BACTERIAL ENDOCARDITIS

BY

H. W. BALME, M.D., M.R.C.P.

A. E. DORMER, M.B., B.S.

Research Assistant

The Medical Unit, St. Bartholomew's Hospital

Antibiotics that are purely bacteriostatic have proved to be disappointing in the treatment of subacute bacterial endocarditis, for it appears to be necessary to sterilize the valve lesions, and for this a bactericidal drug or a bactericidal mixture of drugs is usually required (Garrod, 1953). In both the following cases of subacute bacterial endocarditis treatment with oxytetracycline ("terramycin") or with other bacteriostatic antibiotics seemed at first to be indicated, but even with full dosage the infection was not controlled in either case, although the organisms were sensitive. Effective treatment was thus delayed. When, later, antibiotics with bactericidal action were employed both cases responded promptly.

Case 1

A girl aged 14 was admitted to hospital on October 28, 1952, under the care of Dr. G. W. Hayward. Three years previously she had been treated in Hamburg Military Hospital for subacute bacterial endocarditis due to *Str. viridans* and had received a four-weeks course of penicillin, 50,000 units three-hourly. Thereafter she remained well until a month before her admission here, when she developed febrile symptoms, a few painful spots on the fingers, and later transient stiffness of the neck. At the onset she was given a short course of sulphonamides and then of penicillin, but with the persistence of symptoms she was referred for investigation.

On admission she was febrile, petechiae were present on the right thumb, the spleen was palpable, and she had mitral stenosis. There was no clubbing of the fingers. Investigation showed a moderate normochromic anaemia, normal white count, normal urine without increase in red cells, normal electrocardiogram, and a blood culture positive for *Str. viridans*. This organism was inhibited by 0.04 unit of penicillin and by 0.3 µg. of oxytetracycline per ml.

On November 1 treatment with penicillin was begun with a dose of 1,200,000 units intramuscularly at 12 noon, the preparation used being "abbocillin," 1.5 ml. of which contains procaine benzyl penicillin, 900,000 units, together with buffered crystalline penicillin potassium, 300,000 units. At 12.15 p.m. a severe reaction started. She vomited, became very flushed, and then developed a rigor. The blood pressure fell and the pulse was for a while imperceptible at the wrist. The temperature rose to 103° F. (39.4° C.), but fell rapidly and by that evening she was feeling fairly well again. A test dose of penicillin was then given, 50,000 units subcutaneously. Fifteen minutes later a weal 2 cm. in diameter developed, with an area of erythema 8 cm. in diameter, at the site of injection; a control of saline given at the same time produced a weal 2 mm. in diameter with no surrounding erythema.

Following this the patient remained afebrile, with repeated negative blood cultures, until November 18, and during this period no further treatment was given. But on that day fever recurred and blood culture again revealed *Str. viridans*,

apparently the same organism that had been isolated previously. Another tender spot appeared on the right hypochondrium.

In view of the severity of her reaction to penicillin it was now decided that she should be treated with oxytetracycline instead, the organism being sensitive to it, and this was started on November 22 in a dosage of 750 mg. six-hourly. This gave a blood level of 24 µg. of oxytetracycline per ml. when measured four and a half hours after a dose. Within 48 hours the fever settled again, and blood cultures taken on the fourth day of treatment remained sterile. Treatment was continued for six weeks, but on January 1, 1953, two days before the end of the course, fever again recurred and blood culture once more revealed *Str. viridans*. The organism appeared to be the same as that isolated previously, and still showed no resistance to oxytetracycline. During the next two days further petechiae appeared, the spleen became palpable again, and the patient was evidently ill.

It was now obvious that penicillin, to which the patient had earlier shown sensitivity, had to be used, and it was hoped to overcome possible reactions by simultaneous injection of penicillin and an antihistamine (Maslansky and Sanger, 1952). Treatment was therefore started again on January 5, when she received by injection a mixture of crystalline penicillin, 100,000 units, with 50 mg. of mepyramine maleate; this was followed by a slight urticarial reaction. The next day the same mixture was injected six-hourly, a minimal urticarial reaction following the first of these injections; but thereafter no further reactions were experienced. The next day the same mixture was given three-hourly. The following day 250,000 units was given three-hourly and the antihistamine was changed to oral promethazine hydrochloride, 25 mg. six-hourly. On the fifth day the penicillin was increased to 650,000 units three-hourly, at which level treatment was then carried on for six weeks, but the antihistamine was stopped altogether on the sixth day. The infection was promptly controlled once more, and the patient declared she felt better than when being treated with oxytetracycline.

At the end of the course there was no evidence of activity of the disease, and she was discharged on March 6 apparently well. On readmission for dental treatment on June 4, 1953, no evidence of recurrence could be found.

Case 2

A woman aged 25 was admitted as a case of enterococcal endocarditis that had proved resistant to treatment with single and combined antibiotics. Following a septic abortion she had been found to have mitral stenosis, intermittent fever, multiple petechiae and a few larger peripheral emboli, scanty haematuria, and clubbing of the fingers. The spleen was not enlarged. Blood cultures had repeatedly yielded *Str. faecalis* sensitive to chloramphenicol, aureomycin, and oxytetracycline but resistant to penicillin and streptomycin. Treatment, starting on July 19, 1952, had consisted of penicillin, up to 12 mega units daily for six weeks, followed by aureomycin, 2 g. daily for 18 days, then oxytetracycline, 6 g. daily for 23 days, then oxytetracycline and aureomycin together for 7 days, and, finally, oxytetracycline, 6 g., and chloramphenicol, 3 g. daily, for 20 days, all without effect on the fever, on the occurrence of peripheral emboli, or on the general condition of the patient.

On admission here under the care of Professor R. V. Christie on November 20, 1952, the diagnosis of subacute bacterial endocarditis was confirmed. Blood cultures yielded *Str. faecalis* again, inhibited by penicillin, 2.5 µg. per ml.; streptomycin, 10 µg. per ml.; aureomycin, 0.3 µg. per ml.; oxytetracycline, 0.6 µg. per ml.; and chloramphenicol, 10 µg. per ml.; but none of these drugs sterilized the inoculum when used singly. The effects on the culture of mixtures of these drugs were then observed, using the following concentrations: penicillin, 1 µg. per ml.; streptomycin, 10 µg. per ml.; aureomycin, 5 µg. per ml.; and oxytetracycline, 5 µg. per ml. Aureomycin and oxytetracycline alone,

and mixtures of penicillin or of streptomycin with either aureomycin or oxytetracycline, left the bacterial population approximately static. Penicillin and streptomycin when used alone permitted growth to occur, but when they were used together they then formed the only combination discovered that would actually sterilize the inoculum in 24 hours.

Accordingly on November 28 treatment was started with penicillin, 2,500,000 units three-hourly, and streptomycin, 0.5 g. six-hourly, and this was continued for six weeks. Blood samples taken at various times during the day indicated that the penicillin level varied from over 80 to about 20 units per ml., and the streptomycin level remained at about 27 µg. per ml. From December 17 until January 8 probenidol was also given, 0.5 g. six-hourly, but it had little or no effect on the penicillin blood level.

Treatment was stopped on January 8, and thereafter repeated blood cultures have remained sterile. The patient was well when last seen on June 9.

Discussion

In both these cases bacteriostatic antibiotics were first employed in treatment, but, in spite of adequate dosage and although the organisms were fully sensitive, the disease was not controlled by them. This initial failure represented a serious hazard to the patients, for during all the time that infection remains there is an increasing danger of major emboli, renal failure, and irreversible damage to the heart: it has been established that the prognosis depends greatly on the speed with which effective treatment is started (Cates and Christie, 1951). It is not denied that bacteriostatic antibiotics are sometimes effective in this disorder, but the disadvantage of using them when bactericidal drugs are available as an alternative lies in the danger that, should they not work, the time lost whilst using them may well make all the difference to the patient's chances of ultimate recovery.

This being so, it may be as well to examine the reasons why bacteriostatic agents were used at all in the two cases described. In Case 1 the reaction of the patient to her first dose of penicillin was alarming, and the necessity of avoiding a repetition of it was taken as a good indication for a change over to oxytetracycline; but this decision was proved by events to be unwise. It had not been appreciated at this time that desensitization could be so simple a process. Fortunately in her case the delay during the time she was given oxytetracycline instead apparently caused no harm. It may be worth noting, however, that even severe reactions to penicillin do not necessarily preclude the use of the drug, as the technique of desensitization to it can be simple and effective.

In Case 2 treatment with chloramphenicol, aureomycin, or oxytetracycline seemed to be indicated on bacteriological grounds by virtue of the results of the usual sensitivity tests, but, as pointed out by Garrod (1953), the situation is in reality more complex than this. Thus the organism was with difficulty inhibited but not killed by penicillin and streptomycin acting singly; it was more readily inhibited but not killed by chloramphenicol, aureomycin, and oxytetracycline; but it was actually killed by the combined effect of penicillin and streptomycin when acting together. It was not until this situation had been revealed that effective treatment with the bactericidal mixture of penicillin and streptomycin could rationally be instituted.

In these two cases a great contrast was shown between the effectiveness of bactericidal as compared with bacteriostatic drugs. Since it has been shown (Cates and Christie, 1951) that 92% of relapses occur within one month of cessation of treatment it seems likely that both have now been cured, by penicillin in the one case and by penicillin combined with streptomycin in the other, whereas even prolonged treatment with the bacteriostatic antibiotics had previously been ineffective. They thus support the view held by Garrod that effective treatment for subacute bacterial endocarditis usually demands that the drug employed must have bactericidal and not merely bacteriostatic action.

Summary

Two cases of subacute bacterial endocarditis are reported.

The first case was treated with oxytetracycline because of severe reactions to penicillin, but the infection was not controlled by it, although the organism was sensitive. Subsequent use of penicillin, "covered" by antihistamines as described in the text, rapidly cleared the infection.

The second case was treated with chloramphenicol, aureomycin, and oxytetracycline because the organism, *Str. faecalis*, was sensitive to these drugs and resistant to penicillin and to streptomycin. Nevertheless the infection was not controlled by them. When it was subsequently shown that a combination of penicillin and streptomycin acting together was bactericidal whilst the other antibiotics had bacteriostatic action only, treatment with this combination was started, using penicillin in very large doses. The infection was then rapidly controlled.

It is emphasized that the delay caused by first using bacteriostatic antibiotics may well be dangerous because of the likelihood of continued progression of disease, and that every effort must be made from the onset to discover the appropriate bactericidal drug or bactericidal mixture of drugs.

We are indebted to Professor R. V. Christie for his assistance and encouragement in the preparation of this report, to Professor L. P. Garrod for his help and criticism and for the detailed laboratory work, to Dr. G. W. Hayward for permission to publish his case and for his advice with respect to it, and to the house-physicians who looked after the patients and assembled much of the information about them.

Medical Memoranda

Oesophagitis Dissecans Superficialis

Sloughing of portions of the oesophageal wall is a recognized consequence of contact with scalding fluids or strong caustic or acid solutions. Phlegmonous oesophagitis may uncommonly result from pyogenic infections of the mucous and submucous coats, spreading, perhaps, from a primary infection of the fauces or larynx or originating at the site of a neoplastic ulcer or impaction of a foreign body. Thrush oesophagitis not infrequently gives rise to pseudo-membrane formation, while extension to the upper oesophagus of pharyngeal diphtheritic ulceration has been reported.

There remains for mention a lesion characterized by extensive dissection of the squamous epithelial lining of the oesophagus from its underlying corium in the form of a tubular cast—oesophagitis dissecans superficialis. The following case is recorded on account of the rarity of the condition and the obscurity of its aetiology.

CASE REPORT

A married woman aged 37 was admitted to hospital late at night on October 15, 1951. She had been in her usual good health until about an hour after her evening meal, which had been swallowed without difficulty, when she noticed a sensation of something sticking in her throat. Repeated retching brought the object into her mouth. It was found to be of fleshy substance and apparently attached to the throat. She went to her doctor, and with further

retching and some traction the object was completely removed to the accompaniment of severe tearing pain in the throat and the regurgitation of a small quantity of bright red blood.

Clinical examination on admission revealed no abnormality apart from obvious extreme discomfort on swallowing. There was no pyrexia. The patient presented her specimen (see illustration) in a bottle. It consisted of a flimsy collapsible tube 12 in. (30 cm.) in length and approximately 1 in. (2.5 cm.) in diameter, with a greyish-white, thin, translucent wall. At one end the lumen was slightly constricted and the termination abrupt and regular; at the other end the diameter appeared to widen, the wall of the tube was torn longitudinally, and the free margin was frayed, with adherent blood clot on the outer surface. From

the appearance of the cast and the method of its production it seems likely that initial separation had occurred at, or close to, the cardia, followed by regurgitation of the free end and a progressive stripping of the oesophageal epithelium. The freeing of the more firmly adherent upper portion had been incomplete and accompanied by pain and bleeding.

There was no history of the ingestion of any irritant substance. The diet was habitually bland, and on the day of admission had been in every way unexceptionable. There were no significant points in the personal or family history.

Treatment was directed to allaying the patient's anxiety and relieving the severe dysphagia. The discomfort on swallowing even saliva was considerable, and was confined to the region of the upper oesophagus. It was greatly reduced by the use of amethocaine hydrochloride lozenges. Within a week soft solids could be swallowed with comfort. At review three weeks later there was no complaint of dysphagia on a full diet and barium studies of the oesophagus were normal.

Histological examination showed the wall of the cast to be composed of stratified squamous epithelium resembling the normal oesophageal lining, with fragments of fibrous tissue attached to the separated surface. There were no inflammatory or degenerative changes.

COMMENT

A comprehensive review of the literature by Patterson (1935), in which he lists 17 previously recorded cases, adding one of his own, represents the most recent available publication on the subject and brings out the main features of the condition. The incidence has been equally distributed between the sexes, and the ages of the patients have varied between infancy and 69 years. The good prognosis is emphasized, and, as is to be expected from the superficial nature of the epithelial separation, in no case has subsequent stenosis occurred. Repeated cast formation, however, was a feature in three of the cases reviewed by Patterson, and Muir (1951) mentions a similar example.

As regards aetiology, infiltration of the deeper layers of the cast by inflammatory cells is not infrequently described,

and has been taken as evidence in support of an inflammatory basis for the lesion. In many other cases, however, as in the present one, no such histological feature has been present, and the systemic upset to be expected in the presence of an inflammatory process has been lacking. Significance has also been attached to a story of repeated minor trauma, chemical and physical, the result of dietary indiscretions, and Patterson explains his own case along such lines. In others the production of the cast has followed the swallowing of such varied substances as alcohol, chloroform, industrial spirit, hard crusts, or unusually hot food. No such mechanism can have been operative in the present example, and comparison of the incidence of the condition with the probable incidence of such minor oesophageal trauma would seem to indicate the unimportance of this factor.

Psychogenesis and muscular spasm with resultant epithelial devascularization have also received mention. The suggestion that the condition may represent an atavistic tendency akin to casting of the skin in lower species is not phylogenetically credible.

It may be concluded that no satisfactory explanation has as yet been put forward for what is a rare, benign, but distressing condition.

I am indebted to Dr. T. H. Crozier for permission to publish this case and to Dr. T. H. Crozier and Dr. D. A. D. Montgomery for their encouragement and advice. Dr. A. L. Wells kindly supplied the histological report, and Mr. D. McA. McHaffey the photograph.

Armchair Dermatitis

This account of two recent cases is written in order to draw attention to a characteristic dermatitis in which the exogenic agent might be overlooked.

Case 1.—A grocer aged 44 had a history of sensitivity to turpentine in 1947. For three months he has had a rash starting below the right elbow and then spreading to below the left elbow. The rash cleared whilst he was on holiday, but relapsed when he returned home. He works with his sleeves down, but takes off his coat when sitting in his armchair at home. On examination there was a subacute patch of eczematous dermatitis over the extensor aspect of both forearms below the elbows. A patch test to the artificial leather of his armchair was positive.

Case 2.—A goods guard aged 32 had had eczematous patches on the extensor aspects of his forearms for two years. He previously worked as a shunter with his sleeves rolled up, but for the last two months in his present job he had kept his sleeves down without benefit. At home he sits in an armchair with his coat off and his sleeves rolled up. On examination there was a patch of lichenified eczematous dermatitis over the extensor aspect of both forearms below the elbows. A patch test to the artificial leather of the chair was positive.

These patients presented an identical picture of a chronic patch of eczematous dermatitis over the extensor aspect of each forearm below the elbows. The site of the lesion on apparently covered areas seemed to rule out an external irritant; the appearance of the rash suggested a diagnosis of localized neurodermatitis, though this is usually limited to, or more marked on, one arm, usually the left in right-handed persons. Further questioning of Case 1 revealed the patient's habit of sitting at home with his coat off and sleeves rolled up, resting his forearms on the artificial leather of his chair. In Case 2 the diagnosis was made at once from its similarity to the first one. In both instances patch tests with the artificial leather from the chair were positive.

HAND INJURIES

Functional and Surgical Anatomy of the Hand. By Emanuel B. Kaplan, M.D., F.A.C.S. (Pp. 288; 132 figures. £4.) Philadelphia and London: J. B. Lippincott Co. 1953.

Surgery of Repair as Applied to Hand Injuries. By B. K. Rank, M.S. (Melbourne), F.R.C.S., F.R.A.C.S., and A. R. Wakefield, M.S. (Melbourne), F.R.C.S., F.R.A.C.S. Foreword by Sir Gordon Gordon-Taylor, K.B.E., C.B., LL.D., Sc.D., F.R.C.S., F.R.C.S.(Ed.), F.R.A.C.S., F.A.C.S., F.R.C.S. (Canada). (Pp. 256; 188 figures. 40s.) Edinburgh and London: E. and S. Livingstone. 1953.

War and industry have this in common, that they both produce injuries of the hand, injuries the repair of which to-day forms one of the most important problems by which the surgeon is faced.

Fortunately the progress of surgery has made possible repairs which 20 years ago would have seemed hopeless, and the surgeon may now treat grave injuries with every prospect of success. But this success has been achieved only by laborious effort and by a new appreciation of the anatomy and function of the hand such as may be found in the books under review. The reader may at first be appalled by the amount of detail involved, but he will gradually realize that it is upon this detail that progress has depended. The field has in fact become highly specialized, and success can be attained only by those who are prepared to give the time and attention which such specialization demands.

Kaplan treats the anatomy of the hand from a very original standpoint, consistently bearing in mind the function which it serves. Profuse illustrations based on special dissections and drawn by an artist who evidently combines anatomical knowledge with a high degree of artistic skill enable the reader to appreciate and visualize descriptions of detail which might otherwise be obscure. As an example we would mention the chapter devoted to opposition, the exquisite and most complex movement by which the thumb is brought into symmetrical relation with each finger in turn. We would only suggest, however, that it is a function of the whole hand and not of the thumb alone. The chapter on surgical approach is of real value, particularly the description of Dupuytren's contracture illustrated by special dissections of a novel character.

Equally original is the description of hand injuries by Rank and Wakefield, the importance of which in industry can scarcely be overestimated. Their approach is essentially practical and is based on a wide experience of every type of injury.

They fully appreciate the importance of what might at first seem trivial injuries and show how subsequent deformity may be avoided; and they give superb examples of the results which can now be obtained in injuries which might well be regarded with despair. Perhaps the grafting of flexor tendons is one of the most dramatic advances, with a recovery of function of value untold. An interesting chapter is the one on injuries of the hand in children and the special problems involved. But no reference is made to the curious fact that the nerves in children are very nearly as large as those in adults, out of all proportion to the other structures, so that suture of such a nerve as the deep branch of the ulnar is easy, with a functional result which can rarely be obtained in the adult. This is a small point and in no way detracts from the great value of the book or the splendid achievement of the results it describes.

The two books are in many ways complementary and will well repay the study of surgeons who are working in this difficult and important field.

HENRY SOUTTAR.

ULCERATIVE COLITIS

Ulcerative Colitis and Its Surgical Treatment. By Bryan N. Brooke, M.Chir., F.R.C.S. Foreword by F. A. R. Stammers, C.B.E., T.D., B.Sc., Ch.M., F.R.C.S. (Pp. 147; 89 figures. 37s. 6d.) London: E. and S. Livingstone Ltd. 1954.

"The surgery of ulcerative colitis is essentially destructive. It comes in where medicine has failed, and has no place as an adjuvant to medical treatment." This statement, made by me in 1940, is quoted as an introduction to Chapter V by the author, who adds, "Since that time the approach to treatment has entirely changed." The only change is in the interpretation of the word "medicine." I use it to mean "treatment by non-operative means." Mr. Brooke gives it the interpretation of treatment by one holding the right trade-union ticket. Otherwise we have no quarrel.

I agree wholeheartedly with him that "physician and surgeon should act together in a unit," not alone in the treatment of ulcerative colitis, but in that of peptic ulcer, thyrotoxicosis, and hypertension. Apart from this terminological dissonance, the purpose of Mr. Brooke's book is to show that the surgical treatment of ulcerative colitis comes in when medical treatment has failed. There is a stage up to which recovery is possible without surgery, but after the colonic mucous membrane has been destroyed beyond a certain point no "adjuvant" operation such as appendicostomy, caecostomy, or temporary diversion have any place. The author gives careful thought to the possibility of eventually restoring anal defaecation, and comes to the conclusion, as have all surgeons with sufficient experience (and sense), that the attempt is unjustified.

The book is a record of personal experience and the statement of a personal viewpoint. Mr. Brooke's particular message is the belief that the omnibus category of ulcerative colitis includes three distinct conditions—ileocolitis involving the lower ileum and proximal colon, ulcerative colitis involving eventually the whole large intestine but appearing earliest and maximally in the distal colon, and proctosigmoiditis, which is limited to the distal colon. Many surgeons consider that these three are but manifestations of the same disease and that every gradation is found between them, but the author makes a good case for the segregation of the first at any rate.

The surgical treatment is admirably described, and the author's own results, which are better than most, are analysed in detail. The book is well produced, as are all monographs emanating from the Livingstone stable. The illustrations, which include a wide assortment of radiographs and many photographs and photomicrographs in colour, are excellent. It is a book that should be read by every surgeon who may deal with this distressing disease, and certainly by every candidate for a higher surgical degree.

HENEAGE OGILVIE.

THE THYROID

The Thyroid: A Physiological, Pathological, Clinical and Surgical Study. By T. Levitt, M.A., F.R.C.S.(Eng.), F.R.C.S.(Ed.), F.R.C.S.I. (Pp. 606; 502 illustrations. £5 5s.) Edinburgh and London: E. and S. Livingstone Ltd. 1954.

This book is a sumptuous expansion of the findings and thesis that Mr. Levitt published in the *Lancet* in 1951. He considers that diseases of the thyroid, excluding inflammatory and neoplastic conditions, can all be regarded as a part of six phases in the continued process of degeneration of the toxic thyroid gland. The histology of these phases in sequence is: (1) epithelial hyperplasia, (2) lympho-epithelial hyperplasia, (3) focal lymphoid hyperplasia, (4) diffuse lymphoid hyperplasia, (5) fibro-lymphoid hyperplasia, and (6) fibrosis. These were found to correlate with incidence and severity of thyrotoxicity, which was high in the early groups and diminished in the later ones. Group (5) is Hashimoto's type of disease and (6) Riedel's.

The material on which this thesis is based, 2,114 consecutive thyroidectomies, is presented in numerous tables, photographs, and diagrams. A well-illustrated description of the

pathological and clinical features is given of the average case in each phase. But the objective means by which the thyroid or patient was coded into the scheme are withheld. Thus, on the pathology side, we read that three carefully selected blocks were taken from each gland and on their histology were allocated a place on the epithelial-lymphoid-fibroid scale. We are not told whether the selection of blocks was done on an anatomical basis or on appearance. Nor are we given the average weights of the resected thyroid tissue. We have no idea how the proportion of lymphatic to epithelial tissue was assessed, whether by cell counts or measurement of cellular areas. There is no reference to controls, done, for instance, on post-mortem material from euthyroid patients. Clinically the patients are designated as mild, moderate, or severe thyrotoxic, but the criteria used to separate the cases studied are not given. We cannot tell from the tables whether the designated state refers to the patient at the time of operation or many years previously. Mr. Levitt states that toxicity was present or had been present in all 30 of the patients in the Hashimoto group. In 18 it was mild. He later says, with regard to the diagnosis of mild toxicity, that "all the intuitive ingenuity of the observer is required to elicit the evidence of any mild toxic phase in the previous history. Close co-operation of the patient's relatives has proved invaluable in assessing this type of patient." One cannot avoid the impression that Mr. Levitt's enthusiasm and belief in his thesis have led him to strain fact to fit theory.

This impression is strengthened by the tone of the chapters on the physiology of the thyroid and its relation to the other endocrine glands of the body. These, like the rest of the book, are presented in the main as a series of hypotheses which flow in abundance and are put down in such a manner that they read as statements of fact, whereas in truth they are mostly theory. For example: "A refractory interval or rest phase intervenes between secretion and proliferation, in order to promote the process of natural recovery. During this interval, the relatively non-receptive epithelial cells of the acinus fail to respond to the stimulus of the thyrotropic hormone." "Under the influence of stress the pituitary secretes, in varying degrees, an excess of its many tropic hormones, which include the two factors with which we are immediately concerned—thyrotropin and collagenin."

This is an unusual and very personal medical book. The production is magnificent—in fact, quite seductive. But I am afraid that the work as a whole will irritate the serious student beyond measure.

CHILD HEALTH AND THE STATE

Child Health and the State. By Alan Moncrieff, M.D., F.R.C.P. Newsholme Lectures, 1953; London School of Hygiene and Tropical Medicine. (Pp. 48; 6s.) London, New York, and Toronto: Geoffrey Cumberlege (Oxford University Press), 1953.

Scratch a paediatrician and you may or may not find an exponent of child health. But there is no need to scarify Professor Moncrieff, because his work and his publications have long since established him as a distinguished leader in child health. This little book contains the three lectures delivered by him as Newsholme Lecturer for 1953.

The first lecture, on infant welfare, is wise and sound and evolutionary rather than revolutionary in tone. Indeed, one gets the impression that the author feels that we are on the right road but there is still a lot of mileage to cover—and that is true. Professor Moncrieff appears to believe that the local health authority child welfare service is a State service. The medical officer of health and his colleagues are employed by and responsible to a local authority and not to any Ministry or Minister, and on the financial side, although the State is responsible for providing nearly all the remuneration of consultants and general practitioners, it provides only about half the amount of the salaries of local authority medical officers.

The second lecture, on school health, is more stimulating, perhaps because there is more to argue about. A combined

child health service which is here suggested, as it has been before, seems to be right and inevitable.

The third lecture deals with the deprived child and will be found to be highly acceptable by those who enthuse about the work of the Curtis Committee and highly controversial by those who do not. The author suggests that the selection of the Home Office as the central administrative department was welcomed for two reasons, one of which was "because where homes are concerned it is not unnatural to consider that the title of the office has some meaning!" So now we know, and let us not mar the cosy contemplation of this agreeable conception by recalling some of the other functions of the Home Office.

This is a most interesting book. It will please the many who will find themselves in general agreement with the author; many others will find that the lectures are stimulating and constructive but also productive in places of disagreement. The latter group is likely to get the best out of this book.

GADGETS FOR THE DISABLED

Gadgets. (Pp. 78; illustrated, 2s. 6d., plus 3d. extra for postage. Obtainable from offices of the Association.) London: National Association for the Paralyzed, 1953.

"The object of this booklet is to give information about the various gadgets and appliances, already manufactured in this country or easily made, which can help to overcome the everyday problems of disabled people." This opening sentence taken from the introduction summarizes the contents of the booklet but gives no indication of the immense amount of trouble that has been taken in its preparation. While similar publications have been available in the United States for some years, this is the first comprehensive work that has appeared in Britain. Being loose-leaf, it can be readily kept up to date. It is divided into five sections ranging from "Mobility" to "Recreation." Each section gives a brief description of the gadget or apparatus, together with the name and address of the manufacturer, and indicates, where necessary, if it can be obtained under the National Health Service. Many of the gadgets are simple adaptations of articles in ordinary use to the needs of the disabled—as, for example, the non-spill plastic cup designed for infant-feeding, which has been found very helpful for those patients with a tremor or poorly co-ordinated movements of the hands. Many useful hints are included, such as smearing the inside of an egg-cup with rubber solution to create a non-skid surface. At the other end of the scale there are details of the elaborate lifting devices used for patients who are bedridden.

The work of collecting and cataloguing these various gadgets has been undertaken by the National Association for the Paralyzed with the help of many allied organizations. To those whose work brings them into daily contact with the severely disabled this booklet will prove a very useful source of reference, and to the many others who are not aware of the great strides that have been made in this particular branch of rehabilitation it will be a mine of information.

DONAL BROOKS.

A useful by-product has come from an investigation into the occurrence and distribution of essential hypertension carried out by the Division of Epidemiology and the Bureau of Applied Research (both units of Columbia University) and the Recess Commission on Hypertension of the Massachusetts State Legislature. It is a *Bibliography of the World Literature on Blood Pressure, 1920-1950*, in three volumes. Vol. 1 is an author catalogue of over 16,000 articles, reports, textbooks, and monographs. Vol. 2 is a subject index to the first volume and also includes an alphabetical list of co-authors whose contributions appear in Vol. 1. In Vol. 3 there are about 1,500 abstracts of papers selected from Vol. 1. Many of these are concerned with the incidence, prevalence, trend, and distribution of hypertension according to age, race, sex, occupation, and climate. The bibliography is edited by E. K. Koller and J. Katz, Columbia University, New York.

ANAESTHESIA IN OUT-PATIENT DEPARTMENTS

The out-patient department sees little of trained anaesthetists. The main reason is that there are not enough of them, another is that both they and their administrative and professional colleagues consider that the anaesthetic work there is too simple to justify the presence of a specialist anaesthetist. It is not surprising therefore that the standard of anaesthesia there is apt to fall short of that in the major operating theatres, nor that accidents occur; it is amazing that they are so few. Even so, the Registrar-General's reports show that in England and Wales an average of some 60 deaths a year have been reported for the past twenty years due to nitrous oxide alone, and to this figure must be added those deaths due to other anaesthetics. The subject was aired at the Section of Anaesthetics of the Royal Society of Medicine recently by Dr. J. G. Bourne,¹ who drew attention to what is well known among anaesthetists—the low potency of nitrous oxide as an anaesthetic and the hazards that may follow attempts to obtain more than light anaesthesia with this reputedly "safe" anaesthetic. He advocated the use of a more potent agent, such as cyclopropane. Nitrous oxide is safe only in the sense that, if the patient breathes air, recovery even from the acute asphyxia of overdose occurs within a minute or two. No other interpretation of "safety" can be admitted, since nitrous oxide anaesthesia has all the lethal properties of acute anoxia when sufficient oxygen is not administered. An altogether wrong impression of this supposed safety still persists, and many are not aware that McKesson, the real pioneer of nitrous oxide anaesthesia, insisted that very large doses of morphine pre-operatively were needed to make nitrous oxide a satisfactory anaesthetic.

Most of the deaths in casualty and out-patient departments are of fit patients undergoing minor operations, and expert anaesthesia would probably have averted many of them. The remedy, however, is not simple and lies only partly in the particular anaesthetic used. Experience has shown that the

substitution of one drug by another will not prevent loss of life in anaesthesia. It is open to question, for instance, whether the substitution of nitrous oxide by cyclopropane, as suggested by Bourne, would appreciably reduce these accidents—quite apart from the new and added risks of explosion. It is not sufficient to take as sole criteria the likes of the patient and of the surgeon without reference to the anaesthetist's skill or the known physical and pharmacological hazards of the drug. Of the many valuable ideas propagated by Dr. Ralph Waters, of Wisconsin, perhaps the two outstanding are that to the patient the skill of the anaesthetist is of greater importance than the pharmacology of the drugs he uses, and that death is more likely to be due to some gross and obvious physiological cause such as respiratory obstruction or inhalation of vomit than to the more obscure pharmacological effects of the drug.

In discussing methods of anaesthesia in the out-patient department, the special circumstances there must be taken into account: the large number of patients treated every day; the need for them to be ambulant soon after their operation; and the need to use anaesthetic procedures which carry little inherent risk such as that of explosion or ease of overdose. At the inquest on a death in a casualty department in Birmingham² recently a pathologist expressed the opinion that trilene was particularly dangerous except in the hands of specialists, and he considered also that every patient should have premedication. His opinions received wide publicity, but few anaesthetists would agree with them. "Trilene" is one of the most commonly used anaesthetics in Britain and has deservedly acquired a reputation for safety. Its use is taught to students in nearly every medical school. In midwifery its administration is widespread and it will probably be placed in the hands of every midwife. Finally, at the Royal Society of Medicine meeting the other evening Laycock made a special plea for trichlorethylene in out-patient anaesthesia. As to premedication, atropine should without doubt be given if possible to every patient, but sedatives are another matter. The stay of the patient in the out-patient department might be unduly prolonged, while the certainty of the added risks of respiratory depression would more than balance the occasional benefit to the apprehensive patient. To advocate that only specialists should administer anaesthetics in out-patient departments is a counsel of perfection.

Difficulty is now being experienced all over the country in obtaining anaesthetists of any sort. There is a shortage of trained men and women in this specialty, and how to attract new entrants is at present the concern of the various national bodies dealing

¹ Bourne, J. G., *British Medical Journal*, 1954, 1, 452.

with anaesthetic affairs. Many undergraduates are not at present getting the training in anaesthetics they should, in spite of the requirements of the G.M.C. The time allowed to this subject compared with others is often too short in relation to its importance to the community. That the training of undergraduates in anaesthesia falls short of what it should be is also made clear in an admirable report by Harbord³ based on questionnaires sent to every medical school in the country. Teachers of anaesthesia find they are not getting the opportunities to carry out the necessary training in simple and safe methods. Some indeed in their frustration feel that anaesthesia is better kept out of the hands of the non-specialist altogether and its study limited to postgraduates. But until the number of trained anaesthetists is much greater the undergraduate must still be taught the subject and taught it well, so that when he qualifies he has one or two simple methods at his command. The problem of anaesthetics in out-patient departments is therefore bound up with the larger one of the training of undergraduates and the supply of future specialists. It deserves the closest study.

ARTICULAR CARTILAGE AND OSTEOARTHRITIS

Osteoarthritis has been recognized as a clinical entity for about 100 years, and accounts of its pathology—such as the important paper of Nichols and Richardson¹—have for half that time provided a description of the morphological changes constituting the disorder. Histological studies of this sort have directed attention to the degenerative changes in articular cartilage—described as “fibrillation” of the superficial part of the normally uniform cartilage matrix—from which all the other tissue changes of the deranged joints stem. In particular the more recent work of Bauer and his colleagues^{2,3} at Boston has emphasized the role of exaggerated wear and tear of cartilage in the pathogenesis of osteoarthritis.

Chemical studies have taught us much about the structure and function of cartilage, for in recent years an increasing number of papers have appeared on the chemical constituents of cartilage.⁴ For a long time a mucopolysaccharide, chondroitin sulphate, has been known as an important constituent of articular cartilage, and many of the elastic properties of the tissue are thought to depend on its presence. This substance was isolated from cartilage as long ago as 1890 by Schmiedeberg,⁵ and more recent chemical studies on this constituent have been summarized by Meyer.⁶ In

1944 Hirsch⁷ demonstrated histologically that the degenerated articular cartilage of the patella in early osteoarthritis (“chondromalacia of the patella”) loses its normally intense metachromatic staining reaction with certain basic dyes. Since chondroitin sulphate is regarded as responsible for this reaction, he suggested that the abnormal cartilage contains a diminished amount of this constituent and brought forward some chemical evidence in support of this thesis.

More precise chemical confirmation of changes in the chondroitin content of articular cartilage in osteoarthritis has now come from the Canadian Red Cross Memorial Hospital, Taplow. In a preliminary paper Matthews⁸ described how chemical estimations of collagen and chondroitin sulphate were carried out on samples of articular cartilage obtained at necropsy from a variety of normal joints. He found that the chondroitin sulphate content of cartilage from the knee-joint is greater than that of similar tissue from the shoulder-joint, but that the reverse holds for collagen. When weight-bearing and non-weight-bearing areas of articular cartilage were compared, the former were found to contain more chondroitin sulphate and less collagen. Matthews suggested that the greater resilience needed in weight-bearing areas is provided by the higher mucopolysaccharide content.

More recently the same author has described similar determinations in cartilage from osteoarthritic knee-joints. His results⁹ show increased amounts of collagen relatively to chondroitin sulphate, and suggest that the fibrillary change in articular cartilage, which is the essential structural abnormality in osteoarthritis, reflects different rates of loss of these two substances by the degenerating cartilage. As Matthews points out, “The evolution of fibrillation is the result of a vicious circle in which loss of chondroitin sulphate leads to decreased resilience, which in turn facilitates the mechanical perpetuation of the process.” This type of chemical study provides us with a clearer picture of what is happening in the abnormal cartilage of an osteoarthritic joint, and it is to be hoped that further studies—both chemical and histochemical—will throw light on the factors which, under normal circumstances, hold in check the degenerative process

REMUNERATION OF CONSULTANTS

The Report of the Interdepartmental Committee on the Remuneration of Consultants and Specialists—the Consultants Spens—was published nearly six years ago, in May, 1948, and, along with the parallel report on the remuneration of general practitioners, was accepted by both the Government and the medical profession. This acceptance by the Government undoubtedly played a very large part in persuading the profession to enter the National Health Service, albeit with much reluctance. The two Spens reports are highly important documents and their significance may easily be lost sight of as time passes. In effect they lay down a standard of living for a learned profession which now to a large extent depends for its income upon the State. When the dispute over the remuneration of general practitioners dragged on over the months leading up to the Danckwerts award, signs were not lacking of a desire on the part of the Government to abandon the G.P. Spens Report. With such a report safely out of the way a severe limitation on the Government's capacity for arbitrary action would have been removed. The dispute, it is hardly necessary to repeat, was over the conversion of the Spens recommendations into the present-day value of money.

The negotiations which for a long time now have been in train on the remuneration for consultants and specialists are on the same theme. The recommended items of remuneration for consultants and hospital medical staffs were in terms of the value of money in 1939, and the recommendations were all governed by the second paragraph of the Spens report, which, in part, reads as follows:

“At an early stage in our deliberations it appeared to us that social and economic conditions were not yet sufficiently stable to justify the basing of our recommendations on evidence relating to remuneration in the post-war period, and the Evidence Committee was accordingly asked to obtain information of incomes earned in the year 1938–39. . . . We leave to others the problem of the necessary adjustments to present-day values of money, but we desire to emphasize as strongly as possible that such adjustments should have direct regard not only to estimates of the change in the value of money but to the increases which have in fact taken place since 1939 in incomes both in the medical and in other professions. In our judgment it is only if corresponding changes are made in the incomes of consultants and specialists that the recruitment and status of the various branches of specialist practice will be maintained.”

The “others” who are now faced with the “problem of the necessary adjustments to present-day values of money” are those who sit round the table

¹ *British Medical Journal Supplement*, 1953, **1**, 104.

of Whitley Committee “B.” The Management Side of this committee is made up of representatives of the Ministry of Health and the Department of Health for Scotland and of the hospital boards. The Staff Side is appointed by the Joint Consultants Committee (whose terms of reference, incidentally, exclude consideration of remuneration), and its members include those prominent in the Royal Colleges and Scottish Corporations and the British Medical Association. Their task is not enviable. Consultants and hospital medical staffs form a much less homogeneous body than do general practitioners, and they have very much less experience in negotiation. To this extent, then, the Staff Side is weakened, and the Management Side will accordingly be able to deploy its forces more effectively. Furthermore, certain new features have been introduced which make comparison with 1939 difficult—for example, payment of clinical teachers, and the merit awards for some third of all consultants and specialists. Was it in the minds of the members of the Spens Committee that these awards would be adjusted by whatever “betterment factor” might be agreed upon? Now that the awards, conceived of as “prizes,” have become pensionable increments to income, logic would suggest that an upper adjustment is called for. But those negotiating for consultants may find that strict logic here, as in other circumstances, is not necessarily a sound guide.

Correspondents in these columns and elsewhere have shown a growing sense of impatience and alarm over these various matters, and rumour has added its distorting voice. It is well, therefore, to recall the policy of the British Medical Association, which in this matter is represented by its Central Consultants and Specialists Committee. In the Annual Report of the Council last year¹ it was stated that the Staff Side of Committee “B” of the Medical Whitley Council had notified the Management Side in June, 1952, “of its intention to submit a claim for a review of the remuneration of hospital medical staff in order that the intention of the Consultant Spens Committee might be fulfilled and the salary scales recommended by the committee and based on the 1939 value of money should be adjusted to meet post-war conditions.” This was accepted by the Representative Body at Cardiff. Not only that, Dr. E. B. Smith, a general practitioner, put forward a motion that “an adequate betterment factor should now be accorded to the consultants and specialists, in conformity with the intention of the Spens report . . .”: the Representative Body carried this motion unanimously. On the same occasion the position was put forcibly and

clearly enough by Dr. T. Rowland Hill, Chairman of the Central Consultants and Specialists Committee, who, as reported,¹ said:

"In this matter they took their stand on the Spens Report, which defined the remuneration for different grades of hospital medical staffs, and which had been publicly accepted by the Government immediately after the inauguration of the Service, and which had also been accepted by the medical profession. . . . It might suit the dictates of political expediency to regard the Report as obsolete but that was something to which the representatives of the profession would never agree."

If either of the two big branches of the profession—general practitioners and consultants—departs from the recommendations of the two Spens reports as the basis of their deliberations, they will be on shifting sands. The decisions and actions of the one branch must have repercussions on the other. If to-day the consultants were to allow themselves to accept terms on any other basis they would prejudice the future not only for themselves but also for general practitioners. It may have been political expediency which induced the Government of the time to accept the Spens recommendations. Any fundamental change in policy must be made with the full consent of the profession's representatives; otherwise it would be interpreted as political trickery if any section of the profession were forced out of an agreed position by those who represent the Government.

IMMUNIZATION OF YOUNG BABIES

It is only within the last five or six years that such workers as Parish, Barr, Glenny, Randall, and Bousfield, in England, and Vahlquist, in Sweden, became interested in finding out what objections, if any, there were to immunizing children against diphtheria at a very young age. Holt meanwhile had been turning his attention to the development of powerful and less irritant diphtheria prophylactics, suitable for administering to infants. At first these investigations on young infants were prompted mainly by scientific curiosity, but later, with the advent of combined diphtheria and whooping-cough prophylaxis, the advantage of really early immunization against whooping-cough became obvious. Pertussis strikes early in life and strikes hard. With diphtheria prophylaxis the position is different: this disease now practically never occurs under the age of 1 year in this country. When it is proposed to immunize a young infant against the two diseases, an age for treatment must be chosen at which a satisfactory response to both antigens is obtainable. Now that diphtheria is no longer feared by the public, whooping-cough prophylaxis can become the bait for maintaining a satisfactory level of diphtheria immunization. A circular sent out by the Ministry of Health a few days ago is disturbing in that it shows that the proportion of babies who are immunized before

they reach the age of 1 year is well below the desired figure of 75%. In the first half of 1953 only 31.5% of babies under 1 year were immunized. Probably in the future immunization will be undertaken at a rather earlier age than is usual at present, and this should help to improve the present figure.

Barr and Llewellyn-Jones have recently shown that the use of mixed antigens may be a difficult matter technically. It has been known for some time that young infants with fairly large amounts of maternally endowed antitoxin are apt to respond either poorly or tardily to injections of diphtheria antigens. Elsewhere in this issue we publish a further helpful contribution to the subject from Dr. N. R. Butler, Miss M. Barr, and Mr. A. T. Glenny. Their carefully recorded investigations stress the complexity of antitoxin responses in such young subjects as week-old children, and their results seem to show that active immunization should not be undertaken in any sort of routine manner until a rather higher age. In infants 3 months old, interference with the development of immunity by residual maternally endowed antitoxin would be rarely encountered in our present population: at the most, occasional retardation of response to stimuli is likely to be met with at this age.

Several investigators are working on this problem at present, and it is too early to come to a decisive opinion. It does, however, appear that a mixture of purified fluid diphtheria toxoid and pertussis vaccine, given by subcutaneous injection in three doses at monthly intervals, is a satisfactory prophylactic for all babies of from 2 or 3 months of age upwards. The proportion of negative Schick reactions has been found by several workers to be highly satisfactory at reasonably long intervals after the inoculation. So far as can be judged at present, the results of the immunization against pertussis are also encouraging. This combined antigen, as originally produced by Holt, contained 30 Lf units of diphtheria toxoid and 10,000 million pertussis organisms in 1 ml. Similar preparations are now available from other sources.

Both Ungar and Bousfield have shown that the addition of pertussis vaccine to diphtheria toxoid greatly increases the antigenicity of the latter. So good is this mixture that the use of A.P.T. or P.T.A.P. in a combined prophylactic is now both unnecessary and undesirable when a three-injection course of treatment is to be given. The prophylactic, containing no mineral carrier, can be safely injected subcutaneously into young infants, and some believe that this method of administration may diminish the risk of post-injection paralysis. It seems logical to avoid intramuscular injections when the poliomyelitis virus is in evidence. If poliomyelitis becomes prevalent in an area all whooping-cough and combined prophylaxis should be stopped for the time being, but diphtheria prophylaxis may be continued alone, with a mild antigen. Probably three subcutaneous injections at monthly intervals of purified fluid toxoid afford the safest and yet fully adequate method of treatment. Only if the poliomyelitis risk becomes serious in an area should diphtheria immunization be abandoned entirely for the time being.

THE NORTHERN IRELAND TUBERCULOSIS AUTHORITY

The Northern Ireland Tuberculosis Authority, which has recently published its seventh annual report, was established in 1946 "for the purpose of securing, in co-operation with sanitary and other local authorities, the prevention and more effective treatment of tuberculosis and kindred diseases." A short account of the Authority was included in a recent survey¹ of the health services of Northern Ireland. A single authority charged with responsibility for a specific disease was unprecedented, but in Northern Ireland at that time there were no local health authorities organized on a county basis, although each of the two county boroughs had health departments. It was felt that an intensive campaign against the disease was needed and that this could best be conducted by a public body with power to act in all spheres over the whole Province. Consequently the Authority was given wide functions, which included the prevention of the disease, and the ascertainment, treatment, accommodation, and aftercare of patients. To carry out this work the Authority was composed of seventeen members nominated by the local authorities and by the Minister of Health and Local Government. Originally the officers of the Authority included a medical director and deputy director, but these posts were abolished as a result of a reorganization following the adoption of the Spens Report, and this, together with the fact that only one of the seventeen members of the Authority had a medical qualification, gave rise to much justifiable criticism. In 1952, however, the Authority co-opted two more medical men and appointed a medical advisory committee to advise on medical policy.

The resources taken over in September, 1947, were largely centred on Belfast, where there was a 350-bed sanatorium, an orthopaedic hospital with about 50 beds for children, a chest clinic with x-ray facilities, and a static mass miniature radiography unit. Elsewhere there were 129 beds in three hospitals; in two of these out-patient clinics were held. These clinics had x-ray equipment, but the forty-four dispensary premises which were also inherited had no medical facilities and many were rooms rented in private houses.

Considerable reorganization has taken place since the Authority assumed command. At present it controls eight hospitals with about 900 beds, while a further 700 beds are available in hospitals administered by the Northern Ireland Hospitals' Authority. There are now twenty-seven chest clinics scattered over the Province; nearly all are located at hospitals and have diagnostic facilities. The static mass miniature radiography unit has been supplemented by two mobile units. Administratively the country is divided into four areas, one of which has three subdivisions; each area or subdivision has a consultant chest physician and two or more chest or assistant chest physicians. The Authority has a team of about forty health visitors, and each area has a lay executive officer.

¹ Elder, A. T., *Brit. J. prev. soc. Med.*, 1953, 7, 105.

² *British Medical Journal*, 1954, 1, 368.

The degree of success attained by the venture is not easily assessed, because it is impossible to know what might have been achieved by other methods. The impression gained is one of steadily increasing activity along conventional lines. Thus, since the Authority took over, the number of available hospital beds has increased to about 1,600, or by about 30%. Clinic attendances have increased from 44,000 in 1948 to about 60,000 in 1952, while the annual number of mass miniature radiography examinations has increased from about 32,000 to 75,000. Meanwhile the annual number of new notifications (all forms) has fallen from nearly 3,000 to less than 2,000; in 1952 the notification rate was 134 per 100,000 of the population. Similarly, mortality has been more than halved; the death rate from all forms fell from 69 per 100,000 in 1948 to 30 per 100,000 in 1952.

The introduction of a B.C.G. service in July, 1949, requires special mention as a new step in prevention in Northern Ireland. At present vaccination is limited to Mantoux-negative contacts of tuberculous patients, nurses, medical students, and other specifically exposed persons, newborn children, school leavers, and volunteers.

By the end of 1952, 13,000 vaccinations had been carried out by the Authority's officers and by the medical staff of the Royal Belfast Hospital for Sick Children. A study of infant vaccination carried out at this hospital by Dr. Honor M. Purser was reported in this *Journal* recently,² and she makes it clear that the use of B.C.G. is warmly welcomed. Plans have been made for the county borough and county health authorities to co-operate in this service.

As the county health and county welfare authorities and the Northern Ireland Hospitals' Authority became effective it seemed likely that some overlapping of duties would be inevitable unless liaison and co-operation were readily established with these younger bodies. By the end of 1952 several schemes of mutual aid were in existence. Thus the local authority health departments are informed of notifications, and on request their nurses undertake home nursing with equipment provided by the Tuberculosis Authority. Again a home help service is operated on behalf of the Authority by four of the local authority health committees and by one of the county welfare committees. It appears that the Authority is well aware of the danger of duplicating services, but the degree of co-operation achieved is still imperfect. The closing stages of this experiment will be watched with interest, not only in Northern Ireland but elsewhere. If it can be judged a success, then it might well point the way for the conduct of campaigns against other diseases in other parts of the world.

LEPROSY

For many years progress in knowledge of leprosy and in ability to control the disease has been very slow. Although the bacillus was recognized eighty years ago (it was possibly the first pathogenic bacillus seen in

human tissues) it has defied all attempts at cultivation, and no animal has been found susceptible. This means that experimental work has been greatly handicapped. Treatment has been of limited value, and attempts to prevent infection in the community have been based on isolation measures which have too often caused concealment of the disease till it was far advanced. Most experienced leprosy workers have been pessimistic about the possibility of controlling the disease in the individual or the community. In recent years, however, advances in treatment and in immunology have changed the outlook of anti-leprosy work, and a review of the present situation has recently been attempted by the newly formed W.H.O. Expert Committee on Leprosy, which held its first meeting in Brazil in November, 1952. Some workers may feel that the first report¹ of this committee is too optimistic, but none can deny that much more can be done for leprosy than in the past.

The report states that "public health and not public fears and prejudices" should determine leprosy control policy, and even in these enlightened days this still cannot be emphasized too strongly. Measures for making isolation less rigid, more humane, and more practicable are suggested, and a warning is given against keeping the children of leprosy parents in special institutions for unnecessarily long periods. There is a marked difference in the degree of infectivity of "open" and "closed" cases, and members of the committee found no justification for departing from the widely practised policy of confining segregation to open cases.

The possibility that B.C.G. vaccination may have a place in the control of leprosy is at present being investigated, and Lowe and McNulty² recently described in this *Journal* some immunological studies having a bearing on this work. The W.H.O. expert committee takes the view that B.C.G. vaccination cannot be officially recommended as a control measure until large-scale trials have been conducted.

The members were of the unanimous opinion that sulphone treatment is greatly superior to methods of treatment previously in use. The parent sulphone (diaminodiphenyl sulphone, D.D.S., dapsone) has many advantages. Thiosemicarbazones are useful alternatives, but not suitable for mass treatment because of their toxicity. Streptomycin and isoniazid do not appear to be of much value in leprosy. Cortisone and A.C.T.H. have been used successfully in the treatment of the acute phases and complications of leprosy, and in sulphone allergy.

Other sections of the report are concerned with the classification of leprosy, with the lepromin test, and with histopathological examinations. These will be of interest mainly to specialists, but the document as a whole will be useful to leprologists and public health workers alike, and will, to use its own words, "contribute to the disappearance of the unnecessary horror attached to leprosy," and help to encourage anti-leprosy work along rational and humane lines.

FRUCTOSE IN DIABETES MELLITUS

There has recently been a revival of interest in the metabolism of fructose, especially in relation to the clinical problem of diabetes mellitus. The observation that diabetic animals can assimilate fructose more efficiently than glucose is not new. Minkowski¹ in 1893 showed that when fructose was given to depancreatized dogs the liver quickly produced glycogen, and this has been confirmed more recently by *in vitro* studies on liver slices from diabetic rats.² A number of American authors^{3,4,5} have studied the effect on normal and diabetic subjects of 10% intravenous infusions of fructose, and showed that fructose was utilized more rapidly than glucose by both groups. Insulin plays no part in this, although it will modify the rise in blood glucose which follows fructose infusion in the diabetic. It has been estimated that approximately 40% of the fructose is removed by the liver, presumably to form glycogen, since there is an accompanying fall in serum inorganic phosphorus⁶; a further fraction appears in the urine even at low blood concentrations, since there is no renal threshold for fructose. The level of pyruvic, lactic, and other acids rises sharply, and this is a theoretical objection to the use of fructose in diabetic acidosis. However, Daughaday and Weichselbaum⁷ could find little change in the degree of acidosis in nine patients with diabetic ketosis after infusions of fructose, and there seems to be no danger at infusion rates of less than 1.5 g. per kg. per hour. Oral administration is unsatisfactory in that much of the fructose is converted to glucose during its passage through the splanchnic area.

The finding that fructose is utilized normally by the patient with diabetes raises some interesting questions. For instance, Weichselbaum and his colleagues⁵ found large quantities of free fructose in the muscles after fructose infusion, and they believe that this hexose, unlike glucose, can be taken up by peripheral tissues in the free non-phosphorylated form, which would help to explain its rapid disappearance from the bloodstream. The ability of the diabetic to metabolize fructose supports the theory of the Coris that insulin is concerned in the phosphorylation of glucose by a specific hexokinase (glucokinase). It is known that there is a separate enzyme, fructokinase, present in liver and muscle, which is uninfluenced by insulin action. Exactly where fructose enters the carbohydrate cycle is not yet established, but the production of large amounts of citric, lactic, and pyruvic acid suggests that it is metabolized differently from glucose. Further research on this should clarify some of the details of carbohydrate metabolism. Besides its theoretical interest, fructose may prove to be a more useful sugar in conditions where glucose has a time-honoured place—for example, in the treatment of hypoglycaemia. It remains to be seen whether it will supplement established methods in the treatment of diabetic coma.

CLINICAL PATHOLOGY IN GENERAL PRACTICE

SIMPLE SKIN PATHOLOGY

BY

JOHN O. OLIVER, O.B.E., M.B., B.S.

Director of Pathology, St. John's Hospital for Diseases of the Skin, London; Lecturer, the Institute of Dermatology

In addition to the histological examination of biopsy specimens, often essential for accurate diagnosis, the clinical pathologist may give useful assistance in the diagnosis and treatment of some diseases of the skin.

As skin disease may be a local manifestation of a general disorder of the body, it follows that many of the investigations commonly performed by the clinical pathologist will have a place in dermatology. Some of these investigations are dealt with elsewhere in the present series, and it is necessary only to name them here. Others peculiar to dermatology justify more detailed attention. It may be useful to list the more important investigations which may be needed to aid in the diagnosis of skin diseases.

List of Examinations

"Parasitology"	Bacteriology	Culture of infecting organisms Sensitivity of organisms Culture of urine and faeces Sputum for tubercle bacilli
	Mycology	Direct and cultural examination of hairs, skin, and nails for fungus (dermatophytes) Examination for yeast-like organisms
	Animal Parasites	Fleas, lice, and bed-bugs Scabies Threadworms
Biochemistry	Blood	Glucose tolerance (and blood sugar) Cholesterol Serum proteins Diffusible calcium Uric acid
	Urine	17-Ketosteroids General chemical analysis Porphyrins
Haematology	Blood	Cell counts Haemoglobin estimation Bleeding and clotting times Blood platelets E.S.R. L.E. cells
	Bone marrow	Cell counts L.E. cells
	Serology	Wassermann reaction (or Kahn test)
Histology	Examination of biopsy specimens	

Bacteriology

When interpreting the result of bacterial cultures allowance must be made for the normal flora of the skin. Staphylococci which do not produce coagulase—*Staphylococcus albus*—and diphtheroid bacilli are commonly found, and occasionally other organisms such as coliform bacilli and *Proteus vulgaris*. Also there is a great difference between the isolation of a true infecting organism and a mere contaminant—for instance, pathogenic staphylococci (that is, coagulase producers) derived from the nose and trans-

ferred to the lesion. However, cultures of skin lesions are often useful in assessing the condition and also to some extent in regulating treatment by demonstrating sensitivity to antibiotics and sulphonamides, if these are under consideration. A sterile throat swab is the usual collecting implement and is, of course, most useful when pus or actual discharge is visible. Smears made on glass slides (from a second swab) should be taken at the same time. Mention should be made of examination of the gums or of ulcers in the mouth for the organisms of Vincent's angina. A smear made on a microscope slide is generally of greater value to the bacteriologist than a swab in this condition.

The malignant pustule of anthrax deserves special note, as, although anthrax is a rare condition, except as an occupational hazard, early diagnosis, often a matter of difficulty, is important. Smears should be made on glass slides of serum from a vesicle or from material scraped (gently) from the lesion. In addition, swabs are useful to provide cultural confirmation of any organisms seen in the direct film. Handle such material with special care.

As it is well recognized that normal commensals multiply rapidly in any skin lesion, it is important to take swabs for culture from the best situation in any given case, thus:

Scabbed or Crusted Lesions.—The surface of the lesion and the surrounding skin should be cleaned with 70% spirit, the crust removed, and a swab taken from underneath.

Vesicles, Pustules, or Bullae.—After cleansing with 70% spirit, the lesion is punctured and torn with a sterile needle, and the tip of a swab inserted in the cavity.

Fissures and Ulcers.—The skin should be cleansed with 70% spirit as near to the edge of the lesion as possible. A swab should then be drawn along the fissure several times, or rotated with firm pressure beneath the advancing edge of the ulcer.

In every case it is important to provide an adequate clinical description of the lesion for the guidance of the pathologist.

If bacteriological examination of urine is required, a catheter specimen is essential in the case of women, but a midstream specimen after "cleaning-up" may suffice from men. Vaginal swabs are generally useless for the cultivation of gonococci, but if these organisms are suspected the use of "preserving medium" will help in cultural investigation if the patient cannot attend the laboratory. Smears made from swabs may be of some use for direct identification of organisms, but the hosts of secondary invaders commonly encountered limit success when seeking gonococci. For *Trichomonas vaginalis* a small quantity of discharge collected in a capillary pipette is the only sure way of providing a suitable specimen. The tip of the pipette can be sealed off in a bunsen or spirit flame for transport purposes.

Bacteriological examination of faeces is not often required in dermatology, but in any case specimens present no special difficulties. Sputum examination for tubercle bacilli may be required as part of the general overhaul, and here again the usual methods of collection apply.

Fungal Infections

The examination of skin lesions for the presence of fungus is very necessary. Clinical appearances are often deceptive, and before excluding the possibility of ringworm on clinical

*Stuart's transport medium with special buffered swabs as used at the Whitechapel V.D. Clinic is required. The medium is a "sloppy" agar in bijou bottles filled to the brim in which the broken-off swab is immersed for transport.

grounds it is wise to have a thorough microscopic examination of skin scrapings made for the presence of fungus, either mycelium or spores, or both. Nails, too, are an important source of error, if laboratory examination is omitted, especially in early cases.

Now that ringworm of the scalp is much less commonly seen diagnosis depends far more on adequate mycological examination of hairs from suspected cases. Wood's light† is invaluable in demonstrating the typical fluorescence associated with microsporum infections (*Microsporum audouinii*, the commonest cause of human ringworm, and *Microsporum canis*, which also affects cats and dogs) but is useless for trichophyton infections, as no fluorescence occurs (except very faintly in favus). Unfortunately this aid to diagnosis, and the selection of the best material for examination, is not often available in practice.

Since infection is chiefly in the region of the hair follicle, breakage of the hair occurs at the mouth of the follicle or 2 to 3 mm. above it. Thus with a hand or watchmaker's lens search must be made for short broken-off hair stumps

FIG. 1.—Diagram of the lesion in ringworm of the scalp, showing short broken hair stumps among normal hair. Solid black lines represent infected hair.

and some of these extracted by means of Whitfield's forceps, after swabbing the suspected area with spirit (Fig. 1). If forceps are used to depress the scalp immediately around suspected follicles, extraction of the hair is greatly facilitated. Hair stumps are placed on a clean microscope slide, another slide is pressed on to the hairs, and the two slides are secured between elastic bands for transport to the laboratory. If a microscope is at hand immediate examination may be carried out, using a drop of 20% potassium hydroxide on the slide and applying a coverslip. Both low-power ($\frac{1}{4}$ -in.) and high-power ($\frac{1}{8}$ -in.) dry lenses are employed, but the examination needs practice and it is better to seek laboratory confirmation unless some experience has been gained.

Skin lesions require scraping with a blunt scalpel. The active edge of the lesion quite near the normal skin margin is the most fruitful place for examination. Vesicles should be treated by snipping with fine scissors and submitting the "dome" of the vesicle for examination. Care must be taken to distinguish between the so-called "ide" eruptions near a primary focus, since these do not show the presence of fungus (see Fig. 2). Scrapings or other fragments of skin are conveniently transmitted between two glass microscope slides held together with elastic bands or in minute paper packets reminiscent of those for a chemist's powder. Potash specimens may also be made and examined microscopically.

Nails should be pared with sharp scissors or manicurist's nail clippers well into the diseased or misshapen area; and any cheesy material scraped out from under the nail (see Fig. 3). These specimens may also be transmitted in paper packets or in very small glass tubes.

Cultural examination of mycological specimens is at present restricted to special laboratories only, hence the importance of direct microscopical examination in clinical

†From a specially screened mercury vapour lamp.

practice. The need for cultural examination may, however, justify seeking help from one of the special laboratories (for instance, the department at St. John's Hospital for Diseases of the Skin), as identification of species plays a part in the epidemiology and prognosis, and also may determine special treatment.

Apart from the commoner dermatophyte (or ringworm) infections other superficial conditions due to fungus may be met with. In pityriasis versicolor examination of scales from the macules reveals clusters of typical round thick-walled budding cells with short mycelial filaments (*Malassezia furfur*). In erythrasma of the groins, axillary region, and other flexures examination of scales from the macular rash will show very delicate filaments, which appear to be breaking into coccil and bacillary forms (*Nocardia minutissima*). In trichonocardiosis minute nodules form on the hairs (of axillae and pubis), leading to lack of normal lustre and some brittleness. Discoloration of the hair results from superadded infection with pigment-producing micro-organisms and the hairs appear yellow, but may be black or even red. The colour may diffuse and stain the skin and clothing. Obviously affected hairs with nodules must be sought with a lens and plucked out with forceps for delivery to the pathologist between glass slides.

Otitis externa, either subacute or chronic, may be due (very rarely) to mycotic infection (*Aspergillus* species). Examination of the lining exudate is called for in these cases, and microscopical search is made for mycelium and sporing heads of fungus. This examination is not readily made on specimens submitted through the post.

FIG. 3.—Ringworm of the nails. (A) Thickened nail with surface discoloured but otherwise unaltered. (B) Thinned, separated nail, with debris beneath surface discoloured but otherwise unaltered. (C) Irregularly thickened, raised soft or brittle nail, with surface destroyed.

Monilliasis

Infections with yeast-like organisms are becoming recognized more frequently. Monilliasis has long been known, but its importance has been increased owing to the action of

FIG. 2.—Vesicles of tinea pedis. Primary vesicles contain fungus, secondary vesicles do not.

antibiotics, which may disturb the balanced flora of the mouth, throat, gut, vagina, and even of the skin. In all these situations the causative organism *Candida albicans* exists as a normal commensal. Other factors may also lead to disturbance of the normal flora and an excessive multiplication of yeasts. Cutaneous monilliasis may simulate the ringworm or dermatophyte infections, though usually pruritus is a feature of monillial infection, whilst maceration of the skin or mucosae is also more common. Nail infections yield less destruction and debris formation, but more paronychia with monillial than with dermatophyte infections. Similar specimens serve for the diagnosis of monillial as for dermatophyte infections—namely, skin scrapings, nail clippings, and swabs from mucous membranes.

Animal Parasites

Usually little laboratory aid is required in establishing a diagnosis of bites from fleas, lice, or bed-bugs. Sometimes it is useful to confirm the presence of nits on hairs, and this is easily done with a low-power microscope, which reveals the eggs attached to the hair at some distance from its root, depending on the lapse of time since deposition by the adult female (Fig. 4).

The diagnosis of scabies on the other hand often requires laboratory aid, unless the practitioner is prepared to confirm the presence of the parasite microscopically. The acarus of scabies is only just visible to the naked eye, and a watchmaker's lens is recommended when examining the fine wavy dark lines of the skin lesions forming the burrows or runs, which occur on the fingers, wrists, palms, buttocks, etc. The usual method advocated for discovery of the parasite is to run a sterile flat cutting-edge Hagedorn needle into the burrow below the acarus, which is often seen more clearly against the darker background of the needle point. An upward movement of the needle severs the burrow and lifts the acarus free, the parasite generally co-operating in this by clinging to the needle point. While this method is quite useful, a more certain one is to gently scrape the whole area of the "burrow" with a blunt scalpel (as in taking ringworm specimens of skin). This provides debris in which

cover of the parasite is to run a sterile flat cutting-edge Hagedorn needle into the burrow below the acarus, which is often seen more clearly against the darker background of the needle point. An upward movement of the needle severs the burrow and lifts the acarus free, the parasite generally co-operating in this by clinging to the needle point. While this method is quite useful, a more certain one is to gently scrape the whole area of the "burrow" with a blunt scalpel (as in taking ringworm specimens of skin). This provides debris in which

Fig. 5.—Ova of acarus in scraping of burrow. ($\times 60$.)

the parasite and her eggs (some containing larvae and others empty) may be identified on a glass slide with coverslip, using the lower-power microscope lens (Fig. 5). If it is desired to scrape the lesion an addition of some water, or 7% potassium hydroxide, will assist the operation. Material collected can, of course, be submitted to a laboratory (between glass slides) if necessary.

The possibility of infestation with threadworms, although not a common cause of pruritus ani (except in children), has sometimes to be considered. The method of establishing the diagnosis has been described by Dr. K. B. Rogers earlier in this series (January 16, p. 147).

Biochemical and Haematological Investigations

It is only necessary here just to touch on the biochemical and haematological investigations which may help in the diagnosis of skin conditions. The tests are described in other articles in this series.

In cases of furunculosis, for example, it is advisable to exclude diabetes as a predisposing cause by investigating the blood sugar. A blood cholesterol estimation (normal range 150-250 mg. per 100 ml.) may be helpful in xanthomatous conditions in which a marked rise is the rule—for example, up to 350 mg. or more per 100 ml. In lupus erythematosus the albumin/globulin ratio may be reversed from the average value of 2:1 to less than unity. The estimation of the diffusible fraction of the calcium in the serum has a place in the control of treatment of lupus vulgaris with calciferol.

In virilizing conditions, some of which may be associated with excessive hairiness, the urinary 17-ketosteroids will give assistance, while in cases of suspected light sensitization, or photodermatitis from contact with substances such as eau de Cologne, examination of the urine for porphyrins may be indicated. The best specimen for the laboratory is the early morning urine, following restriction of fluids overnight to concentrate the porphyrins.

The bleeding and clotting times and the platelet count will be required in cases of purpura. The E.S.R. is a useful index of activity in conditions such as lupus erythematosus. In acute systemic lupus erythematosus (but not in the other varieties of the disease) the Hargraves L.E. cell may be demonstrated in specimens of oxalated blood from peripheral vessels. A sternal marrow preparation gives the haematologist an even better chance of finding L.E. cells. Lastly, the Wassermann reaction (or Kahn test) will help in the diagnosis of syphilitic lesions of the skin.

Histology

The technique of skin biopsy is a minor surgical procedure similar to that for excision of a disfiguring "spot," except that all damage to the tissue removed—by rough handling or gripping in forceps—must be avoided at all costs. It must be emphasized that without observation of the lesion *in situ* the histologist requires an accurate description of the lesion, including site of the biopsy, age and sex of the patient, and a brief clinical history. Not all skin diseases can be diagnosed histologically, but, given suitable material and provided with adequate information, the expert is likely to make a diagnosis in upwards of 60% of cases, varying with the quality of the material and the adequacy of the descriptive notes.

The conditions most usefully examined are: small tumours of, or immediately below, the skin; and lesions associated with thickening of the skin, chronic discoloration, bullous eruptions, and ulcers thought to be malignant.

In its simplest form the biopsy incision is elliptical (see Fig. 6) with overlapping ends, some 2 cm. long and 0.5 cm. across at its widest point. The line of incision should follow the natural lines of cleavage of the part. The incision must be deep enough to include some of the subcutaneous fat. Preliminary cleaning of the skin with 70% spirit containing 1% "dettol" is the ideal. A 2% procaine solution, preferably without adrenaline, is infiltrated around (but not

under) the proposed area of excision. The incision is made with the point of a Bard-Parker scalpel fitted with a new No. 15 blade. Cutting must be at right angles to the surface of the skin. The excision line is best raised at the extreme

FIG. 6.—Plan of biopsy incision to include both normal skin and part of the lesion.

tip with a Kilner hook (or fine pair of "mosquito" forceps) to avoid damage during undercutting of the subcutaneous fat. The incision must be planned to include a portion of normal skin at one end of the specimen.

The specimen so obtained may be laid gently fat side downward on a small piece of blotting paper—to absorb any blood—and the whole transferred to a suitable bottle containing either 70% alcohol or saline with 10% of formalin—that is, 4% formaldehyde—the latter being preferable as it preserves fat more completely. The greatest possible care is necessary in handling biopsy specimens to avoid all pressure on the excised fragment, except at its extreme tip, which may be held gently with fine forceps.

Two or three fine sutures of ophthalmic nylon will serve to bring the edges together and the X-shaped ends allow of healing with a flattened and inconspicuous scar.

My thanks are due to Mr. R. C. Syms, chief technician in my department, for many useful points in technique and for most of the sketches.

Reports of Societies

LUNG RESECTION IN PULMONARY TUBERCULOSIS

A combined meeting of the Metropolitan Regional Tuberculosis Societies to discuss the place of resection in the treatment of pulmonary tuberculosis was held at the London School of Hygiene and Tropical Medicine on February 13, under the chairmanship of Dr. J. L. LIVINGSTONE.

The opening speaker was Mr. RONALD EDWARDS, who began by admitting that, because of the relatively short time for which resection had been practised, it was not yet possible to make any real comparison of its results with those of the various forms of collapse therapy. He described how in 1949 he and his colleagues at Liverpool had considered the analogy between pulmonary tuberculosis and other chronic inflammatory processes in the lungs. In chronic staphylococcal infection, for example, it was possible after overcoming the infecting organisms to remove the damaged pulmonary tissue. With the use of antibacterial drugs, might not a similar policy be feasible in tuberculosis?

The Case for Resection

Mr. Edwards then discussed the varieties of disease for which he undertook resection:—(1) *The Caseous Nodule.*—When a lesion of this sort had a diameter of more than 2 cm. he regarded it as being potentially dangerous, and especially so if there had been evidence at any time of cavitation in it. When he began to resect these lesions it was usually possible to find tubercle bacilli in them. More recently, after longer periods of antibacterial drug treatment, far fewer bacilli had been seen and it was frequently impossible even to culture them. The bacteriologists had been unable to give a clear answer to the question whether or not these organisms were dead. This clearly was the crucial question, because it would seem unnecessary to remove tissue incapable of producing progressive disease. Mr. Edwards answered by saying that he believed that many of these treated lesions if not removed do, in fact, cause later spread of disease. (2) *Destroyed Lung.*—This was generally accepted as an indication for resection. (3) *Bronchiectatic Areas.*—Mr. Edwards pointed out that localized bronchiectasis due to non-tuberculous disease was frequently treated by resection, and he thought that similar considerations applied to bronchiectatic areas in association with tuberculosis. He regarded treatment with thoracoplasty as unreasonable in the presence of bronchiectasis and preferred to remove the affected portion of the lung. (4) *Fibro-calcic Disease.*—Under this heading Mr. Edwards discussed the sort of cavitated lesion which used to be and still often was treated by means of thoracoplasty when situated in the upper part of the lung. He pointed out that it was now widely accepted that isolated cavitated disease in the apical segment of the lower lobe was best treated by resection, and he thought it unreasonable to treat a similar condition in the upper lobe differently merely because of its site. Such disease in the upper lobe was frequently entirely or almost entirely confined to the posterior and apical segments, and he had often restricted his resection to the affected segment or segments. These segments were often destroyed and functionless, and if collapsed under a thoracoplasty were bronchiectatic. On these grounds also, he thought resection was the preferable treatment. (5) *Empyema Associated with Underlying Pulmonary Disease.*—The treatment of tuberculous empyemas with the older methods of thoracoplasty preceded by repeated aspiration or surgical drainage was far from satisfactory, and modern methods of excising the empyema with the affected part of the underlying lung were a very great advance.

Mr. Edwards said that he had not entirely given up thoracoplasty; especially when the pulmonary disease was rather widespread he might carry out a thoracoplasty if the most severely affected area was suitably situated for this form of treatment. He felt that if a patient was to be treated by resection it should be possible to remove all the major areas of disease. On some occasions this might necessitate an operation on each side of the chest. In the elderly also Mr. Edwards preferred thoracoplasty to resection, which was usually not well tolerated. So far as pulmonary function is concerned, Mr. Edwards did not think that resection had any marked advantage over thoracoplasty. In fact, he found it often advisable to do a small thoracoplasty as well as the resection to prevent over-expansion of the residual lung. Referring to post-operative complications, Mr. Edwards admitted that a bronchial fistula was a worse disaster than any of the complications of thoracoplasty. However, it was very rare, and apart from this he had found the complications of resection less troublesome than those of thoracoplasty. Thus, spread of tuberculous infection to the lower part of the same lung or to the other lung, which Mr. Edwards regarded as a feature of thoracoplasty, was a much more serious event than any of the commoner complications of resection.

Patients treated by means of resection were usually back to active life in six to nine months after operation. Mr. Edwards described how in association with the chest physicians of his area much of the preliminary treatment and

aftercare was carried out at home, and many of his patients were in hospital for a few weeks only. In conclusion he gave some of the results of a recent survey of the patients he had treated over the past five years. The number of patients operated on five years ago was 11, of whom 10 were alive and well. Those treated four years or more ago number 112, of whom five were dead (three post-operatively), 10 not well, two lost sight of, and 95 well and working. So far as his total figures were concerned, Mr. Edwards and his colleagues had operated on 1,023 patients with a post-operative mortality of 1.95%. These were rightly acclaimed by the other speakers as truly remarkable results.

A More Conservative View

The next speaker was Mr. T. HOLMES SELLORS. While accepting resection as an essential part of the modern treatment of pulmonary tuberculosis, he wished, he said, to put forward a more conservative view than that of Mr. Edwards. He wondered whether pulmonary tuberculosis could really be safely regarded as a purely local phenomenon rather than as part of a general disease. Little was known of the fate of the caseous nodule, and he questioned the need to remove all small lesions of this sort. He pointed out, as had Mr. Edwards also, that the social background of the patients had often an important bearing on whether or not they could be treated surgically. Thus, lesions which might well be best excised from a patient who needed to return to vigorous manual labour could often be left alone in a patient who followed some quiet sedentary occupation.

Mr. Holmes Sellors felt that the complications of resection were considerable and could not be ignored. He gave his own figures for thoracoplasty and for resection for the years 1946 to 1952. He had carried out thoracoplasty on 1,171 patients compared with 538 resections. He showed diagrams illustrating the sort of lesions for which he regarded resection as being indicated. These were large, solid foci; thick-walled, unclosed cavities under artificial pneumothoraces; cavities in the apical segments of lower lobes; unclosed cavities beneath thoracoplasties; acute progressive destruction of a lung; and a shrunken, fibrosed, destroyed lung. He showed slides of radiographs illustrating some of these conditions, and made the point that, unlike Mr. Edwards, he did not regard upper lobe bronchiectasis as a contraindication to thoracoplasty. He thought that broncho-stenosis rather than bronchiectasis was an indication that resection and not collapse therapy should be used.

Medical Experience

Dr. J. G. SCADDING spoke next. As a physician he had a much smaller number of patients who had been treated by means of resection, but he had the advantage of being able to follow personally the course of each one. Since 1948, 45 of his patients had been treated in this way. He divided these for purposes of description into 25 cases in which the indication for resection was strictly localized disease, 12 in which it was residual localized cavitated or large caseous lesions after previous treatment by other methods, 6 in which resection was accompanied by pleurotomy for tuberculous disease of the pleura, and 2 with localized tuberculous bronchiectasis. One of the main points upon which Dr. Scadding laid emphasis was that the disease requiring treatment should be strictly localized. He had used lateral as well as antero-posterior tomograms in addition to postero-anterior and lateral radiographs to be as certain as possible that the lesions were confined to those pulmonary segments which it was proposed to resect. As an example of one variety of localized disease, Dr. Scadding showed slides of radiographs of a patient with a lesion of the bronchial cold abscess type. The presence of this sort of lesion could often be suspected from tomograms, which show a thickened bronchus leading up to a sharply outlined nodule with smaller satellite nodules. After preliminary treatment with antibacterial drugs this kind of lesion was best treated with resection. Dr. Scadding also showed radiographs of a pneumonic localized lesion which, again after

preliminary treatment and care in demonstrating the absence of disease in other parts of the lung, had been treated by resection of the affected segment. Another condition which Dr. Scadding had treated by means of resection was tuberculous bronchiectasis. By this he meant a progressive caseous ulceration and distension of bronchi. The residua of previous treatment formed another group of conditions which had been treated by means of resection.

Dr. Scadding then spoke of the very real improvement in the treatment of tuberculous empyema which had come with the use of pleurotomy either alone or, as in the cases to which he referred, in association with the removal of underlying diseased pulmonary tissue. In this group he mentioned two of particular interest in which pleuro-pneumectomy was undertaken for the acute rupture of tuberculous cavities into the pleural space with the rapid development of a pyo-pneumothorax. In one of these the rupture was into an existing artificial pneumothorax. Dr. Scadding considered that collapse treatment, either medical or surgical, was still to be preferred in cases in which localization of the disease was not so precise, and stated that, in the period reviewed, about twice as many of his patients had been treated by surgical collapse procedures as by resection.

Discussion

In the discussion which followed a number of physicians as well as surgeons took part. In replying to some of the points raised, Mr. RONALD EDWARDS said that he regarded patients between 16 and 20 years old as not very suitable for resection. He found that their disease tended to be unstable, and he preferred to carry on their treatment with other measures until they were older. He said that he now did a thoracoplasty after every upper lobectomy, and also very frequently after segmental resection of the upper lobe, as he had found that this tended to reduce the incidence of air leaks into the pleural cavity.

Preparations and Appliances

"HYBRID" PHARYNGEAL AIRWAY

Dr. A. H. GALLEY, of King's College Hospital, London, writes: Some anaesthetists still prefer to use a Hewitt or a Phillips pharyngeal airway because of their ample cross-section and ease of insertion. Unfortunately, they both have metal flanges which occasionally cut or bruise the lips when used with a mask held in place by a Clausen harness,

PHILLIPS 'HYBRID' GUEDEL

for only too often the flange has a way of slipping under the cushion of the mask and being pressed into the flesh. To circumvent this complication I have had a "hybrid" airway made which has a Phillips-type end or shank, but a rubber flange, like that of the Guedel—thus combining the better features of each of these airways. The manufacturers are Messrs. A. Charles King Ltd., 27, Devonshire Street, London, W.1.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Valvotomy in Mitral Stenosis

SIR,—The suggestion made by Dr. H. E. S. Pearson (*Journal*, January 23, p. 216) that valvotomy might benefit patients with extreme narrowing of a rigid mitral orifice is certainly one which concerns us. The main purpose of our paper (*Journal*, November 14, 1953, p. 1059) was to guide those not closely associated with cardiac surgery in the selection of cases most likely to benefit from valvotomy, and to this end we emphasized the importance of a pliant diaphragmatic valve. We do not for a moment suggest that surgery should be confined to ideal cases. If we can offer a reasonable chance of some measure of relief to hopelessly crippled patients, then we must be prepared to take greater risks for less benefit.

As long as the mitral valve is operable, that is to say of diaphragmatic type and not completely rigid, then we may extend the scope of valvotomy to relatively unfavourable cases, for example to those with very large hearts, with long-standing failure, or complicated by systemic hypertension, pregnancy, and to those over 50 years of age. In such cases, however great the operative hazard, those who survive it are likely to be rewarded. Extension of the scope of operation to valves which are anatomically unsuitable for surgical correction, as Dr. Pearson suggests, is quite another matter, for here the reward is problematical.

It is true, as Dr. Pearson shows, that minimal widening of an extremely constricted orifice will permit a considerably increased flow, but this applies to flow in two directions. Owing to the higher pressure gradient between ventricle and auricle during systole, widening of a completely rigid valve may increase regurgitation disproportionately to normal flow, and the result may be the reverse of beneficial. The limits of operability in respect of rigid valves have not yet been fixed, and in a doubtful case surgical exploration of the mitral orifice is sometimes justifiable before it is finally classed as inoperable.

While we are much in sympathy with Dr. Pearson's plea, nevertheless we believe that the paramount indication for mitral valvotomy must remain the presence of a valvular lesion which is amenable to surgical correction. Given this indication, then greater operative risks may properly be accepted in otherwise unfavourable cases.—We are, etc.,

Rheumatic Heart Disease Complicating Pregnancy

SIR,—I agree heartily with Drs. Frank Denny and Anthony Ryle (*Journal*, January 23, p. 215) that the life of the under-privileged mother living with her increasing family in a single room at the top of a tenement will surely throw an intolerable strain on a diseased heart.

The religion of the majority in Eire makes no ethical objection to the limitation of the family under such circumstances. It does, however, distinguish between natural and artificial means of doing so. Natural means such as continence or the use of the safe period are considered to be in accordance with the natural law, whereas artificial means such as contraception, therapeutic abortion, or sterilization are considered contrary to that law, on the grounds that the first is a perversion, or turning away of a function from its natural purpose, the second is a direct killing of an innocent life, and the third a self-mutilation unnecessary to the life and health of the whole body. Nor does the excellent end in view justify these unworthy means.—I am, etc.,

Dublin.

JOSEPH BARNES.

Reaction to Blood Transfusion

SIR,—We were rather concerned to read Dr. R. D. Barnard's letter (*Journal*, February 6, p. 332) suggesting that *in vitro* compatibility tests between dextran and suspensions of recipients' erythrocytes should be routinely carried out when the use of this plasma substitute is being considered. Is Dr. Barnard aware that several of the macromolecular substances currently available as plasma substitutes produce pseudo-agglutination of erythrocytes to a greater or lesser degree, depending on the molecular size and the concentration of the polymer which is used in the test? For this reason, if cells are suspended in a 6% clinical dextran solution and examined after 5 to 10 minutes, virtually 100% of potential recipients would be assumed unsuitable for infusions of these plasma substitutes, if we interpret Dr. Barnard correctly. It has, of course, been known for some time that erythrocytes suspended in solutions of gelatin, gum acacia, polyvinyl alcohol, and dextran are agglutinated by incomplete antibodies. When these colloid media are used as alternatives to 20% albumin, it is necessary to avoid rouleaux formation by choosing a dilution and molecular size of the polymer which will still promote cell agglutination by the incomplete antibody. It is true that many macromolecular substances possess potential antigenicity for man, but surely this does not imply that they can stimulate the production of specific blood group antibodies *in vivo*, nor can one arrive at the same conclusion because these macromolecules enhance erythrocyte agglutination by incomplete antibodies *in vitro*.

In view of the fact that the clinical use of these plasma substitutes, and particularly dextran, has been extensive since 1949, and has been associated with an extremely low incidence of reactions,^{1,2,3} it would appear that Dr. Barnard's conclusions are invalid on the basis of practical experience. Finally, we would like to stress that it is essential to obtain a sample of the recipient's blood prior to the infusion of these plasma substitute solutions both for grouping and especially for later cross-matching if blood is required, in order to avoid any error due to the pseudo-agglutination effect—i.e., rouleaux formation—mentioned above. We are, etc.,

FRANK FLEICHER.

The Normal Blood Count

SIR,—I must apologize for the error in the computation of M.C.V. and M.C.H.C. (*Journal*, February 6, p. 326). The most convenient formulae are:

$$\text{M.C.H.C.} = \frac{\text{Hb. expressed in grammes per 100 ml.}}{\text{Packed cell volume, as \%}} \times 100$$

$$\text{M.C.V.} = \frac{10 \times \text{packed cell volume, as \%}}{\text{Rbc in millions per c.mm.}}$$

Fortunately, these errors cause only a shift in the decimal point, and, since the normal range is repeated several times in the article, I hope that they will cause little inconvenience.—I am, etc.,

London, N.W.10.

GEORGE DISCOMBE.

The Basis of Sensation

SIR,—Dr. E. D. Adrian in his Banting Memorial Lecture (*Journal*, February 6, p. 287) asks for new light in the field of the physiology of sensation. This new light might well come from a study of mental hospital patients, many of whom have intense sensory experiences, and where pathological lesions of the sensory tissues (ear, nose, and muscular tubes) are more commonly found than nerve lesions. It is possible that Dr. Adrian sees the problems only through the eyes of a neurophysiologist, and "advertising the difficulties" may be the surest way of "getting out of the wood." His admission that he cannot

see how further knowledge of brain physiology will help us to reconcile mind and matter is commendable, and follows Sherrington. A sharing of the "obscurity" is the first step in solving the problem.

The proof that the olfactory bipolar cells have discriminatory function is, however, not complete, since his admirable demonstration of olfactory selectivity did not go further peripherally than the mitral cells of the lobe. This leaves a doubt of the selective ability of the hair cells, which ought to be analogous to hair cells elsewhere and respond only to mechanical stimulation, as do those of the semicircular canals, the cochlea, and, in lower forms of life, the trigger cells and otocysts. The arrangement of a crown of six or more hairs on the olfactory bipolar cell seems particularly well adapted to mechanical stimulation by traction of the mucus secreted by the supporting cells. If these supporting cells reacted to odours by secretion or structural change, they might be the actual discriminatory cells. It is the basilar membrane of the cochlea which is the real analyser of sound-wave frequency, and visual selectivity is a function of the cells containing visual red and purple—i.e., not of the nerve elements. The contractile tissues which appeared during evolution before the nerve tissue must have had some selective properties. The male moth, with a rudimentary nervous system, has an almost unbelievable sensitivity, commensurate with the size and branching of the antennae, to the odour of the female, and moreover can discriminate in the presence of other odours.

A simple operation in animals frees the supporting cells of the olfactory tissues from all nerve elements. Such animals (and human beings who have lost the nerve elements by disease) might still have a specific reaction to odours of these supporting cells, and by training conceivably would associate them with other experiences.—I am, etc.,

Birmingham.

F. A. PICKWORTH.

Conquest of Plague

SIR,—In recent years there has been a disposition to deny to the late Professor Kitasato the honour of having been the first to discover *Pasteurella pestis*. The denial has been based on slight discrepancies in the cultural characteristics of the organism as described by him. Yet no criticism was ever voiced by contemporary authors of standard works, such as Manson, or Muir and Ritchie.

It is therefore good to see that Professor G. S. Wilson (*Journal*, December 26, 1953, p. 1433) has now put the matter in proper perspective by remarking that the differences between Kitasato's and Yersin's descriptions "were such as would not be regarded nowadays as of any serious differential importance." One might be tempted to add that if Kitasato's organism was not *P. pestis*, what was it? And why has it never been seen or heard of again?

In May, 1894, my father was a medical officer in the Colonial Medical Service in Hong Kong. It fell to his lot to diagnose the first case of plague found there, and on his shoulders rested a great deal of the work in the early stages of the epidemic. Among his duties was to take Kitasato and Yersin round the hospitals on their arrival in Hong Kong. He kept a diary, and the following brief extracts may not be without interest. They confirm the statements of Dr. L. Fabian Hirst (*Journal*, December 26, 1953, p. 1432).

"Sunday, May 6 (in Canton): Went into town to see plague and saw large number of cases with Rennie. May 8 (back in Hong Kong): . . . 1 a.m. Diagnosed Ah Hung as suffering from plague and isolated him. May 12 . . . rabbit and guinea-pig injected from Ah Hung. 26 deaths reported from plague. Ah Hung died. May 15 . . . guinea-pig dead in the morning. June 13 . . . Kitasato and Co. taken round. June 14 . . . Kitasato discovered bacillus. June 15 . . . wired *Lancet*. June 16 . . . took Frenchman (Yersin) round in afternoon. June 20 . . . P.M.s galore. Japs hard at work. June 23 . . . Frenchman got his bacillus. June 27 . . . slides off to Woodhead (German Sims: these slides were shown at the B.M.A. Annual Meeting in Bristol). June 28 . . . dined with Kitasato and Aoyama at Hong Kong Hotel. After getting home, called up an hour later and went back

to hotel to find Aoyama and Ishigami with high temperatures and glands. . . . Aoyama axillary and Ishigami femoral. Aoyama got it from mortuary case. July 1 . . . Aoyama very ill. July 3 . . . Aoyama and Ishigami still struggling. July 7 . . . Aoyama very ill. (He recovered.) July 10 . . . Kitasato's paper transmitted to *Lancet*."

It will be seen that Yersin took a week to find his bacillus. The reason for this was that he would not work in the same building as Kitasato, and it took him some time to get up his own mat-shed in which to work.—I am, etc.,

Victoria, Australia.

J. M. A. LOWSON.

Reduction of Fracture with Succinylcholine Chloride

SIR,—The following case of a fractured cervical spine which normally would have required traction with skull callipers, but which was fully and completely reduced by the use of thiopentone ("pentothal") plus succinylcholine chloride ("scoline"), may be of enough interest to your readers for its reproduction in the *British Medical Journal*.

A male Dyak, aged 26, was admitted to Miri Hospital with a 12 days' history of trauma during a drunken fight, followed by

unconsciousness, after which he was found to be paralysed completely from the neck down. On admission a transverse section of the cord was indicated at and below the level of the 5th cervical segment. His urine was heavily blood-stained, most likely from a ruptured kidney, but, as his condition has not deteriorated and the urine is clearing, to date this has not been investigated. X rays showed a crush fracture of the body of the 6th cervical vertebra with dorsal displacement of the left articular facet behind that of the 5th cervical. With the patient supported in the usual way, reduction was attempted without anaesthesia by gradual hyperextension with no success. Atropine 1/100 gr. (0.65 mg.) was then given intravenously very slowly, and ten minutes later, after thiopentone 0.2 g. intravenously, succinylcholine chloride 1 ml. (50 mg.) was given. During the apnoeic period oxygen was supplied rhythmically through a face-piece only. A click was heard, but after x ray only partial reduction had occurred. Fifteen minutes later, 0.15 g. of pethidine and 1.4 ml. (70 mg.) of succinylcholine chloride were given, and by means of traction by hand plus hyperextension excellent reduction occurred easily, and confirmed by x rays. The patient has been kept in bed with the head hyperextended and between sandbags. No plaster has been applied yet. Some return of sensation to the arm has occurred, probably due to relief of pressure on the 5th cervical nerve trunks,

Before reduction.

After second reduction.

and he can appreciate abdominal pain (? vagus carrying pain fibres from the gut). After 48 hours, with routine supportive treatment, his morale and general condition are excellent, and time only will tell what recovery, if any, occurs with the cord condition.

The ease with which reduction of the fracture dislocation between the 5th cervical and the 6th cervical vertebrae was effected by use of a short-acting muscle relaxant indicates that the day of skull callipers may have passed for all but exceptional cases.—I am, etc.,

Miri, Sarawak.

K. F. D. SWEETMAN.

Presternal Oedema in Mumps

SIR.—The report by two members of the Epidemiological Research Unit at Cirencester (*Journal*, January 30, p. 258) on the occurrence of swelling over the manubrium sterni in cases of mumps prompts me to record a brief note of an outbreak of mumps in a boys' school in February and March, 1936. It occurred simultaneously with an outbreak of influenza, so that many cases could not be admitted to the sanatorium owing to lack of room and they were therefore nursed in their respective houses. It was in one of these houses that a number of cases of preternal oedema was observed in one dormitory. The oedema was well marked and was associated with swelling of the parotid and submaxillary glands and in some cases the testes were also involved, though the testicular swelling appeared some days later. That this is not invariably so is shown by two more recent cases in which the orchitis preceded the parotitis by several days. Although there have been outbreaks of mumps at fairly frequent intervals in this neighbourhood during the past 21 years, at no time have I observed any other case of preternal oedema.—I am, etc.,

Sherborne.

A. G. JEAFFRESON HARRIS.

Press Publicity

SIR.—Mr. Ritchie Calder (*Journal*, January 30, p. 271) is unable to understand why certain eminent doctors appear to be outside the medical ethic. The profession at large are equally puzzled. We have seen leaders of the profession publicized by the B.B.C., bulletins on famous patients reading like the "mentioned in dispatches" after a battle, and articles in the popular press with the name and photograph of the author. At the Annual Meeting a resolution moved by the East Yorkshire Branch (*Supplement*, July 18, 1953, p. 49) designed to promote discussion of these matters was energetically shepherded out. Medical ethics are likely to remain a mystery so long as the leaders of the profession pay lip service to them.—I am, etc.,

Hull.

J. CLAPHAM COATES.

The New Insulin Zinc Suspensions

SIR.—Considerable confusion has arisen for practitioners over the new insulins; and, although there have been many publications about detailed observations, it ought to be helpful to general practitioners to have a short description of them and their uses. The following is based on an inset in the last edition of *The Diabetic Life*.¹

The Novo Insulin Laboratories in Denmark have produced three new preparations, now also manufactured in Britain, which promise an advance in treatment. They have discovered that, by using an acetate buffer instead of phosphate, insulin can be linked to zinc to produce long-acting insulins without the use of protamine, globin, or other added proteins. Hence, for one thing, the occurrence of local allergy is minimized. I shall describe the clinical use of only one, "lente," as the most generally useful; and I shall use the more meaningful terms of "lente," "semi," and "ultra" rather than the more technical chemical terms on which the *British Pharmacopoeia* insists. They are all cloudy insulin zinc suspensions, identical in appearance.

(1) Semilente: insulin zinc suspension (amorphous). This is the quickest acting with a duration of some 10–15 hours, depending on the size of the dose. It resembles the action of globin and of NPH insulin. (2) Ultralente: insulin zinc suspension

(crystalline). Slow onset, but very prolonged action, like protamine zinc insulin. (3) Lente: insulin zinc suspension. A mixture in the same bottle of 30 parts of (1) and 70 parts of (2). It thus provides a mixture of quick and long action insulins, such as have been successfully used in appropriate mixtures of soluble and protamine zinc insulin. Its action is probably smoother and more regular than the latter mixture. All the above insulins can be mixed and retain their individual characteristics: more semilente can be added in the syringe to provide quicker initial action, more ultralente to prolong action. Old types of insulin cannot be mixed with the new. Soluble (regular) insulin remains as the quickest and strongest in action, the most valuable for emergency use.

In new cases the initial dose of lente would be 20–30 units before breakfast, or 30–40 units in severely ketosed patients. Every three to four days blood and/or urine sugar tests should be carried out on out-patients or, better, daily on in-patients. The best tests are short-period tests before the evening meal and before breakfast, these times being usually those of maximum lente insulin action, when the tests should be good. If heavy sugar is found then, an increase of 5–10 units is required: for hypoglycaemia a similar reduction. The carbohydrate of the diet should be spread to meet continuous insulin action as in treatment with mixtures of protamine zinc insulin and soluble insulin. New cases, both adult and children, have responded excellently.

In changing established cases there is no hurry and little point, until more exact knowledge accumulates, in trying to change patients well controlled on any one injection-a-day treatment. To make the change it seems a good general rule to give, as lente before breakfast, the total units of the previous daily dosage of insulin. The above-mentioned tests should then be used to make necessary adjustments. Some very severe diabetics, dependent on large doses of soluble insulin, have done badly on the attempted change and I now hesitate to try it.

At present I do not know enough to dogmatize about these new preparations, but think, with modifications that are sure to come, that they introduce an important and simplifying advance which I hope will cancel the need for protamine zinc insulin, and certainly globin and NPH insulin. I hope so, because we now have the extremely confusing situation for doctors of seven insulins on the British market.—I am, etc.,

London, W.1.

R. D. LAWRENCE.

REFERENCE

¹ *The Diabetic Life*, 1952, 14th ed. Churchill.

SIR.—I wish to comment on the insulin zinc suspensions and the articles and correspondence about them (*Journals*, November 7, 1953, pp. 1021, 1023, and 1027; November 28, pp. 1215 and 1216; and December 12, p. 1325). While there are three varieties of insulin zinc suspension, known as insulin zinc suspension (amorphous), insulin zinc suspension, and insulin zinc suspension (crystalline)—"semilente," "lente," and "ultralente" insulin respectively—there are, in fact, only two new insulins—insulin zinc suspension (amorphous) or semilente insulin, and insulin zinc suspension (crystalline) or ultralente insulin; insulin zinc suspension (lente insulin) is a ready-made mixture of insulin zinc suspension (amorphous) and insulin zinc suspension (crystalline) in the proportions 3:7. Insulin zinc suspension (lente insulin) is therefore not an insulin in its own right, but a mixture of two other insulins. When one uses insulin zinc suspension (lente insulin) one is using not so many units of insulin zinc suspension (lente insulin) but so many units of insulin zinc suspension (amorphous) and so many units of insulin zinc suspension (crystalline) in the form of a mixture. For example, 40 units of insulin zinc suspension (lente) is really 12 units of insulin zinc suspension (amorphous) and 28 units of insulin zinc suspension (crystalline) as a mixture. I think it is essential to have this fact clearly in one's mind.

I think insulin zinc suspension (lente insulin) is the first commercially made mixture of insulins to be marketed. A set mixture such as insulin zinc suspension (lente insulin) cannot be expected to suit all diabetics, nor does it do so. Would it not be better to have available only insulin zinc suspension (amorphous) and insulin zinc suspension (crystalline) and with them make the mixture which controls each diabetic best? Mixtures of protamine zinc insulin and regular insulin, and of "isophane insulin" and regular insulin have long been used, and the mixtures were usually made by the patient in the syringe each day, just before injection, though sometimes larger quantities of the

required mixture were made by the physician and supplied to the patient. This practice of using mixtures suited to the individual diabetic proved satisfactory, and could be carried out using insulin zinc suspension (amorphous) and insulin zinc suspension (crystalline); it will, in fact, be necessary, as insulin zinc suspension (lente) does not suit all diabetics—quite a few of them are best suited by other proportions in the mixture. To market other ready-made mixtures would lead to chaos. It is feasible to make mixtures of insulin zinc suspension (lente) with either insulin zinc suspension (amorphous) or insulin zinc suspension (crystalline), but I think it confusing, as the exact composition of these secondary mixtures in terms of insulin zinc suspension (amorphous) and insulin zinc suspension (crystalline) is not immediately obvious and takes some working out. It seems to me simpler (and more understandable) to make whatever individual mixture is required with insulin zinc suspension (amorphous) and insulin zinc suspension (crystalline). In view of this, is insulin zinc suspension (lente) essential?

Insulin zinc suspension (amorphous) and insulin zinc suspension (crystalline) should be made in U.40 and U.80 strengths to allow any necessary mixture to be of reasonable bulk. At present they are available only in U.40 strength, though insulin zinc suspension (lente) is supplied in U.40 and U.80 strengths. Many diabetics need a large number of units of insulin daily, and the use of U.40 strength insulin results in a bulk dose, which is neither comfortable nor practicable. Even if U.80 insulin zinc suspension (lente insulin) is mixed with U.40 insulin zinc suspension (amorphous) or insulin zinc suspension (crystalline) the bulk of the resulting mixture can be uncomfortably large. I understand Dr. R. D. Lawrence's concern (*Journal*, November 28, 1953, p. 1215), because there are now seven insulin preparations on the British market (and on the Australian too). It is confusing, but it is not so easy to reduce the number. Regular insulin is essential. Globin insulin, protamine zinc insulin, and isophane insulin are used by so many diabetics that they will be in demand for a long time. Reduction of the number of insulin zinc suspensions from three to two, by discontinuing insulin zinc suspension (lente insulin) might well be considered further.

In any case, insulin zinc suspension (amorphous) and insulin zinc suspension (crystalline) should be available in both U.40 and U.80 strengths. I am, etc.,

Melbourne, Australia.

T. A. F. HEALE.

Non-specific Urethritis

SIR.—My investigations into the aetiology and clinical features of non-specific urethritis since 1942, and Dr. R. R. Willcox's recent report (*Journal*, January 2, p. 13), prompt me to put forward some points not generally appreciated.

Nomenclature.—From the literature, non-specific urethritis is as yet too often identified with non-gonococcal urethritis while, on the other hand, most venereologists are aware of a specific urethritis having the following characteristic features: (1) Incubation period following exposure is longer than that of gonorrhoea—i.e., ten days to one month; (2) a urethral discharge which, even when profuse, is clinically distinguishable from that of gonorrhoea; (3) smears are abacterial; (4) culture is negative; (5) dark-ground examination negative for *Trichomonas vaginalis*; (6) fails to respond to treatment by arsenical preparations; (7) in which there is no evidence of stricture. It is admitted that the above does not distinguish non-specific urethritis from urethritis following enteritis, but I believe these are aetiologicaly identical.

Organism.—The "blue colonies" reported by Willcox from urethral scrapings are, in my opinion, demonstrable in ordinary smears stained by Gram, and a characteristic feature of the larger "blue bodies" is that their central area stains much more faintly than the periphery, giving a "thick ring" appearance. These bodies with the central clearer area which vary in size from 1–6 μ are also easily seen by dark-ground illumination. The significance of these bodies appears to me to merit further research, not however from a viral but from a protozoal aspect, since certain protozoal bodies are rather similar in appearance and size. In smears these bodies have another characteristic—i.e., grouping of the smaller bodies into epithelial-like forms with dispersion throughout the slide of the larger (? more adult) bodies. Finally, dark-ground examination reveals two further features: hair-like fine structures varying in size from 8–12 μ in length; and bodies suggestive of pleuro-pneumonia-like organisms. The significance of the former is doubtful, and

I would suspect that they are merely fine fibrin threads except for their length within such narrow limits.

Results of Treatment.—In gonorrhoea penicillin cures the great majority of cases, and within two weeks crystal-clear urines are obtained in the two-glass test. In a very small percentage, however, a "gleet" having all the characteristics of non-specific urethritis remains, which, like non-specific urethritis, is uninfluenced by further penicillin. Since to-day the systemic triad (arthritis, iritis, keratoderma blennorrhagica) only occur in these latter cases of dual infection, it follows that gonococcal rheumatism, etc., do not exist.

In varying percentages the discharge in non-specific urethritis disappears with sulphonamides and other antibiotics, but continuing urethral pathology is indicated by the presence of persistent threads in the "first" glass, for long periods after cessation of treatment. This fact, together with the high relapse rate known to occur in non-specific urethritis and the absence of any comparable disease in the female, should prevent cure being applied to the results obtained by these substances.—I am, etc.,

London, S.E.5.

F. L. LYDON.

"Sulpenin" as a Cause of Ureteric Blockage

SIR.—A case of sulphonamide anuria following "sulpenin" therapy was reported by Mr. J. G. Callanan (*Journal*, January 16, p. 138). On the day this issue was delivered a similar case was admitted to the wards of the Urological Unit in Newcastle.

This patient had been given sulpenin for chest complications during an attack of influenza. The dose taken was more than that advised by the manufacturers, 48 tablets being taken in less than three days. Haematuria, dysuria, oliguria, and left-sided abdominal colic brought him to our care. At cystoscopy, the left ureter was found to be blocked with debris at 1.5 cm. and a catheter would not pass this point. Dramatic relief of symptoms followed the alteration of the reaction of the urine by alkalis given by mouth and intravenously. It is of interest that, at about the same time, another patient in the same practice, receiving treatment with sulpenin in smaller doses, developed similar symptoms. In this case the haematuria and colic subsided rapidly when potassium citrate was given by mouth, and we did not have the opportunity to observe her.

The risk of crystallization of the acetylated drugs in the urine may be diminished by the use of compounds of this nature, but it is not abolished. The dosage must be carefully determined, and an adequate fluid intake is required to clear the drugs without too great a concentration in the urine. The relief of symptoms which followed the administration of alkalis in these cases suggests that it would be worth while to give mist. pot. cit. as a routine, as was the practice in the earlier days of sulphonamide therapy.—I am, etc.,

Newcastle-upon-Tyne.

HOWARD JAMISON.

Medical Needs in the Gold Coast

SIR.—I read with great interest Mr. Ian Fraser's interesting article, appealing for young doctors to go out to the Gold Coast (*Journal*, October 31, 1953, p. 987), and also the subsequent correspondence. It is clear that the Gold Coast and other British Colonies offer a rich field of medical work, but there are certain awkward practical questions which occur to any young doctor in this country who contemplates a career in the Colonial Medical Service.

The following occur to me: (1) I wish to embark on a career which will keep me happily employed for at least 20 years, preferably longer. What certainty is there, with the British Commonwealth developing politically at its present rate, that I shall not find myself unemployed after 5, 10, or 15 years, just when my family responsibilities are at their heaviest? (2) Can I be certain that if my appointment is prematurely terminated for some reason, such as the grant of self-government, I shall receive fair financial compensation? And what help can I expect from the Colonial Office, Ministry of Health, or other bodies, in securing re-employment? It seems to me that doctors who sacrifice prospects in the United Kingdom in order to assist the U.K.

Government's colonial policy overseas deserve some special assistance from that Government on return. (3) I understand that the Colonial Service pensions are paid, not by the U.K. Government, but by the government of the colony in which the officer last served. Is there any guarantee that a colony which is granted full self-government will continue to pay such pensions?

Perhaps I am too "security-minded" in asking these questions, and perhaps I ought to be prepared to take a chance on some of them. I feel sure, however, that it would be very helpful to recruitment if Mr. Ian Fraser or some other authority could provide the answers.—I am, etc.,

SENIOR REGISTRAR.

Medical Auxiliaries

SIR,—My council would appreciate a little space to reply to your annotation (*Journal*, February 6, p. 325) in order that a clearer picture may be presented to your readers regarding the new regulations affecting medical auxiliaries.

The National Health Service (Medical Auxiliaries) Regulations, 1954, due to come into force on April 1, are not based on the recommendations of the Cope report, the Minister having already made it quite clear that he did not intend to implement that report. His expressed intention to remove certain anomalies and injustices have been amply demonstrated in the new regulations, and by being fair to all parties concerned the Minister has initiated the most important piece of constructive statesmanship ever evolved in the history of medical auxiliaries. Statutory registration, one of the foundation aims of the Physiotherapists Association, is the next and obvious step, and the Minister intends to set up a working party to consider the best means of bringing this about. Meanwhile the new regulations are to be an interim measure pending State registration which, without doubt, all responsible medical auxiliaries urgently desire. It is perhaps unfortunate that the full qualifying requirements affecting members of this association were omitted from the published regulations, and the following information may help to clear up this point.

As a body founded by ex-Service physiotherapists primarily to represent their interests, the entry standard was judged to be a Service grading "Class I" physiotherapist. To meet war exigencies, the normal basic course was reduced to three months, and this was followed by a nine-month period in a Service hospital under supervision of a surgical specialist and superintendent physiotherapist. At the end of this first year, a Grade III qualification was granted, provided that the usual examination had been passed. At the end of the second and third years, advancement to Grades II and I were possible after suitable examination. At the latter stage the Physiotherapists Association considered the applicant eligible for its own open examination. Membership was granted only after these qualifications had been satisfied and the open examination successfully passed.

While, therefore, only a basic preclinical training of three months had been served, the period of 33 months which followed, in which the physiotherapist studied and gained experience in Service hospitals, brought the total period to three years, the same period as that required by the Chartered Society of Physiotherapy. It will be seen that no standards are in danger, but in fact the experience and responsibilities of the Service physiotherapist would be in advance by nature of the very work upon which it was engaged. It is therefore misleading and incorrect to suggest that standards other than those of the Chartered Society of Physiotherapy may be short of the requirements.

The educational curriculum submitted by the Physiotherapists Association to the Ministry of Health and to education authorities has received strong support, and it may be interesting to record that, while the association planned for a length of training lasting three years and nine months, it has been asked to trim its syllabus so as to conform with a general three-year course. From this it appears that the standard sought by the association is in advance of that thought necessary by the Ministry and its medical advisers. The technical colleges have evinced so much interest in our syllabus that there have been concrete offers to teach it, and hospital facilities will be provided by the Ministry, with whom the association has had recent talks.

The association's aims are, *inter alia*, improvement of status; promotion of postgraduate work and research; establishment of open examinations for unregistered prac-

tioners, thereby ensuring an adequate yardstick; and the establishment of a specialist corps in the armed Services and Civil Defence. How then can it be suggested that standards exist which are below the requirements?—I am, etc.,

London, W.1.

Physiotherapists Association Ltd.

The College of General Practitioners

SIR,—Since the College of General Practitioners was founded so largely through the publicity of the *Journal*, I should be grateful for your publication of the following as being of general interest to actual or prospective members.

Your current "Medical News" column (*Journal*, February 13, p. 407) contains a note on "Research Newsletter No. 2" of the College of General Practitioners, published in the February *Practitioner*. Although I am a founder member of the College of General Practitioners, for which honour I paid a subscription of 10 guineas, I have not received a copy of this Newsletter. Neither did I receive a copy of Newsletter No. 1 until the College's first annual report reached me, where it was reprinted from the *Practitioner*. Apparently, therefore, I am expected to add the cost of the *Practitioner* to what must obviously be regarded as a merely nominal subscription. As I already take two medical weeklies, neither of which has so far published Newsletter No. 2, and of which only the *Journal* has even given it mention, I do not feel justified in this extra expense. I understand that only doctors on the research register of the College of General Practitioners receive these Newsletters, but surely it is not too much to expect that all College members should receive them.

I may add that all the communications I have received from the College since I joined nearly one year ago can be counted on the fingers of one hand, with digits to spare. In particular, I have received no personal notice at all of its lectures, which, in any event, seem to have been held at 5.30 p.m. or thereabouts, when I, in common with most G.P.s, am holding my evening surgery. If the general lethargy of the College of General Practitioners since its foundation, as exemplified by the above facts, is at all disturbed by their publication, you, Sir, will have done the College a further service.—I am, etc.,

London, E.9.

D. G. BERRY.

The Winter Vomiting Disease

SIR,—After reading Dr. J. H. Whittle's letter (*Journal*, February 6, p. 333) on the subject of winter vomiting disease, I feel that I should like to make a few comments.

Like Dr. J. F. Goodall (*Journal*, January 23, p. 197) I feel that it is a separate entity from infective hepatitis. Following are some of my reasons. From my own experience I would only differ from Dr. Goodall's account of the syndrome in that I have not found diarrhoea to be a constant symptom. Indeed, in the majority of my cases it has been absent.

As Dr. Goodall remarks, the onset is often during the night after the patient went to bed feeling perfectly well. If, however, the attack begins during the day it is usually preceded by intense vertigo, but I have never been able to detect nystagmus. The patient is usually afebrile. The epigastric pain is often a result of repeated vomiting. I think, rather than a separate symptom. The vomiting lasts from 24 to 48 hours and stops as dramatically as it starts if the practitioner is lucky, just after the patient has taken his first dose of whatever has been prescribed, in my own case usually glucose and water. Following this the patient feels limp and out of sorts, with no appetite for a day or two. Headache is sometimes pronounced. The duration of this period is definitely related to age and general state of health. It seems to be exclusively a disease of cold weather.

Two years ago I had the opportunity of seeing over 300 cases of both frank and abortive cases of infective hepatitis during a severe epidemic which occurred in this practice. In the abortive cases anorexia always precedes the vomit-

ing. Indeed, this was the most constant symptom. Vomiting was infrequent. The stools were loose and pale but not necessarily frequent. The duration was from two to three weeks or longer. Infective hepatitis occurs at all times of the year.

Like Dr. Goodall I have also noted in the case of winter vomiting disease that someone else in the house often has a head cold, and I have no doubt that a virus is the causative agent.—I am, etc.,

Brampton, Cumberland.

FRANCES I. PANTON.

SIR,—The article on this subject by Dr. J. F. Goodall (*Journal*, January 23, p. 197) was timely, for the condition he described is widespread in parts of London at present. This condition can be diagnosed with fair accuracy on clinical grounds provided that the typical pale, putty-coloured stools are seen. When examined in the laboratory it is common, in my experience, for such stools to show a gross excess of microscopic fat globules. This steatorrhoea is usually found on the second and third days of illness and may be present for longer periods. When seen in epidemic circumstances it is almost diagnostic of "winter vomiting disease," since gross steatorrhoea is very rare indeed in bacterial and parasitic diarrhoeas in this country.

It should be remembered, however, that pale stools without fat globules are found at times in coliform gastroenteritis, dysentery and giardiasis, especially among young children, and for this reason it is wise to have the diagnosis substantiated by laboratory examination: for the antibiotics or chemotherapy which will help to cure the first group of diarrhoeas may well do further damage to the injured digestive tract in the case of "winter vomiting disease."—I am, etc.,

London, N.9.

MAIR E. M. THOMAS.

Myelomata of Bone

SIR,—Having recently reviewed the local cases of myelomatosis, I would like to corroborate Mr. A. Naylor and Dr. F. E. Chester-Williams's views (*Journal*, January 16, p. 120). This condition can be protean in its manifestations, and the presenting symptoms are often at wide variance with the classical text-book descriptions. In 49 consecutive cases here the diagnosis was considered initially in only 5, and in 17 was entirely unsuspected prior to necropsy. After 1944, when marrow aspiration became a more widely used diagnostic measure, the number of cases per 1,000 hospital admissions more than doubled, but an increased awareness of the condition attendant on a research project which began in January, 1952, has raised the number of cases per 1,000 admissions from 0.158 to 0.473 in the past two years as compared with the previous seven-year period.

As yet there is no known cure, but early diagnosis is essential for adequate evaluation of the newer therapeutic agents. Findings which we have found to be suspicious, and which are not particularly stressed in the literature, are: (a) the association of anaemia, a high erythrocyte sedimentation rate, and marked rouleaux formation, (b) normal or hypotensive blood pressure with proteinuria and microscopic urinary elements in a middle-aged person, and (c) an unexplained bleeding tendency. The all too common habit of excluding the diagnosis because of a negative roentgenological skeletal survey is unwarranted, because the x-ray picture may be entirely negative in spite of widespread disease.

On one minor point I would disagree with Mr. Naylor. Bence Jones proteinuria has been present for over two years in one of our patients, who has, even after a recent exhaustive reinvestigation, an apparently solitary large plasmocytoma of the sacrum. The recent work of Collier and Jackson¹ suggests that Bence Jones proteinuria is pathognomonic of this condition, and that its reported finding in other conditions is due to deficiencies in laboratory technique.—I am, etc.,

Vancouver, Canada.

Piperazine in the Treatment of Threadworms

SIR,—It is misleading of your correspondent Professor T. Gordonoff (*Journal*, February 13, p. 394) to quote his one experiment of giving piperazine to rats and draw a conclusion that this very useful drug should not be given to out-patients, for he does not make it clear that, relative to body weight, he gave enormously greater doses than were recommended by Dr. R. H. R. White and Mr. O. D. Standen (*Journal*, October 3, 1953, p. 755). It appears that Professor Gordonoff "once gave piperazine by mouth to rats" and that some of them died after doses of 4 to 5 g. per kg. Dr. White and Mr. Standen recommended 0.05 to 0.075 g. per kg.—i.e., a dose fifty to one hundred times smaller.

It is difficult to see any usefulness in Professor Gordonoff's letter. Aspirin is accepted as one of the safest drugs, and this opinion is not affected by the fact that doses of 250 gr. (16.5 g.) might be fatal in a man. The margin of safety of piperazine is high; Mr. Standen (*Journal*, October 3, 1953, p. 757) records survival of 100% of 13 mice given 2 g. per kg., and in the doses of 0.075 g. per kg. recommended for treating threadworm infection it can be given to out-patients with safety. For treating roundworm infection I have used double the dose recommended by White and Standen and seen no ill effects. Professor Gordonoff speaks of the danger that "mothers, if there is no therapeutic effect, will increase the dose." Ten times the dose that White and Standen suggest is unlikely to be dangerous to life, and what other drug treatments can claim the 97% success which followed treatment of threadworm infection on the doses recommended by White and Standen?—I am, etc.,

London, S.E.1.

RONALD MAC KEITH

SIR,—Piperazine adipate, a sparingly soluble salt of piperazine, does not exhibit the toxic properties shown by the parent base and its soluble salts referred to by Professor T. Gordonoff (*Journal*, February 13, p. 394). In extensive toxicological and pharmacological studies, to be published shortly, we have found no evidence of any acute or chronic toxicity on administering piperazine adipate to mice, rats, dogs, and other animals, even in doses of up to 7 g. per kg.

By contrast with the neurotoxic effects of preparations of piperazine hydrate referred to by Dr. R. H. R. White and Mr. O. D. Standen (*Journal*, December 5, 1953, p. 1272), no side effects whatever have been found on administering tablets of piperazine adipate ("entacyl") clinically, and eradication of threadworms appears to be secured in children and adults in two days by doses not exceeding 1.8 g. daily. Piperazine adipate, incidentally, has also been found effective against a wide range of roundworms and hookworms. It seems likely that the striking absence of toxic effects in piperazine adipate derives, in contrast to soluble forms of piperazine, from its low degree of absorption due to its relative insolubility.—I am, etc.,

London, N.1.

FRANK HARTLEY.

Infant B.C.G. Vaccination

SIR,—There are certain points about Dr. Honor Purser's most interesting account of her experience in B.C.G. vaccination of the newborn (*Journal*, February 13, p. 368) which demand comment. The first is her recommendation that 0.2 ml. of vaccine (0.15 mg.) should be given routinely. We have shown¹ that this dose is unnecessarily large; furthermore, the larger the dose the greater the incidence of complications. The second point is that Dr. Purser says that "it is admitted (Gaisford, 1953) that the percentage of cases giving a positive tuberculin reaction one year after vaccination falls off enormously if a smaller initial dose of vaccine is given." Gaisford said no such thing. In the preliminary report on our work which you published in 1951² we said that 0.1 ml. was satisfactory for routine immunization, and that larger doses were unnecessary and apt to produce complications. Subsequently, using 0.05 ml. routinely, we have maintained a 100% conversion rate and

have reduced the incidence of complications to 0.3%. There is as yet no evidence of any waning sensitivity in these infants one year after vaccination. Of those infants originally vaccinated with 0.1 ml. (twice our present recommended dose) 99.5% are still positive after two years.

Thirdly, Dr. Purser says that she confirms that regional adenitis and abscess formation are due to too deep rather than too large a dose of vaccine. This is contrary to our experience with more than 4,000 newborn vaccinations. Deep injections—i.e., partly subcutaneous instead of completely intradermal—lead to abscess at the site of injection, and not in the regional lymph node. This was also the finding of Palmer and Edwards, who, in the reference quoted,³ make no mention of adenitis—confining their remarks to the inoculation site. Fourthly, Dr. Purser refers to the vaccination of "premature babies," but in fact she did not vaccinate any such until they reached 5½ lb. (2.5 kg.) in weight—at which time they could no longer be considered premature. We have vaccinated a number of premature infants down to 3 lb. (1.36 kg.) in weight and would warn that, contrary to expectation, such infants require an even smaller dose than full-term infants, for they react more readily with adenitis. Fifthly, there is considerable objection to giving the vaccine into both arms as a routine procedure. We have found that subsequent injections—e.g., of pertussis vaccine or vaccinia—may—even if given six months after B.C.G.—cause a flare-up in the axillary node. This can be obviated by confining the B.C.G. to one arm, leaving the other free for any subsequently desired injection without risk.

We would suggest that the best procedure is to use a vaccine containing a known number of organisms per ml., and that in the near future it may be possible to determine the optimal number of bacilli to be injected, based on the infant's weight. The actual number of bacilli required will, of course, depend on the type of vaccine used.—We are, etc.,

WILFRID GAISFORD.
MARGARET GRIFFITHS.

Treatment of Tuberculous Meningitis

SIR,—In my letter (*Journal*, May 2, 1953, p. 991) I drew attention to the very gratifying results obtained by means of A.C.T.H. in severe cases of tuberculous encephalitis in children. Therefore I read with great interest the article of Winifred C. M. Bulkeley (*Journal*, November 21, 1953, p. 1127) on the combined treatment of tuberculous meningitis with A.C.T.H. and isoniazid. As since December, 1951, I have had the opportunity to observe about 50 cases of tuberculous encephalitis treated with A.C.T.H. and 150 treated with isoniazid, may I be allowed to add a few remarks concerning this method of treatment?

As regards the effects of A.C.T.H. treatment on severe encephalitic forms in the early period of disease, my results were not so encouraging as those observed by Dr. Bulkeley. The frequent failure of response to the hormone in these cases is perhaps due to the exhaustion of the adrenal cortex, as a result of the severe course of the disease. Unfortunately, I had no opportunity to apply cortisone in such cases, but a combined treatment with A.C.T.H. and dehydroascorbic acid gave us here more interesting results. Very good effects were obtained with A.C.T.H. in cases of deterioration of general condition with eventual inflammatory reactions provoked by initial high doses (10–20 mg./kg.) of isoniazid (Herxheimer type of reaction).

The most important domain of A.C.T.H. therapy in tuberculous encephalitis is, however, the late period of the disease, characterized by dynamic neurological attacks, accompanied by lowered chloride levels in the C.S.F. ("late neurological disturbances" as we call them), especially after the provocative, intrathecal applications of tuberculin (purified protein derivative) (1 ml.), as I pointed out in my previous letter. I reported likewise there that A.C.T.H.

often reduces the protein level of C.S.F. and also sometimes re-establishes the free communication in cases of blockade. Isoniazid intrathecally applied can, however, have a similar effect. The reabsorption of the basal exudate and prompt recovery can also be observed after exclusive isoniazid treatment.

We, too, did not observe any symptoms of deterioration of the clinical status of our patients after A.C.T.H. administration, nor any clinical or radiological evidence of spreading of pulmonary tuberculosis. A detailed report of our experiences will be published shortly.—I am, etc.,

B. HALIKOWSKI,

Pediatric Department of the Research Institute
for Tuberculosis.

Warsaw.

Neomycin in Pyogenic Skin Diseases

SIR,—Undoubtedly the article on this subject by Dr. Ronald Church (*Journal*, February 6, p. 314) will provoke interest not only in dermatologists but also in general practitioners who have to cope with these infections. Because my interest has been aroused, I wish to make some gentle criticisms of this paper. First, though other antibiotics such as aureomycin, chloramphenicol, and bacitracin are mentioned, there is no reference whatsoever to terramycin, which appears to me to be not only perhaps the most effective antibiotic in pyogenic skin diseases but also by far the least likely to provoke reactions. Wright and Tschann¹ treated 845 patients with terramycin ointment; of 90 with impetigo contagiosa, 82 were cured within 24 hours to 7 days. The results in sycosis barbae were more impressive than in this series, and only four developed a reaction to the ointment not to the drug but to the soft paraffin base. My experience in over 200 patients treated with terramycin ointment tallies closely with this. The response to treatment in suitable cases has been as good as with aureomycin ointment and far better than neomycin: only one case of contact dermatitis developed, in a patient whose skin had already reacted to many drugs, including aureomycin. In comparison, in my series of over 100 cases in which neomycin was used the skin of eight patients reacted to the drug, and the results of the ointment were not nearly so satisfactory as with either terramycin or aureomycin.

My experience is that terramycin and aureomycin ointments are the most efficient preparations for such cases, but have the disadvantage that they cannot be easily obtained by general practitioners. Neomycin, however, is obtainable in ointment form, is made by at least two chemical firms, and is probably the next in order of effectiveness. The tendency of chloramphenicol, penicillin, and streptomycin to provoke contact dermatitis in a high percentage of cases makes them undesirable for local application to dermatoses. So far, I have not treated a sufficient number of patients with the other antibiotics such as erythromycin to form any conclusions about their action.—I am, etc.,

Edinburgh.

The Action of Penicillin Resistance

SIR,—Hotchkiss¹ has pointed out that penicillin resistance can be transferred in pneumococci if sensitive organisms are cultivated in a medium to which has been added an extract of the resistant pneumococci; a proportion of the resulting organisms become penicillin resistant and continue so on subcultivation. The active or transforming factor appears to be a desoxyribonucleic acid, and he concludes that the penicillin resistance is therefore determined by the desoxyribonucleic acid composition of the cell. We are writing this to show that the conclusions arrived at by Hotchkiss and earlier by us,² and by others, notably Vourekas,³ Winner,⁴ etc., definitely speak for the intimate association of penicillin sensitivity or resistance of a particular pathogen with its ribo- or desoxyribonucleic acid content.

It was known and confirmed by us that pus, which is a source of nucleic acid, does not inactivate penicillin. In

Obituary

E. P. CATHCART, C.B.E., M.D., D.Sc.,
LL.D., F.R.S.

We record with regret the death in Glasgow on February 18 of Professor E. P. Cathcart, emeritus professor of physiology in the University of Glasgow, at the age of 76. Though he was best known as an expert on nutrition, his interests were wide and his knowledge extensive; consequently his advice was eagerly sought, and few men can have served on so many expert committees.

Edward Provan Cathcart was born at Ayr on July 18, 1877, and was educated at Ayr Academy and Glasgow University.

After graduating M.B., B.Ch. in 1900 he went abroad to continue his studies and visited Berlin, Munich, and St. Petersburg. On his return to this country he became a research scholar at the Lister Institute, but he gave up this appointment in 1905, when he became Grieve Lecturer in Chemical Physiology at the University of Glasgow.

He proceeded to the degree of M.D. in 1904 and took the D.Sc. in 1908.

In 1911 he was appointed an honorary research associate at the Carnegie Institute, Washington. Cathcart was elected to the chair of physiology at the London Hospital in 1915, and during the first world war he was called upon to advise the Government and the Services on many physiological problems. In the R.A.M.C. he held the honorary rank of lieutenant-colonel. In 1919 he returned to Glasgow as Gardiner Professor of Physiological Chemistry, and in 1928 was appointed Regius Professor of Physiology, a post from which he retired in 1947. He became a Fellow of the Royal Society in 1920 and was appointed C.B.E. in 1924.

Professor Cathcart's nutritional studies and his interest in industrial problems led to his appointment to numerous committees. At one time or another he was a member of the Medical Research Council, the Agricultural Research Council, the League of Nations Technical Commission on Nutrition, the Army Hygiene Advisory Committee, the National Advisory Council on Physical Training (Scotland), the Ministry of Health's Advisory Committee on Nutrition, the Committee on Nutrition in the Colonial Empire, and the International Labour Office's Committee on Industrial Hygiene. He was also chairman of the Industrial Health Research Board from 1933 to 1940, and of the Committee on Scottish Health Services. At the Annual Meeting of the B.M.A. in 1931 he was president of the Section of Pathology and Biochemistry. In 1933 he was appointed the representative of the University of Glasgow on the General Medical Council. He was the first chairman of the Western Regional Hospital Board (Scotland), but he had to resign from this appointment after only a few months because of ill-health.

[T. and R. Annan & Sons, Glasgow.]

our further work, therefore, we had studied the nature of the nucleic acid in relation to its action on penicillin bacteriostasis. This was necessary on account of the high percentage of desoxyribonucleic acid in penicillin resistant pathogens. The ratio of the relative amounts of the two types of nucleic acid differs in different organisms, but is very much correlated with the sensitivity of resistance of these organisms to penicillin. It is also now well recognized that fundamental differences exist between the basic proteins of the Gram-positive and Gram-negative organisms and probably in their mode of combination with the nucleic acids.⁵ It is also interesting to note that in the Gram-negative organisms so far examined the ratio of the desoxyribonucleic acid to ribonucleic acid is considerably higher than that in the Gram-positive bacteria. The results of studies with pus nucleic acid, which was proved to be of the desoxyribo type,^{6,7} thymus nucleic acid, also of the desoxy type, as well as with yeast nucleic acid, which is of the ribose type, showed that the desoxy type of nucleic acid has no antagonizing action on penicillin, while ribonucleic acid always exerted strong anti-penicillin action. This finding is in accord with our earlier results. Thus bacteria contain two nucleotide systems, one of the ribose type and the other of the desoxy type, and these two systems form a functional unit though not combined in a morphological unit. Malmgren and Heden⁸ have argued that the desoxy ribose organella which undergoes fission could form an equivalent to the euchromatin of the metazoan cells, and the ribose type system would be looked upon as a functional counterpart to the heterochromatin. While the former induces the formation of gene proteins, the latter controls the formation of the cell proteins. This latter process is reflected in great changes in the contents of the ribose nucleotides in the individual bacterium. These facts also appear to be significant on the sensitivity or resistance of a pathogen to penicillin.

It is well known that penicillin acts on actively young bacterial cells and not on adult ones. Casperson and his colleagues,⁹ on the basis of ultra-violet absorption measurements, have concluded that a high ribonucleic acid content is characteristic of the cells in which protein synthesis is vigorous for purposes of growth or secretion, and those cells or tissues such as pancreas, liver, gut, embryo, etc., which are actively engaged in the process of protein synthesis contain higher concentrations of ribonucleic acid than the adult cells or tissues. All the above facts individually and collectively justify conclusions to which we had already drawn attention in our earlier publications.—We are, etc.,

The Value of Physiology in Medicine

SIR,—Dr. George Graham in his Harveian Oration (*Journal*, January 30, p. 225) makes a statement which in my opinion needs to be emphasized frequently to those persons engaged in medical research which involves experiments on animals.

Dr. Graham says that "it is of importance to repeat the work on different animals, for they often differ considerably." Two important facts need continually to be kept in mind by the investigator: (1) To submit that because a certain animal reacts in a certain way to a specific substance therefore the human animal will react in a similar way can be both a fallacious and misleading submission. (2) The investigator should have a sound knowledge of the physiology of the animal used in the experiment.—I am, etc.,

London, W.1.

R. F. GUYMER.

Cathcart wrote numerous papers on the subjects in which he was interested. His book, *The Physiology of Protein Metabolism*, was first published in 1911, and the results of his inquiry in 1929 into the physique of men and women in industry appeared as *The Human Factor in Industry*. He was an Honorary Fellow of the Royal Faculty of Physicians and Surgeons of Glasgow, and he received the honorary degree of LL.D. from two universities—from St. Andrews in 1928 and from Glasgow in 1948.

During the last war he was a member of the scientific committee set up in 1940 by the War Cabinet's Food Policy Committee and of the B.M.A. Committee on War-time Problems of Nutrition.

Professor Cathcart married Dr. Gertrude Dorman Bostock, and there were three daughters of the marriage.

We are indebted to Professor R. C. GARRY for the following appreciation: In all sciences, as the body of knowledge grows, specialization becomes inevitable. A point is reached, often suddenly, when the interests of the various workers in a science diverge. Then each worker pursues his own line of inquiry, dropping, as he goes, a curtain of new techniques and of new knowledge between himself and his former colleagues. Physiology is peculiarly vulnerable to this process. Cathcart, who first graduated in medicine in Glasgow in 1900, embarked on his scientific career just before this process of fission became marked. He was a medical biologist of the old school, interested in the physiology of the whole man, and he remained so to the end. We shall not see his like again.

Chance drew Cathcart to biochemistry. As a young man he went to Germany to study bacteriology. On the day he turned into the laboratory of Carl Voit the die was cast. In 1905 Cathcart became the first Grieve Lecturer in Physiological Chemistry in the University of Glasgow. The following were fruitful years. There was the classical work on metabolism in starvation, quickly followed by authoritative studies on the metabolism of protein. In spite of his research activity Cathcart found time to travel widely. For a while he worked with Pavlov in Russia; he used the Pavlov stomach-pouch technique in Glasgow, but never really took kindly to animal experimentation. More significant for the Glasgow school was work with Benedict in America on indirect calorimetry and on exchange of energy in man.

In 1915 Cathcart was appointed to the London University chair of physiology in the London Hospital. But in 1919, at the invitation of the university, he returned to Glasgow to occupy the newly founded Gardiner Chair of Physiological Chemistry. During the first world war he had played an active part in the solution of physiological problems which arose in the Services. His work on the expenditure of energy by the soldier is still definitive. In the years after the war he became interested in the broader social aspects of nutrition. His dietary surveys threw a flood of light on the food habits of the people. He was somewhat critical of what he considered to be the excessive emphasis placed on the importance of vitamins; he believed that if one took care of the calories the vitamins took care of themselves. In this attitude he probably underrated the potentialities for mischief on the part of those who process and manufacture the urban food of to-day. By a natural transition he became interested in the physique, stature, and growth of human beings. Instinctively, and possibly with some justification, he reacted against the unconfirmed belief that rapidity of growth in childhood and in adolescence and attainment of great stature are inevitably sure indications of individual and social well-being.

In 1928 Cathcart succeeded Noël Paton in the Regius Chair of Physiology at Glasgow. Never very interested in the more chemical aspects of biochemistry, his translation from one chair to the other was logical and did no violence to his interests. His study of metabolism, of energy ex-

change, of physique, and of nutrition continued. He developed an interest in psychology, and in his later years he very happily turned his attention to histology.

Cathcart was completely out of sympathy with the jejune mechanistic theories of biology so popular in the first half of this century. He took great pleasure in the attitudes of J. S. Haldane and of Smuts. While not decrying the importance of research on isolated organs or systems, he doubted greatly if such studies could ever explain the integrated activity of the whole organism. Such an attitude, combined with his forceful, robust, and manly personality, not unmingled with a Puritan streak in his personal relationships and behaviour, made Cathcart an outstanding member of the academic community. So he continued to the end, ever stressing the duties and responsibilities of those who were dedicated to the profession of medicine. He cast a kindly, but somewhat critical and sceptical, eye on all those who made sweeping claims for progress in medicine and in the social order as a whole.

Cathcart retired from his chair in 1947 after 40 years of practically continuous devoted service to physiology and to his university. Fortunate were the undergraduates who came under his influence, and even more fortunate the members of his staff who had the privilege to work under his direction and to share his enthusiasms. He leaves a widow and three daughters, all medical graduates of his own university. Physiologists the world over share in their loss.

Sir GEORGE ELLISTON, M.C., M.A.,
D.L., J.P.

The announcement of the death of Sir George Elliston, which took place in London on February 21, will be received with regret in the medical profession, especially among those members of it serving in the field of public health. Although not a medical man, Sir George Elliston had hereditary and lifelong connexions with medicine. His father, himself the son of a doctor, was Dr. W. A. Elliston, of Ipswich, who was President of the British Medical Association when the Annual Meeting was held in that town in 1900, and was also one of the early presidents of the Medical Defence Union. An uncle, George Sampson Elliston the elder, was the first medical officer of health for Ipswich. One of Sir George Elliston's brothers was Guy Elliston, financial secretary to the British Medical Association, whose premature death in 1918 deprived the Association of a most promising officer. The youngest of the brothers, Dr. Chatterton Elliston, practised for many years in Cornwall.

George Sampson Elliston was born in 1875 and was educated at Framlingham College in Suffolk, and St. Catharine's College, Cambridge, taking his B.A. in 1896 and his M.A. in 1919. In 1897 he joined the well-known printing firm of Sir Joseph Causton and Sons, of which he was a director for many years up to the time of his death, and in 1904 he married Miss Alice Louise Causton, daughter of the then head of the firm. In 1901 he was called to the Bar by Lincoln's Inn.

One of his achievements of which he was most proud was the foundation of the *Medical Officer*, a weekly journal for medical men in the Government and municipal services, which he edited continuously for more than 40 years. During the first world war he was one of the few laymen commissioned in the Royal Army Medical Corps, serving in France with the B.E.F. as hygiene officer. For his services in the war he received the M.C. In 1919 he was appointed secretary of the Society of Medical Officers of Health, which office he held until 1930, when his son, Mr. G. I. C. Elliston, succeeded him. From 1931 until 1945 he was Conservative member of Parliament for Blackburn, and for

part of the time he was honorary secretary of the Parliamentary Medical Committee, acting as a skilled interpreter of medical and allied matters to his fellow members. He carried through most diligent and conscientious work at Westminster. The second world war recalled him to temporary duties at the Society of Medical Officers of Health, while his son, the secretary, was serving with the Navy. The Society had already made him an honorary fellow and elected him to its council as "a person eminently distinguished in the advancement of the public health."

Another field of work which engaged his attention was connected with the Corporation of the City of London. For several years he was chairman of the Corporation's public health committee, and a noteworthy duty which fell to him was to arrange the City dinner in 1948 to celebrate the centenary of the Public Health Act and the appointment of Sir John Simon as the City's first medical officer of health. Perhaps it was as chairman of the board of management of the London School of Hygiene that he obtained the greatest satisfaction. Under his chairmanship the school flourished, and no one was better pleased at its success than Sir George himself.

His energies found many other outlets. He was for a time president of the National Smoke Abatement Society, a member of the council of the Cremation Society, and a governor of Birkbeck College, Christ's Hospital, and the City of London School. In 1933 he was made a justice of the peace for the county of London, and in 1942 a deputy lieutenant of the county. He was knighted in 1944. Into every sphere of his very active life he carried urbanity and kindness, made many friends, and appeared to make no enemies. Lady Elliston with two sons and a daughter survive him. One other son was killed in the Normandy landing in 1944.

Dr. H. W. ROBINSON, who was a general practitioner in Bradford, Yorkshire, died on February 5 at his home in Cleckheaton, Yorkshire. Henry Whitterton Robinson was born on May 27, 1892, his father being the late Dr. A. H. Robinson, J.P. He studied medicine at Leeds University and graduated M.B., Ch.B. in 1914. After holding a resident post at Bradford Royal Infirmary he joined the R.A.M.C. and served as a medical officer with the West Yorkshire Regiment in France, being awarded the M.C. After demobilization he joined his father in practice at Low Moor, where nearly all his life was lived. In spite of ill-health he had a busy practice and became one of the best-known doctors in the Bradford area. During the last war he organized the medical service of the West Riding Home Guard Division, and held the rank of lieutenant-colonel. As a result of his very heavy commitments during the war years his health broke down, and he had two major chest operations in 1949 and 1950. He came back to work, however, and his courage and determination kept him going until the day before his death. He leaves a widow, a son, and a daughter.

P. MCE, writes: By the death of Dr. Harry Robinson, Bradford has lost one of its most highly respected and widely beloved general practitioners. His popularity was shown by the rapid growth of the practice of which he was for many years the senior partner. From a twin practice it grew to a group practice of five partners. Dr. Robinson was a most capable doctor, cheerful and happy in disposition, devoted to his work, and with a warm personal interest in his individual patients. In spite of chest trouble during many years—the sequel to pneumonia followed by an empyema and a thoracoplasty—he became a scratch golfer and the popular and esteemed captain of the Cleckheaton Golf Club. Being of a loyal and generous nature, he had a wide circle of friends, by whom he will be held in grateful memory.

Dr. VALERIE JONES, who died suddenly on January 28 after a very brief illness, had acted as registrar to the children's unit in the Newport and Monmouthshire hospital groups since January, 1952. She was 27 years old, and her death at so early an age, and at the beginning of a career showing the greatest promise, is mourned by all who knew her. Valerie Jones studied medicine at Edinburgh, qualifying in 1949 and being awarded a gold medal in surgery. She filled the posts of house-surgeon and house-physician (paediatrics) at Morriston Hospital, near Swansea, with conspicuous success, and, as always, left many friends behind on completing these appointments. She then spent a year as an assistant in general practice in Gorseinon, again proving herself a most successful and conscientious doctor, who, despite her academic leanings, adapted herself to the problems of practice with her natural enthusiasm and drive. In 1951 she took the D.C.H., and in the following year joined the newly formed paediatric unit in Newport and Monmouthshire, quickly proving her great worth. She was incapable of work other than of the highest quality, and combined a detailed knowledge of medicine with the ability to apply it practically and with great common sense. Every sick child was a challenge to her, and nothing was left undone that could be of help to the patient. She transmitted her faith and enthusiasm to her colleagues, medical and nursing, and, more important still, to her patients. She enjoyed her life to the full, and, despite being engrossed in her medical work, made time to interest herself in literature, music, and travel. She was always a stimulating companion to those around her, and had a natural capacity for making friends, being always ready to give help to others. She will be greatly missed by her host of friends, and the deepest sympathy is extended by all to her mother and father in the loss of their only child.—T. A. B.

Dr. H. E. BATEMAN died at Micklegate, Yorkshire, on February 9, after a long and courageous fight against failing health. He was 94 years of age. Hinton Ernest Bateman was educated at Kings School, Canterbury, and received his medical training at St. Bartholomew's Hospital, London, where he qualified in 1883. In 1886 he started working at the Dispensary in York and practised throughout his long life in that city. He is still remembered in York as an impressive figure riding in a brougham in winter and a victoria in summer to visit the many eminent people who were his patients. He became a pioneer of radiology, and during the 1914-18 war worked unceasingly at the Military Hospital in York as a radiologist. In consequence of exposure to irradiation by the inadequately screened apparatus of those days he became a victim of progress in his own branch of medical science. As the years went by he had numerous operations, and finally, when he was 91 years of age, his left arm was amputated. He bore his trials with admirable courage and showed a strength of character worthy of the highest traditions of his profession. Dr. Bateman was married twice and had two sons, one of whom entered the medical profession, and the other served in the Forces as an Army chaplain. He had the sadness to lose both sons in the course of his lifetime. His wife, who nursed him courageously throughout his long illness, survives him.—J. K. W.-P.

Dr. LIONEL WILSON BRADSHAW died on February 8 at his home at Scarborough at the age of 75. He studied medicine at the Leeds medical school, where he qualified in 1907. After holding resident posts at the General Infirmary, Leeds, he had some experience in general practice and then settled at Barnoldswick, in Yorkshire, where he was a much respected and successful family doctor for many years. By nature sensitive and conscientious, he became a friend and adviser to all his patients, who gave to him their affection and trust. His anxiety was always that everything possible should be done for the comfort and welfare of those under his care. In these days it would be unusual for a family doctor to know, as he did, every detail of the family and their relations, as well as the doubts and fears of them all. When Dr. Bradshaw retired from

his busy practice he was genuinely surprised at the way in which the people of Barnoldswick showed how much they had appreciated his work among them. He was high in the esteem of the St. John Ambulance organization, and he acted as police surgeon for the West Riding police in his locality. Having a liking for the sea, he acted for a time as ship surgeon after retirement. During the last war he became deputy medical officer of health for the City of Wakefield, and did valuable work in that capacity. He was a man of many interests, but his retiring nature made him averse to medical politics, though he often expressed his fears lest the conditions of service under the National Health Service Act would deny to the family doctor that priceless personal relationship with his patients that made family practice, for him, a real vocation. He was a profound Christian, and for many years read the lessons in his parish church. The profession will miss men of Bradshaw's sterling quality. Our sincere sympathy is extended to his widow.—J. LE F. B.

We record with regret the death at the age of 81 of Mr. H. R. MAYNARD, who was secretary of King Edward's Hospital Fund for London from 1906 to 1938. Henry Russell Maynard took a first in modern history at Oxford in 1901, and from 1903 to 1907 he was resident at Toynbee Hall, being also for a time secretary of the Mansion House Unemployed Committee and of the London Unemployed Fund. With his strongly developed social conscience he was admirably qualified to take on the post of secretary of King Edward's Hospital Fund, which had been founded in 1897 for the "support, benefit, or extension of the hospitals of London." During his long years of service the work of the Fund increased greatly in importance and gave a lead to hospitals in the rest of the country, and indeed the world. Mr. Maynard was created C.V.O. in 1932, and in 1938 he was made clerk to the general council of the Fund. When he retired in 1941 he became a member of the general council.

Dr. SYDNEY TIBBLES writes: Having practised in the next room to my old friend Dr. WILLIAM GRIFFITH, I feel I cannot let the obituary notice in the *Journal* of January 23 (p. 217) pass without adding my appreciation of his great kindness to patients and everyone else. Unfortunately he was predeceased by his wife, who had been an invalid for years and whom he greatly missed in the latter part of his life.

We record with regret the death on February 15 of Lady HORDER, wife of Lord Horder. She was the only daughter of Mr. Arthur Doggett, of Newnham Manor, Hertfordshire. Lord and Lady Horder celebrated their golden wedding in 1952.

Medical Notes in Parliament

CARE OF THE MENTALLY SICK

The House of Commons used a private Members' day on February 19 for a survey of the care and accommodation of the mentally sick, and at the end of the discussion adopted a resolution recognizing the advances made in recent years, but expressing concern at the serious overcrowding in mental and mental deficiency hospitals, and the high proportion of obsolete buildings, the acute shortage of nursing and junior medical staff, and calling for adequate provision for the modernization and development of this essential service.

Mr. KENNETH ROBINSON, a member of the North-west Regional Hospital Board, who moved the resolution, touched on many aspects of development since the passing of the Mental Treatment Act in 1930, and the shortcomings still prevailing. Sir FREDERICK MESSER, who served on the same board, seconded. Mr. Robinson mentioned television as an important amenity having therapeutic value as well, and said that he would not be happy until every mental

defective hospital had a television set in almost every ward. He also said there did not seem to be enough younger doctors coming into the mental health service.

Dr. REGINALD BENNETT, who said he had practised for some years as a psychiatrist, and for many of those years in mental hospitals, said the revolution in mental medicine and mental hospitals consisted of one thing—that, whereas previously the mental hospitals were limbo, to-day the whole outlook had changed from the merely custodial to a dynamic one, where treatment was given and hope provided. He knew hospitals which occupied deplorable buildings but which achieved a magnificent therapeutic record and high morale. Dr. Thomas Beaton had performed a revolutionary service in Portsmouth, in that there was none of the unreasoning terror among the local people about visiting out-patient clinics at the mental hospital. In another neighbourhood people still regarded it as some kind of penitentiary. Nursing and recruitment were a dreadful problem largely because mental nursing had been so widely misrepresented. What he sought to establish by the debate was that there were ways of using buildings which made some beds twice as useful. He was appalled at the terrible disincentives applied to girls who wished to become nurses. He did not believe they were really short of beds in mental hospitals. There was a big future, and brilliant new treatments were coming out all the time. If attention was given to the use of existing beds it was not necessary to rebuild all the Crimean War buildings at once.

Mr. SOMERVILLE HASTINGS said the Health Service had one great advantage—it enabled medical problems to be looked at as a whole, and because of that he had great hopes for the future of the treatment and prevention of many forms of mental disease. Did potential mental nurses realize that they would have an exceedingly interesting life? Did doctors realize that this was not the backwater it used to be, but that there were great possibilities for doing real good in the mental health service? The chief point to which he wanted to call attention was that mental diseases could be and must be treated much earlier than was ever realized thirty years ago. Much more should be done for mental out-patients. He wanted to see them at ordinary general hospitals and health centres, and treated there at times that would not cause too much interference with their daily affairs. On the nursing difficulty, he did not think it wise to insist that every mental nurse should be doubly qualified: a basic training in general nursing and then psychological study seemed to him enough.

Dr. A. D. D. BROUGHTON said that about 50% of hospital beds were occupied by mental cases, and it was ridiculous to be spending only 1% of the expenditure on medical research on mental illness.

Government Reply

Miss PAT HORNSBY-SMITH, Parliamentary Secretary, Ministry of Health, in a necessarily concentrated reply to a wide debate, said there was no evidence that mental illness or mental deficiency, as such, was increasing. The figures must be reconciled, however, with the fact that people were living longer and there was thus a larger number of aged patients who were mentally ill; and that with the new outlook people were coming voluntarily for treatment, so that in the past 15 years the number admitted to mental hospitals had doubled. The percentage of voluntary patients varied from 45 to 75 for males, and from 40 to 70 for females, according to the regional averages. The national average was 60%. These were voluntary patients in mental hospitals only; they did not include mental deficiency institutions.

The average number of beds per 1,000 population was 2.8, and the Ministry would like to see a standard of 3.5. There were unfortunately 1,640 unstaffed beds, but, in spite of that and the long waiting-list, in the five years of the Health Service the number of patients in mental hospitals had increased by 5,600. The actual waiting-list on the mental deficiency side on December 31 last was 8,521, compared with estimates previously given of 9,290, so that some

advance had been made. For the year 1953-4 there were schemes to provide 1,314 new beds for the mentally deficient, and in 1954-5 for another 1,200. Other schemes would bring into use some 3,000 beds in the next six years.

The major problem was nursing staff. The number had risen by 2,800 over five years, but there had been a serious decline in student nurses of 1,500. There were now 15,000-odd trained nurses, 4,500 student nurses, 174 assistant nurses, and 10,500 nursing assistants. There was no guarantee that the establishment of a roll of a new type of mental assistant nurse would lead to any substantial influx of candidates. Experience in the general hospitals suggested that the establishment of a grade of trained enrolled assistant nurses was a very slow process.

The cadet scheme was being closely investigated, but it raised difficulties. It would be virtually a continuance of education, and they had to consider whether it was an educational cost or a medical one. It was an expensive way of getting potential labour which, for those two years, was contributing very little to the Service. There was also a strong school of thought that the two years of adolescence and development between 16 and 18 should be spent by potential recruits to the mental health service in gaining experience in the world in other activities, to increase their fitness for the strain and responsibility of mental nursing. Others might dissent, but it was not unreasonable to be cautious about bringing 16- and 17-year-olds into association with mental hospitals except under strict supervision and with every assurance that they would not be used in the wards until they had reached the age of 18.

INDUSTRIAL DISEASES BILL

The Industrial Diseases (Benefit) Bill was given its third reading in the House of Commons on February 18.

Mr. R. H. TURTON, Parliamentary Secretary, Ministry of Pensions and National Insurance, said the Minister was engaged on discussions with the T.U.C. and interested parties on the two schemes to be made under the Bill's provisions. The first scheme was to extend the Pneumoconiosis and Byssinosis Benefit, Scheme of 1952 to partial cases, and there were formidable administrative difficulties. It might well bring some 40,000 claims, entailing 20,000 examinations. That number was nearly as large as all the examinations for pneumoconiosis being made under the Industrial Injuries Scheme, and it was clear that medical help would have to be obtained in such a way as not to interfere with the work on other schemes. Preliminary inquiries about the second scheme, to deal with cancers covered by the Workmen's Compensation Acts, led to the belief that it should not present great complications, since the numbers involved were much smaller. The scheme would be operated independently, and would be introduced as soon as it was ready.

Dr. H. MORGAN said this was one of the subjects which gave most trouble to the few doctors who specialized in diseases caused by industry. Dr. BARNET STROSS said it looked as though this Bill would cover all cases of inhalation of dust and the resulting fibrosis. The flat rate payment of 20s. for partial disablement was a mistake, because the men concerned were moving into a stage of deterioration. He hoped the Minister would introduce schemes for men who suffered not only from the inhalation of dust but from inhalation of fumes, who had a marked pulmonary fibrosis, and in particular bronchitis and emphysema.

Mr. OSBERT PEAKE, Minister of Pensions and National Insurance, said that the new scheme would be administered by the same board as that which administered the scheme for total incapacity established under the 1951 Act, and which, under the chairmanship of Mr. Paul Sandlands, Q.C., had given great satisfaction.

The Lung Cancer Inquiry

Mr. J. R. BEVINS, replying to a question addressed to the Lord President of the Council, stated on February 18 in

answer to Mr. Emrys Hughes that the statistical investigation into the relationship between smoking and cancer of the lung was carried out by members of the Statistical Research Unit of the Medical Research Council during the years 1948-52 at a total cost of about £7,000. The investigation was not in any way hampered by lack of funds. Subsequently a panel under the Government Actuary considered the results of the investigation: the cost of this was very small.

M.R.C. Expenditure

Figures of total expenditure on research by the Medical Research Council, and the proportion spent on research into mental health, were given on February 15 by Mr. J. R. BEVINS, who, as Parliamentary Secretary to the Ministry of Works, answers in the Commons for the Lord President of the Council. They were:

Year	Total Expenditure	On Mental Health
	£	£
1945-6	295,000	3,311
1946-7	415,000	300
1947-8	618,000	984
1948-9	770,000	5,991
1949-50	1,216,000	14,963
1950-1	1,363,671	18,176
1951-2	1,616,500	21,780
1952-3	1,505,917	21,361

In addition to these sums the Medical Research Council has during this period devoted a considerable proportion of its resources to researches into psychological and neurological problems. In the year 1952-3, for example, over £51,000 was spent on research in psychology and over £42,000 on research in neurology.

Vital Statistics

Week ending February 13

The notifications of infectious diseases in England and Wales during the week included pneumonia 931, scarlet fever 1,161, whooping-cough 1,916, diphtheria 11, measles 1,846, dysentery 669, acute poliomyelitis 21, paratyphoid fever 4, and typhoid fever 0.

Infectious Diseases

In England and Wales during the week ending February 6 the number of notifications increased by 297 for measles (from 1,190 to 1,487) and by 52 for dysentery (from 572 to 624), and decreased by 256 for whooping-cough (from 2,240 to 1,984) and by 43 for scarlet fever (from 1,058 to 1,015).

Two-thirds of the increase in the incidence of measles was contributed by two counties, a rise of 96 in Norfolk (from 220 to 316) and 95 in Cumberland (from 65 to 160). The largest fluctuation in the local trends of whooping-cough was a decrease of 38 notifications in London (from 83 to 45). Only very small changes occurred in the local trends of scarlet fever. 19 cases of diphtheria were notified, and these were 3 more than in the preceding week.

21 cases of acute poliomyelitis were notified, and these were 1 more for paralytic and 2 fewer for non-paralytic cases than in the preceding week. The largest returns were 3 cases—in London, Kent, and Essex.

The greatest increases in the notifications of dysentery were 64 in Lancashire, 30 in Norfolk, and 28 in Sussex. The largest returns during the week were Lancashire 140 (Preston C.B. 36, Swinton and Pendlebury M.B. 22, Preston R.D. 16, Oldham C.B. 15, Bolton C.B. 12), London 99 (Hackney 38, Islington 16), Yorkshire West Riding 89 (Bradford C.B. 27, Leeds C.B. 25), Norfolk 45 (Norwich C.B. 43), Middlesex 41 (Hornsey M.B. 11, Tottenham M.B. 11),

Sussex 37 (Battle R.D. 19, Brighton C.B. 11), Staffordshire 36 (Cannock U.D. 28), Warwickshire 20 (Birmingham C.B. 18), and Kent 18 (Chatham M.B. 10).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1945-53 are shown thus -----, the figures for 1954 thus ———. Except for the curves showing notifications in 1954, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending February 6 (No. 5) and corresponding week 1953.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Medical News

Vitamins in Margarine.—At present margarine, as a condition of licence for its manufacture, must contain added vitamins A and D. Control ends on May 8, and with it the statutory obligation on manufacturers to add these vitamins. The Ministry of Food's food standards committee, which has been looking into the question, has now issued a report recommending not only that vitaminization of domestic margarine should continue but that the amount of vitamin A in it should be brought up to the level ordinarily found in butter. The committee says that the National Food Survey has shown that vitaminized margarine is an important source of vitamins A and D in the national dietary, particularly among the less well off and those with large families. The present levels of vitaminization are 450-550 I.U. vitamin A and 90 I.U. vitamin D per ounce (28 g.). The proposed new level for vitamin A is 760-940 I.U. per ounce. Interested parties are given until March 19 to make their views known, after which, presumably, new legislation will be introduced.

Royal Hospital and Home for Incurables, Putney.—The Duke of Devonshire, speaking at a reception at the Time and Life Building in London last week, opened an appeal for £100,000 to ensure the continuance of the Royal Hospital and Home for Incurables at Putney, whose centenary will be celebrated in July of this year. As its new president, he said that the hospital gave shelter to 260 resident patients, the majority of whom were able to leave their wards daily to use the downstairs rooms. It might be asked, the president continued, why the hospital had not been taken over by the State under the National Health Service. The point he wanted to stress was that it was a home as well as a hospital and was felt to be so by those incapacitated by disease or injury who were cared for there. It was feared that if the hospital were taken over by the State the home-like amenities, so important for the welfare of the incurable, would cease to be provided. The hospital was founded by Dr. Andrew Reed in 1854 for the purpose of relieving "men and women over the age of 30 who are hopelessly disqualified for the duties of life by disease, accident, or deformity, and who are considered after careful examination to be beyond the likelihood of cure." Most of the patients in the hospital are sufferers from such conditions as rheumatoid arthritis, Parkinson's disease, disseminated sclerosis, and disease of the heart. Patients with cancer, epilepsy, psychosis, or contagious or infectious disease are not admitted.

International College of Surgeons.—The College is holding its Ninth Biennial International Congress at São Paulo, Brazil, from April 26 to May 2, and also a meeting of its Joint European Sections at Turin on June 1 and 2. Fellowship of the College is open to British surgeons who are Fellows of one of the Royal Colleges, without entrance fee for the time being, at an annual subscription of five guineas. The headquarters of the College are in Chicago. The treasurer and secretary for the British Isles is Dr. J. F. Brailsford, 20, Highfield Road, Edgbaston, Birmingham, from whom may be obtained application forms for Fellowship and further details of the College's activities.

Chair of Surgery at Leeds.—Mr. J. C. Goligher, assistant surgeon at St. Mary's Hospital, London, has been appointed to the newly instituted Chair of Surgery at the University of Leeds. Mr. Goligher graduated at Edinburgh in 1934. He was a Hunterian professor of the Royal College of Surgeons of England in 1951, and has recently held a research fellowship at the College's Buckston Browne Research Farm. His main interest is gastro-intestinal surgery.

British Abstracts of Medical Sciences.—Section A III of *British Abstracts*, which covered the subjects of physiology,

biochemistry, anatomy, pharmacology, and experimental medicine, has now been replaced by *British Abstracts of Medical Sciences*. This publication will appear monthly and contain abstracts from the world literature on anatomy, biochemistry, experimental biology, experimental medicine, microbiology, pathology, pharmacology, and physiology. The chief editor is Dr. C. C. N. Vass (St. Thomas's Hospital Medical School), and the editorial office is at the Lister Institute, Chelsea Bridge Road, London, S.W.1. The annual subscription is £10. Although the fields covered by *British Abstracts of Medical Sciences* and *Abstracts of World Medicine* overlap to a small extent, the former will be of value primarily to the laboratory and research worker, whereas the latter caters principally for the clinician. Moreover, the two journals differ somewhat in the type of abstract published, those in *British Abstracts of Medical Sciences* being mainly brief and "indicative," and those in *Abstracts of World Medicine* being fuller and of the "informative" type. *Abstracts of World Medicine* is published monthly by the British Medical Association and the annual subscription is £4 4s.

Rheumatoid Arthritis: A Handbook for Patients.—A handbook on rheumatoid arthritis for doctors to give to their patients has just been published by the Empire Rheumatism Council. It tells the layman something about the nature of the disease and then goes on to discuss treatment. Copies may be obtained free of charge from the Empire Rheumatism Council, Tavistock House North, Tavistock Square, London, W.C.1.

Smokeless Zones for Bradford.—Bradford Corporation has approved an order which will create 20 smokeless zones in its area in about a year's time. Nineteen of the zones are council estates where the burning of smokeless fuel is already a condition of tenancy. There is reported to be local opposition to the order on the grounds of the expense to the tenants of the estates.

British Schools Exploring Society.—Applications are invited for the posts of honorary physician and honorary surgeon to the 1954 expedition to Northern Quebec (July 28 to September 15). The cost will be about £180. Applicants should write as soon as possible to the secretary, c/o Royal Empire Society, Northumberland Avenue, London, W.C.2.

Dr. E. B. Strauss, physician to the department of psychological medicine, St. Bartholomew's Hospital, has been awarded the honorary degree of Doctor of Natural Philosophy in the University of Frankfurt on the occasion of his 60th birthday.

Dr. David Nabarro, who is 80 on February 27, is to receive a presentation on that day from his colleagues and friends at the Hospital for Sick Children, Great Ormond Street, where he was for many years director of the pathology department.

COMING EVENTS

Association of Graduates, Royal College of Surgeons in Ireland.—The annual dinner will take place in the College at Dublin on March 13 at 7.30 p.m., the night of the Rugby international between Ireland and Wales. Tickets may be obtained from the honorary secretary at the College, and guests of either sex may be invited. The annual general meeting will be held at 6 p.m. on the same evening.

Airborne Medical Society.—The annual dinner will be held in Surgeons' Hall, 18, Nicolson Street, Edinburgh, 8, at 7.30 for 8 p.m. on March 20. Members who have not received a copy of the circular recently sent out should apply to the hon. secretary, Dr. J. S. Binning, Medical Department, Eastern Region, Marylebone Station, London, N.W.1.

The Faculty of Radiologists are organizing courses for candidates for the D.M.R.D. and D.M.R.T. (R.C.P.Lond., R.C.S.Eng.) starting in October, 1954. Further information will be found in the advertisement columns (p. 42).

NEW ISSUES

Journal of Clinical Pathology.—The next issue (Vol. 7, No. 1) is now available. Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Journal of Neurology, Neurosurgery, and Psychiatry.—The next issue (Vol. 17, No. 1) is now available. The contents include:

TRAUMATIC EPILEPSY AFTER CLOSED HEAD INJURY. Gilbert Phillips.
DEMONSTRATION OF "BR" IN NERVE CELLS. Sven-Olaf Brattgård and Torsten Lindqvist.
FRONTAL LOBE WOUNDS CAUSING DISINHIBITION. Hugh F. Jarvis.
A HISTOLOGICAL AND CHEMICAL STUDY OF THREE CASES OF DIFFUSE CEREBRAL SCLEROSIS. W. Blackwood and J. N. Cumings.
POST-ENCEPHALITIC PARKINSONISM WITH AMYOTROPHY. J. G. Greenfield and W. B. Matthews.
A STUDY OF EIGHT SURGICALLY TREATED CASES OF SPONTANEOUS SUBCORTICAL HAEMATOMA. Aloys Werner.
DIMERCAPROL IN THE PRE-NEUROLOGICAL STAGE OF WILSON'S DISEASE (HEPATOLENTICULAR DEGENERATION). C. G. Warnock and D. W. Neill.
STUDIES OF THE CONNECTIONS OF THE FORNIX SYSTEM. H. M. Daltz and T. P. S. Powell.
THE TREATMENT OF DYSTROPHIA MYOTONICA WITH A.C.T.H. Oliver Garai.
BOOK REVIEWS.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Archives of Disease in Childhood.—The next issue (Vol. 29, No. 143) will be available in a week's time. The contents include:

TUBULAR INSUFFICIENCY AND RENAL DWARFISM. G. Fanconi.
CHONDRO-OSTEO-DYSTROPHY (MORQUIO'S DISEASE). W. F. Townsend-Coles.
NON-INFLAMMATORY LARYNGEAL STRIDOR IN INFANTS. James Crooks.
A CASE OF PHAECHROMOCYTOMA IN CHILDHOOD. M. Israelski, A. C. Kendall, and R. E. Shaw.
HORMONAL SEX REVERSAL IN A FEMALE. W. J. Matheson and E. M. Ward.
BLOOD SUGAR LEVELS IN BABIES BORN OF DIABETIC MOTHERS. George M. Komrower.
LABORATORY OBSERVATIONS ON THE VISCIDITY OF MECONIUM. John L. Emery.
HAEMOGLOBIN LEVELS IN PREMATURE INFANTS. Malcolm Arthurton, Donough O'Brien, and Trevor Main.
A CONGENITAL RENAL TUBULAR DEFECT. J. Luder and Dorothy Burnett.
A SECOND CASE IN THE SAME FAMILY OF CONGENITAL FAMILIAL CEREBRAL LIPIDOSIS RESEMBLING AMAOYTIC FAMILY IDIOSY. N. J. Brown, Beryl D. Corner, and M. C. H. Dodgson.
MONGOLISM IN BOTH OF MONOZYGOTIC TWINS. Robert J. Young.
HEPATIC NECROSIS IN DISSEMINATED HERPES SIMPLEX. R. C. B. Pugh, G. H. News, and J. A. Dudgeon.
A CLINICAL STUDY OF THE DRAUGHT REFLEX IN HUMAN LACTATION. Clair Isbister.
PETECHIAE WITH CYANOSIS IN THE NEWBORN. N. C. Elphinstone, M. Brenda Morris, and Simon Yudkin.
THROMBOCYTOPENIC PURPURA IN THE NEWBORN. M. Brenda Morris.
CHRONIC MYELOID LEUKAEMIA IN A CHILD PRESENTING AS ACUTE POLY-ARTHRITIS. G. A. Bedwell and A. M. Dawson.
ANNULAR PANCREAS IN THE NEWBORN. P. P. Rickham.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Monday, March 1

MEDICAL SOCIETY OF LONDON.—8.30 p.m., meeting of Fellows. Third Letchman Lecture by Mr. N. C. Tanner: Surgery of Peptic Ulcers and its Complications.

Tuesday, March 2

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor J. H. Kellgren: The Supporting System and its Disorders.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. I. Muende: Pigmentation. ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor D. J. Robertson: Congenital Arteriovenous Fistulae of the Extremities.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Professor L. J. Witts: Anaemias of Pregnancy. WEST END HOSPITAL FOR NERVOUS DISEASES.—5.30 p.m., Mr. J. Minton: Ocular Manifestations in Nervous Disease. Part I.

Wednesday, March 3

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Epidemiology of Fungous Infections. INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Dr. E. G. B. Calvert: Surgery and the Diabetic.

MIDLAND MEDICAL SOCIETY.—At Birmingham Medical Institute, 8.15 p.m., Dr. E. Baylis Ash and Professor J. R. Squire: Allergy. OXFORD UNIVERSITY.—At Radcliffe Infirmary, 5 p.m., Litchfield Lecture by Sir Charles Symonds: Recent Advances in Our Knowledge of Epilepsy. SOCIETY FOR ANALYTICAL CHEMISTRY.—At Burlington House, Piccadilly, W., 4.30 p.m., A.G.M. Bernard Dyer Memorial Lecture by Dr. E. B. Hughes, D.Sc., F.R.I.C.: Contribution of Public Analysts and Other Analytical Chemists to Public Welfare.

Thursday, March 4

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor G. M. Bull: Regulation of Body Water.

INSTITUTE OF CHILD HEALTH.—5.30 p.m., Dr. D. W. Winnicott: A Case and its Management.

INSTITUTE OF LARYNGOLOGY AND OTIOLOGY.—At Royal College of Surgeons of England, 5.30 p.m., Mr. F. A. Williamson-Noble: Diseases of the Orbit and its Content Secondary to Pathological Conditions in the Nose, Sinuses, and Throat.

LIVERPOOL MEDICAL INSTITUTION.—5 p.m., visit of Manchester Medical Society. Dr. H. T. Howat and Mr. R. L. Holt: Medical and Surgical Aspects of Pancreatic Disease.

MIDLAND TUBERCULOSIS SOCIETY.—At Birmingham Chest Clinic, joint meeting with Midland Branch, Society of Medical Officers of Health, and Association of Industrial Medical Officers. Dr. J. E. Geddes, Dr. A. Meiklejohn, and Dr. E. L. M. Millar: Social Aspects of Chronic Respiratory Disease.

OXFORD UNIVERSITY.—At Southfield School, Glanville Road, Cowley Road, Oxford, 8 p.m., Dr. A. G. M. Weddell: Science and Medicine.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Mr. W. F. Nicholson: History and Development of Surgical Treatment of Pulmonary Tuberculosis.

ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Lieutenant-Colonel P. Cuddon: History of the Provision for Army Pensioners.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.30 p.m., Otolaryngology Lecture by Mr. F. A. Williamson-Noble: Diseases of the Orbit and its Content Secondary to Pathological Conditions in the Nose, Sinuses and Throat.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Professor A. G. R. Lowdon: Calculus Disease of the Biliary Tract.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., psychiatry demonstration by Dr. M. Partridge.

SOCIETY FOR CULTURAL RELATIONS WITH THE U.S.S.R.—8 p.m., Dr. L. Crome: Recent Progress in Soviet Medicine.

Friday, March 5

BIRMINGHAM UNIVERSITY.—At Chemistry Theatre, Edgbaston, 5 p.m., Huxley Lecture by Professor D. M. S. Watson, D.Sc., F.R.S.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. G. B. Dowling.

INSTITUTE OF NEUROLOGY.—5 p.m., Dr. Gonzalo Lafara (Madrid): Familial and Sporadic Myoclonic Epilepsy: its Neuropathology and Classifications. LEEDS AND WEST RIDING MEDICO-CHIRURGICAL SOCIETY.—7.30 p.m., clinical meeting.

ROYAL MEDICAL SOCIETY, Edinburgh.—8 p.m., dissertation by Mr. J. W. Delamore: Problem of Pain.

ROYAL SANITARY INSTITUTE.—Sunderland sessional meeting (morning). Mr. W. G. Carey, F.R.I.C.: Modern Developments in the Examination of Food and Drugs; Dr. P. B. Crone: Bacteriological Side of Food Poisoning; Mr. H. C. Bishop, A.R.I.B.A.: Modern Planning of School Buildings and Housing Estates.

WHIPPS CROSS HOSPITAL MEDICAL SOCIETY.—8.30 p.m., clinical meeting.

Saturday, March 6

INSTITUTE OF LARYNGOLOGY AND OTIOLOGY.—11.30 a.m., Professor A. A. J. Van Ermond (Utrecht): Survey of Vestibular Function.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Cox.—On February 10, 1954, at Nuffield House, Guy's Hospital, London, S.E., to Elizabeth (formerly Padbury), wife of Dr. A. G. Charlton Cox, a daughter—Margaret Elizabeth.

Dally.—On February 14, 1954, at 41, Wiltshire Road, London, S.W., to Ann Mullins, M.A., M.B., B.S., wife of Peter Dally, M.B., B.S., a daughter.

Evans.—On February 7, 1954, at 387, Queen's Road, New Cross, London, S.E., to Alexa (formerly Mitchell), wife of Dr. Carlton John Evans, a sister for Alexa and Mary—Caroline Frederica.

Jones.—On February 16, 1954, at their home, "Froyle," Ty-Gwyn Road, Cardiff, to Pauline (formerly Jackson), wife of Hugh Owen Jones, M.S., F.R.C.S., a daughter.

DEATHS

Benson.—On January 12, 1954, at Moore House, Moore, near Warrington, Lancs., John Keith Hamilton Benson, M.B., Ch.B., B.D.S., F.D.S., R.C.S.

Bollans.—On January 29, 1954, in Woods Hospital, Glossop, Derbyshire, Manchester, Lancs., Robert Wilfred Bollans, M.B., Ch.B., J.P., of The Gables, Hatfield.

Corrigan.—On January 29, 1954, Alexander Duncan Fraser Corrigan, M.B., Ch.B., of Duns, Berwickshire.

Davey.—On January 29, 1954, at "Walton House," South Parade, Northallerton, Yorks., John Milton Davey, M.B., Ch.B.

Hicks.—On January 17, 1954, at Northampton General Hospital, Robert Thomas Hicks, O.B.E., M.R.C.S., L.R.C.P., Lieutenant-Colonel, I.M.S., retired, of 72, Kingsley Road, Northampton, aged 51.

Hildreth.—On January 20, 1954, at Tunbridge Wells, Kent, George Albert Hildreth, M.B., B.S., Lieutenant-Colonel, I.M.S., retired.

Kayton.—On January 25, 1954, at his home, Kensington, London, S.W., Maurice Edward Kayton, L.R.C.P.&S.Ed., L.R.F.P.S., D.P.H., late of Ashfield House, Annesley Woodhouse, Nottingham, aged 73.

Kemp.—On January 21, 1954, at the County Hospital, York, Norah Kemp, M.B., C.M., of 18, Coda Avenue, Bishopthorpe, York.

Kutek.—On January 24, 1954, at his home, London, S.W., Antoni Kutek, M.D.

McConnell.—On January 19, 1954, Samuel Ernest McConnell, M.B., Ch.B., of 9, Hawthorn Road, Gatley, Cheshire, aged 42.

Miles.—On January 18, 1954, Herbert Leslie Miles, M.R.C.P., of Cromal House, Droitwich, Wores.

Norman.—On January 15, 1954, at Edware, Middlesex, George Blake Norman, M.B., B.Ch., aged 78.

Robertson.—On January 10, 1954, at his home, Ashburnhams, Bishops Cleeve, Shropshire, Charles Robertson, M.D., aged 87.

Watson.—On January 20, 1954, at Del Rey House, Cheltenham, Glos., Charles Henry Watson, D.S.O., M.B., F.R.C.S.Ed., L.D.S., Lieutenant-Colonel, I.M.S., retired.

White.—On January 18, 1954, at his home, St. Merryn, Braunton, North Devon, Edward Barton Cartwright White, M.R.C.S., L.R.C.P.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Inheritance of Schizophrenia

Q.—How is schizophrenia inherited? A patient of 34 has been advised against having children because her sister-in-law has schizophrenia. There is no other history of mental disease on either side. What increased risk would there be of her having affected children?

A.—It is probable that schizophrenia is a class name for a number of genetically distinct disorders, and that in some families the mode of inheritance is different from what it is in others. It is also probable that in some cases causation is not genetic but predominantly environmental. It would therefore be desirable, before giving any definite eugenic prognosis, to know the family history in much greater detail, together with information about the normal members of the family.

However, taking all forms of schizophrenic psychosis together, the genetic factor is important. If the patient has a schizophrenic sister-in-law, her children would be nephews and nieces of a schizophrenic. Their expectation of developing schizophrenia at some time in their lives has been estimated (Kallmann) as approximately 4%—that is, about four times as great as the expectation for the average member of the population. If the prospective parents themselves are mentally stable, healthy, and happy with one another, this risk could be regarded as somewhat of an overestimate. In that event, and assuming that they would much want to have one or more children, the risk of schizophrenia for the children would not appear to be an unjustifiable one for reasonable people to take.

The Facts of Life

Q.—One is sometimes asked by parents how and when they should give their children instruction on the "facts of life." At what age should sex instruction be given, and what form should it take?

A.—This question creates a mental picture of the Victorian father taking his son to his study for a man-to-man chat on the evening before the boy leaves home. If a formal episode of instruction for either boy or girl is envisaged, then, whatever age is chosen as being appropriate for it, it is likely to be too late—the child will already have heard a garbled story from its friends and school-fellows and will have added to it by a few shrewd guesses. Moreover, such set explanation is difficult as well as unsatisfactory, and is usually embarrassing for both parent and child alike.

The extent to which sex education should be carried out and the form it should take are very much matters of opinion. The problem is in any case a very personal one, and its solution depends a good deal on the personalities of both the instructor and the instructed. In general, however, information on sex, as on most matters, should be given piecemeal as the child develops, and should be begun as soon as the child asks questions and provides opportunities. It should be merely one aspect of knowledge, gradually and naturally acquired by the child as part of growing up, and it should be treated like any other subject. The nature of the instruction must be moulded to suit the age and mental development of a particular child, but replies and explanations should be truthful, although simple and not necessarily conveying the whole truth. Difficulty can arise if the child happens to ask a direct question in the presence of comparative strangers. It may then be best to leave it unheeded and unanswered rather than to say an thing which is fictitious or which will make the child think it has said some-

thing wrong. The question will inevitably arise again at what is likely to be a more favourable moment for answering it.

One rule should be that knowledge should always anticipate events. For example, a girl should know of menstruation before it occurs. As puberty approaches or is established, and if the parents then consider that more detailed instruction in sex physiology is desirable and is beyond their scope, recourse may be had to books such as *Attaining Womanhood* and *Attaining Manhood*, by George W. Corner (George Allen and Unwin, Ltd., London, 1953).

Salivary Gland Swelling

Q.—A patient complains of pain and swelling in the region of the submandibular gland at meal times. No stone has been demonstrated clinically or radiologically. Is it worth trying to stimulate salivation with mercury to "flush out" the gland, are antibiotics indicated, or is there any other treatment for this tiresome condition?

A.—Despite the clinical and x-ray appearances in this case it is very probable that the patient has a stone in the salivary duct. Such a stone may be quite small, in fact no larger than a pin's head. Scrupulous digital palpation of the floor of the mouth just after the patient has sucked a piece of lemon may reveal the stone. It is not uncommon for a very small stone to be missed in the x-ray films, and these should certainly be repeated. Sucking a piece of lemon may bring the stone forward into the duct and thus enable it to be seen in an occlusal film of the floor of the mouth. In the ordinary lateral oblique views of the submandibular region a stone may be superimposed on an area of dense bone. It is usually wise to take further shots from different angles.

It is most unlikely that the symptoms described are due to anything else but a stone. Subacute infection, such as is sometimes seen in the parotid gland, is rare. It would be useless to prescribe mercury preparations, and, in the absence of superimposed infection by a sensitive organism, antibiotics are without value. Even if repeated investigation of this case fails to reveal a stone it is worth while considering exploration of the duct.

Massive Transfusion Causing a Haemorrhagic State

Q.—Are massive blood transfusions, particularly of citrated blood, apt to lead to a haemorrhagic state? I have noticed in such cases that a needle prick will continue to ooze for a long time and there has also been bleeding from the site of operation.

A.—There seems to be little likelihood of massive transfusions with citrated blood leading to a haemorrhagic state. Mollison¹ has calculated that as much as five litres of citrated blood can be given to an adult without signs of citrate toxicity developing. On the other hand, it is at least theoretically possible that a very massive haemorrhage might lead to a haemorrhagic state by causing a serious loss of platelets and other clotting factors. Correspondingly, massive transfusion would replace the latter, but not the platelets. It is doubtful, though, in practice whether the platelet count ever gets reduced to dangerous levels as the result of haemorrhage in an otherwise healthy person. In any case capillary tone is an important factor in controlling haemorrhage from minute vessels, and it seems in fact more likely that the observations prompting this question were the result of diminished capillary tone developing for some obscure reason rather than due to the effects of blood loss or transfusion *per se*.

REFERENCE

¹ Mollison (1951). *Blood Transfusion in Clinical Medicine*. London.

Dosage of Thyroid

Q.—In treating cases of hypothyroidism, is there any harm, or benefit, in giving rather more thyroid than is necessary just to keep the patient euthyroid?

A.—If rather more thyroid than necessary is given in the treatment of hypothyroidism the patient would become

hyperthyroid rather than euthyroid; it is inadvisable to render a patient hyperthyroid. Treatment should be started with an initial dose of $\frac{1}{2}$ gr. (32 mg.) a day (for adults); this is increased each week by $\frac{1}{2}$ gr. until the optimal minimal dose is found. A good plan is to increase the dose gradually until signs of overdosage appear—for example, tachycardia and irritability; treatment is then stopped for two weeks and is resumed at a dose of 1 gr. per day less than the overdose.

Parapertussis

Q.—At present there is an epidemic here of paroxysmal cough, worse at night and accompanied by vomiting and occasional lung complications, but without a whoop—otherwise it is indistinguishable from whooping-cough. Is this parapertussis? How is the diagnosis established? What treatment is advised for parapertussis, and what notification (if any) is required?

A.—Recently, at least in the London area, there has been a good deal of respiratory infection in children, often very severe in infants, with much bronchospasm. Radiologically a patchy bronchopneumonia limited to the lung bases has been a common feature. Some of the cases had coughs and a tendency to vomiting, suggestive of pertussis, but in those I saw there was no bacteriological or haematological support for the diagnosis.

Out of a large experience, I have seen only two cases of parapertussis confirmed by the laboratory. Generally only about 1% of any series of whooping-cough cases show *H. parapertussis*, although there are records of considerably higher percentages. Probably these infections present quite commonly as a mild clinical disease recognizable as whooping-cough, but even more often as a mild coryza and bronchitis without whoop. A definite diagnosis can be based only on skilled laboratory help. Clinically either pertussis or parapertussis may be indistinguishable from coryza or mild bronchitis. Differentiation is by culture and by agglutinin and absorption tests.

The treatment of parapertussis is symptomatic and, if diagnosed early (before tenth day of disease), by antibiotics—for example, chloramphenicol, aureomycin, or terramycin, in doses proportional to the patient's weight. Notification should be as whooping-cough.

Counter-irritant Ointments for Rheumatism

Q.—As most proprietary preparations used for local application in rheumatic conditions seem to have been placed in Category 5 or 6, could you kindly recommend an alternative counter-irritant cream? I would like it to be non-greasy, not to stain or damage the clothes, and to be free from odour.

A.—It is very questionable whether slight irritation of the skin over a painful rheumatic lesion has any significant beneficial effect, which no doubt explains why many proprietary counter-irritant creams have been placed by the Cohen Committee in Categories 5 or 6. Aspirin provides an alternative and more effective approach. Nevertheless several counter-irritant ointments have been retained in the *National Formulary* and can therefore be prescribed on Form E.C.10, though it is doubtful if their official cachet really endows them with any particular therapeutic efficacy. One of these is the *B.P.C.* unguentum iodi denigrescens cum methylis salicylate. When well rubbed in it is non-greasy and will not stain or damage the clothes, though it must be confessed that it has a characteristic but not unpleasant odour. It contains 5% methyl salicylate in non-staining ointment of iodine.

Thallium Poisoning

Q.—What are the symptoms and signs of thallium poisoning? How should it be treated? Thallium sulphate is used here (Turkey) as a rat poison.

A.—There have been several reports of thallium poisoning following the accidental or deliberate ingestion of rat poisons with food. The first symptoms are tingling and

pains in the hands and feet, followed by paroxysmal abdominal pains with vomiting. The next symptom is weakness of the extremities and this may be followed by mental disturbances. The breath is foul, the lips may be blistered, and a purple line on the gums has been reported. Chronic poisoning is associated with gastro-intestinal disturbances, muscular weakness, and pains in the limbs. Loss of hair may accompany both acute and chronic poisoning. There is no specific treatment, but one report¹ claims the successful use of dimercaprol (BAL), 300 mg. daily for eight days, in treating a single case. Ginsburg and Nixon² give a good account of acute poisoning.

Hazards of Fluoroscopy

Q.—I spend about half my working day in the x-ray room, examining the chests of merchant seamen by fluoroscopy. I should appreciate information on the following points: (a) The immediate and long-term risks to health attendant upon prolonged fluoroscopy examination; (b) the optimum operating kilovoltage and milliamperage; and (c) the maximum amount of time which can be spent daily on screening if the optimum kilovoltage and milliamperage figures are adhered to.

A.—(a) If a fluoroscope is adequately protected and properly used there is no risk to health. There is no evidence that prolonged screening leads to malignancy; epithelioma does occur in chronic radiation dermatitis, but if lead gloves are used there is no risk of dermatitis.

(b) For chest screening 65–70 kV at 3 mA is adequate if the operator is fully adapted.

(c) A screening session of three hours is about the maximum desirable, but there are no rules or regulations defining the optimum period.

Craving for Salt

Q.—My daughter, aged 7, has a normally healthy appetite, but she desires enormous quantities of salt. She eats the equivalent of about a heaped teaspoonful of it at each meal (four times a day), taking it on her bread-and-butter as other people would jam. Is this habit of any significance and will it do any harm if persisted in?

A.—Small children sometimes develop cravings for the most odd foods, and a craving for salt is not very unusual in them. It is most unlikely to be more than a transient peculiarity of behaviour, but it is just possible, at any rate theoretically, that the desire for salt represents some physiological need, and that the child actually requires the extra salt. It is in any case a harmless oddity, and probably if she is allowed to indulge her taste for salt, and no further notice is taken of the habit, she will soon tire of it.

"Any Questions?" Book.—The second book of selected "Any Questions?" is available, price 7s. 6d. (postage 6d.). Copies may be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: Aitology, Westcent, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 4499. TELEGRAMS: Bimedadv, Westcent, London.

YESTERDAY AND TO-MORROW IN CHILD HEALTH*

BY

CHARLES McNEIL, M.D., LL.D., F.R.C.P., F.R.C.P.Ed.

Professor Emeritus in Child Life and Health, University of Edinburgh

This address gives a short review in general terms of child health in the last hundred years. Although the examples and figures used in it have been drawn mainly from Scotland, the history has been much the same in England, Wales, and Ireland, and indeed far beyond these islands: it has been similar both in the measures taken to promote child health and in the results obtained. From such a historical survey we can get a perspective view of the growth of the subject and of its future progress.

The Infant Death Rates

Child health is a phrase full of meaning, but is so wide and deep in its meaning that it is difficult and perhaps impossible to define it. As an idea in the mind and as an object of human effort it is as old as the human family; and long before human records were kept the health and well-being of children must have been deeply cherished by their natural guardians, their fathers and mothers. But as a medical concept, and especially as a medico-social problem, it emerged in Britain about the middle of the last century; while the actual phrase—child health—obtained a recognized place in the medical vocabulary only about twenty years ago. It was the publication, for England and Wales in 1840, and for Scotland in 1855, of the numbers of births, deaths, and marriages, and of the population that drew attention to public health and to child mortality, for among these figures, called vital statistics, was included an infant death rate.

This infant death rate (or infant mortality rate) is the number of babies dying in the first year of life in every thousand who survive birth. These rates do not completely measure child mortality, for they omit the heavy loss of infants during birth (stillbirths), and also the considerable loss of children over 1 year of age. None the less, as these infant death rates rise and fall they fluctuate with the stillbirths and the deaths of older children; and they have long been accepted as giving in terms of death an index in reverse of the health of the child community. These infant death rates are given for the whole country and for its units of towns and country districts; so that if the infant death rates have fallen for one or over several years, we say that the state of child health in Scotland or in Glasgow is better; while if these rates have risen we feel that child

health is worse. It is impossible to exaggerate the value of the infant death rates, which have now been published each year in Scotland for nearly a hundred years. These figure-measurements first disclosed the extent of child mortality; next they gradually uncovered the sinister and formidable league of causes that was producing such a wastage of child life; and then they brought into action, with slow and painful effort, various social and medical agencies to remove these causes. And now to-day, with a good deal accomplished in the reduction of child mortality, we tend to put still wider meanings into the phrase child health.

We realize that the child cannot be isolated as a person; and as we become aware of the connexions of child health with the fundamental social realities of family and home we see that child health in this wider context is at the centre of the nation's well-being. This wide conception of child health and the vision of its future fulfilment have been gradually reached by the use of the instrument of measurement that we have in the infant death rates.

Yesterday in Child Health

Let us look back over almost a hundred years of infant death rates in Scotland, for by giving the figures at the beginning and the end of the century we shall have a simple measure of the progress of child health in that time. The infant death rates for Glasgow for the same periods are added because later I make some remarks upon Glasgow, where the problem of infant mortality was perhaps more serious and more difficult than in any other large Scottish town. The infant death rates for Scotland and Glasgow were:

	1855-60	1952
Scotland	120	35
Glasgow	179	41

The figures speak for themselves and show a great reduction for Scotland and one relatively greater in the case of Glasgow. And the difference would be even greater if stillbirths were added; but stillbirths have been registered only in recent years. Even with incomplete figures we can see that in the last hundred years the tide of death has gone back a long, long way from the shore of infant life, or, to make a positive statement, that there has been a great gain in child health.

In running the eye over the figures in the years between the beginning and the end of the century a surprising fact becomes apparent. The great reduction over the century was not a steady downward trend

*The first G. B. Fleming Memorial Lecture, given in Glasgow on April 15, 1953. Dr. Geoffrey B. Fleming was Senior Physician at the Royal Hospital for Sick Children, Glasgow, and Professor of Child Health in the University of Glasgow from 1930 to 1947. The above address was prefaced by a tribute to his work and character.

throughout; there was nothing of the inevitability of gradualness about it. In fact, the infant death rates in Scotland hardly moved down at all during the first fifty years of the century; they fluctuated near 120; they rose to 130 in the 1891-1900 decade; and stood again at 120 in the 1901-5 period. But during the next fifty years (1906-52) the infant death rates have gone steadily down, with an acceleration since 1941. Is there any explanation of these tides of infant mortality remaining obstinately high for the first fifty years, and of their receding steadily during the next fifty years? We can answer the question only if we know something of the efforts that were being made to remove conditions hostile to infant life during the two periods. In any case the very different behaviour of the infant death rates in Scotland from 1855 to 1905 and from 1906 to 1952 justifies the division of our chosen "yesterday" into two periods of fifty years each.

It is interesting that in England and Wales the levels of infant death rates remained steadily high during the same 50-year period; indeed, they were at a higher level, remaining between 140 and 150. The English figures began to fall sooner than in Scotland. Presently they reached and then passed the Scottish levels, maintaining these lower levels until in 1952 the infant death rate in England and Wales was 28 and in Scotland it was 35.

The First Fifty Years: 1855-1905. Sanitation and the House

The first fifty years saw the first real beginning of sanitation as an organized community movement in Scotland; and naturally sanitary reform began in the largest towns. I take Glasgow as an example of the prevailing insanitary conditions in Scottish towns. Glasgow was first among Scottish towns for the size and density of her population, and was worst in her sanitary conditions. Her citizens were aware of these dangerous conditions; and in 1855, the first year of this first 50 years, the Loch Katrine Waterworks Act was passed which was to give Glasgow the finest water supply in the United Kingdom. This was followed by the creation of a sanitary department in 1862, and the appointment of her first medical officer of health the following year in the person of Dr. W. T. Gairdner, who was to become a distinguished physician. He was succeeded in 1872 by Dr. James Burn Russell, the second in a notable line of Glasgow medical officers of health. Before Russell took up his duties, great measures of sanitary reform had been carried out in water-supply, drainage, sewerage, removal of refuse, and paving, lighting, and cleansing of streets. The city as a whole and its streets had been cleaned up; but many thousands of its houses remained grossly insanitary. Russell held office till 1892; and he has left a record of sanitary and housing conditions in Glasgow during these 20 years, both in his official reports and in his addresses to the Glasgow Philosophical Society and other public audiences (Russell, 1905). These addresses were given to inform the citizens of what was happening in their midst, and to rouse their conscience to support official action and to engage in voluntary effort.

From the outset the new medical officer of health was convinced that further progress in Glasgow sanitation and public health would depend more than anything else on improvement of the housing conditions. He set himself to study the insanitary house. He listed the many ways in which a house could be insanitary—in structure, in sanitary conveniences, in lighting and ventilation, etc.; and high on his list he placed overcrowding. He noted the effects of such houses on the men, women, and children who lived in them in terms of disease and moral degradation. He was a firm believer in the principle of measurement, and he applied it wherever he could. He was like the man in Ezekiel's prophecies; and he went into and through the houses of Glasgow "with a line of flax in his hand, and

a measuring reed"—into the many-roomed mansions of Blythswood and the one- and two-roomed houses of Bridgegate. And he counted the number of persons who lived in each house. Thus after great labour he produced a house census for the whole city in which houses were graded according to the number of their rooms, the number of persons who lived in them, and the average air space for each person; and alongside these different grades of house he placed their general death rates and the infant death rates. All this work was embodied in official reports, but the gist of it was given to the citizens of Glasgow in these public addresses already mentioned.

These popular lectures give the classic account of the insanitary house, supplying the facts and figures, and adding vivid pictures of such houses and their effects upon their inhabitants. In a famous address, "Life in One Room," he told his audience that in 1881 the population of Glasgow was 511,520, and of this total 126,000 (a quarter) lived in one room, and 228,000 (nearly a half) lived in two rooms, and gave figures showing the high general death rates and the soaring infantile mortality rates in such houses. In another address, on "Uninhabitable Houses," he takes his audience inside "a one-roomed house . . . where there is no artificial light but a glimmer of light from a handful of red ashes, and going in one hears voices but sees no one, and 'where in the innermost recesses of the apartment, the air seems a residue of all the breath that had ever been breathed into it.'"

In 1891 Russell reviewed the progress of sanitary reform in Glasgow and for Scotland for the previous 30 years; he claimed that housing conditions had improved, giving facts and figures, and in support of his claims he showed the steady fall of the general death rates. But the fall in the infant death rates was trifling and insignificant, and these were to rise sharply in the next decade. He was sensitive about Glasgow's high infant mortality, and in another address he referred to this in one of his vivid phrases. Speaking of the quinquennium 1876-80 he says: "Glasgow makes away with 147 in every thousand of her children before she has had them in her fatal arms," but he notes with a kind of sad satisfaction that the infant death rate in Liverpool at the same time was 162.

Russell was a great man, and in his fight for sanitary reform in Glasgow he was single-minded, and concentrated his thought and effort on the dwelling-house as the final end of good sanitation. This task was a gigantic one and could not be finished in a single life, and when he died in 1904 much remained to be done.

Next year, 1905, saw the completion of 50 years of infant death rates in Scotland. I have already mentioned that the infant death rates remained steady throughout this period at 120 per 1,000, with small fluctuations; while the general death rates, starting at 20.7, had steadily fallen to 17 at the end (1901-5). In terms of health, we can say that the health of the whole population of Scotland, young and old, had become better in these 50 years; while the health of infants under 1 year remained at the same poor level. We know now that of all the death rates the infant death rate is the most sensitive to insanitary conditions; and by the end of this 50-year period (1855-1905) housing conditions in Glasgow and throughout Scotland had not reached a degree of improvement that was reflected in a lowered infant mortality, and during the same time no other effective aid, medical or social, was reaching mothers in their care of children inside these insanitary houses.

The Second Fifty Years: 1906-52. Mother and Child

In 1906, at the beginning of this second period, a national conference met in London to discuss infant mortality and measures for its reduction. The significance of this was that general attention was focused on the problem of infant mortality and its urgency. Still more significant were the words of Mr. John Burns, then President of the Local Government Board in England, in his address to the Conference: "Let us concentrate on the mother. What the

mother is the children are. . . . Let us glorify, dignify, and purify motherhood by every means in our power." In these words the Minister of State concerned with public health gave his blessing and support to efforts already being made, both by municipalities and by voluntary bodies, to assist mothers in their task of child care. I shall not overload this address with details of when and where in England and in Scotland milk depots, infant clinics, and schools for mothers were begun, but these agencies were already at work before 1906, fairly extensively in England, and here and there in Scotland. They were now extended; and they were gathered into a national system in the Maternity and Child Welfare Services Act of 1918. This Act might be described as a Special Education Act for Mothers; for its main benefits were that it provided mothers with teachers who gave them simple lessons in the care of their children.

I have already spoken of Dr. Russell, of Glasgow, and how he concentrated his effort on the good house as the end of sanitation in a well-governed city, and how he showed that bad houses brought disease and death to those within it, and especially to the children. But throughout the period of 50 years in which he lived bad housing was so widespread and deep-rooted that the movement of child health and also for general health was largely occupied with improving the sanitation of the city and of its houses. And now, in 1906, John Burns, of Battersea, spoke to the representatives of four nations and urged them to deal with the problem of infant mortality by concentrating on the mother. This is a simple phrase, but powerful in its wide and deep implications. For the mother is the housekeeper in a double sense, keeping both the house and her children and husband. The sanitary department does not sweep and clean her house, and the doctor and nurse do not feed or wash her baby. And when John Burns added, "What the mother is, the children are," he was stating in simple words a great truth, and indeed was filling in almost the whole truth of infant and child health. The two foundation stones of child health are a good house and a good housemother. And of a good mother much is required: a good conscience, both a sanitary conscience towards her house and all its materials, and a maternal conscience towards her children; a mind that knows how to keep the house clean and how to feed her baby; and a strong body and capable hands.

These are the abstract principles that govern the life and health of the mother and her children; and now we can speak of practical results. This advice to concentrate on the mother has been followed out for the last 50 years; and it has given a better understanding of her problems, separating the things that must be done for her from the things that she alone can do. It has strengthened services already at work, and has brought new services into action.

The care of the mother's general health and her careful supervision in pregnancy and in her confinement have been undertaken in the new service of antenatal clinics which have strongly reinforced the work of the maternity hospitals. The combined antenatal-maternity service has reduced maternal deaths, has raised the level of health in mothers, and has also reduced infant deaths during birth and in the first month after birth.

At the same time the care of the sick child has been greatly improved by increased accommodation in children's hospitals, by the building of new hospitals and especially of fever hospitals, and by advance in knowledge of disease in children and in the power of its treatment. This better knowledge of disease in children, put at the disposal of family doctors and practised in the home, has also strengthened the general service of the sick child.

Education of the Mother in Child Care

This had begun in a feeble and scattered way before the second period of 50 years had opened; and it was firmly established only in 1918 by the inauguration of the child welfare service. This was a new and great enterprise; an attempt on a national scale to provide the mother with

education in all the tasks of child care which she alone can give. The doctors and health visitors were the teachers, giving their lessons at the infant clinics and inside the homes; but the practice of these lessons in child care rested in the instructed mind and in the strong and willing hands of the mother in her home.

The important part of this education was in the feeding of infants and in domestic sanitation. Infant-feeding had long been a subject of study in children's hospitals; and it was mainly a study of the use of clean cows' milk as a substitute for breast milk. At first cows' milk mixtures were complicated, and the instruction in their use reached mothers only indirectly or not at all. But by the time the new child welfare service was begun the use of cows' milk for infants had been much simplified, and instruction was now given by an army of teachers, and directly into the ears of mothers. For the young baby, the right use of cows' milk is a matter of life and death, and thousands of infant lives must have been saved by this national education of mothers in infant feeding.

The Children's Hospitals

The teaching children's hospitals had always had a double function—the advance of knowledge of disease and its treatment, and the study of health and the instruments that secure it; and the courses of instruction both in disease and in health were steadily extended and given to increasing numbers of medical students. Further, the establishment of chairs and departments of child health, first in Glasgow in 1924 and later in Edinburgh, Aberdeen, and St. Andrews, took place in this period and strengthened the status of the subject in all the four Scottish medical schools; while the title of child health encouraged teaching and study in the whole field of child medicine.

I have given a short account of the more important results that have followed the London Conference on Infantile Mortality in 1906, with its slogan, "Let us concentrate on the mother." Throughout this second period of almost 50 years the work of sanitation and of replacing bad houses with good ones went on. The building of new houses was seriously interrupted during the two wars; but since 1945 it has been resumed, and at a greater pace than ever before. In addition, great attention has been paid to the mother and her children; old services of hospital care for mother and child have been extended and strengthened, and the great new experiment of education of the mother in her own care of her children has had a full trial of 30 years. In short, much effort has been made both for better houses and for the betterment of the mother and children who live in them. Under this combination of effort what progress has been made in child health, measured by infant death rates? The figures for the first quinquennium of the period under review (1906-10) and for the last completed year, 1952, are given for all Scotland, and for Glasgow; and will answer the question.

	1906-10	1952
Scotland	112	35
Glasgow	130	41

This fifty-year period began with a slight improvement; and this continued steadily throughout, with an acceleration since 1940, and reached low levels in 1952. There can be no doubt that in the second 50 years there has been a great improvement in child health. While most of us will agree that improved housing, the education of mothers in child care, and the better hospital care of the mother and the sick child have each played a part in the result, there may be argument about the order of their importance.

Near the end of his work in Glasgow James Russell, still grappling with his unfinished task of improving housing conditions, made a remarkable statement, a prophetic statement, but with no date of its fulfilment. "I see nothing in the nature of things," he said, "why life in the town should not be as healthy as the country." Within 50 years of his death in 1904, his prophetic hope has been realized in the infant death rates for Edinburgh and Aberdeen, and

almost realized for Glasgow. In 1952 the infant death rate for all Scotland was 35: for her rural areas it was 33, for Edinburgh 29, for Aberdeen 30, and for Glasgow 41. When we consider the factors of size and density of population, the presence of "heavy industries," and the legacy of insanitary houses, Glasgow's present low infant death rate entitles her to the place of honour among the larger Scottish towns.

To-morrow in Child Health

We have looked back over a hundred years of work for child health, and have noted the great progress made in the past 50 years. The ideas and the acts of this long yesterday will be carried forward into to-morrow. What are the prospects, immediate and more distant?

Let us name the list of the existing services of child care. They are communal and domestic sanitation; the antenatal, maternity, and neonatal services; the children's and fever hospitals; the child welfare service; family doctors; and, greatest of them all, the home service of mothers. This great array of agencies and their increasing efficiency will ensure in the lengthening years of to-morrow a continuing and steady reduction of the existing rates of infant deaths. A few examples will show the low levels of infant death rate that have already been reached: England and Wales (1952), 28; Holland (1951), 25; New Zealand (1951), 23; and Sweden (1951), 20. These rates do not measure the total infant loss, but this total loss can be obtained when stillbirths are added, and the total sum of infant deaths is divided into the two main groups of the early "catastrophic" deaths and the later "careless" deaths. Thus for New Zealand, in 1951, the first group of natal-neonatal deaths—that is, including stillbirths—gave a total death rate of 40, and the second group of deaths in the first year (after the first month) gave a rate of 7.

The Irreducible Minimum of Infant Deaths.—A closer examination of these record low levels of total infant loss shows that further reduction is still possible, until the irreducible minimum is reached, made up by the inevitable hazards and accidents of infant life; and we may be sure that the larger fraction of this minimum will lie in the natal-neonatal group. In 50 years' time, or longer, we might expect from one or two countries such rates of total infant loss as 20 for the natal-neonatal group, and 5 for the 11 succeeding months of the first year. But this attainable optimum will be reached only through the steady pressure and increasing efficiency of the services of child care.

I shall now give some notes upon each of these services of child care and upon their future contribution to child health.

Sanitation and Housing.—Only a few words are required on this subject. Local authorities and their medical officers of health know better than anyone else the importance of keeping general sanitation in all its aspects at the highest level, and of improving housing conditions and building new houses. Bad houses remain, but they are few in comparison with the thousands that Dr. Russell counted in Glasgow in his famous survey of 1881. Overcrowding remains, but the pace of building new houses increases year by year. And let us not forget that the fruit of good sanitation can be brought to perfection only by good houses and good housekeepers.

Antenatal, Maternity, and Neonatal Services.—This triple service is expanding in each of its branches. It grapples with difficult problems both in mother and in child, and with a high infant loss during birth and early infancy. The reduction of the maternal and infant death rates in the last two decades is the proof of its success. A further reduction in deaths from prematurity is certain to continue, both from the preventive work in the antenatal clinics and from the extending special care of premature newborn babies.

Children's and Fever Hospitals.—The future contribution of these hospitals will be mainly in curative medicine, in the diagnosis and treatment of serious illness, and in the deep study of the many problems of disease that remain

unsolved. Their teaching hospitals are well supplied with material of disease in childhood, but they lack the clinical material and experience of healthy infants and children. This lack of material can be supplied in the clinics of the child welfare service.

Future of the Child Welfare Service: Provision of Training Schools

The curative work of the service in the treatment of many kinds of minor disorder and in the diagnosis of serious illness at the clinics is of great value. But more valuable is its preventive work. This has a double aim—(1) to reduce to a minimum the number of infant and child deaths, and (2) to raise to a maximum the quality of life in the survivors—and a single method of achieving it by the education of mothers in the manifold kinds of child care and in the right use of each.

The two aims of this young child welfare service are an immense task. The first aim—the mastery of fatal disease in infants—has gone a long way towards achievement; the second aim of maximum health in childhood is only beginning, and its full accomplishment can come only in the far-distant future. Here and there suggestions are heard that, with the great reduction of the infant death rates, the personnel and work of the child welfare service may now be cut down, and that a partial demobilization in the civil war against disease in children might now take place. But there is no discharge in this war; the death rates must still be kept down, and the new campaign of raising levels of health in children is only beginning. And for this longer and more difficult campaign the child welfare service must be strengthened and given new and better weapons.

The most important work of the service is the education of mothers in the care of children. For this its doctors and nurses require better training than they now receive. There is an urgent need for the provision of training-schools in infant child health, these to be located in child welfare clinics. At present the doctors of the service get their training in child health in a children's hospital as part of the course of teaching in diseases of children. But the children's hospitals lack the essential clinical material of mothers and healthy infants and children. Such material, both for study and for training, can be provided only in a child welfare clinic, and, best of all, in one attached to a maternity hospital where the clinic has a close link with the nurseries of the newborn. I have already given the argument in favour of this proposal (McNeil, 1945) in an article "The Clinical Material of Child Health: where to obtain it; and how to use it." This argument was based on my conduct of such a clinic in Edinburgh for 17 years, and upon a teaching course in infant and child health given to medical students at the Maternity Pavilion, University of Edinburgh. This personal experience has convinced me that the most immediate and important need for the child welfare service is the provision of centres of study and schools of training in child health. These would, I believe, do for the new service what the use of hospitals for the study and teaching of disease has done for the medical practice of disease in children. The child welfare service with its own training-schools would steadily gain in power, authority, and prestige.

The Home Service of Mothers

The work of the mother for her children at home is the foundation and centre on which all the other activities of child care are built. In 1906 John Burns said: "Let us concentrate on the mother. . . . Let us glorify, dignify, and purify motherhood by all means in our power." These words set a target that is still far from being reached. But they turned the attention of medical and social reformers from the circumstantial things of child care—sanitation and the house—and towards the central persons—the mother and child at home; and they created in the child welfare service a national system of education of mothers in child care.

Fifty years later infant mortality, the subject of the London conference in 1906, has been brought under strong control in many countries, and to this massive achievement the new service of education has made an indispensable contribution. But great, difficult, and unfinished tasks of promoting the health of infants and children remain; and these tasks will lie largely in the hands of the child welfare service.

ANAEMIA IN KWASHIORKOR

BY

E. B. ADAMS, M.B., B.Sc., M.R.C.P.

Assistant Physician, King Edward VIII Hospital, Durban

Kwashiorkor has been defined by Brock and Autret (1952) as a nutritional syndrome of African infants and children comprising retarded growth, alterations in skin and hair pigmentation, oedema, fatty infiltration, cellular necrosis or fibrosis of the liver, and frequently a variety of dermatoses. Mortality is heavy in the absence of proper dietary treatment.

The anaemia often found in kwashiorkor is usually mild in degree, normocytic or slightly macrocytic, and has responded somewhat slowly during treatment of the syndrome by high-protein diets (Altmann and Murray, 1948; Trowell *et al.*, 1952). In East Africa, where tropical infestations are common, sometimes there is hypochromia, responding to iron treatment; often there is slight macrocytosis, but megaloblastic change rarely if ever occurs (Trowell, 1949). Lehmann (1952) believes that this macrocytosis without megaloblastic change is due to the presence of reticulocytes following blood loss. In Johannesburg, where parasitic infestations are infrequent, Altmann and Murray have observed a more constant blood picture. They considered anaemia to be due to deficiency of protein. Three of their 34 cases showed macrocytosis, while others became macrocytic on high-protein diets. In the marrow smears of six cases abnormal cells were seen suggestive of lack of liver principle or folic acid, but, as Trowell has also observed, the red-cell precursors were of an intermediate type or macronormoblastic, there were some giant metamyelocytes, but true megaloblasts of Ehrlich were not seen. Walt *et al.* (1950) also record a moderate, slightly macrocytic normochromic anaemia in their cases in Durban. In three, all fatal, anaemia was severe, but there was no megaloblastic change. Macrocytosis was reported by van der Sar (1951) to be common in his 31 cases of kwashiorkor in Curaçao, but in only one was the bone marrow megaloblastic.

It is now generally accepted that the syndrome is due to deficiency of protein in the diet, and that it responds well to treatment with high-protein diets, anaemia slowly improving at the same time. It is said that the anaemia does not respond to folic acid, vitamin B₁₂, or liver extracts (Trowell *et al.*, 1952), although Piéraerts (1950) believes it will respond to these after protein replacement.

The possible relationship of this anaemia to protein deficiency, the occurrence of macrocytosis, and the reports that in the bone marrow there are features of megaloblastic change without the full picture seen in

megaloblastic anaemias have prompted the present investigation, in which haematological findings in a series of cases of kwashiorkor are described.

Clinical Material

Twenty-one cases have been studied—nineteen of African and two of Indian origin. The ages ranged from 1 to 5 years, with a mean of 2 years 3 months. Eleven were male and ten female.

In each case pitting oedema, dermatosis, and lowered plasma proteins were present. With the absence of complicating diseases these were the only criteria used in the selection of cases. Pitting oedema was always found in the legs and usually in the hands. Often facial oedema and generalized anasarca were marked. The dermatosis was similar to that described by Gillman and Gillman (1951) and by Brock and Autret (1952). Total plasma proteins ranged from 3.5 to 4.9 g.%, with a mean of 4.05 ± 0.10 g.%, and the albumin fraction from 1.2 to 2.6 g.% about a mean of 1.89 ± 0.04 g.% (see Table I).

TABLE I.—Plasma Proteins Before and After Treatment, and Plasma Bilirubin on Admission

Case No.	On Admission			After Treatment	
	Total Protein (g.%)	Albumin (g.%)	Bilirubin (mg./100 ml.)	Total Protein (g.%)	Albumin (g.%)
1	4.3	1.6	0.9		
2	4.0	—	0.9	6.7	4.0

21	4.6	1.8	0.3		
Means	4.05 ± 0.10	1.89 ± 0.04		6.70 ± 0.23	3.89 ± 0.07

d=died. * = removed from hospital before recovery complete.

No case was included without all these features, but other manifestations of the syndrome such as mental apathy, retardation of growth, and thinning of the hair with reddish pigmentation were present in varying degree. The liver was enlarged in 12 cases. In none was the spleen palpable. Abnormalities were not detected in the heart or nervous system, and lymph nodes were never enlarged. No specific changes were observed in the tongue although it was sometimes red, and there were no significant lung changes clinically or on x-ray examination except in two of the fatal cases which showed radiological evidence of bronchopneumonia.

Stools were sometimes watery and occasionally oily, but diarrhoea was not a marked feature. Stools were always examined, usually on three consecutive days. *Entamoeba histolytica* was isolated in two cases, but there was no dysentery. Ova of ascaris were observed in three cases, while in one of these there were hookworm ova, but here the test for occult blood was negative. This low incidence of parasites indicates the small chance that intestinal infestations were responsible for the anaemia in this series.

Plasma bilirubin was estimated in every case, but in none was it elevated (see Table I).

Treatment consisted of soured milk (maas) or this and a hydrolysed protein preparation ("casydrol") given in alternate feeds until convalescence, when ward diet was added.

Eleven patients made an excellent recovery, with disappearance of all symptoms, loss of oedema and skin changes,

and gain in weight and vitality. Hair changes often persisted. Three children died, permission for necropsy being refused. Seven were removed from hospital against advice before recovery was complete. There was a return of total plasma proteins and albumin to normal values in all cases, with complete clinical recovery except in one in which a final estimation was not made (see Table I).

Methods

Blood was obtained from the jugular veins in all cases, and all haematological investigations were done by me, using dry sterile syringes with ammonium and potassium oxalate as anticoagulant. Haemoglobin was determined by a photometric method. Packed cell volumes were estimated in duplicate and red cells counted in a double chamber filling. Reticulocytes were counted by the method of Dacie (1950). Aspiration specimens of iliac marrow were obtained from every case by iliac puncture and stained with May-Grunwald-Giemsa. Mean corpuscular diameters were measured by the method of Price-Jones (1933).

The Anaemia

On admission most cases showed only mild anaemia. Often, however, there was a drop in haemoglobin, red cells, and packed cell volume in the first week, although this sometimes occurred later. This drop took place without evidence of haemolysis or blood loss. If the lowest haemoglobin levels recorded are examined it is seen that the degree of anaemia encountered in these cases is not so mild. In 14 cases haemoglobin was below 9 g.%, while in six it was less than 7 g.% (see Table II).

White-cell counts tended to be high, with a range from 7,450 to 19,200 per c.mm., about a mean of 12,700 per c.mm. but otherwise they usually showed no departure from normal. Platelets always appeared to be plentiful and platelet counts were not done.

Hypochromia was seen only once—in Case 14 after treatment, when it was of mild degree. Mean corpuscular haemoglobin concentrations varied from 26 to 36%, with a mean of 31%.

Examination of the bone marrow showed normoblastic erythropoiesis in 13 cases and in these there were no abnormalities in the myeloid series. In the remaining eight cases the marrow deviated from normal in varying degree. In two there were some megaloblasts of Ehrlich as well as normoblasts and giant metamyelocytes (Cases 17 and 20). There were also macronormoblasts, some of which had nuclei with several lobes. The bone marrow in the other six cases showed a few giant metamyelocytes and occasional macropolycytes. The red-cell precursors were mainly normoblastic, but a few showed megaloblastic features. In these the cartwheel appearance of the nuclei was absent, a finer chromatin structure taking its place. They are presumably the cells described by Altmann and Murray as being of intermediate type. Premature haemoglobinization was sometimes seen; fully haemoglobinized erythroblasts were sometimes large, occasionally with lobed nuclei, but orthochromatic megaloblasts were not seen.

These cases with bone-marrow abnormalities appear to form a series, at one end of which the marrow is almost normal with only giant metamyelocytes, while at the other there is some definite megaloblastic change.

Cell Size

There was mild macrocytosis in 11 cases in which the mean corpuscular volume was above 100 μ^3 . It did not appear to be related to the bone-marrow changes just described: in those with normoblastic erythropoiesis the mean was $98.0 \pm 2.7 \mu^3$, while in the group with abnormal marrow there was a mean of $103.9 \pm 2.8 \mu^3$, the difference not being significant (see Table II). In most of the blood films the red cells appeared somewhat large, with some anisocytosis, but little poikilocytosis. Even in the two patients with partial megaloblastic change, the cells in the

blood films were round, but in one anisocytosis was marked (Case 17). This is demonstrated in the Price-Jones curve from this case, which shows broadening of the base and macrocytosis (see Fig. 1). Less variation was observed in other cases. There was some macrocytosis even in cases

FIG. 1.—Erythrocyte diameter distribution curve from Case 17.

FIG. 2.—Erythrocyte diameter distribution curve from Case 16.

FIG. 3.—Erythrocyte diameter distribution curve from Case 8.

with normal marrow—for example, Case 16, in which the M.C.V. was 98 μ^3 , the mean of the group (see Fig. 2)—and in others with giant metamyelocytes and some intermediate red-cell precursors—for example, Case 8 (Fig. 3). Reticulocytosis did not seem to be the cause of the macrocytosis in any of these cases.

TABLE II.—Blood Counts on Admission and After Recovery, and Lowest Haemoglobin Recorded

Case Histories

(i) Normoblastic Anaemias

In this group of 13 patients, the bulk of the series, anaemia was usually mild, although in one child who died haemoglobin on admission was only 6.3 g.%. The mean haemoglobin on admission was 9.7 g.%, while in the seven cases that recovered completely the mean on discharge was 10.9 g.%. Folic acid was used in one and vitamin B₁₂ in another without effect, and ferrous sulphate was ineffective in both. Usually the anaemia increased in severity while the condition of the child improved in all other respects, the blood count after full recovery being slightly higher than on admission, as illustrated by the following example.

Case 14.—An African girl aged 3 years was admitted with gross oedema and patchy pigmentation and desquamation of the groins. Plasma proteins were 3.5 g.%, with 1.9 g.% albumin. Haemoglobin was 10.8 g.%, with 3,760,000 red cells per c.mm., haematocrit 34%, reticulocytes 1.2%. The bone marrow was normoblastic. On maize diet only oedema disappeared in three weeks—when plasma proteins had reached 5.3 g.%, with 3.2 g.% albumin. Hb was then 8.6 g.%, but despite general improvement the blood count dropped steadily. Injection of 50 μ g. of vitamin B₁₂ had no effect. The lowest count was 6.1 g.% Hb, 2,360,000 red cells per c.mm., haematocrit 21.5%, while at the same time plasma proteins were 7 g.% and albumin 4 g.%. Slight hypochromia was now observed in the blood film. Later ferrous sulphate was given by mouth, although the count had already begun to rise. The rate of increase did not appear to be altered. When the child had fully recovered the Hb was 11.2 g.%, red cells 4,510,000 per c.mm., and haematocrit 35.5%.

(ii) Anaemias With Giant Metamyelocytes and Some Red-cell Precursors of Intermediate Type in the Bone Marrow

In this group of six cases the effect of diet only was observed in three. In one with 7.7 g.% Hb on admission (Case 4) anaemia slowly decreased as the child recovered, the Hb reaching 9.4 g.%. The haemoglobin of another with 10 g.% on admission dropped to 8.6 g.% in four days, rising slowly to 11.9 g.% when clinical recovery was complete (Case 18). Reticulocytes, counted daily for two weeks, reached a peak of 7.2% on the ninth day. The fourth child

(Case 19) was admitted with 9.5 g.% (haematocrit 31%), which dropped rapidly to 7.1 g.% (haematocrit 22%) on the sixth day, when he died. There was a peak reticulocyte count of 2.8% on the third day.

One child was given folic acid five weeks after admission. Haemoglobin was rising slowly on diet alone, and there was no reticulocyte increase.

In contrast, two patients with similar bone-marrow pictures responded to treatment with a crude liver extract and vitamin B₁₂.

Case 8.—An African child aged 20 months was admitted with a two-weeks history of swelling of the whole body, vomiting after feeds, anorexia, cough, and passing soft yellow stools. The temperature was 101.6° F. (38.7° C.), pulse 120, and respirations 20, weight 14½ lb. (6.6 kg.). There was marked oedema of the arms, legs, and face, and a red tinge of the hair. Black-pigmented skin changes were present in the inguinal region, with central desquamation, and there were similar lesions on the legs. The mucous membranes were pale. The liver and spleen could not be felt and there were no other abnormalities. The Hb was 6.6 g.%, red cells 2,060,000 per c.mm., haematocrit 21.5%, reticulocytes 2.6%, leucocytes 9,550 per c.mm. (the Price-Jones curve from this case is shown in Fig. 3). The bone marrow was mainly normoblastic, but there were some giant metamyelocytes and the nuclear structure of a minority of the basophil erythroblasts was rather fine. Plasma proteins were 4.9 g.%, albumin 2.2 g.%, bilirubin 0.2 mg. per 100 ml. No pathogens were detected in six stool specimens. The test for occult blood was negative. Urine was normal. X-ray examination of the chest showed marked striations in the right middle lobe, but the Mantoux test was negative, and x-ray films showed no change three weeks later. Free acid was present in the gastric juice after histamine.

On high-protein diet alone reticulocytes reached 5.8% on the fifth day, and oedema began to decrease. After two weeks, however, there was rapid deterioration; on the 17th day the Hb was only 4.7 g.%, with 1,370,000 red cells per c.mm., and haematocrit 15.5%. No reticulocytes were seen. 150 ml. of compatible blood was transfused and 1 ml. of a crude liver extract ("pernaemon") given by intramuscular injection. Seven days later there was a reticulocyte peak of 10.4%.

Two further injections of the same liver preparation were given, the blood count rising steadily to 13.7 g.% Hb in seven weeks, with 4,580,000 red cells per c.mm., and haematocrit 45%. Plasma proteins were 5.9 g.%, albumin 3.9 g.%. There was now no oedema, skin changes had disappeared, and the child was well and happy.

Case 12.—An African infant aged 4 had the same pattern of disease. Anaemia became more severe as oedema subsided and plasma proteins increased, although there was again no haemolysis or blood loss. The admission Hb of 9 g.% dropped in seven days to 7 g.%, with 1,880,000 red cells per c.mm., haematocrit 21.5%, and reticulocytes 2.3%. There was histamine-fast achlorhydria. Injection of 50 μ g. of vitamin B₁₂ was followed in six days by a reticulocyte peak of 12.7%, and the blood count increased on this and further injections of vitamin B₁₂ to reach 11.7 g.% Hb, 3,850,000 red cells, and haematocrit 38.5% on full recovery.

(iii) Megaloblastic Anaemias

There was megaloblastic change in the bone marrow of two infants. In one, who was removed from hospital against advice, there were many typical megaloblasts of Ehrlich and giant metamyelocytes in the marrow (Case 20). These changes were present but less well marked in the other (Case 17), who died, so it was not possible in either to observe the response of the anaemia to treatment.

Case 17.—A male African child of 18 months was admitted with a history of swelling of the body for one month, loose stools, and a cough for two weeks. His diet had consisted entirely of sump porridge and tea. His temperature was 100.4° F. (38° C.), pulse 112, respirations 22, weight 18 lb. (8.2 kg.). He was listless and apathetic, with gross swelling of the whole body and pitting oedema of the limbs and trunk. Facial oedema had occluded one eye. The hair was fine in texture and reddish brown. Widespread dermatitis was present, with scaling on the limbs and lower trunk, large areas of desquamation, and raw bleeding lesions on the legs. The right ear was discharging. The liver was large and firm, but the spleen was not palpable. No other abnormalities were detected. The Hb was 5.5 g.%, red cells 1,950,000 per c.mm., haematocrit 19%, reticulocytes 2.9%, leucocytes 16,500 per c.mm. The blood film showed many macrocytes, some microcytes, but only occasional poikilocytes (mean corpuscular diameter

7.42 μ , standard deviation 1.3 μ , macrocytosis 15%, microcytosis 4.2%—see Fig. 1). Fifteen normoblasts and macronormoblasts and one intermediate megaloblast were seen per 100 white cells, which included one large metamyelocyte. Iliac marrow showed normoblasts, some basophilic megaloblasts, many large haemoglobinized erythroblasts with lobed nuclei, and giant metamyelocytes. Abnormalities were absent in the urine and stool, although the latter was oily. Plasma proteins were 3.5 g.%, albumin 1.5 g.%, bilirubin 0.4 mg. per 100 ml. On admission there were no abnormal chest signs, but x-ray examination on the following day showed bronchopneumonic infiltration in the right upper lobe with an associated pleural effusion, detectable clinically on the next day. This appears to have been a terminal bronchopneumonia, for the child died shortly afterwards. Permission for necropsy was refused.

Discussion

Kwashiorkor is a syndrome due to protein deficiency in the diet, and it might be expected that the anaemia accompanying it has the same cause, as Altmann and Murray have suggested. Cartwright (1947) has reviewed the evidence that protein deficiency produces anaemia in animals, while Keys *et al.* (1950) have shown experimentally in man that anaemia develops during starvation. In prisoner-of-war and concentration camps anaemia was often associated with low plasma proteins following starvation (Vaughan *et al.*, 1945; Leyton, 1946; Mollison, 1946; Walters *et al.*, 1947), but it was not established that this was a primary protein-deficiency anaemia. Leyton demonstrated a relationship between the plasma protein level and haemoglobin, but Mollison was not able to show a similar correlation. He considered anaemia to be due to lowered metabolism and not to any specific deficiency.

It is difficult to assess the role of protein deficiency in the production of anaemia in kwashiorkor. Often in severe cases anaemia is mild, and there is no correlation between the haemoglobin on admission and the plasma proteins in this series of cases (see Fig. 4). It has been seen that there is often a drop in haemoglobin and haematocrit levels while oedema is decreasing and plasma proteins are increasing, which appears to exclude protein deficiency as the cause of anaemia. These changes, however, can probably be explained by variations in blood volume. In his oedematous cases at Belsen, Mollison found the blood volume to be lowered, but in other studies of hunger oedema there are conflicting reports (Denz, 1947). On indirect evidence in these oedematous cases of kwashiorkor, it seems likely that the blood volume is initially low and that it rises as soon as plasma proteins increase. As a result the blood count appears to drop. In no case has there been evidence of haemolysis or blood loss, and the changes in blood counts were often so rapid that they could be explained only by changes in blood volume. Under these circumstances the reticulocyte count, which is independent of changes in blood volume, will be a better index of response to treatment than haemoglobin or haematocrit levels. In most cases treated with high-protein diets only there have been small early rises in the reticulocyte count. Similar small rises were observed by Altmann and Murray. It is thus possible that some factor present in soured milk (maas) has stimulated erythropoiesis; but other factors such as increased metabolism might be responsible, and no definite conclusion can be drawn regarding the effect of protein replacement on blood production.

FIG. 4.—Relationship between haemoglobin on admission and total plasma proteins (●), and between haemoglobin and plasma albumin (×).

tions in blood volume. In his oedematous cases at Belsen, Mollison found the blood volume to be lowered, but in other studies of hunger oedema there are conflicting reports (Denz, 1947). On indirect evidence in these oedematous cases of kwashiorkor, it seems likely that the blood volume is initially low and that it rises as soon as plasma proteins increase. As a result the blood count appears to drop. In no case has there been evidence of haemolysis or blood loss, and the changes in blood counts were often so rapid that they could be explained only by changes in blood volume. Under these circumstances the reticulocyte count, which is independent of changes in blood volume, will be a better index of response to treatment than haemoglobin or haematocrit levels. In most cases treated with high-protein diets only there have been small early rises in the reticulocyte count. Similar small rises were observed by Altmann and Murray. It is thus possible that some factor present in soured milk (maas) has stimulated erythropoiesis; but other factors such as increased metabolism might be responsible, and no definite conclusion can be drawn regarding the effect of protein replacement on blood production.

In Nigeria, Woodruff (1951) describes the predominant anaemia in pregnant African women living on protein-deficient diets as macronormoblastic and seldom megaloblastic. He showed by liver biopsy that the liver is diffusely fibrosed in many cases, and in others infiltrated with fat, and he believes that the similarity to kwashiorkor extends to the anaemia. Both may be due to underlying chronic liver disease, which is known to be accompanied by macronormoblastic erythropoiesis (Bodley Scott, 1939). Woodruff's bone-marrow findings are certainly similar to those described in this paper, but the two anaemias differ in some respects. It is perhaps worthy of note that, contrary to his experience in West Africa, severe megaloblastic anaemia of pregnancy, responding to folic acid and sometimes to vitamin B₁₂, is not uncommon among African and Indian women in Durban, many of whom live on diets low in protein.

In infancy, megaloblastic anaemia has been reported by Zuelzer and Ogden (1946), who described 25 cases. Zuelzer *et al.* (1947) carried out serial studies of the bone marrow in patients with infantile megaloblastic anaemia. They showed that there are patterns varying from predominantly normoblastic to frankly megaloblastic marrow pictures, and in all they record satisfactory responses to folic acid. Zuelzer and Ogden believe that nutritional deficiencies are partly responsible for the production of megaloblastic anaemia in infancy, and it would be surprising if nutritional megaloblastic anaemia were not sometimes encountered in a severe nutritional syndrome like kwashiorkor.

In the cases presented here it has been seen that megaloblastic transformation of the marrow occurs, although it is unusual. Dacie and White (1949) have described megaloblasts in the bone marrow of mild cases of Addisonian pernicious anaemia, the degree of deviation from normal being closely linked with the severity of the lack of haemopoietic factors. In East Africa, Foy *et al.* (1952) have described two groups of macrocytic or normocytic anaemia. In one there are giant stab cells in the bone marrow with erythroblasts, macronormoblasts, and megaloblasts in various stages of development; in the other giant metamyelocytes are present without megaloblasts. Both respond to haemopoietic substances. In kwashiorkor there is also a group in which the marrow contains giant metamyelocytes and some cells which are intermediate between normoblasts and megaloblasts. In two of these there have been satisfactory responses to crude liver extract or to vitamin B₁₂, so it would appear that these cases are examples of developing stages of nutritional megaloblastic anaemia.

There are also similarities between this marrow picture and the type of bone-marrow change in idiopathic steatorrhoea reported by Cooke *et al.* (1948). In kwashiorkor, Thompson and Trowell (1952) have demonstrated a deficiency of pancreatic enzyme production. Some of the stools examined in this series were microscopically oily, but clinically they were neither bulky nor fatty. Subclinical fat-absorption defects, with associated anaemia, however, have not been excluded, since fat-balance studies in African infants are technically difficult to perform.

In the detection of this type of anaemia in kwashiorkor examination of the blood alone for macrocytosis is of little help. Non-megaloblastic macrocytic anaemias occur in a variety of conditions. When appreciable anaemia is found on admission, or when it develops as oedema disappears, the bone marrow should be examined, and in those cases with megaloblastic change—partial or complete—liver extract, vitamin B₁₂, or folic acid should be administered in addition to high-protein diets.

Summary

In a series of 21 cases of kwashiorkor, selected only on the presence of pitting oedema, dermatosis, and lowered plasma proteins, appreciable normocytic or macrocytic anaemia was found in six cases, while two-thirds of the children had less than 9 g.% haemoglobin.

Anaemia may increase considerably as oedema decreases and plasma proteins rise. In this way severe anaemia may be unmasked.

Megaloblastic change was present in two cases. In six others there were bone-marrow abnormalities consisting of giant metamyelocytes and scanty red-cell precursors of intermediate type. Two of these had satisfactory haematological responses to crude liver extract or to vitamin B₁₂.

The possible relationship of this anaemia to protein deficiency, liver disease, and nutritional megaloblastic anaemia is discussed.

I thank Dr. Pauline Klenerman for giving me full access to her cases of kwashiorkor in African children, Dr. N. A. Rossiter for facilities to study Indian children under his care, and Dr. J. Parker, medical superintendent, for permission to publish these cases. Thanks are also due to Dr. J. Thomas, Director of Pathological Services, and his staff for their help with the biochemical estimations; and to Dr. Joan Scragg and the sisters for their assistance.

The Minister of Education has issued a circular (272, 1954) about the precautions necessary to avoid food poisoning in the preparation and service of meals in school canteens. One of the objects of the Food and Drugs Amendment Bill at present before Parliament is to secure better hygienic conditions in places where food is prepared or served. The prevention of the contamination of food served in canteens depends, however, in large measure on the constant vigilance and the observance of hygienic practices by the canteen staffs. The Minister emphasizes that the risks of food poisoning are present wherever meals are prepared and served, and that there is no reason whatever to think that school canteens are more exposed to them than other forms of corporate meals. After briefly describing some typical examples of outbreaks of food poisoning in school canteens, the circular goes on to consider the prevention of food poisoning in schools under the following headings: Co-operation between medical, teaching, and kitchen staff; health of food handlers; hygienic conditions in the kitchen; the preparation and cooking of food; domestic animals and pests; milk supply; and notification of outbreaks of food poisoning to the medical officer of health. Under the last heading it is recommended that authorities should take steps to ensure that any outbreak of food poisoning is notified immediately, preferably by telephone, to the borough or district medical officer of health, so that he can begin his investigations and take precautionary measures without delay.

ADRENOCORTICAL FUNCTION IN BURNED PATIENTS WITH SPECIAL REFERENCE TO A.C.T.H. AND ADRENALINE TESTS

BY

SIMON SEVITT, M.D., M.Sc., F.R.C.P.I., D.P.H.
(Consultant Pathologist, Birmingham Accident Hospital and
Medical Research Council Burns Research Unit)

This paper is concerned with the activity of the adrenal cortex of burned patients, and in particular with a search for evidence of adrenocortical failure arising during the illness. The investigation is based on the spontaneous changes in the blood eosinophil count in burned patients, on the changes in the circulating eosinophils induced by injection of pituitary adrenocorticotrophic hormone (A.C.T.H.) or adrenaline, and on other findings.

In a previous paper (Sevitt, 1951) it was shown that a definite pattern of changes affects the number of blood eosinophils after burning (Fig. 1). Within a few hours their number is found either to be falling or to have fallen to low or zero values. This eosinopenia, which is accompanied by a neutrophil leucocytosis and commonly by some lymphopenia, is maintained for a variable number of days, after which the count begins to rise, to reach a peak value within the next few days. Evidence was produced which indicates that the eosinopenia after burning is a sensitive reflection of adrenocortical hyperactivity. This pattern of changes has been confirmed by Evans and Butterfield (1951) and by Wight *et al.* (1953).

The period of eosinopenia during which eosinophils are few or absent in the blood stream is maintained for varying periods in different patients and is terminated by the post-eosinopenic rise (Fig. 1). The duration of the periods of eosinopenia was estimated in 35 patients with an accuracy within $\pm \frac{1}{2}$ day. In Fig. 2 these periods are plotted against the skin area burned, which is expressed as a percentage of the total skin area. In patients with burns covering less than 10% of the body area the periods of eosinopenia are only one or two days, but are longer, usually three to five days, in those more extensively burned. The relationship between the eosinopenic period and the percentage area seems to be an exponential zone with its concavity facing to the left, rising steeply between four and six days after burning.

FIG. 1.—Serial blood eosinophil counts during the first week after burning in three patients. In one patient the falling of the count soon after burning is seen, and this is followed by a period of eosinopenia, which is present in all three. The eosinopenia lasted 1, 5, and 7 days respectively in the three patients and was followed by a rise in the count.

Several points, however, fall away from the correlation zone. On clinical evidence it was concluded that in those patients with a more prolonged period of eosinopenia—for example, Case 22—the percentage area burned underestimated the degree and duration of shock and stress. On the other hand, a period of eosinopenia appreciably shorter than that "expected" from the area burned may be due to one of three causes. Firstly, stress after burning may be less than expected

FIG. 2.—Relationship of the percentage body area burned to the duration of eosinopenia in 35 patients (see text). † = died. The numerals are case numbers.

from the area burned, and this may be reflected in physiological abatement of adrenocortical activity (Case 27); secondly, the eosinophils may become resistant to the action of adrenal steroids; and, thirdly, adrenocortical failure may be suspected (Case 29, see below).

Eosinophil Changes in Those Fatally Burned

Eighteen patients were investigated, including the eight previously reported (Sevitt, 1951). Eleven died during the period of eosinopenia, including one who died four hours after burning whilst the eosinophil count was falling. It is concluded that these patients died with hyperactive adrenal cortices. Their ages varied from 1½ to 77 years (five were younger than 12 years, four older than 75 years), nine were females, and the extent of body areas burned ranged from 30% to 80% in the different patients.

In the other seven patients post-burn eosinopenia was not present at the time of death (see Table). In two of them (Cases 29 and 30) adrenocortical failure may have occurred.

In Case 29, which was reported previously, there was a zero eosinopenia for only 1½ days after burning, indicating

adrenocortical hyperactivity during this period. After this a sudden hyperpyrexia and a rapid deterioration of the patient took place. At the same time the eosinophils returned "prematurely" to the blood stream and the patient died a few hours later. Biochemical changes in the heart blood removed immediately after death were consistent with acute adrenocortical failure, but previous oliguria complicated the picture. Case 30 is discussed later.

In the remaining five patients (see Table) there was no evidence of adrenocortical failure. One patient (Case 28) died three hours after burning without a fall in the eosinophils, but eosinopenia may have occurred had he lived long enough. Two (Cases 32 and 36) died a few days after normal periods of post-burn eosinopenia, and these indicated that adrenocortical hyperactivity was present at least for the duration of the eosinopenia. In Cases 44 and 49 the normal A.C.T.H. or adrenaline tests five and seven days before death (15 and 10 days respectively after burning) indicated normal stimulative reserves of the adrenal cortex at the time of the tests.

Stimulation of the Adrenal Cortex by A.C.T.H. and Adrenaline

An injection of A.C.T.H. or cortisone in normal persons produces a significant fall in the blood eosinophil count, but in patients with Addison's disease cortisone, but not A.C.T.H., produces this effect (Thorn *et al.*, 1947; Dougherty and White, 1947; Forsham *et al.*, 1948; Hills *et al.*, 1948; Prunty, 1950). A.C.T.H. therefore does not act directly on the peripheral organs, but its action is mediated through an increased glyco-corticoid secretion from the adrenal cortex.

The secretion of A.C.T.H. by the anterior pituitary is under hypothalamic control probably via an endocrine secreted by the hypothalamus into the hypophyseal portal blood supply (de Groot and Harris, 1950; Hume and Wittenstein, 1950). Hume and Wittenstein also showed that this hypothalamic-adrenocorticotrophic activity can be produced by nervous stimuli from an injured area and that this activation occurs through the spinal cord. This is obviously of significance in burns.

Intravenous adrenaline produces an increase of adrenocortical activity (Vogt, 1944), but this does not occur in the hypophysectomized animal (Long and Fry, 1945). From this and other work we may conclude that a small dose of adrenaline has little or no direct effect on the adrenal cortex, although this is not necessarily true of large doses, and that adrenaline produces its major effect on the adrenal cortex indirectly through the pituitary gland (Harris, 1951). The site of action of adrenaline is uncertain. It may be the adeno-hypophysis itself (McDermott *et al.*, 1950), but, if not, it is above this level, possibly in the hypothalamus. In future discussion the site of action of adrenaline will be referred to as the hypothalamic-pituitary or supra-adrenal level.

Seven Patients in Whom the Post-burn Eosinopenia Was Not Present at the Time of Death

Case No.	Sex and Age (Years)	Surface Area Burned	Interval Between Burning and Death	*Eosinophils	A.C.T.H. and Adrenaline Tests	Conclusion
29	F 9	42%	1½ days	Post-burn zero eosinopenia rising to 11, 99, and 127 a few hours before death ("premature" rise)		Adrenocortical hyperactivity after burning, possibly followed by adrenocortical failure
30	F 5½	49%	15 "	Post-burn eosinopenia 4½ days. Antemortem eosinopenia	A.C.T.H. test on 5th day = rise of 26%	Adrenocortical hyperactivity after burning and before death, ? temporary period of adrenocortical failure
28	M 80	40%	3 hours	257, 276, 268, at 1½, 2, and 2½ hours		None
32	F 36	50%	9 days	Post-burn eosinopenia 4½ days		Hyperactive adrenal cortices a few days before death
36	F 38	45%	8 "	Post-burn eosinopenia 5 days		
44	M 9	25%	20 "		Normal adrenaline test 15th day.	Normal functional reserves of adrenal cortices at times of death
49	F 2½	30%	17 "		Normal A.C.T.H. tests 8th and 10th days	

* Hours and days refer to period since burning; other numerals are eosinophils per c.mm. of blood.

A.C.T.H. and Adrenaline Tests on Burned Patients

If a lesion is present in the adrenal glands—for example, bilateral destruction by haemorrhage—neither A.C.T.H. nor adrenaline will depress the eosinophil count.

If a recent lesion is present at the hypothalamic-pituitary level in a patient with intact adrenal glands, an injection of a small amount of adrenaline will have no effect on the adrenal cortex and the eosinophil count will not fall. On the other hand, injected A.C.T.H. will stimulate the adrenal cortex and the eosinophil count will fall. Failure of adrenaline to lower the eosinophil count could reflect a disturbance at the supra-adrenal level: conversely, if an adequate eosinopenia is produced by a small dose of adrenaline the hypothalamic-pituitary adrenocortical mechanism may be considered intact.

A.C.T.H. and adrenaline tests were therefore performed on burned patients. The 21 patients tested were among the more severely burned and were all "shock" cases transfused with plasma or dextran. Twenty had burns involving 20% or more of the body surface, eight 30% or more.

The other factors involved in the interpretation of results are considered later.

Techniques of the Tests

One or two eosinophil counts on capillary blood were made one to 30 minutes before the injection, after which the counts were repeated hourly for four to six hours. The eosinophil counts were plotted against time after injection and the maximum change in the count was expressed as a percentage of the pre-injection level: a fall was given a negative value—for example, -60%—and a rise a positive value—for example, +15%.

The B.P. solution of adrenaline, 1 in 1,000, was used and 0.3 ml. (≡ 0.3 mg.) was injected subcutaneously or intramuscularly.

The A.C.T.H. used (batch numbers J 16205, 27111, 27511, and 28112) was first shown to have the expected eosinopenic activity in normal adults and children. In five of the nine children tested the amount injected was 10 to 12.5 mg., in the remainder of the 14 patients tested 20 to 25 mg. was used.

It was not possible to standardize strictly the times of injection, but in two-thirds of the tests the drug was injected between 10 and 11 a.m., and in most of the remainder before 1 p.m. Abnormal results were repeated when possible.

Eosinophil counts were made by the direct "wet-field" method of Dunger (1910), using the eosin-acetone-water diluting fluid. The blood was diluted 1 in 20 in two pipettes and the cells in 0.65 c.mm. were enumerated in four Fuchs-Rosenthal fields.

Normal Eosinophil Response to A.C.T.H.

In normal people the blood eosinophils fall within an hour or so of injection and continue to fall during the next two to four hours, reaching their minimum level about three to five (usually four) hours after the injection (Fig. 3). Forsham *et al.* (1948), Prunty (1949), and others have shown that an injection of 25 mg. of A.C.T.H. produces an eosinophil depression of 50% or more, usually 60 to 90% four hours after injection, and this has been our experience.

Care was taken in interpreting results because it was thought that the blood level of eosinophils after the injection of A.C.T.H. or adrenaline could be influenced by factors unrelated to the injection. The first of these is the pre-injection level of the eosinophil count. If this is already low, adrenocortical hyperactivity may already be present, little or no additional activity may be produced by the injection, and a significant eosinopenia may not occur. Secondly, since some of the tests were performed during the post-eosinopenic rise of the eosinophil count, this spontaneous elevating effect might have antagonized the eosino-

phil-depressing effect of A.C.T.H. or adrenaline. Thirdly, in the diurnal variation of the blood eosinophils there is a morning fall in the count up to about 12 noon, after which the count rises. Therefore, in interpreting the present results, not only the maximum percentage fall in the count and the shape of the curve were considered, but also the possible influence of the above factors.

Normal results were obtained in 12 of the 14 tests with A.C.T.H., the eosinophils falling by 60% to 87% in 11 of them (Fig. 4), and in the twelfth a nearly normal fall of 46% was found. This is not considered significant, as four days later the response to adrenaline was normal. In all but three of the patients the tests were performed 10 days or less from the time of burning and one to five days from the end of the eosinopenic period—that is, during or soon after the post-eosinopenic rise.

Therefore, in these 12 patients, including one who died a week later, there was no evidence of adrenocortical failure of adrenal gland origin. Three of them, however, showed abnormal eosinophil reactions to adrenaline (see below).

FIG. 4.—Normal A.C.T.H. and adrenaline tests in severely burned patients. Each point is the result of one test. It is represented by a numeral which is the pre-injection value of the blood eosinophil count per c.mm. Its vertical position expresses the maximum percentage lowering of the count. The interrupted horizontal lines at -50% for A.C.T.H. and -40% for adrenaline represent the upper limits considered to be normal. The dotted vertical lines join the results of two or more tests on one patient. Fourteen of the A.C.T.H. tests were normal. These were done on 12 patients, one of whom subsequently died. Eleven of the adrenaline tests were normal, and these were done on nine patients, one of whom subsequently died. + = died.

Normal Eosinophil Response to Adrenaline

In normal people the shape of the eosinophil curve following adrenaline (Fig. 3) differs from the response to A.C.T.H. Usually little or no fall in the eosinophil count is found at an hour after injection; thereafter the count falls to reach its lowest level at two to three hours, and at four hours the count may be rising again. The adrenaline effect is usually slower and shorter than the effect of A.C.T.H. The maximum fall in the count varies between 45% and 70%.

Here it will be assumed that a lowering of the blood eosinophil count to 40% or more of the pre-injection level is normal, provided that the shape of the curve is within normal limits.

Normal curves were found in 9 patients (11 tests: Fig. 4) of the 12 patients tested, with maximum eosinophil depressions ranging from 47 to 70% (average 61%). Eight were tested within 15 days of burning, one of whom died from duodenal obstruction 20 days after burning and five days after the adrenaline test. Subsequent tests on one patient were also normal, as were the responses to A.C.T.H. in two others. Therefore, in these nine patients there was no evidence of adrenocortical failure. Indeed, the results indicated a normal function of the supra-adrenal adrenocortical pathway.

Abnormal Response to A.C.T.H.

Two of the 12 patients tested responded abnormally and one subsequently died.

Case 30

A girl of 5½ years, having burns involving 49% of the body area, was admitted shocked and with haemoconcentrations six hours after burning. She received 6 litres of intravenous plasma and 300 ml. of blood. Attacks of hyperpyrexia occurred on the first and ninth days after burning and slight jaundice on the fourth day. Her burns became colonized with *Ps. pyocyanea*.

Eosinopenia was present on admission and lasted just over four days, indicating hyperactivity of the adrenal cortex during this period. On the fifth day, during the post-eosinopenic rise of the eosinophil count, 12.5 mg. of A.C.T.H. was injected, but the eosinophil count never fell. Instead it rose from 108 per c.mm. before injection to a maximum level of 135 (+26%) at four hours after the injection (Fig. 5). Her blood pressure was normal (120/80) and normal blood glucose values (120 to 140 mg. per 100 ml.) were found. She became anaemic and was transfused. Her condition worsened, eosinopenia reappeared on the ninth day (eosinophils 12 per c.mm.), and was maintained until her death 15 days after burning, zero values being found during the last three days.

At necropsy, purulent bronchitis was found. The adrenals were swollen and congested; histologically very little cortical lipid remained and small foci of haemorrhage were present. Such changes are common in fatally burned patients, particularly in children who die during the period of eosinopenia, and are largely due to intense adrenocortical hyperactivity (unpublished observations). However, many of the columns of the zona fasciculata were transformed into pseudo-acinous or pseudo-tubular structures by an albuminous exudate containing occasional polymorphs. These changes were noted by Rich (1944) in diphtheria and in meningococcal and other infections, and he suggested that they may explain the circulatory collapse. The lymph nodes of the lymph glands, tonsils, and the spleen showed central degenerative changes with oedema, cytoplasmic swelling, and rupture. These changes, which are commonly found after burning (Bardeen, 1898; Baker, 1945), also occur after the injection of A.C.T.H. and are probably due to adrenocortical steroids.

the period of eosinopenia, and are largely due to intense adrenocortical hyperactivity (unpublished observations). However, many of the columns of the zona fasciculata were transformed into pseudo-acinous or pseudo-tubular structures by an albuminous exudate containing occasional polymorphs. These changes were noted by Rich (1944) in diphtheria and in meningococcal and other infections, and he suggested that they may explain the circulatory collapse. The lymph nodes of the lymph glands, tonsils, and the spleen showed central degenerative changes with oedema, cytoplasmic swelling, and rupture. These changes, which are commonly found after burning (Bardeen, 1898; Baker, 1945), also occur after the injection of A.C.T.H. and are probably due to adrenocortical steroids.

FIG. 5.—Case 30. Abnormal blood eosinophil reaction to an injection of 12.5 mg. of A.C.T.H. The eosinophil count does not fall after the injection, suggesting that adrenocortical failure is present.

The abnormal response to the A.C.T.H. test during life and the pseudo-acinous degeneration of the adrenal cortex found at necropsy support a diagnosis of adrenocortical failure. However, the reappearance of eosinopenia on the ninth day after burning and the degeneration of lymphoid tissue found at necropsy do not support this view. If adrenocortical failure occurred it was a temporary phenomenon.

Case 52

A 6-year-old girl with burns involving 45% of her body was admitted shocked and with haemoconcentration one and a half hours after burning. She was transfused with dextran, plasma, and blood. Eosinopenia was found, and lasted three and a half days, indicating early adrenocortical hyperactivity. On the fifth day after burning, at the peak of the post-eosinopenic increase of eosinophils, 20 mg. of A.C.T.H. was injected. An unusual curve was obtained: the eosinophils did not fall from the pre-injection level of 287 per c.mm. for two and a half hours after the injection; at three and a half hours the count was falling sharply to a maximum depression of 49% at four hours, but at five hours the eosinophils had increased to more than their pre-injection level. Three days later the test was repeated, and this time the count rose hourly for five hours from the pre-injection level of 152 per c.mm. On the following (ninth) day a test showed a curve of nearly normal shape though the maximum fall was only 39%, but on the sixteenth day a normal curve was found (-73%). Biochemical investigations on the eighth and ninth days gave normal values for blood glucose (120 mg. per 100 ml.) and serum chloride (595 mg. per 100 ml.), but the serum sodium (285 mg. per 100 ml.) and the serum potassium (15.1 mg. per 100 ml.) were slightly low. On the seventeenth day the child excreted 1.2 mg. of 17-ketosteroids in the urine, probably normal for her age (King, 1951).

Clinically the child was never very seriously ill and she made a good recovery. If the abnormal eosinophil responses to A.C.T.H. on the fifth and eighth days indicate adrenocortical failure, then this was of short duration and of no clinical significance. On the other hand, the four A.C.T.H. injections may have excited a therapeutic effect.

Abnormal Responses to Adrenaline

Results of tests were abnormal in three patients, each of whom responded normally to A.C.T.H. Two were children in whom the abnormal responses were associated with a temporary abnormal mental state. When the children recovered mentally the adrenaline responses were found to be normal.

Case 31

A girl of 8 years with burns involving 47% of the body surface was admitted shocked and with haemoconcentration two hours after burning. Her transfusion with 6.2 litres of plasma and 1 litre of blood was probably excessive, as a temporary attack of pulmonary oedema occurred soon after. She became pyrexial—100–102° F. (37.8–38.9° C.). Meanwhile post-burn eosinopenia was found, and lasted 4.7 days. Her mental state and behaviour at this time became abnormal. She was confused, irritable, and querulous. Six days after burning, at the peak of the post-eosinopenic rise of the eosinophils, adrenaline failed to lower the eosinophil count significantly (-12%) (Fig. 6). This was confirmed two days later (-4%), and again on the 38th day after burning (-11%), although on the 15th day an A.C.T.H. injection produced a normal eosinophil response. Gradually,

FIG. 6.—Case 31. Abnormal blood eosinophil responses to adrenaline occurred on the 6th, 8th, and 38th days after burning, when little or no change in the eosinophil counts followed the injections. However, the response to the A.C.T.H. test on the 15th day was normal. During this time the child was mentally abnormal. An adrenaline test was normal on the 94th day, when the child's mental condition had returned to normal.

with careful nursing and feeding, blood transfusion, and successful skin cover by grafting, the child improved. Three months after burning, when she had once again become a likeable, normal, and intelligent child, an injection of adrenaline produced a normal eosinophil-depression curve (-45%).

Case 43

A girl of 9 years with burns involving 33% of the body area was admitted one and a half hours after burning, shocked and with haemoconcentration. She was transfused with 6 litres of plasma in the first 24 hours: a short-lived oliguria and oedema of unburned areas occurred.

Meanwhile the patient had become delirious and irrational (? cerebral oedema). Eosinopenia was found, and lasted three days. On the sixth day after burning, and at the peak of the rising eosinophil curve, the eosinophil response to A.C.T.H. was normal, but two days later an injection of adrenaline failed to lower the eosinophil count (Fig. 7). At 14 days, when her mental condition was improving, adrenaline depressed the eosinophil count by 40%—"borderline" normal result. Within a month of burning she was behaving naturally and was mentally normal. Four months after burning an adrenaline test produced a normal eosinophil depression curve to adrenaline was normal (-77%).

The third patient with an abnormal response to adrenaline was a man in whom the A.C.T.H. response was normal. Clinically there were no unusual features, and it was not found possible to repeat the test.

Discussion

In a previous paper it was concluded that adrenocortical hyperactivity always occurs after significant burning (Sevitt, 1951). This was confirmed and extended in the present study, the main aim of which was to determine whether physiological failure of the adrenal cortex occurs in some patients. This was considered important, since "replacement" therapy with A.C.T.H. or cortisone may be indicated.

In 5 of the 54 patients studied there was evidence suggestive of adrenocortical failure. In one patient the evidence was based largely on a "premature" return of the blood eosinophils after a relatively short post-burn eosinopenia associated with clinical deterioration and, soon after, the death of the patient. In the absence of a post-mortem examination the evidence could not be conclusive. In two patients the eosinophil responses to A.C.T.H. were abnormal. One of them was not unduly ill, and the initial abnormal reactions to A.C.T.H. found within 10 days of burning were succeeded by a normal test a week later. In the other patient the abnormal reaction to A.C.T.H. and the pseudo-acinous change in the adrenal cortex found at necropsy support a diagnosis of adrenocortical failure, but the development of an ante-mortem eosinopenia and the finding of degenerative changes in the lymphoid tissue at necropsy indicate that the patient died with hyperactive adrenal cortices. If adrenocortical failure occurred in these two patients it was no more than a temporary phenomenon.

Nevertheless, two of these three patients died. The prognosis of severely burned patients with a tentative diagnosis of adrenocortical failure, based either on a premature rise

in the eosinophil count or on an abnormal eosinophil response to A.C.T.H., may be very serious. Therefore, in spite of the uncertainty whether or not adrenocortical failure occurred or was of clinical significance, it is suggested that such patients should be treated with cortisone as soon as the tentative evidence of adrenocortical failure is obtained.

Two children showed abnormal eosinophil reactions to adrenaline, associated with disturbed mental states: the reactions became normal when the mental conditions of the patients were either improving or had returned to normal. This association may be more than a coincidence. The cerebral changes may have involved not only the higher centres to produce mental disturbance but the lower centres, including the hypothalamic area or its central connexions, and so have interfered with the site of action of adrenaline. With recovery of the brain, adrenaline would again become eosinopenic. On the other hand, adrenaline tests performed on a child with a "true" encephalitis developing during the burn illness gave a normal result. Treatment with A.C.T.H. may be indicated in these patients.

Summary

A study of adrenocortical activity was made in 54 burned patients. It was largely based on the spontaneous changes in the eosinophil count found after burning, and, in 21 of the patients, upon the changes induced by a test dose of A.C.T.H. or adrenaline.

It is concluded that adrenocortical hyperactivity always occurs after significant burning. In 49 out of the 54 patients there was no evidence of subsequent adrenocortical failure, and these included 16 of the 18 patients who died.

In five patients, two of whom died, there was evidence of adrenocortical failure. In one a "premature" rise in the eosinophil count after burning was associated with clinical deterioration, and death soon occurred.

Twelve of the 14 patients tested with A.C.T.H. gave normal eosinophil depression curves, indicating normal stimulative reserves of the adrenal cortex. However, eosinopenia was not induced in a young girl tested on the fifth day after burning, suggesting that adrenocortical failure was present; but the spontaneous eosinopenia developing a few days later indicated that, if failure had occurred earlier, it was of short duration. She died 15 days after burning. In another child, not unduly ill, several abnormal reactions to A.C.T.H. were found within 10 days of burning, but on the sixteenth day the test was normal. She survived.

In nine out of twelve patients tested with adrenaline, normal eosinophil depression curves were obtained. The abnormal results found in two children indicated adrenocortical failure at the hypothalamic-pituitary level, since the A.C.T.H. tests were normal. The children were confused and irrational at the times of the abnormal reactions, but later, when normal adrenaline reactions were found, mental recovery had taken or was taking place. It is suggested that both the mental disturbance after burning and the persistence of circulating eosinophils after adrenaline were due to similar changes affecting the cerebral cortex and hypothalamus respectively.

I am in part-time employment of the Medical Research Council. The A.C.T.H. was made by Armour Laboratories and was obtained through the courtesy of the allocation committee of the Medical Research Council. Thanks are due to Messrs. R. Gill and C. Richardson, of the photographic department of the hospital, for photographing the figures, to various members of the

laboratory staff for help with the eosinophil counts, and to Miss M. Hayes. Finally, the co-operation of Sister M. Nicholls and other members of the nursing staff is gratefully acknowledged.

THE ACHLORHYDRIC PATIENT WITH DYSPEPSIA

BY

B. F. SWYNNERTON, D.M., M.R.C.P.

Weir Research Assistant, Wandsworth Hospital Group

AND

NORMAN C. TANNER, F.R.C.S.

Senior Surgeon, St. James's Hospital, London

Among those patients who are referred to hospital with a complaint of dyspepsia there remain after routine investigation an appreciable number in whom no satisfactory diagnosis is reached despite the fact that they give the impression of having organic disease. Such cases are usually labelled functional or nervous dyspepsia, or, if there is no free hydrochloric acid secreted in response to a test meal, achlorhydric dyspepsia. Gastroscopic examination will provide a satisfactory explanation of the symptoms in a large proportion of cases. Not only may small ulcers and ulcer scars which have been missed at a barium meal x-ray examination be discovered by this means, but it is also the most satisfactory method of confirming the presence of and differentiating gastritis. Where gastritis is found it is, however, impossible to give a reliable prognosis regarding the future comfort of the patient or to assess the possibilities of complications such as bleeding, ulceration, or the development of gastric carcinoma. As many patients have gastritic changes without dyspepsia it is also impossible to be dogmatic on how much the patients' symptoms are attributable to the gastric condition.

Schindler (1947) has given a good working classification of chronic gastritis. He divides cases into four types—hypertrophic, superficial, and atrophic gastritis, and gastritis in the post-operative stomach.

Chronic hypertrophic gastritis seems to be a very rare condition in this country and is not to be confused with the simple hypertrophy with thick folds and prominent areae gastricae which is a normal variant and is the usual finding in patients with hyperchlorhydria and duodenal ulcer. In hypertrophic gastritis intra-

mucosal scarring has led to unevenness of the mucosal pattern, and there may even be pseudo-polypoid changes.

In chronic superficial gastritis there is uneven congestion of the mucosa and excess adherent mucus. Simple diffuse reddening of the mucosa is a physiological state, whereas a stippled or variegated appearance is pathological. Non-adherent mucus is a normal exudate and mucopus is usually swallowed sputum.

The atrophic group is characterized by thinning of the gastric folds, inability to distinguish the areae gastricae, and, when atrophy is marked, by the ability to see the intramucosal and submucosal vessels through the thinned mucosa (Fig. 1). There is often an element of inflammation, shown by congestion along the tips of the folds and by stippling of the mucosa. The appearance of gastric atrophy may be generalized or patchy, and a localized variety is not infrequently seen in the vicinity of ulcer scars. This latter is in reality a new thin mucosa or a stretched mucosa around a scar (Fig. 2).

FIG. 1.—Gastroscopic view of atrophic gastritis, showing visible submucosal vessels.

FIG. 2.—Gastroscopic view, showing atrophic gastritis with vessels more prominent in the vicinity of a healed gastric ulcer. Either a true adenoma is present or there is pseudo-polypoid change as a result of scarring. The folds towards the greater curve are normal.

Present Investigation

The case summaries of all patients attending the Gastroenterological Clinic, St. James's Hospital, London, during the years 1940-6 inclusive have been studied. Where a finding of achlorhydria on a first fractional test meal using gruel as the stimulant was recorded and where some address for the patient was given, the case reports have been abstracted. Certain groups have been followed up during 1952, giving minimum and maximum observation periods of five and twelve years.

These patients are almost without exception those with gastro-intestinal symptoms. It is well known that the

absence of free hydrochloric acid need not produce symptoms. It occurs in a proportion of otherwise normal people, it is an invariable accompaniment of pernicious anaemia, and is common in such diverse conditions as rheumatoid arthritis, steatorrhoea, and various chronic skin diseases.

The records of 403 patients with achlorhydria have been found, and these have been grouped as follows:

Carcinoma of the stomach	63
Pernicious anaemia	15
Advanced atrophy without pernicious anaemia	113
Superficial gastritis and early atrophy	126
Chronic duodenal ulcer	13
Normal gastroscopy—no other cause found	21
No gastroscopy—no other cause found	52

These figures give no true indication of the incidence of the different conditions. Superficial gastritis and early atrophy are not necessarily associated with achlorhydria. Gruel is a comparatively weak stimulant, and had it been combined with an injection of histamine some cases would certainly have secreted hydrochloric acid. In some cases the finding was either false or only temporary. Thus, in the duodenal ulcer group, although the majority had pyloric stenosis with retention gastritis, there were some in whom the tube was evidently not in the stomach. Such cases can usually be eliminated, as no starch can be found in any sample of the gastric aspiration. In the present series, however, we have not been able to exclude them, since a number were referred from other hospitals merely for gastroscopy, and no detailed reports of the analysis are available.

Some of the groups can be disposed of rapidly. Active duodenal ulcers are never associated with achlorhydria, except when complicated by retention gastritis. In this paper we are not concerned with those patients who presented initially with a gastric carcinoma, and this group is not analysed.

The gastroscopic appearances of patients with pernicious anaemia are identical with those of atrophic gastritis. Weighty evidence suggesting that pernicious anaemia is a precursor of gastric carcinoma has been advanced by Kaplan and Rigler (1945, 1947) and Rigler, Kaplan, and Fink (1945), but confirmation of their conclusions must be awaited, since Wilkinson (1945), in a series of 1,600 patients with pernicious anaemia, was unable to find any such association. In the present series there are only 15 patients. The majority did not have gastric symptoms. Nine are still alive, four are dead (one from gastric carcinoma two and a half years after gastroscopic discovery of atrophic changes), and the remaining two have not been traced.

The bulk of the paper is devoted to the superficial gastritis, the early atrophic, and the advanced atrophic groups associated with achlorhydria. The remaining two—those with normal gastroscopic findings and those in whom no gastroscopy was performed—are referred to only where they have something of interest to offer.

Superficial Gastritis; Gastric Atrophy

Patients with advanced atrophy are easily separated from the remainder by reason of the presence of visible submucosal vessels on gastroscopy. In the case of chronic superficial gastritis and early atrophy, however, there seems to be no sharp dividing line, and, at any rate in the presence of achlorhydria, the two conditions overlap. For this reason no attempt has been made to separate them, and they are referred to hereafter as the early atrophic group. A further complication in analysing these patients is that at any stage acute gastric erosions, acute, subacute, or chronic gastric ulcers, or old ulcer scars may occur. The presence of these alters the clinical findings to some extent, and it will often be necessary to separate the cases from their parent groups. There are a few cases of chronic gastric ulcer with achlorhydria in which the gastric mucosa was reported on as normal. Their inclusion in this analysis should not affect the results, as the chronic gastric ulcer cases are dealt with separately where they depart from the

general run of the findings. Patients in whom the only evidence of advanced atrophic changes was in the vicinity of ulcer scars are placed in the early group.

The Atrophic Groups

The data concerning the age and sex of the patients are outlined in Table I.

TABLE I.—Atrophic Gastritis—Age and Sex Incidence

Age Group	Early Atrophy			Advanced Atrophy		
	Men	Women	Total as %	Men	Women	Total as %
Under 30	1	5	4.8	—	3	2.7
30-40	13	3	12.7	8	3	9.7
40-50	13	11	19.0	11	9	17.7
50-60	20	17	29.4	21	18	34.5
60-70	17	11	22.2	19	14	29.2
70-79	6	7	10.3	4	2	5.3
Unknown	1	1	1.6	1	—	0.9
Total	71	55		64	49	

The ratio of men to women is about four to three in each group of the patients, but further division (Table II) suggests that this inequality may be due to the inclusion of patients with gastric ulcers.

TABLE II.—Atrophic Gastritis—Sex Incidence

	Early Atrophy		Advanced Atrophy		Combined	
	Men	Women	Men	Women	Men	Women
Acute erosions	7	10	6	13	13	23
Acute ulcers	6	3	6	3	12	6
Subacute "	1	2	2	1	3	3
Chronic "	27	7	7	4	34	11
Ulcer scars	9	9	4	2	13	11
Remainder	21	24	39	26	60	50
Total	71	55	64	49	135	104

The acute-erosions group has been taken to include not only cases in which an erosion was actually seen, but also those with manifest haemorrhage in which no lesion other than gastritis was found. Table II shows that these erosions were nearly twice as common in women as in men, while chronic gastric ulcers were three times more common in men than in women. If the erosion cases are kept with their parent groups and the ulcer cases are not included there is no great difference in the sex incidence.

The age distribution in the various subgroups is approximately the same, the highest incidence being in the fifties. As can be seen from Table I, there is a wide distribution, the youngest patient in the advanced atrophy group being a 17-year-old girl and the oldest a 79-year-old man. If the population at risk is taken into account there is probably an increasing incidence with increasing age.

TABLE III.—Atrophic Gastritis—Age at Onset of Symptoms

Age Group	Ulcers + Atrophy	Remainder	
		Early Atrophy	Advanced Atrophy
10-20	1 (1.2%)	1 (1.7%)	4 (5.4%)
20-30	9 (10.8%)	4 (6.9%)	6 (8.1%)
30-40	15 (18.1%)	13 (22.4%)	15 (20.3%)
40-50	26 (31.3%)	11 (19.0%)	14 (18.9%)
50-60	21 (25.3%)	14 (24.1%)	20 (27.0%)
60-70	9 (10.8%)	11 (19.0%)	10 (13.5%)
70-79	2 (2.4%)	4 (6.9%)	5 (6.8%)
Total	83	58	74

Patients in whom the age at onset was unknown have been omitted.

The onset of symptoms is commonest between the ages of 30 and 60, with a maximum incidence in the fifties (Table III). There is little difference between the early and late groups. Where there is a concomitant ulcer the distri-

bution resembles more closely that of chronic gastric ulcer, with a maximum incidence in the forties.

The data concerning the length of history of symptoms are set out in Table IV, where it has been necessary to subdivide the groups. A greater number of patients with

TABLE IV.—Atrophic Gastritis—Length of History of Symptoms

Length of History (Years)	Combined Groups				Remainder	
	Erosions	Acute and Subacute Ulcers	Chronic Ulcers	Scars	Early	Advanced
Under 1 ..	13 (38.2)	9 (39.1)	11 (28.2)	6 (28.6)	16 (38.1)	17 (30.4)
1- ..	8 (23.5)	4 (17.4)	12 (30.8)	7 (33.3)	14 (33.3)	12 (21.4)
5- ..	4 (11.8)	3 (13.0)	2 (5.1)	1 (4.8)	6 (14.3)	10 (17.9)
10- ..	5 (14.7)	4 (17.4)	8 (20.5)	6 (28.6)	5 (11.9)	8 (14.3)
Over 20 ..	4 (11.8)	3 (13.0)	6 (15.4)	1 (4.8)	1 (2.4)	9 (16.1)
Total ..	34	23	39	21	42	56

Patients in whom the length of history was unknown have been omitted.

early atrophy present with a short history of symptoms than do those with advanced atrophy. This is not unexpected, since atrophy is presumably a progressive process. Indeed, it is probable that gastritis is a degenerative rather than a true inflammatory condition. However, nearly a third of those with advanced atrophy have a history of under one year's duration. Possibly some added factor such as inflammation, an exogenous irritant, or a transitory erosive process is required for the production of symptoms.

It has been suggested that the low acid values associated with chronic gastric ulcer are secondary to the presence of the ulcer. Table IV suggests that this is not necessarily so. In a series of 498 patients with chronic gastric ulcers previously analysed, about 40% gave a history of symptoms of under five years' duration, while in the present series the figure is 60%. This increase is explained by the inclusion of patients who were found at other hospitals to have a short history of symptoms combined with achlorhydria and an ulcer crater, and who were referred here for gastroscopic examination to exclude malignancy. This does not interfere with the finding that low acid values in chronic gastric ulcer are often associated with a long history of ulcer symptoms, and we again stress that chronic gastric ulcer is in most cases probably the outcome of degenerative changes in the gastric mucosa (Tanner, 1951).

Symptomatology of the Atrophic Groups

Epigastric Pain and Discomfort

Over 90% of patients complained of epigastric pain or discomfort, the most common form being pain related to meals (Table V).

TABLE V.—Chronic Gastritis—Pain Related to Meals

	Pain Related to Meals	Remainder
Early atrophy, including erosions ..	37 (59.7%)	25 (40.3%)
Late ..	47 (56.0%)	37 (44.0%)
Acute and subacute ulcers ..	14 (38.3%)	10 (41.7%)
Chronic ulcers ..	36 (81.8%)	8 (18.2%)
Ulcer scars ..	10 (43.5%)	13 (56.5%)

Patients in whom the symptomatology was unknown are not included.

The erosion cases have been kept with their parent group. If they are separated the findings are not materially altered. The patients with chronic gastric ulcer are more likely to complain of post-prandial pain than the remainder, but of those without a demonstrable break in the continuity of the gastric mucosa over half complain of this symptom. The mode of production of the pain is intriguing and obscure. It appears to differ little from that accompanying peptic ulceration, though in the late atrophic group it seems to come on more often directly after eating. This is not always so, but the details of the time relationship to meals are insufficient for statistical analysis.

In some patients the pain is relieved by alkalis (it is well known that many achlorhydric dyspeptics complain of "acidity"). In some cases vomiting, and in others taking food, gives relief; some find that nothing helps. Relief from taking food follows the general rule that the longer the interval between eating and the onset of pain the more likely is food to afford relief.

Comparatively few patients in whom ulcer scars in addition to atrophy were found complained of post-prandial pain, since these patients not infrequently present with manifest haemorrhage without a previous history of dyspepsia.

Only 8% of patients with chronic ulcers (compared with 18% in the early atrophic and 25% in the late atrophic groups) complained of pain unrelated to meals.

The symptoms of fullness or discomfort after meals were rarely prominent in the chronic ulcer patients, but were present in 18% of the early atrophic and 15% of the late atrophic parent groups.

Manifest Haemorrhage

It has been found in this clinic that 50% of patients with haematemesis or melaena in whom no gross cause is found for the bleeding have gastroscopic evidence of atrophic changes (Tanner, 1949). The data in the present series are set out in Table VI.

TABLE VI.—Chronic Gastritis—Manifest Haemorrhage

	History of Haemorrhage	No History of Haemorrhage
Early atrophy, including erosions ..	17 (27.4%)	45 (72.6%)
Late ..	18 (21.4%)	66 (78.6%)
Acute and subacute ulcers ..	13 (54.2%)	11 (45.8%)
Chronic ulcers ..	11 (25.0%)	33 (75.0%)
Ulcer scars ..	10 (43.5%)	13 (56.5%)

TABLE VII.—Haemorrhage

	Haemorrhage with Preceding Dyspepsia	Haemorrhage as Sole Symptom
Early atrophy, including erosions ..	13	4
Late ..	14	4
Acute and subacute ulcers ..	11	2
Chronic ulcers ..	11	—
Ulcer scars ..	6	4

There is a history of haemorrhage in about a quarter of the cases of early and late atrophy, but when these are complicated by acute or subacute ulcers or ulcer scars the figure is doubled (Table VI). The incidence where there is an additional chronic ulcer is not higher than for the parent groups, and is approximately the same as in patients with chronic ulcers without achlorhydria (Swynnerton and Tanner, 1953).

In an appreciable number of cases haemorrhage may be the only symptom (Table VII).

In some cases an obvious lesion may be found from which the bleeding comes, but in others there may be no obvious bleeding point even in those rare cases which continue to bleed and come to necropsy. However, one of us has seen acute erosions overlying visible submucosal vessels (Tanner, 1949), and it may be that these patients are more

FIG. 3.—Gastroscopic view of an acute erosion, overlying a visible submucosal vessel.

susceptible to mucosal erosion than normal and a shallow erosion into a submucous vessel may cause copious haemorrhage (Fig. 3).

Other Symptoms

Nausea, Vomiting, Anorexia, Weight Loss.—The symptoms of nausea and vomiting, anorexia, or weight loss are present in approximately a fifth of the patients (Table VIII).

TABLE VIII.—Nausea and Vomiting, Anorexia, Weight Loss

	Nausea and Vomiting	Anorexia	Weight Loss
Early atrophy, including erosions ..	12 (19.4%)	11 (17.7%)	14 (22.6%)
Late ..	16 (19.0%)	13 (15.5%)	19 (22.6%)
Acute and subacute ulcers ..	2 (8.3%)	4 (16.7%)	7 (29.2%)
Chronic ulcers ..	6 (13.6%)	6 (13.6%)	10 (22.7%)
Ulcer scars ..	1 (4.3%)	5 (21.7%)	6 (26.1%)

Note: The totals on which percentages are based may be obtained by reference to Tables V or VI.

The presence of an ulcer does not greatly affect the incidence except in the case of nausea and vomiting, which is less frequent when an ulcer is present. So far as possible those patients who vomited merely in an attempt to relieve their symptoms and those who were afraid to eat have been omitted.

Bowel Habit.—Complaints of diarrhoea or constipation as prominent symptoms were uncommon, the maximum incidence being in the parent late atrophic group, in which one in ten complained of diarrhoea and one in twenty of constipation. Bowel habit is dealt with more fully in the late analysis.

Lassitude and anaemic symptoms were complained of by less than one in ten of the patients. Other more uncommon main complaints included belching, regurgitation, and dysphagia.

Conclusions on Symptomatology

Over 90% of the patients complained of epigastric pain or discomfort, most often related to meals. One in five was troubled with vomiting, anorexia, or weight loss; and one in three had manifest haemorrhage at some stage during the course of the disease. To sum up, there is no definite clinical picture to distinguish chronic atrophic gastritis from peptic ulceration or gastric carcinoma, and it may at times mimic gall-bladder disease, hiatus hernia, or many other disorders.

Associated Conditions

Gastric Adenoma.—In five of the 113 patients with advanced atrophy there were coexistent gastric adenomata—in two a single adenoma was seen; in one there were two adenomata, and in two the adenomata were multiple. In the early atrophic group one woman had two adenomata, and in one man a doubtful adenoma was seen at a later date.

Gall-bladder Diseases.—Six of the 113 patients in the advanced atrophic and 7 of the 126 in the early atrophic groups had a past, concurrent, or subsequent history of gall-bladder disease. Since the two conditions may be indistinguishable clinically, mistakes concerning the causation of symptoms are bound to occur. Thus patients who have had a cholecystectomy may return to hospital with their symptoms unaltered, while others in whom both conditions are found at the same admission may be permanently relieved by cholecystectomy. It is even possible that the dyspeptic symptoms of gall-bladder disease (not, of course, colic) may be due to a coincident gastritis or duodenitis, for it is well known that flatulent dyspepsia may persist after cholecystectomy.

Chronic Respiratory Infections.—Fourteen patients in the late and 10 in the early groups suffered from chronic bronchitis. It is not possible to say whether the two conditions are associated, since chronic bronchitis is a common condition in South London, but an incidence of 10% would seem to be high. Four patients in the late group have been diagnosed as suffering from pulmonary tuberculosis, and

another gave a past history of tuberculous peritonitis. In the early atrophic group two gave a history of pulmonary tuberculosis.

Tertiary Syphilis.—Three patients in the late and two in the early groups had tertiary syphilis. Three of these had syphilitic aortitis and the other two had tabes dorsalis. In one of the former, submucous gastric swellings were seen on gastroscopy, and these disappeared after antiluetic treatment.

Other Associated Conditions.—These include psoriasis (2), chronic dermatitis (1), osteoarthritis (3), rheumatoid arthritis (1), haemophilia (1), cystinuria (1), and diabetes mellitus (1).

Late Results

The method of follow-up of patients was the same as that previously described (Swynnerton and Tanner, 1953). Results are rather less complete than in the follow-up of cases of chronic gastric ulcer, for two reasons: (1) that the records of addresses and next-of-kin were often less detailed; and (2) that four of the patients referred from other hospitals were war refugees from Malta and Gibraltar whom it has proved impossible to trace. The general results of the follow-up investigation are given in Table IX.

TABLE IX.—Atrophic Gastritis—General Results of Follow-up

	Early Atrophy	Late Atrophy
Alive—adequate information ..	78 (61.9%)	82 (72.6%)
“—inadequate “ ..	2 (1.6%)	1 (0.9%)
Dead ..	38 (30.2%)	22 (19.5%)
No information ..	8 (6.3%)	8 (7.1%)
Total ..	126	113

Deaths

The causes of death in the early and late atrophic groups, in those with a gastroscopically normal mucosa, and in those in whom no gastroscopy was performed are shown in Table X.

TABLE X.—Causes of Death

	Late Atrophy	Early Atrophy	Normal Mucosa	No Gastroscopy
Gastro-intestinal:				
Gastric carcinoma ..	—	3	—	1
“ ulcer ..	—	2	—	—

Unknown ..	—	2	—	2
Total ..	22	38	11	13

The figures in the early atrophic group again draw attention to the fact that the dyspepsia may be due to causes other than the gastritis, and one should not be satisfied with a single diagnosis of chronic gastritis before excluding all other possibilities. Thus the two patients with carcinoma of the gall-bladder both died less than two months after gastritis had been found. It would seem possible, too,

that in a number of those dying of "heart failure" the achlorhydria and gastroscopic appearances may have been secondary to chronic cardiac disease.

The average age at death in the advanced atrophic group was 67.6 years, only two patients having died under the age of 60—one of tuberculosis and the other of syphilitic aortitis. Of those patients still alive at least one is over 90. In the early atrophic group the average age at death was 65.

In the advanced atrophic group, apart from the one patient who died of uncontrolled gastric haemorrhage, no patient appears to have died either as a direct or as an indirect result of atrophy.

Carcinoma of Stomach

In the late atrophic group none of the traced patients have developed a gastric carcinoma and only two of them have developed a malignant tumour elsewhere in the body. In some 3% of all people the cause of death is attributed to gastric carcinoma (Registrar-General, 1953), so it is reasonable to suppose that if atrophic gastritis is a precursor of gastric carcinoma one might find a certain number of cases in the present series. The essentially negative findings are in line with the only other series of gastroscopically confirmed cases found in the literature. Findley *et al.* (1950) followed for five years or more 100 patients, of whom 49 had "mild," 33 "moderate," and 18 "pronounced" atrophy, and found none who developed gastric carcinoma.

In the early atrophic group four patients have developed gastric carcinoma and seven a carcinoma elsewhere in the body. The former are analysed further:

Case 1.—A man aged 52 was admitted on December 5, 1941, with an eighteen-months history of epigastric pain immediately after meals. Fractional test meal analysis showed achlorhydria. Gastroscopic examination revealed no gross abnormality apart from fine congestion of the mucosa. Barium-meal examination revealed no lesion. He was reinvestigated in 1943 and 1944 on account of recurrent symptoms. On both occasions a barium-meal examination was normal. In 1943 gastroscopy showed thinning of the mucosa without visible vessels and a small adenoma. This latter was not seen in 1944. He was seen at the follow-up clinic in April, 1952, when he still complained of similar symptoms. On examination a large epigastric mass was palpated. He was admitted and died following removal of a large adenocarcinoma of the body of the stomach.

Case 2.—A man aged 70 was admitted on February 3, 1942, with a two-years history of epigastric pain two to three hours after meals associated with anorexia and vomiting. Fractional test meal analysis showed achlorhydria. Gastroscopy revealed marked congestion of the mucosa and a chronic gastric ulcer at the angulus. In view of his general condition a gastro-jejunostomy instead of a partial gastrectomy was performed after failure of the ulcer to heal on medical treatment. He continued to have recurrent dyspepsia, and the ulcer was again seen gastroscopically in August, 1944. He was readmitted in May, 1947, when he had an epigastric mass, a palpable irregular liver, and ascites. He died a few days later. Permission for a necropsy was refused.

Case 3.—A woman aged 73 was admitted on February 17, 1945, with a four-years history of vague epigastric pain and recent lassitude. A barium-meal examination showed no lesion. Fractional test meal analysis showed achlorhydria. Gastroscopy revealed a mucosa which was thin in patches and associated with speckled congestion. For technical reasons the examination was incomplete, and it was thought that there might be a lesion at the angulus. She was readmitted in May, 1948, with a six-months history of pallor, lassitude, and anaemic symptoms. There was no further mention of dyspepsia. Severe hypochromic anaemia was found. During her stay in hospital she developed sudden pain in the epigastrium and died on June 9, 1948. At necropsy a small flat carcinoma was found arising $\frac{1}{2}$ in. (1.3 cm.) proximal to the pylorus. In addition there was a subphrenic abscess.

Case 4.—A man aged 51 was admitted on August 25, 1941, with haematemesis preceded by a week of epigastric discomfort after meals. Fractional test meal analysis showed achlorhydria. Barium-meal examination showed an innocent ulcer on the lesser curve and this was confirmed gastroscopically. The gastric mucosa was reported to be otherwise normal. The ulcer was

shown to be soundly healed seven weeks later. He returned in May, 1946, with a history of recurrence of dyspepsia for the past year. On gastroscopy the ulcer was thought to be innocent, but at operation and on section it was found to be a diffuse infiltrating spheroidal-cell carcinoma.

Apart from the presence of achlorhydria there is no factor common to these four cases. In three there was mucosal congestion, in two an apparently innocent chronic gastric ulcer, and in two evidence of atrophy of the mucosa. It is not possible to reach any conclusion on the study of these cases.

Pernicious Anaemia

One patient, a 69-year-old man, was diagnosed as suffering from pernicious anaemia three years after the initial gastroscopic diagnosis of advanced atrophy. Two other patients gave family histories of pernicious anaemia.

Late Results in Patients Still Alive

In the advanced atrophic group eight patients have had partial gastrectomies performed—seven for chronic ulcer and one for gastric polyposis—leaving 74 for late assessment. The early atrophic group is loaded with patients with concurrent chronic gastric ulcers, and, since these ulcers are just as apt to recur as those in patients without achlorhydria, it has been decided to omit them from the late analysis. Fifty patients remain alive and were followed up. The subsequent course of events in the two series is shown in Table XI.

TABLE XI.—Chronic Gastritis—Late Results

	Early Atrophy Excluding Chronic Ulcers		Late Atrophy		Total	
	No.	%	No.	%	No.	%
No further trouble	13	(26.0)	18	(24.3)	31	(25.0)
Occasional mild symptoms	16	(32.0)	21	(28.4)	37	(29.8)
severe	1	(2.0)	3	(4.1)	4	(3.2)
Frequent or constant symptoms	20	(40.0)	32	(43.2)	52	(41.9)

The results in the two series are very similar. Just over half the patients have had little or no further trouble from their stomach. Chronic superficial gastritis and the earlier stages of atrophy are conditions which may heal completely (Schindler, 1947), and, as we know from patients with pernicious anaemia, advanced atrophy need not cause symptoms.

Nearly all the patients in the advanced and many in the early atrophic group were advised to take a mixture containing hydrochloric acid, but only 11 have continued to do so, while 59 take alkalis more or less regularly.

The reason for this swing from acid to alkalis is threefold. First, patients find hydrochloric acid unpleasant to take, no matter how much diluted or disguised; secondly, dyspepsia means to general practitioners a prescription for alkalis, and the recommendation to prescribe acid is soon forgotten; and, thirdly, many patients find that alkalis are effective for relieving their symptoms. A wide variety of alkalis were used with good effect.

The bowel habits of 39 patients with early atrophy and 59 with advanced atrophy are known (Table XII). Constipation is common in the advanced atrophic group, while diarrhoea, either in attacks or as a constant looseness of the motions, is present in one in ten.

TABLE XII.—Bowel Habit in Patients with Atrophic Gastritis

	Early Atrophy	Advanced Atrophy
Normal	22 (56.4%)	24 (40.7%)
Constipation	12 (30.8%)	27 (45.8%)
Diarrhoea	5 (12.8%)	6 (10.2%)
or constipation	0 (0.0%)	2 (3.4%)

Discussion

The diagnosis of chronic gastritis should be accepted as the cause of the patient's symptoms only after exclusion of all other possible conditions. Confirmation of its presence will be obtained only by gastroscopic examination. Blind biopsy methods such as that described by Wood *et al.* (1949) may help to elucidate the process of gastritic changes, but will be unreliable for diagnosis, as the condition is often patchy.

The prognosis regarding symptoms is somewhat better than in the medical treatment of chronic gastric ulcer, since about half the patients have very little subsequent trouble. Amongst the other half there are a few who become disgruntled, finding that different regimes of treatment have little effect on their symptoms. A dietary regime similar to that used in patients with chronic gastric ulcer should be followed, and during exacerbations bed rest will undoubtedly hasten relief and may be followed by long remissions. A mixture containing hydrochloric acid should be prescribed, to be taken well diluted during meals, and the patient should be allowed to experiment until he finds the most effective flavouring agent, which is most likely to be one of the citrus fruit juices (Bockus, 1944). Hydrochloric acid therapy is usually sufficient to control attacks of achlorhydric diarrhoea, but in obstinate cases it may be supplemented with phthalyl or succinylsulphathiazole. A few patients are of the opinion that acid prevents or terminates attacks of dyspepsia, but this does not appear to be the general finding. If hydrochloric acid is badly tolerated or fails to relieve the symptoms when taken regularly over a period of time, one of the non-absorbable alkalis may be tried, or "autolavage" by taking 1 dr. (4 g.) of sodium bicarbonate in water before meals, as recommended by Spriggs and Marxer (1943).

Supplementary vitamin-B complex is often given to these patients, since there is evidence that a deficiency leads to a decrease in gastric acidity. It has been reported by several observers, notably by Jones, Benedict, and Hampton (1935), that in patients with pernicious anaemia there may be regeneration of the gastric mucosa with liver therapy, but this has been denied by others who regard advanced atrophy as an irreversible state. In this clinic one of us (N.C.T.) has seen a patient with pernicious anaemia whose gastric mucosa showed patchy regeneration on liver therapy. Until there is more evidence on the action of liver extract and vitamin B₁₂ on the stomach it would seem to be inadvisable to use them in simple atrophic gastritis for fear of masking the development of pernicious anaemia. Surgery appears to play little part in the treatment of atrophic gastritis. As Schindler (1947) remarks, "there is no reason to believe or to hope that the pain will be alleviated by surgical interference." Patients who have had partial gastrectomies performed for a coexistent ulcer or ulcer scar are not infrequently seen with their symptoms unaltered. In cases of uncontrolled haemorrhage a total gastrectomy would have to be contemplated to guarantee success, since the bleeding areas are often multiple and widely scattered, but in practice a partial resection usually leads to diminution and sometimes to cessation of bleeding.

Opinions concerning the role of chronic gastritis as a precursor of gastric carcinoma have been as much at variance as in the more familiar "ulcer-cancer" controversy. The histological examination of stomachs resected for cancer provides little evidence, for, even if there were general agreement on the degree of gastritic changes, it would still be impossible to decide whether these were the primary condition or whether they were secondary to the presence of the neoplasm. The solution of the problem is therefore a clinical one. The most important work done from the clinical aspect has been that of Comfort and his colleagues (1947) at the Mayo Clinic. They have studied a series of patients with gastric carcinoma who had had gastric analyses performed before the development of the carcinoma. They found that the proportion of low or

absent free hydrochloric acid values was greater than normal in these patients, suggesting that carcinoma arises in an already diseased stomach. It must be borne in mind, however, that this was a selected series of patients, since they were those in whom the carcinoma was preceded by many years of dyspepsia, and it is not possible to estimate the importance of chronic gastric disease in the development of gastric carcinoma as a whole.

In the present investigation none of the traced patients with advanced atrophic changes have developed gastric cancer. This is negative evidence which is suggestive but by no means conclusive, and, ideally, all these patients should be seen again in another five to ten years. The negative findings are to some extent supported by the sex incidence, which is not that of gastric carcinoma. It is now well established that gastric adenomata are prone to become malignant, and Schindler (1947) has reported that these adenomata are seven times more common in people with gastric atrophy than in those without. The adenomata are presumably secondary to or a variant of the atrophic changes and may form a connecting-link between the atrophy and the development of carcinoma. In the early atrophic series, in which four patients developed gastric carcinoma, it is not possible to estimate whether this is a significant incidence, and the factors involved were multiple. In only two was there macroscopic evidence of atrophy.

It will have been noticed that in 11 of the cases of advanced atrophy there were concomitant chronic benign gastric ulcers. It is usually taught that a diagnosis of gastric ulcer is incompatible with a finding of complete achlorhydria. In some of the present cases the atrophy was patchy, but in others it was generalized, and in these the capacity of the stomach to secrete acid in response to any stimulant must be negligible. It seems probable that hydrochloric acid is essential for the initial formation of the ulcer, but not for its maintenance. This latter may be due to poor healing powers in the degenerate atrophic mucosa and also, possibly, to superadded infection or trauma.

Summary

An analysis and late follow-up has been carried out on a series of patients who were found to secrete no free hydrochloric acid in response to a test meal using gruel as the stimulant. Two main groups of gastroscopically confirmed patients have been dealt with in some detail, the one comprising 113 cases of advanced atrophic gastritis, and the other 126 cases of chronic superficial gastritis or early atrophic gastritis.

The analysis is complicated by the frequent co-existence of gastric erosions or ulcers.

If patients with chronic gastric ulcers are excluded there is no great difference between the incidence in the two sexes.

There is a wide distribution in the age incidence, the majority of patients in the two groups presenting at hospital between the ages of 40 and 70. Information is given on the length of history and age at onset of symptoms.

Over 90% complain of epigastric pain or discomfort, which is usually related to eating.

Over a quarter give a history of manifest haemorrhage, and in one in five of these haemorrhage is the sole symptom. Complaints of nausea, vomiting, anorexia, and weight loss are frequent.

Less common main symptoms include diarrhoea, constipation, anaemia, belching, regurgitation, and dysphagia.

In the advanced atrophic group constipation is four times more common than diarrhoea.

Of associated conditions gall-bladder disease seems to be most important, since it may be clinically indistinguishable from atrophic gastritis, and since there may be direct association between the two. Other associated conditions which may be of aetiological significance include chronic bronchitis, pulmonary tuberculosis, tertiary syphilis, cardiovascular disease, and certain chronic skin and joint conditions.

In the late atrophic group 22 patients (19.5%) have died. In only one, a case of uncontrolled gastric haemorrhage, was there any connexion between the atrophic gastritis and the cause of death. No patient in this group has developed a gastric carcinoma.

In the early atrophic group 38 patients (30.2%) have died. Four of these have developed a gastric carcinoma, but, apart from the absence of free hydrochloric acid, no common factor could be found.

One patient with advanced atrophy was subsequently found to have developed pernicious anaemia.

Among those patients still alive the results in the two groups are very similar. About half have had very little subsequent trouble, but the course of the disease seems to have been little influenced by a variety of regimes in the remainder.

The treatment of atrophic gastritis is discussed.

Some of the evidence concerning the role of chronic gastritis as a precursor of gastric carcinoma is presented, and the apparently anomalous finding of peptic ulcer of the stomach in the absence of free hydrochloric acid is discussed.

We are greatly indebted to the many people, not least the patients themselves, who co-operated in the follow-up. We wish to thank Miss Temple and Mrs. Strong, of the Records Department, St. James's Hospital, and Miss Kirwin for the many hours spent unearthing ancient records, and the latter for her secretarial assistance. The cost of the investigation was met from a grant from the Weir Research Fund.

The latest issue of *Scientific Film Review* includes appraisals of five medical films. "Coarctation of the Aorta" (E. R. Squibb & Sons), intended for students and society meetings. "Haemolytic Disease of the Newborn" (St. James's Film Unit) depicts the technique of replacement transfusion. "Marrow Puncture" (I.C.I.) surveys the techniques of marrow puncture in patients of various ages. It is intended for housemen and postgraduate students. "Venepuncture" (I.C.I.) demonstrates the technique in adults. These four films are in colour. A black-and-white film mentioned is "Prevention of Infection of Babies in Hospital" (British Film Institute), a comprehensive survey of modes of spread of infection in children's wards. It is for the training of nurses and medical students entering paediatric wards. *Scientific Film Review* is published quarterly by the British Film Institute at an annual subscription of 5s.

RESULTS OF TREATMENT OF CHRONIC VASOMOTOR RHINITIS

PART I. RESPONSE TO PHYSICAL TREATMENT

BY

PHILIP READING, M.S., F.R.C.S.

Surgeon, Throat and Ear Department, Guy's Hospital

AND

KENNETH MALCOMSON, F.R.C.S.

Registrar, Throat and Ear Department, Guy's Hospital

Sufferers from chronic vasomotor rhinitis form a large proportion of all those attending the throat clinics of most hospitals, and we have been impressed not only by the frequency of the disorder but also by the unsatisfactory response to treatment. In addition it is apparent that many of these patients are emotionally upset, and that their disabilities are in part caused and in part magnified by psychological imbalance.

Results of Physical Investigation and Treatment

A series of 127 consecutive patients were studied. Symptoms, rhinological appearances, allergic responses, and the results of treatment were noted, and a superficial assessment of the emotional background was attempted in the throat clinic (by K. M.). As many as possible were invited to participate in more detailed psychological investigation, and those who did attend may fairly be regarded as a representative sample of sufferers from vasomotor rhinitis.

The main symptom in this disease is either paroxysmal rhinorrhoea or persistent nasal blockage. While well-defined examples of each may be recognized, yet in a great number the two clinical pictures are merged, to give symptoms and signs of both. In this series, there were 46 cases of paroxysmal sneezing and rhinorrhoea and 81 of chronic nasal oedema (49 with polypi and 32 without). A brief recapitulation of the two syndromes is appended.

1. Non-specific Paroxysmal Sneezing and Rhinorrhoea

Sufferers often refer to this as a "constant cold" or hay-fever, because of the similarity of the symptoms.

In non-specific rhinorrhoea the characteristic attacks usually occur in the morning, at or soon after waking; or they may be precipitated by some change in body temperature, as in getting out of bed or walking barefoot on a cold floor, by exposure to bright sunshine, by the inhalation of airborne irritants, especially dust, or by emotional stress. There is a feeling of irritation at the root of the nose, followed by sneezing, lacrimation, and a profuse watery discharge. The rhinorrhoea may last for only a few minutes or may continue for several hours, and as many as 50 large handkerchiefs may be soaked in the course of a day. Nasal obstruction, headaches, and anosmia are not usually features of the condition.

The attacks are distinguished from common colds by the nature of the discharge, which is clear and watery and not purulent as in coryza. Secondary infection can follow these attacks, whereupon the discharge becomes thick and yellow, and the infection is then identical with the later stages of a coryza.

Examination of the nose shows that the mucous membrane has a normal appearance, and during an attack the nasal passages are found flooded with thin mucus. Radiological examination of the sinuses indicates no change beyond a slight and occasional mucosal thickening. Repeated

examination of nasal smears often shows the presence of eosinophils. In this series of 46 cases 15 smears were examined, and 5 were positive—a finding to which no importance is attached.

The response of the skin to tests with allergens is usually non-specific, and we have come to the conclusion that allergy plays little part in the aetiology, as is shown in Table I.

TABLE I.—Results of 40 Skin Tests

Reaction:	Slight	Moderate	Strong	Total
Negative	..	..	..	12
General non-specific	1	10	5	16
House dust	2	2	3	7
Grass	4	1	0	5

It may be said that people suffering from non-specific rhinorrhoea have a more sensitive nasal mucosa than sufferers from hay-fever; they show brisker nasal reactions to many more irritants and in many more circumstances than do hay-fever subjects, who have been excluded altogether from this analysis.

The symptoms have an explosive character, the counterpart of which in the somatic nervous system would be termed epileptiform. Since the secretomotor nerves of the nose are from the parasympathetic centres in the hypothalamus, such an autonomic "epileptiform attack" would manifest itself in the fashion outlined in the symptoms. Such a concept places the disorder amongst other stress disorders such as asthma and duodenal ulcer, in which the cholinergic system seems to play a leading part.

This hypothesis is in part borne out by the effect of division of the greater superficial petrosal nerve. This nerve is occasionally damaged in fractures of the petrous bone or invaded by new growths, resulting in a "dry nose." From a study of such patients as we have been able to examine in whom this nerve has been injured, it is clear that the greater superficial petrosal nerve is in fact the secretomotor nerve to the nasal mucosa.

For some considerable time a patient has been sought whose rhinorrhoea was so intractable to medical measures and so distressing that any form of relief would be welcomed. When finally such a patient was found, Mr. Murray Falconer performed at our request a section of this nerve through a subtemporal craniotomy. This produced complete homolateral cessation of rhinorrhoea, and the patient is now anxious, after a lapse of six months, to have the other side operated upon. However, our approach must be cautious. The employment of a major surgical operation to rid the patient of what is at the worst a severe discomfort can be justified only if the results can honestly be predicted as completely satisfactory, and if it is reasonably without risk.

Treatment

When the skin tests show no specific reaction or show sensitivity to several allergens, it has proved of little value to attempt hyposensitization or desensitization.

The antihistaminic drugs have been of great value in the control of the rhinorrhoea. To find the particular drug which will prove most effective in any individual nose is a matter of trial and error. It is surprising how often a slight alteration in the radical attached to the ethylenediamine nucleus may make one antihistaminic effective and another useless in the control of symptoms. A combination of antazoline and tripeleminamine, such as "dibistin," gives a wider range of control. Results are often gratifying, but treatment must be continuous to correct this persistent disorder, and many patients find daily dosage over months and years very tiresome. That is to say, treatment by these drugs is in no sense treatment of the causes of the disorder, but is merely palliative.

The drowsiness occasioned by antihistaminics can be adequately countered by the administration of amphetamine or dexamphetamine sulphate.

Of the 46 patients suffering from non-specific rhinorrhoea, 32 derived a satisfactory degree of suppression of symptoms from the use of antihistaminics. Two required zinc ionization and have remained symptom-free up to the time of writing (21 months), and three have been relieved for a similar period by specific desensitization (see Table I—three patients with strongly positive reactions to house dust). In five all forms of treatment were completely fruitless.

It may be worthy of remark that some of these patients derive considerable temporary amelioration from the administration of calcium lactate, 10 gr. (0.65 g.) t.d.s., and parathyroid extract, 1/20–1/10 gr. (3.2–6.5 mg.) t.d.s.

2. Persistent Nasal Blockage

This title is used for want of a better term. "Chronic nasal oedema" emphasizes one of the commonest clinical features of the complaint—namely, nasal polypi. These are a frequent cause of nasal blockage in vasomotor rhinitis (Table II).

TABLE II.—Cause of Obstruction (81 Cases)

	No.	%
Polyp	41	53
Swelling of inferior turbinates	16	20
Polypoid swelling of middle turbinate	12	15
Mulberry swelling of posterior pole of inferior turbinate	5	6
Deviated septum with vasomotor features	5	6

When the inferior turbinate is swollen the obstruction is due to vascular dilatation under vasomotor influences rather than to extracellular fluid collections. Lucas (1952) has demonstrated the contrast between the filled and closed vascular bed, and one is led to conclude that oedema is not the main factor in this type of obstruction.

Eosinophils may be present in the nasal secretions as in the paroxysmal type of the disease. Of 12 smears taken 6 were positive. The patient refers to his nasal blockage as "catarrh"—"I blow my nose and nothing comes away." Further questions establish that the obstruction affects one or both sides, intermittently or alternately. It is made worse by any interference with the normal mechanism of regulation of the body temperature. For this reason it is worse at night, when the body surface is covered with heavy non-conductive bedclothes. A warm, moist atmosphere makes the obstruction worse. Provided a source of permanent obstruction in the shape of polypi is not present, energetic physical effort in the open air helps to clear the obstruction.

Paroxysmal sneezing and rhinorrhoea may also be present, but generally there is little nasal discharge. A slight post-nasal discharge, worse in the morning, is the result of accumulation and drying of the mucus secreted overnight. Frontal, retro-orbital, and occipital headaches are not uncommon, and are caused by temporary blockage of the ostia of the nasal sinuses. Anosmia and "nasal speech" are often reported as a result of the nasal blockage.

Treatment

Chronic nasal obstruction can be alleviated by the rhinologist only by mechanical and, to a lesser extent, by pharmacological methods. The use of the antihistaminics has proved disappointing; their effect on polypi is negligible, and on mucosal swelling slight and inconstant.

Surgical removal of nasal polypi, ablation of the engorged posterior ends of the inferior turbinates, and linear cauterization of the middle turbinates are the measures most commonly employed. Zinc ionization has proved valuable in obtaining long-term freedom from symptoms.

TABLE III.—Treatment

Relieved by polypectomy	..	38
Relieved by cautery of inferior turbinates	..	16
Relieved by vasoconstrictors	..	4
Relieved by zinc ionization	..	1
Specific desensitization	..	2
39 tested: 24 positive, 5 strongly positive		
Antihistaminics, slight relief:		
With polyp	..	5
Without ..	..	10

As shown in Part II, stress factors influence both clinical groups. When an organic obstruction such as a polyp blocks the nose little change can be expected in the airway under the influence of emotion. On the other hand, one would expect to find a clearer relationship between emotion and the state of the nose when the rhinitis has an episodic character as in paroxysmal sneezing and rhinorrhoea.

Thanks are due to the Board of Governors of Guy's Hospital and to the Research Committee of Guy's Hospital Medical School for the provision of a grant to one of us (K. M.) in the execution of this work.

RESULTS OF TREATMENT OF CHRONIC VASOMOTOR RHINITIS

PART II. RESPONSE TO PSYCHOLOGICAL TREATMENT

BY

DESMOND O'NEILL, M.C., M.D., M.R.C.P., D.P.M.
Physician, Department of Psychiatry, St. Mary's Hospital
(Formerly Chief Assistant, Department of Psychological Medicine, Guy's Hospital)

AND

KENNETH MALCOMSON, F.R.C.S.
Registrar, Throat and Ear Department, Guy's Hospital

Results of Psychiatric Assessment and Psychotherapy

Thirty-one patients under treatment in the throat and ear department were examined. There are two separate series. The patients in series I (13) were the subjects of a pilot study carried out to discover whether there appeared to be any significant correlation, in general terms, between the emotional life of the patient and variations in nasal symptoms. Those in series II (18) were kept under continuous observation for periods of time varying from 1 to 20 months.

The long-term and short-term behaviour of the illness was reviewed against the background of the patient's day-to-day existence and its vicissitudes. Some attempt was made to deal with emotional tension by psychotherapy in all the patients in series II.

Series I

This series comprised eight women and five men. The age range was 16-66 and the mean age 37.9 years. The patients were interviewed on a few occasions only, and the investigation was on a superficial level. Eight had no other complaints but the rhinitis itself. Case 7 had occasional headaches after an especially laborious task; Case 1 felt sometimes irritable and depressed; and Case 10 was tense and moody. Cases 5 and 8 had multiple symptoms—malaise, "run-down," headache, "indigestion," poor sleep, bad dreams.

When the history of rhinitis was explored by a method which took account of the patient's attitudes, feelings, and reactions to stress, the series could be subdivided into three groups.

Group A.—In four patients no significant association of the symptoms of vasomotor rhinitis with emotional tension could be found. Three of these were placid, stable people who had no mental or physical symptoms of anxiety; nasal function seemed to be influenced by physical agencies, such as change of temperature, but not by emotional state. The fourth was a tense, hostile, paranoid man who showed considerable resistance to a psychiatric approach to his illness. If his resistance and the hostility to which it gave rise had been better handled it might have been possible to demonstrate to him some association of nasal symptoms with feelings, since it was manifest that his feelings were very much disturbed; on the evidence, this association seemed probable but could not be proved.

Group B.—Some relationship between mental state and nasal symptoms was present in eight patients. The emotional states correlated with symptoms in these patients were in the main unpleasant and threatening—anxiety, guilt, resentment, despair. The following case is typical.

Case 10.—A woman of 30 was evacuated from London to the country in 1941. She objected to this move and found her new life dull and tedious; in this setting of frustration and discontent she began to have attacks of sneezing (up to 12 attacks daily, average 12 sneezes each), running of the nose (usually 10 large handkerchiefs daily), and obstruction. Clinically, she had pale swollen inferior turbinates; skin tests were negative. Attacks sometimes followed an argument at work. She was not troubled at all by nasal dysfunction when she was walking out with her boy friend; after he left her she felt disappointed and dejected, and symptoms began again.

Group C.—In one patient rhinitis began at a time of crisis in her life, and its symptoms were plainly related to anxiety. The association between nasal symptoms and emotional tension in this case was thus very close.

The preliminary investigation showed, then, that in only one-third of the series did the nasal disorder bear no relation to stress. Furthermore, it seemed likely that, if some of the patients in group B had been examined more often and a better rapport had been established, other links between the rhinitis and the patient's adjustment might have come to light. It was therefore decided to examine a second series of patients and to keep them under observation long enough to allow variations in the nasal symptoms to be correlated directly with life circumstances and the process of psychotherapy. Information of this kind is more reliable than that taken from the patient's anamnesis.

Series II

This series comprised 11 women and 7 men. The age range was 20-58 and the mean age 35 years. The mean duration of attendance at the out-patient clinic was eight months. During psychotherapy the behaviour of the rhinitis and the patient's attitudes, feelings, and reactions were observed, and the correlation, or lack of correlation, between these was recorded.

Group A

The patient's emotional reaction in three cases was thought to have no influence or an insignificant influence on nasal symptoms. The onset of rhinitis in these patients could not be clearly related to disturbing experiences, and, although there was some association between stress and variations in symptoms, this association did not appear to govern the behaviour of the disorder.

Case 15.—A woman of 48 was left alone when her husband died in 1948. She had few friends and felt isolated from her family. In January, 1951, she caught "flu" and had to stay in bed; she was hurt and disappointed that none of her family came to visit her. Symptoms of rhinitis began after this illness. There did not seem to be any close relation between sneezing and nasal blockage and discharge, and spells of anxiety, tension, and resentment against her family.

Here, although the rhinitis did appear for the first time when the patient was depressed and discontented, it later pursued its own course, apparently uninfluenced by her state of feeling.

Group B

In seven patients emotional tension was one of the main determinants of the illness.

Case 10.—A man of 35 suffered from blocking and running of the nose, "indigestion," and occasional attacks of asthma. The indigestion was very plainly related to anxiety, and some of the asthmatic attacks occurred in a setting of emotional tension. The rhinitis first appeared when he left school and went to work. There were attacks coincident with illness in a relative and in his wife. He experienced a kind of internal agitation when he went to visit his parents: "I feel excited in the stomach." This state was in part pleasurable, but it contained a considerable tension component as well. Three times an attack of rhinitis began at the time of the visit. On the other hand, he had attacks which did

not seem to be related to stress. When the course of the illness was reviewed the attacks associated with emotional tension outweighed the remainder.

Here the stress factor accounted for most of the attacks, but there were others which accompanied a change in climate and some which appeared "out of the blue" for no reason which we could discover. An important association of nasal symptoms in this patient was with relaxation; it was plain from his story that the pathogenic agent was not the relaxation itself but the effort and emotional strain which preceded it. This kind of association is familiar in other stress disorders; it is very often seen in migraine (O'Neill, 1952).

Six of the seven patients had other symptoms besides the rhinitis—anxiety, depression, fatigue, asthma, "indigestion," irregularity of menstruation, and menorrhagia. These may be regarded as mental and physical manifestations of a stress reaction of which the nasal disorder was one component.

The onset of symptoms in five patients occurred at a time of especial difficulty and frustration.

Case 4.—A man of 31 came back to his firm after six years' war service to find that some of his junior colleagues who had not joined up had risen to positions of importance and were now senior to him. "I tried not to be resentful"; but he could not help feeling bitter and indignant. Attacks of sneezing and running of the nose began, and have continued. He observed that annoyance affected the nose: "If my little boy pesters me I sneeze." Nasal symptoms were least in evidence while he was active. "If I mope the nose runs."

Variations in symptoms in these patients could for the most part, though not entirely, be accounted for by their emotional state at the time. This relationship is further discussed below.

Group C

A careful review of the story of the illness in the eight remaining patients led to the conclusion that stress was the dominant factor in the pathogenesis.

Case 6.—Sneezing began in a man of 32 when he was working in a power-station. The work was monotonous and boring, and he felt frustrated: "I want a change. At a loss now. Feel very anxious." In the Army he had risen from the ranks to W.O.I by diligent application to duty; he was ambitious and believed that he could better himself at work if he had the opportunity. At the same time he was reluctant to resign from the power-station, since the job was secure and carried a pension. While he was under observation every attack of nasal symptoms could be related to anxiety. After several discussions of his attitude to work, and the pros and cons of making a move, he decided to stay where he was, and to accommodate himself to the conditions; he became less restless and more content. When last seen, ten months later, the rhinitis had almost disappeared. There were occasional mild attacks after fits of worry and depression.

A change of attitude and emotional state, brought about by reflection and discussion, was accompanied in this patient by improvement in the rhinitis.

Five of the eight patients had other tension symptoms—fatigue, depression, menorrhagia, "indigestion," bodily pains, and migraine.

In all eight, symptoms of nasal dysfunction began when they were passing through an experience that aroused emotional tension. These experiences, it should be noted, were not in themselves very dramatic or extraordinary. They were disturbing to the patient because of the strong feeling which was mobilized, and their importance depended on the patient's own internal conflicts and not upon disaster in the outside world.

Case 18.—Symptoms (irritation, sneezing up to 30 times, and watery rhinorrhoea for several hours) began in a woman of 29 after she started music lessons with a male teacher. To her, marriage was a symbol of independence, and she ardently desired to form the kind of friendship which might lead to it. Strivings in this direction, however, stirred up anxiety because of a strong bond of dependence on her mother. Beneath this was deeper anxiety; she had once entered into a homosexual relationship of which she was very ashamed, and she was most apprehensive lest her feelings for her own sex should prove stronger than her feelings for men.

Variations in the intensity of nasal symptoms were associated with variations in emotional state in every patient in this group.

Correlation of Nasal Dysfunction with Emotional State

The data for this correlation are taken from observations on all 18 patients in series II. Two types of correlation can be considered: (1) long-term—the association of attacks with painful experiences over the whole course of the illness; and (2) short-term—momentary variation of symptoms with state of feeling, such as the appearance of nasal blockage in a fit of anger. Furthermore, the emotional determination of physical symptoms is often, if not always, a complex process; the immediate apparent precipitant may be found to rest upon other and deeper levels of conflict. Examples of this kind of psycho-physical relationship are given below.

Precipitating Symptoms

The immediate precipitants of symptoms may be classed as follows.

Anxiety from various sources (10 cases) was much the most common. In two of these the chief focus of anxiety was hypochondriacal concern.

Case 8.—Nasal obstruction due to polypi, and watery rhinorrhoea, began in a man of 42 after he had gone to consult a doctor about pain in his side. The doctor told him that he was doing too much and had tachycardia. The patient thought that this meant serious heart disease, and became extremely anxious about himself. He was sent to a cardiologist for an opinion and given strong reassurance. He ceased to worry about his heart, and the rhinitis diminished.

A blend of anxiety and resentment was predominant in three patients, and an association of symptoms with feelings of depression and deprivation was observed in three others. In three patients symptoms would often appear in the phase of relaxation after effort.

In some patients nasal dysfunction tended to be more pronounced in states of fatigue, probably because the power to keep in check painful emotions is lessened at such times.

Sex feeling, in the sense of unsatisfied desire, manifestly contributed to the causation of symptoms in two patients; and in a third (Case 18) conflicts over the sexual role, which gave rise to acute anxiety, came to light over some months through dream analysis. In several patients who were investigated at length, attitudes and feelings which had at first been entirely hidden rose to the surface, and it was then clear that the tension caused by these underlay and reinforced the emotional states which acted as the immediate precipitants of physical symptoms.

Case 1.—A man of 34 took over the editorship of a trade journal in 1946. The journal was a "one-man show," and he was alone responsible for its production and management. He took his work seriously and worried about it. Soon after he started the task he began to notice "repeated colds." He kept a chart of the variation in symptoms, and saw that the nose gave least trouble when he was working efficiently and at high pressure; nasal block and discharge at once appeared when he "flopped" after a period of intense effort. The analysis of dreams led almost at once to the themes of guilt and fear of punishment; then to the association of sex feeling and violence; and then the patient recalled that his first marriage had early come to grief because his wife was frigid. One night, in a kind of fugue state, he had made a furious attack on her. The memory of this experience had been wholly suppressed, and its recall caused him intense distress, and brought into consciousness the fear that he might make a similar attack on his present wife. When the guilt and fear linked with these impulses had been ventilated he was relieved, but said that he thought the primary problem had yet to be reached. The dream thoughts then took up the theme of his relationship to his mother, and the hostility and rebellion which as an only child he felt towards her. In speaking on this theme, strong feeling was expressed, and nasal symptoms gradually diminished until, nine months after his first attendance, the rhinitis ceased to give much trouble.

In this patient the intensity of nasal dysfunction was related to work strain. When the tensions which lay beneath

this had been to some extent alleviated, nasal block and discharge were reduced, though the actual situation at work had not altered.

Effect of Psychotherapy upon Nasal Symptoms

All the patients in series II were treated in the out-patient department by repeated interviews for periods ranging from 1 to 20 months. The sources of tension were explored and the patients were given help to deal with these. Dream analysis was utilized in six cases. The results of treatment were:

	Paroxysmal Rhinorrhoea	Chronic Nasal Oedema
Much improved or recovered ..	5	3
Improved ..	3	3
No change ..	2	1
Improvement in rhinitis, development of asthma ..	1	—

It will be seen that in response to treatment there was no significant difference between paroxysmal rhinorrhoea and chronic nasal oedema.

The best results were obtained in cases in which the relationship of the illness to stress was strongest, and six of the eight patients in group C were much improved.

These results suggest that sustained improvement in vasomotor rhinitis can be brought about by the diminution in emotional tension which follows psychotherapy—an improvement that does not depend on the use of antihistamine drugs.

Comment

A comparison of the grouping in series I and II shows that the principal difference is in group C (series I, 1; series II, 6). This suggests that the more that is known about the patient, and the better his reactions are understood, the more does the stress factor stand out. This conclusion is confirmed by the clinical findings in those patients who were investigated at greater length. The patient mentioned above (Case 1 of series II) could not, at his first interview, have told of his attack on his wife, since he was not at that time aware of it. The judgment that a particular disorder is not related to stress is a difficult one to make without a really thorough inquiry.

One of the patients in series II (Case 16), who was most anxious and hypochondriacal and suffered from abdominal discomfort, bodily pains, migraine, tension, and depression, had to consult a doctor about his other symptoms; another (Case 3) looked pale and ill, and was depressed and anxious. Both of these patients were manifestly anxious on examination, and their anxiety and its symptoms were severe enough to warrant their seeking medical advice. The other 16 patients did not seem to be very anxious or very depressed, and would not have asked for a psychiatric appraisal if it had not been offered to them. Few of the patients in either series were able, at their first attendance, to relate the symptoms of their rhinitis to stress, yet they were able to grasp this relationship readily enough when it was made clear to them by the anamnesis, and the more intelligent among them strove to make such modifications in their lives as were necessary to keep symptoms to a minimum.

No specific personality pattern emerged from the psychiatric examination of the patients in series II. Reactions of evasion and retreat (Cases 3 and 5) were represented among the patterns of illness, as well as reactions of combativeness and defiance (Cases 10 and 17). Symptoms of nasal dysfunction could appear in anticipation of stress (Case 13), during the stress itself (Case 7), and after it was over (Case 1).

Once the physical symptoms had appeared, utilization of them in order to gain some advantage was not a feature of the illness in any of these patients. In this respect the disorder resembles duodenal ulcer.

Summary

The results of treatment of chronic vasomotor rhinitis by physical and psychiatric methods are reviewed.

A few patients may be relieved of their symptoms by desensitization, and a few more are benefited by

zinc ionization. Obstruction of vascular origin, and that due to polypi, can be lessened by cautery and polypectomy. Antihistamine drugs are capable of suppressing the symptoms of paroxysmal rhinorrhoea, but only when they are being given continuously. They do not benefit the patient with chronic nasal oedema.

Some relationship between stress and the onset and course of vasomotor rhinitis has been demonstrated from a superficial psychiatric investigation. When the investigation is more prolonged and is carried to deeper levels a close relationship between nasal symptoms and stress can be shown in most patients. Such a relationship was found in 24 of this series of 31 patients. Recovery or sustained improvement followed psychotherapy in 14 of 18 patients treated at some length.

COMPLICATIONS OF MECKEL'S DIVERTICULUM

WITH AN ANALYSIS OF 18 CASES

BY

H. HASHEMIAN, M.B., F.R.C.S.Ed.

AND

E. T. MURRAY, M.B., F.R.C.S.

Department of Surgery, Central Middlesex Hospital,
London, N.W.10

Meckel's diverticulum has been the subject of many authoritative and stimulating papers in the past. It is not a rare congenital abnormality; the complications of this lesion are, however, of such gravity that the subject is always of importance in any consideration of acute abdominal emergencies. The cases reported here illustrate well some of its more serious complications, and it is by keeping such facts constantly in mind that we may hope to reduce the mortality of such lesions.

The first adequate description was published by J. F. Meckel in a series of three papers which appeared between 1808 and 1815. He was apparently the first to associate the diverticulum with the omphalo-mesenteric duct which connects the yolk sac with the intestine during the first few weeks of foetal life. Failure of obliteration of part or whole of the duct results in various anatomical types, ranging from complete patency to the outpouching of intestine, usually of the terminal ileum.

Meckel's diverticulum usually arises from the antemesenteric border of the ileum, about 20 in. (50 cm.) proximal to the ileo-caecal valve, the distance being less as the age approaches infancy. The diverticulum is usually composed of the same three layers which make up the ileum, but at times contains heterotopic tissues; the incidence varies between 15 and 25% of cases. It takes the form of gastric, duodenal, jejunal, and colonic mucosa, as well as pancreatic tissue. The most common type of heterotopic tissue is gastric mucosa, occurring in 16.6% of all cases of Meckel's diverticulum. When present, the heterotopic tissue usually lines the greater portion of the diverticulum, often involving the neck of the sac.

Complications

Meckel's diverticulum attracts the attention of the surgeon as a rule only when one of the several complications of this anomaly develop. These include:

1. *Diverticulitis With or Without Perforation.*—Meckel's diverticulum is subject to inflammatory changes giving rise to symptoms and signs similar to those of appendicitis. It is impossible to distinguish between the two conditions with

any degree of confidence, unless the patient has had his appendix removed at a previous operation. Perforation with peritonitis may occur, the latter being more lethal than that seen with a perforated appendix, owing to less efficient "walling off" and to greater volume and fluidity of intestinal contents.

2. *Ulceration or Haemorrhage or Both from Heterotopic Gastric Tissue.*—Peptic ulcer with haemorrhage or perforation or both is a common complication of Meckel's diverti-

Summary of Cases

Case No.	Age	Sex	Clinical Features on Admission	Pre-operative Diagnosis	Post-operative Diagnosis	Treatment and End-result
1	21	M	Recurrent severe attacks of melaena extending over period of 10 months requiring transfusion. Barium meal and gastroscopy: N.A.D. History of mild ulcer dyspepsia.	? Bleeding duodenal ulcer. ? Bleeding ulcer of Meckel's diverticulum.	Bleeding ulcer of Meckel's diverticulum.	Simple excision of diverticulum, which appeared to be fibrosed at apex. End-result satisfactory.
2	9	M	Admitted with 48-hours history of abdominal pain and vomiting. T. 100.8° F. (38.2° C.). Examination revealed tenderness and rigidity of lower abdomen. Per rectum: tender on right side anteriorly.	Acute appendicitis.	Gangrenous Meckel's diverticulitis.	Simple excision of diverticulum. End-result satisfactory.
3	39	F	History of colicky abdominal pain and vomiting of 4 hours' duration. T. 99° F. (37.2° C.). Tenderness and guarding high in right iliac fossa and right hypochondrium. Previous but less severe attacks of abdominal pain.	Acute appendicitis.	Meckel's diverticulitis.	Simple excision of diverticulum. End-result satisfactory.
4	55	F	Recurrent attacks of melaena associated with vague attacks of upper abdominal pain. Barium meal, barium enema, and gastroscopy normal.	Bleeding duodenal ulcer.	Bleeding ulcer of Meckel's diverticulum.	Simple excision of diverticulum with invagination of the stump. Histology: no heterotopic gastric mucosa.
5	33	F	Lower right abdominal pain associated with vomiting for 3 days. T. 98.4° F. (36.9° C.). Also previous attacks of colicky right lower abdominal pain with vomiting for 3 years.	Acute appendicitis.	Meckel's diverticulitis.	Simple excision of diverticulum. Discharged well 2 weeks after operation. Histology suggests heterotopic gastric mucosa.
6	9	M	Severe recurrent attacks of melaena necessitating blood transfusion. Barium meal: N.A.D.	Bleeding ulcer of Meckel's diverticulum.	Bleeding ulcer of Meckel's diverticulum.	Simple excision of diverticulum. Discharged well 7 weeks after operation.
7	54	F	Lower abdominal pain and vomiting for 3 days. Rheumatic heart disease associated with fibrillation. On examination there was evidence of slight abdominal distension.	Intestinal obstruction.	Intestinal obstruction.	Patient died from toxæmia without any operative intervention. Necropsy showed gangrenous Meckel's diverticulum causing intestinal obstruction.
8	38	M	Colicky lower abdominal pain and vomiting.	Intestinal obstruction.	Meckel's diverticulitis causing intestinal obstruction.	Simple excision of diverticulum. As the diverticulum was kinking small intestine and causing marked obstruction, temporary ileostomy was performed. Discharged well about 7 weeks after operation.
9	10/12	M	Colicky abdominal pain and vomiting, associated with bleeding per rectum. T. 100° F. (37.8° C.). ? Mass felt in right hypochondrium.	Intussusception.	Intussusception caused by Meckel's diverticulum.	Simple excision of diverticulum. Discharged well 8 days after operation.
10	17	M	4 months' history of vague dyspepsia with recent severe attack of melaena requiring blood transfusion.	? Bleeding peptic ulcer of Meckel's diverticulum. ? Bleeding D.U.	Bleeding ulcer of Meckel's diverticulum.	Simple excision of Meckel's diverticulum. Histology showed heterotopic gastric mucosa. Discharged well 12 days after operation.
11	38	M	Intermittent mild abdominal pain for 9 days. Much more severe 24 hours before admission, associated with vomiting. Examination showed tenderness and guarding in right iliac fossa.	Acute appendicitis.	Gangrenous Meckel's diverticulitis.	Excision of diverticulum, plus adjacent portion of small bowel. Discharged well about 4 weeks after operation.
12	10/12	M	Painless melaena for one day. Irritability, especially after feeds for a few days. No abnormality found on examination of abdomen.	? Intussusception. ? Bleeding ulcer of Meckel's diverticulum.	Bleeding ulcer of Meckel's diverticulum.	Excision of diverticulum. Discharged well 8 days after operation.
13	29	M	2 days' history of colicky mid-abdominal pain. Examination revealed tenderness and guarding in right iliac fossa. T. 102° F. (38.9° C.).	Acute appendicitis. ? Meckel's diverticulitis.	Meckel's diverticulitis.	Simple diverticulectomy. Discharged well 11 days after admission.
14	50	M	5 days' history of abdominal pain and vomiting. On examination no definite distension seen but obstructive sounds heard on auscultation.	Intestinal obstruction.	Meckel's diverticulum causing obstruction of small bowel.	Excision of diverticulum plus adjacent portion of small intestine.
15	33	F	20 years' history of pain 4-hour after meals with recent attacks of colicky abdominal pain. One attack of right-sided abdominal pain diagnosed as appendicitis; appendicectomy performed but appendix normal. Meckel's diverticulum was not looked for. Barium meal and gastroscopy negative. Occult blood positive on several occasions.	? Ulcer of Meckel's diverticulum.	Meckel's diverticulum with ulcer on adjacent portion of small bowel.	Excision of diverticulum plus portion of small intestine on each side. The ulcer in this case was in the ileum, 1 cm. proximal to stoma of Meckel's diverticulum. The ulcer had caused ring stricture of small intestine, producing marked intestinal obstruction.
16	45	M	2 days' history of generalized abdominal pain and vomiting; pain more marked in right iliac fossa on day of admission. On examination marked tenderness and guarding in right iliac fossa.	Acute appendicitis.	Gangrenous Meckel's diverticulitis and sub-acute appendicitis.	Simple excision of diverticulum. The diverticulum was divided into two portions by a constriction in its wall, and the larger pouch contained a number of hard stones.
17	18	M	2 years' history of occasional dyspepsia. Recurrent attacks of fairly severe melaena extending over a period of 8 months. On examination tender to right of umbilicus. Barium meal normal.	? Meckel's diverticulum. ? Duodenal ulcer.	Meckel's diverticulum.	Simple excision of diverticulum. Post-operative progress satisfactory.
18	63	F	24 hours' history of acute abdominal pain. Pulse 150, T. 101° F. (38.3° C.). On examination tenderness and rigidity of whole lower abdomen, more marked to right of midline.	? Perforated appendicitis. ? Perforated diverticulitis of colon.	Gangrenous Meckel's diverticulitis with peritonitis.	Simple excision of diverticulum, with satisfactory result.

culum. It is more often seen in infancy and childhood, and is the only complication of Meckel's diverticulum other than umbilical lesions which can be diagnosed pre-operatively. The cardinal symptoms and signs are: (a) history of massive intestinal haemorrhage, (b) an average age of from 10 to 15 years, and (c) abdominal pain. Usually the patient gives a history of previous massive intestinal haemorrhage followed by a period of months, or even years, before recurrence. The haemorrhage is usually massive, although in some cases there may be a history of small and recurrent melaenas. Other conditions giving rise to rectal bleeding are Henoch's purpura, bleeding peptic ulcer, rectal polyp, ruptured rectal varicosities, and early congenital intestinal telangiectasis. In adults, benign and malignant tumours of the gastro-intestinal tract must also be considered. With careful examination it is usually possible to eliminate most of the conditions mentioned. The bleeding gastric or duodenal ulcer may, however, cause difficulty in the diagnosis, because some cases of diverticular ulcer do have a definite pain-food relation (see Case 15). Regardless of other symptoms, a history of massive haemorrhage from the rectum followed by recovery and then recurrence of haemorrhage after the lapse of weeks or months is almost pathognomonic of peptic ulcer of Meckel's diverticulum.

3. *Intestinal Obstruction.*—Meckel's diverticulum may be the cause of intestinal obstruction. The fibrous band connecting the diverticulum to the parietes or other adjacent organs may act as an axis about which the bowel may rotate to form a volvulus. At other times the diverticulum itself may be the leading point of an intussusception, particularly in the broad-based diverticulum. There is no characteristic feature to distinguish it from small-bowel obstruction due to other causes, but this condition must be borne in mind when confronted with a case of intestinal obstruction in infants and children.

4. *Umbilical Fistula and Associated Lesions.*—Lesions of the umbilicus associated with incomplete obliteration of the omphalo-mesenteric duct also occur, and are relatively easy to diagnose.

5. *Neoplasms.*—Tumours, both benign and malignant, have also been reported in Meckel's diverticulum, but are of rare occurrence.

6. *Foreign Bodies.*—Calculi and various foreign bodies have been encountered, giving rise in some instances to inflammation, perforation, and obstruction (see Case 18).

Treatment

It is generally agreed that silent diverticula found incidentally at laparotomy require no special treatment. It is only when a complication supervenes that the surgical treatment becomes a matter of urgency. The detail of operative procedure used must of necessity vary with the findings in the individual case. When intestinal obstruction is found, it is usually due to either a band or an intussusception. The band must be divided and the intussusception should be reduced, and, provided the general condition of the patient is satisfactory and there is no gross distension of bowel, the diverticulum may be resected at the same time. The method of excision, however, varies with different surgeons; some advise excision with closure of the defect by two rows of sutures, or by the same technique as used for appendicectomy, while others believe in resecting the diverticulum plus a portion of adjacent bowel, with subsequent anastomosis. With the former method particular care must be taken to avoid undue narrowing of the lumen. Ladd and Gross (1941) recommend that clamps should be placed at an angle of 45 degrees to the long axis of the bowel to reduce the risk of this complication. In cases of perforation or haemorrhage from an ulcer there is the possibility of heterotopic gastric mucosa extending up to the adjacent portion of the bowel, and it is therefore important to include it in the resection.

Cases of umbilical fistula or adenoma require formal laparotomy, as these conditions are commonly associated

with incomplete obliteration of the omphalo-mesenteric duct, which should be remedied at the same time. In cases of diverticulitis with or without perforation, the general and local condition must be taken into account in deciding the advisability of resection of adjacent portions of the intestine. Diverticula which are sites of tumour formation should be excised, with a few inches of small intestine on each side, including a wedge of the mesentery.

The patients whose cases are reported in the Table were operated upon at Central Middlesex Hospital between 1936 and 1953. They illustrate well some of the more important complications of Meckel's diverticulum.

In seven of the cases the possibility of Meckel's diverticulum as the causative factor was considered, but in only three was the diagnosis made with some degree of confidence. The greater incidence of the condition in males in this series agrees with the findings generally recorded by other writers. There was one death in this series, giving a mortality of 5.5%. This occurred in a patient who was too ill for operation. Heterotopic gastric mucosa was found in two cases; some of the specimens were not submitted to histology, while in others there was no evidence of heterotopic tissue. However, without making several sections from each specimen, such tissue might readily be missed.

The complications of Meckel's diverticulum in childhood have been stressed by many writers, and, while such studies are entirely appropriate, the importance of these complications in adults must also be remembered. This is well shown in the Table, in which two-thirds of the cases were found in adults over the age of 21. In fact, in any acute abdominal emergency, unexplained bleeding from the gastro-intestinal tract, and vague intra-abdominal complaints the possibility of Meckel's diverticulum as the cause must be considered.

Summary and Conclusions

An account is given of the common complications of Meckel's diverticulum, together with a short note on treatment.

Eighteen cases, with one death, are reported and subjected to analysis.

The importance of Meckel's diverticulum as a cause of acute abdominal emergency, unexplained intestinal haemorrhage, or vague abdominal symptoms is stressed.

We wish to thank all members of the medical and surgical staff of the Central Middlesex Hospital, in particular Mr. T. G. J. James and Dr. F. Avery Jones, for their permission to publish these cases.

The annual report of Yale Medical Library for the year ending June 30, 1953, includes some interesting information on the relative use made of medical periodicals. The library receives 1,140 serial publications of all types, and a rearrangement in the reading-room made it necessary to reduce the number of journals housed there. An analysis was therefore made of the recorded use of these journals, and it was noticed that the "current use" of a journal appears to continue for about five years, with the second year after publication being the time of heaviest use. It is shown that the availability of such periodicals is greatly increased if binding is delayed for five years. As much use was made of the two most popular journals together as was made of the 158 least popular on the list combined. Forty journals accounted for nearly half of the total use made of periodicals.

EARLY RECURRENT ACUTE INTUSSUSCEPTION IN CHILDREN

BY

DAVID A. MACFARLANE, F.R.C.S.

Surgical Registrar, St. James's Hospital, London

AND

L. P. THOMAS, F.R.C.S.

Senior Surgical Registrar, Cardiff Royal Infirmary

Acute intussusception in children is not a common condition. Spence and Court (1950) traced every child with this condition in the City of Newcastle-upon-Tyne during a six-year period and found the incidence was 3.8 per 1,000 births, or one case per family practitioner during that time. Recurrence of acute intussusception in children can be expected even less often. Thorndike (1932) reported five cases but found only 75 others in the literature. Since then Killins and Clagett (1941) and Mastin (1942) have described one case each, but the number even with the four cases reported here remains small. The following cases show that a recurrence can occur in the immediate post-operative period, a fact which does not seem to have been emphasized before.

Case 1

A female child aged 7 months was admitted to Bridgend General Hospital on January 22, 1950. She was an only child, was breast-fed until weaning one month previously, and had been quite well until the previous evening, when she began to have attacks of severe abdominal pain which, the mother stated, made the child draw up her knees. There had been some vomiting of food shortly after its ingestion. The bowels had been regular, but no action had occurred since the previous day. There were no urinary symptoms. On examination the child was seen to be in good general condition, and well nourished, and showed no signs of dehydration. Examination of the abdomen was difficult, as the child had repeated attacks of colic. No tumour was felt on abdominal or rectal examination, but whilst the latter was being performed the child had a bowel action with streaks of bright blood and mucus. A presumptive diagnosis of intussusception was made and operation undertaken immediately.

First Operation.—Under general anaesthesia a lower right paramedian incision was made and an ileo-colic intussusception was found, the apex of which had reached the splenic flexure. This was easily reduced. Enlarged mesenteric glands were noted but no cause was found for the intussusception.

The post-operative course was uneventful until January 30, when the child became restless and was obviously in some pain. There was mild infection of the wound but no physical signs were elicited on abdominal examination. Rectal examination revealed a small quantity of foul-smelling soft faeces but no blood. There was some dehydration which warranted an intravenous transfusion of half-strength Hartmann's solution. Examination of the urine showed a moderate growth of coliform organisms. On the following day the abdomen was obviously distended and the bowel sounds were greatly increased and high pitched. A diagnosis of acute small-bowel obstruction was made and laparotomy undertaken.

Second Operation.—Under general anaesthesia a lower left paramedian incision was made and an ileo-ileal intussusception was found with distension of the proximal small intestine. The origin of this intussusception was proximal to the previous one, the distal bowel now appearing normal, and, except for the enlarged mesenteric glands previously

noted, no other abnormality was found. There was some superficial wound infection following the second operation which delayed convalescence, but the child was discharged in a month and was still well three years later.

Case 2

A female child aged 7 months was admitted to Bridgend General Hospital on May 11, 1950, with a history of repeated attacks of abdominal pain and vomiting for two days. She had also been passing blood and mucus per rectum for two days. Previously she had been a healthy child who was breast-fed until the age of 5 months, and had since then been fed on a proprietary milk food. On examination her general condition was good, she was having repeated attacks of abdominal colic, and a tumour was palpable in the left iliac fossa. On rectal examination a mass could be felt at the tip of the finger; it was continuous with the abdominal mass; there was blood on the examining finger; and a diagnosis of acute intussusception was made.

First Operation.—Under general anaesthesia a right paramedian incision was made. Two intussusceptions were found; an ileo-colic one originating just proximal to the caecum, and a colo-colic one in the left iliac fossa. The latter was antiperistaltic in the descending colon. The caecum, the ascending colon, and descending colon each had a long mesentery. The intussusceptions were reduced without difficulty.

The post-operative course was normal until May 15, when the child again had spasms of abdominal pain and vomited copiously. The abdomen was not distended, but the bowel sounds were high pitched and increased, and rectal examination revealed some blood and mucus. Recurrent acute intussusception was diagnosed and laparotomy undertaken immediately.

Second Operation.—A lower left paramedian incision was made and some free fluid found in the peritoneal cavity. An ileo-ileal intussusception 8 to 9 in. (20 to 22.5 cm.) in length was situated 2 ft. (60 cm.) from the ileo-caecal valve, the proximal small intestine being greatly dilated. The intussusception was reduced. No apparent cause for the recurrence was found. The bowel at the sites of the previous intussusceptions was normal. The convalescence was uneventful, the child being discharged in three weeks. There had been no further recurrence on follow-up (1953).

Case 3

A previously healthy male child aged 2½ years was admitted to St. James's Hospital, Balham, on January 21, 1951, with a history of recurrent attacks of abdominal colic and vomiting for the past 36 hours. The bowels had not been open for 24 hours and there were no urinary symptoms. On examination the child was pale and looked ill, but there was no gross dehydration. Some tenderness was present in the right iliac fossa but no tumour was palpable in the abdomen. On rectal examination there was some bloody discharge on the examining finger. A presumptive diagnosis of intussusception was made, and operation performed immediately.

First Operation.—A lower right paramedian incision was made under general anaesthesia and an ileo-ileal intussusception was found about 5 ft. (150 cm.) from the ligament of Treitz; it was reduced. No other abnormality or cause of the intussusception was found.

On January 24 vomiting of most feeds occurred, but no abdominal physical signs were found. Vomiting persisted, and on January 26 some signs of dehydration were apparent and a radiograph of the abdomen showed dilated loops of bowel in the upper abdomen with fluid levels. Laparotomy was immediately undertaken.

Second Operation.—Under general anaesthesia the previous wound was reopened and about 18 in. (45 cm.) from the ileo-caecal valve an ileo-ileal intussusception was found and reduced. A second intussusception about 8 ft. (240 cm.)

from the ileo-caecal valve was also reduced. The cause of the intussusceptions could not be found, and the site of the previous intussusception was normal. The child made an uneventful recovery and was discharged home on February 12.

Case 4

A female child aged 6 months was admitted to Llandough Hospital on October 29, 1952, with a history of vomiting after each feed two weeks earlier; this had become less, and four days before admission the child had had attacks of screaming and drawing up of the legs. She had vomited green fluid and had been constipated for two days, but had passed clots of blood per rectum on the day of admission; only small amounts of urine had been passed. On examination the child showed signs of severe dehydration. A large mass 3 in. (7.5 cm.) in length was palpable in the left iliac fossa, the apex of an intussusception was palpable per rectum, and there was blood on the examining finger. A diagnosis of acute intussusception was made.

First Operation.—The abdomen was opened through a lower right paramedian incision and an ileo-colic intussusception was found, extending to the pelvic colon. It was easily reduced.

On November 2 a loose green stool was passed. On November 4 the child vomited green material, the stool was relaxed and contained mucus. The abdomen was distended and tympanitic; bowel sounds were present. A radiograph of the abdomen showed distension of the small intestine. Treatment by intravenous fluids and gastric suction was begun, but as the condition did not improve laparotomy was undertaken on November 6.

Second Operation.—An ileo-ileal intussusception was found, 10 in. (25 cm.) from the ileo-caecal valve. There was no obvious cause for the intussusception. Convalescence was uneventful, the child being discharged on November 17.

The child was again admitted to the Cardiff Royal Infirmary on February 1, 1953, with a history of sudden onset of screaming and the passage of bright red blood per rectum on one occasion, but no vomiting. On examination the general condition was found to be good, no abnormality was noted in the abdomen, and a hard faecal mass was palpated in the rectum. Plain radiography of the abdomen showed no abnormality. On the following day the bowels opened normally, the child was discharged, and was well on follow-up on March 16, 1953.

Discussion

Killins and Clagett (1941) reported a case of recurrent intussusception at the Mayo Clinic and believed the condition to be rare. They further stated that "the patient, by undergoing two successful operations for intussusception, has become something of a surgical curiosity." Thorndike (1932), in searching the records of the Children's Hospital, Boston, found that 405 cases of acute intussusception in children had been admitted between 1869 and 1932, and of these only five had had post-operative recurrences, which is a ratio of about one in 80. As intussusception itself is not uncommon, this means that a small but nevertheless important number may go on to recurrence. Mastin (1942) reported a case in which three separate intussusceptions took place within twelve months.

The period of time between the initial attack and the recurrence varies considerably. In Thorndike's series the average time was five months and in all his cases the patient had left hospital. Arntzen and Helsted (1929) reported the longest interval between the initial attack and recurrence of eight years, whilst Cohen (1921) reported a case occurring 30 hours after operation. The cases reported above recurred at eight, four, five, and six days respectively after operation, and come into some of the earliest groups recorded.

The cause of acute intussusception when there is no underlying disease such as a tumour or Meckel's diverticu-

lum is still unsettled and theories involving neuromuscular dysfunction and enlarged Peyer's patches still remain unproved. It is therefore not surprising that there is no satisfactory theory for the recurrence of acute intussusception. Mastin (1942) stated that in more than half the cases of acute intussusception the caecum was found to be mobile, and that he anchored the latter in the right iliac fossa. This caecal mobility was present in Case 2, and the long mesentery in both ascending and descending colon may well have been an aetiological factor in the causation of the original intussusception, but it does not explain the recurrence, which was ileo-ileal in origin. In Cases 1, 3, and 4 there was no mobility of the caecum.

Conclusion

Recurrent acute intussusception in children, although rare, is a condition to be borne in mind even in the early post-operative days, and careful observation of these small patients is recommended so that laparotomy may be undertaken early in this condition. The diagnosis is easier to make when there is a longer interval and the patient has been discharged from hospital, but in the post-operative period it may easily be overlooked and an incorrect diagnosis made because the child has already had an intussusception. We wish to draw attention to this possibility of early post-operative recurrence so that treatment may be undertaken. Immediate operation is the form of treatment recommended, and, as imbalance very readily occurs, attention should be paid to the fluid requirements of the child, intravenous infusion being carried out if necessary. If there is a mobile caecum the anchoring of this is suggested as a measure that may prevent further recurrence, but if no such mobility exists no further treatment other than the reduction of the intussusception can be advised until the aetiology of the condition is more fully understood.

Summary

Four cases of early recurrent acute intussusception in children treated successfully are reported.

The rarity and importance of the condition are shown.

The importance of early diagnosis, based on the clinical state and radiological findings, is emphasized.

The treatment is operative, with reduction of the intussusception.

We would like to express our thanks to Dr. Jeffrey W. Jones for permission to publish Cases 1 and 2, to Mr. Norman C. Tanner for Case 3, and Professor A. G. Watkins and Mr. D. B. E. Foster for Case 4; to Mr. F. J. Hedden who performed the original operation in Case 1, to Mr. D. H. Teasdale in Case 3, and Mr. H. Millard in Case 4. Our thanks are also due to Mr. N. C. Tanner and Mr. A. M. Desmond for their helpful criticism of this paper.

At Harrow trust funds of about £20,000 of the former district nursing association are to be used to establish a physiotherapy service for residents confined to their homes. Treatment will be restricted to the less well off, who will pay varying charges according to their means or receive it free if in needy circumstances. The diagnosis and prescription of the family doctor will be sufficient for the physiotherapist to proceed with treatment. It is expected that local private physiotherapists will be willing to undertake the service, but if that is not possible a van, or vans, equipped with apparatus and in charge of a driver-physiotherapist will be used.

CRANIOSTENOSIS WITH FAMILIAL VITAMIN-D-RESISTANT RICKETS

BY

E. N. COLEMAN, M.B., Ch.B.

Formerly Medical Registrar, City Hospital, Nottingham

AND

J. B. FOOTE, M.D.

Consultant Chemical Pathologist, City Hospital, Nottingham

The syndrome of rickets resistant to normal therapeutic doses of vitamin D but amenable to treatment with massive doses (up to 1,500,000 i.u. daily) was first described by Albright, Butler, and Bloomberg (1937). Since then the literature has become extensive, and it is now recognized that the condition is by no means rare. Holt (1950), Scott (1951), and Pedersen and McCarroll (1951) give good accounts of it; the latter, in the course of an account of 25 cases, point out the strongly familial nature of the disease. Albright *et al.* established by metabolic studies that there is a resistance to normal doses of vitamin D not attributable to malabsorption of the vitamin; and Robertson, Harris, and McCune (1942) attribute the complaint to

deficiency of an enzyme, of which vitamin D is said to be the prosthetic group, normally responsible for absorption of phosphate by the gut and its retention by the kidney. Freeman and Dunskey (1950), however, failed to get a restoration of normal serum phosphate despite successful therapy, and they question whether vitamin-D treatment corrects the metabolic defect.

FIG. 1.—The patient aged 6½ (right), with his brother aged 5½.

FIG. 2.—Active rickets (aged 3).

FIG. 3.—Improvement (aged 6½).

The deformities occurring in vitamin-D-resistant rickets are similar to those of classical rickets; indeed, there is no reason to suppose that the mechanism of deformity is in any way different in the two conditions. In one respect, however, there appears to be a difference—that in the familial resistant variety craniostenosis occasionally occurs. This has been stated only once in the literature, by Imerslund (1951), who describes a boy with typical vitamin-D-resistant rickets whose mother has old rachitic deformities. This child has a considerable degree of scaphocephaly following on premature fusion of the sagittal suture, and necessitating craniotomy for the relief of increased intracranial pressure.

This is not the only occasion on which scaphocephaly has been reported, for it is evident in an illustration of one of the cases of Albright *et al.*, and Pedersen and McCarroll mention the deformity while attributing it to rickets. In addition, Scott comments on the existence, in some cases, of frontal bossing with increased antero-posterior skull diameter and decreased transverse measurement. None of these authors, however, make mention of craniostenosis due to premature fusion of the sagittal suture, which clearly occurred in Imerslund's patient, whose mother also showed a small degree of scaphocephaly. No attempt has been made to explain this association of conditions, the one manifested as delay in ossification, the other by its premature occurrence. We regard this association as unusual enough to warrant the following description of a second case showing both phenomena.

Case Report

A boy aged 6 was first diagnosed as suffering from classical rickets when 2-3 years old. He is the eldest of three, the third child having died of meningitis in infancy. Fig. 1 shows the patient with his younger brother. All three were born by caesarean section, as the mother has old rickets with a contracted pelvis and genu valgum. She has no obvious biochemical abnormality apart from the rather low figure of 1.7 mg. of phosphorus per 100 ml. for her plasma inorganic phosphate. She has not got scaphocephaly. No relevant family history was obtained, as the family is not particularly "clannish" and little is known of some relatives. The patient had a normal diet as an infant and an adequate supplement of national cod-liver oil—2 dr. (7 ml.) daily from 1 year onwards. Despite this he developed frank rickets when 2 years old. A photograph (too "grainy" for repro-

duction) at 20 months shows him walking normally, but with the skull deformity already apparent. At 3 years he had active rickets (Fig. 2). He was given routine anti-rachitic treatment (sunlight and fish-liver oils). When first seen by us in August, 1952, at 6½ years, his wrists were as shown in Fig. 3. His skull deformity is shown in Figs. 4 and 5.

Biochemical Investigations (in each case the mean of two or more estimates is given).—Serum calcium, 10.2 mg. per 100 ml.; plasma inorganic phosphate, 2 mg. of phosphorus per 100 ml.; alkaline phosphatase, 31 King-Armstrong units; blood urea, 26 mg. per 100 ml.; urea-clearance test (Van Slyke), 120% of average normal; urine, N.A.D. on numerous occasions. In addition the following were found on one occasion each: plasma chloride, 100 mEq per litre; alkali reserve, 27 mEq per litre; fasting blood sugar, 88 mg. per 100 ml.; faecal fat, 15.7 g. per 100 g. dried faeces (unsplit, 1.4 g.); three-day fat balance, absorption 94%.

After treatment with 50,000 i.u. of vitamin D daily by mouth, starting in early September, 1952, the serum calcium rose slightly to 11.2 mg. and the plasma inorganic phosphate rose progressively to 2.7 mg. after three weeks and to 4.3 mg. in six weeks, but fell to 2.4 mg. after 25 weeks of the same treatment. The alkaline phosphatase did not vary significantly over this period. The only definite biochemical abnormalities were the low plasma inorganic phosphate and the

FIG. 4.—The patient aged 6½.

slightly raised phosphatase. The former responded temporarily to the relatively small dose of vitamin D. Renal function remained normal throughout.

We are indebted to Dr. C. H. Wood, for the following report: "November, 1948:—Generalized decalcification with bowing of long bones; widening of the space between

FIG. 5.—Skull (aged 6½).

epiphyses and metaphyses; saucer-shaped and irregular metaphyses; these changes are more advanced in the legs. Skull: marked scaphocephaly with closure of the sagittal suture. August, 1952:—Appreciable improvement since earlier films, although not healed February, 1953:—Improvement maintained, but still not healed; x-ray films of patient's mother showed typical changes of healed rickets but no scaphocephaly."

There seemed to be little doubt of the diagnosis of vitamin-D-resistant rickets, and more vigorous therapy was instituted. In addition he has well-marked craniostenosis from premature fusion of his sagittal suture, a condition only once previously described in association with resistant rickets.

Summary

The second reported case of craniostenosis associated with vitamin-D-resistant rickets is presented together with evidence to suggest that the association of these conditions may have occurred previously and been mistaken for a purely rachitic phenomenon.

We are indebted to Dr. J. M. Macfie for permission to publish this case; to Dr. C. H. Wood for the x-ray films; and to the department of clinical photography, General Hospital, Nottingham, for the other illustrations.

ANAESTHESIA IN HOSPITAL BREECH DELIVERY

BY

R. G. LAW, M.D., M.R.C.O.G.

Assistant to the Obstetric Unit, University College Hospital Medical School, London

AND

SHILA G. RANSOM, M.R.C.S., L.R.C.P., D.A.

Anaesthetist to the Obstetric Hospital, University College Hospital, London

For practical purposes an infant may be delivered by the breech in one of two very different ways: an assisted breech delivery or breech extraction. The two essential features of the former type of delivery are that labour should be left to the natural forces so far as possible and that any intervention should imitate the normal mechanism of breech delivery. In practice this implies that assistance is confined to the birth of the arms and, more especially, of the head. In contradistinction to an assisted breech delivery, delivery in a breech extraction is entirely operative, the maternal powers playing no part. In most cases intervention is undertaken before the breech has started to distend the vulva, the legs being brought down and delivery completed by a combination of traction and gentle fundal pressure.

In the absence of definite indications for early delivery, choice of methods is dictated by consideration of the foetal hazards. These have been shown to be due to two factors—namely, trauma and anoxia, of which the former is by far the more

common. Although trauma may at times be due to disproportion, in the great majority of instances it may be directly ascribed to one or more of the following causes: undue manipulation of the foetus; manipulation carried out under difficulties; and uncontrolled delivery of the after-coming head. Ideally, therefore, an assisted breech delivery should always be aimed at, since it demands the minimum of intervention. Where, however, indications arise for a breech extraction, it is important that the necessary manipulations—which often involve the passing of the whole hand into the uterine cavity—should be rendered as atraumatic as possible by ensuring good relaxation not only of the perineal floor but also of the uterus itself.

In addition, in both these methods of delivery the foetus may have to undergo a period of oxygen deprivation before delivery of the mouth.

From what has been said, it will be evident that the anaesthetic requirements in breech delivery will to a large extent depend upon the obstetric procedure decided on. Thus, in an assisted breech delivery there must be good oxygenation, restraint in inducing anaesthesia prematurely at a time when reliance should be placed upon the mother's expulsive powers, and rapid and smooth induction of anaesthesia when this is finally necessary. In a breech extraction, on the other hand, as well as good oxygenation there must be good relaxation both of the uterus and of the muscles of the perineal floor.

Analgesia.—No contraindication exists to pethidine, given in doses of 100–150 mg. (Nixon and Ransom, 1951) during the first stage of a breech delivery. Although that drug may depress the foetal respiratory centre to a slight extent, this is not necessarily a disadvantage, since respiratory efforts are best delayed until after the delivery of the mouth. Inhalation analgesia may be required at times to supplement the effect of pethidine. For the period preceding the birth of the breech a nitrous oxide and oxygen mixture (75% and 25%) has the advantage of providing good oxygenation.

Assisted Breech Delivery

Perineotomy

This operation is an essential procedure in all primiparae and in most multiparae. It should be deferred until the breech is widely distending the perineum, in order to reduce the amount of blood loss. The incision should be made under local infiltration analgesia, preferably 1% lignocaine hydrochloride ("xylocaine"). By this means, despite a temporary inhibition of the perineal reflex, strong expulsive efforts usually return within two to three minutes and result in the spontaneous delivery of the breech and trunk.

Some workers (Urnes and Timmerman, 1937; Greig, 1945; Trites, 1948) prefer pudendal block to the local infiltration described above, it being claimed that this procedure gives enough analgesia for the safe and painless completion of delivery. In experienced hands this is a valuable method for selected cases, but it possesses certain disadvantages: (1) If it is carried out too soon the resulting interference with the perineal reflex reduces the incidence of spontaneous delivery of the breech, and early intervention is correspondingly more common. (2) If, in order to derive the maximum benefit from the mother's expulsive efforts, analgesia is delayed until the breech is distending the perineum, it may be impossible to reach the ischial spines. The pudendal nerve must then be blocked at its exit from Alcock's canal at the ischial tuberosities. Since this point cannot at times be determined with accuracy, the resultant analgesia may be insufficient for the routine application of

forceps to the after-coming head, a procedure which we strongly advocate in all cases. (3) The extent of analgesia is insufficient for the safe and effective correction of some of the complications which may arise in the course of delivery.

Delivery of the Arms and Head

While in agreement with a policy of minimal intervention in assisted breech deliveries, we do, however, feel that if carried to excess it imposes a definite risk on the foetus. Occasions may arise, especially in relation to the delivery of the after-coming head, when, owing to unforeseen difficulties, simple measures do not suffice and a sudden need for anaesthesia arises often after loss of much valuable time. It is therefore our custom to allow spontaneous delivery to proceed only until the angles of the scapulae are visible. At this stage anaesthesia is induced, after which the arms are brought down by Løvset's manoeuvre and the forceps applied to the after-coming head.

As already stated, the chief anaesthetic requirements in this type of delivery are that induction should be smooth and swift while maintaining good oxygenation. Every experienced anaesthetist develops his own techniques with which he produces the best results, but for the benefit of those approaching this problem for the first time we feel that mention should be made of some disadvantages of two common methods of induction: (1) thiopentone, and (2) gas, oxygen, and ether. Thiopentone sodium (5% solution) has many advocates (Dippel *et al.*, 1947; Kerr and Moir, 1949; Cox, 1950; Calverley, 1950; Dewhurst, 1952), and at first sight would seem to fulfil all requirements. It is, however, widely felt that the danger of regurgitation and inhalation of stomach contents is a contraindication to the extended use of this substance. With gas, oxygen, and ether, induction is either too slow for the purpose under discussion, or, should induction be deliberately hastened, a period of reduced oxygen intake often results.

We would like to suggest that divinyl ether has properties which recommend it for use in assisted breech deliveries. It may be given in a variety of ways, our preference being to combine it in a closed circuit with oxygen and cyclopropane. After this, anaesthesia may be continued with any suitable mixture, such as gas, oxygen, and ether.

Some obstetricians (Allan, 1935; Rosenfeld, 1940; Cunningham, 1945) recommend that general anaesthesia be induced as soon as the perineum is distended by the breech. We do not, however, subscribe to this view, since the resultant interference with voluntary expulsive efforts substantially increases the frequency and extent of operative intervention. For the same reason low spinal or extradural anaesthesia (Urnes and Timmerman, 1937; Kerr and Moir, 1949) are unsatisfactory. In addition, in the case of spinal anaesthesia there is a slight but definite risk associated with the injection of foreign material into the cerebrospinal fluid.

Neither of the two methods referred to above outweighs in advantages a general anaesthetic withheld until the correct moment—a procedure which is easy to perfect, given the proper degree of co-operation between anaesthetist and obstetrician.

Breech Extraction

In this type of breech delivery the need for a rapid induction is no longer present, while good relaxation of the uterus and of the muscles of the perineal floor is essential if trauma is to be avoided (Potter, 1922; Piper and Bachman, 1929; Greig, 1945; Gustafson, 1949). This in effect means that a sufficiently deep ether anaesthesia must be given, since the use of the only other uterine relaxant—namely, chloroform—is unjustifiable in hospital practice. It might be thought that the degree of foetal narcosis thus produced would be hazardous, but in any event this is preferable to trauma, and in practice seldom gives rise to anxiety.

Drugs such as thiopentone, cyclopropane, and curare are on the whole unsuited to the procedure under consideration, since, although they may or may not produce a rise of uterine tone, they certainly do not relax the uterus.

On the other hand, a spinal or extradural anaesthetic given to a height sufficient to abolish uterine sensation does cause a considerably "heightened reactivity" to stimuli of the uterus (Malpas, 1944; Lull and Hingson, 1948). As a result not only is the risk of trauma both to the foetus and to the mother greatly increased, but, in addition, foetal anoxia may arise owing to placental ischaemia. This form of anaesthesia is therefore entirely contraindicated in breech extraction.

Considerations with Regard to the Third Stage.—A possible argument against the use of ether in breech extraction is that the resultant lowering of uterine tone might predispose to serious post-partum haemorrhage. It is probable, however, that this complication has been over-emphasized in the past; certainly in our experience it has rarely been observed. This may be due to the fact that it has always been our policy to give 0.5 mg. of ergometrine intravenously following the birth of the head. At all events, the danger of a contracted uterus during breech extraction would seem considerably to outweigh that of a relaxed uterus after delivery has been completed.

Summary

Assisted breech delivery and breech extraction are two very distinct obstetric operations requiring different anaesthetic techniques.

The special considerations involved in anaesthesia for such deliveries have been reviewed.

In assisted breech delivery it is recommended that a perineotomy be performed under local infiltration analgesia, inhalation anaesthesia being limited to the delivery of the arms and head.

In breech extraction a high degree of uterine relaxation is necessary. For this reason a deep ether anaesthetic is the only one which may justifiably be employed.

Spinal or extradural anaesthetics are not the most suitable for assisted breech deliveries and are absolutely contraindicated in breech extraction.

Close co-operation between obstetrician and anaesthetist is essential if the best results are to be obtained in this branch of obstetrics.

Conservancy Systems at Collieries is the title of a medical memorandum recently issued by the National Coal Board. It is intended as a general guide for colliery managers. After stating the legal requirements, the memorandum describes various installations for use above or below ground. The standard of sanitation in mines is, not surprisingly, below that in other industries. Both health and morale would benefit if it were improved.

DANGERS OF POLYPHARMACEUTICAL PREPARATIONS CONTAINING FOLIC ACID

BY

CLIFTON P. LOWTHER, M.B., Ch.B., F.R.F.P.S.

Registrar, Western Infirmary, Glasgow

The inclusion of folic acid in proprietary preparations was deplored by Davidson (1948), but, as can be seen from the examination of recent advertising matter, the practice continues. The purpose of this note is to draw attention to the difficulties which may arise when anti-anaemia treatment is undertaken without proper investigation of the case and with preparations of the "blunderbuss" type.

Case Report

A 46-year-old housewife first complained of stiffness of her knees in October, 1952. Treatment with short-wave diathermy was given after she had attended orthopaedic and medical dispensaries. In January, 1953, she developed a short febrile illness associated with vomiting, anorexia, and loss of weight, from which she did not fully recover. In February, at another medical dispensary, no abnormality was found on examination, with the exception of a haemoglobin level of 48% (Sahli). A course of iron was recommended, and the patient was requested to attend for further investigations. Her family doctor gave her a proprietary preparation of iron, and her general condition improved greatly. Her appetite returned to normal and her weight increased, but the stiffness of her legs began to worsen rapidly. She did not return for investigation, but in May, 1953, she fell and was admitted to hospital for treatment of an infected haematoma. After 10 days in bed she was found to be unable to rise or walk, and was transferred to a medical ward for investigation.

On examination the patient was found to have a spastic paraplegia with great muscular weakness, bilateral extensor plantar responses, and complete loss of posterior column sensation in both legs. There was no upset of the function of bladder or bowels. Histamine-fast achlorhydria was demonstrated. Blood examination showed: haemoglobin, 12.3 g.; red cells, 3,600,000 per c.mm.; white cells, 8,000 per c.mm.; P.C.V., 38%; M.C.V., 105.6 μ^3 ; M.C.H.C., 32.1%. Sternal marrow biopsy showed appearances suggesting a partially treated anaemia resulting from deficiency of the haemopoietic principle. Lumbar puncture and radio-scopsy of the lumbar spine showed no abnormality.

A diagnosis of subacute combined degeneration of the cord was made, and treatment with "anahaemin" and vitamin B₁₂ was started (4 ml. of anahaemin on alternate days, and 100 μ g. of "cytamen" daily). Haematological and neurological improvement was rapid, and five weeks later the patient was walking well enough to continue treatment as an out-patient. When last seen she had only very slight ataxia, and examination of the blood and marrow showed normal appearances.

It was found that she had been treated originally with capsules containing iron, vitamin B, extract of raw liver, and folic acid. The amount of folic acid present in each capsule was 1 mg., and she had consumed 3 mg. of folic acid daily for 38 days.

Discussion

The literature on the results of treatment of cases of Addisonian anaemia with folic acid was reviewed by Davidson (1948) and by Israëls and Wilkinson (1949). These authors concluded that folic acid had no place in the treatment of pernicious anaemia. The haematological state not

infrequently remains unsatisfactory (Wilkinson, 1948), and the neurological state is not prevented from deteriorating (Davidson, 1948; Israëls and Wilkinson, 1949). Since then Fuld (1950) and Schwartz *et al.* (1950) have reported poor haematological and neurological results with folic acid therapy. The latter reported 72 cases followed for three and a half years and treated with 5 mg. of folic acid daily: 23 cases developed cord degeneration, in 23 the red cell count and marrow showed relapse, and in 9 cases both occurred. Subacute combined degeneration of the cord has been reported as occurring with doses varying between 5 and 25 mg. daily. In the present case 3 mg. daily was enough to produce a considerable improvement in the blood condition, but did not prevent the rapid development of paraplegia.

In at least two large series folic acid has been given to normal subjects and to cases of anaemia other than pernicious anaemia (Weissberg *et al.*, 1950; Harvey *et al.*, 1950). There was no subsequent development of cord degeneration, and it is thus unlikely that folic acid has any direct toxic effect. The following reports of authors who have had the opportunity of observing large numbers of cases of Addisonian anaemia contain statements which suggest that they have not rejected the possibility that folic acid actually precipitates cord disease. Thus the explosive character of the onset of cord disease, as well as its rapid progression, have been more often noted after folic acid therapy, and have been contrasted with the more insidious disease previously described (Davidson, 1948; Wilkinson, 1948; Ross *et al.*, 1948; Jacobson *et al.*, 1948). The present case also showed these more acute features.

The experience of Conley and Krevans (1951) is interesting, being more akin to the present case. These authors saw 10 patients in 1950 who were suffering from undiagnosed Addisonian anaemia. Five had only neurological symptoms with no associated anaemia, and on this account various diagnoses, such as disseminated sclerosis and syphilis, were entertained. It was established that four out of the five had been given multivitamin preparations containing folic acid. The patients were not aware that they had received anti-anaemic treatment, and in two cases the physician prescribing the capsules was unaware that they contained folic acid. In all cases an excellent response to vitamin B₁₂ was obtained. It was therefore suggested that in all doubtful cases a marked improvement in nervous system signs and symptoms following the injection of vitamin B₁₂ provides strong support for a diagnosis of Addisonian anaemia.

The arguments against the inclusion of folic acid in polypharmaceutical preparations may be summed up as follows: (1) Folic acid temporarily improves the blood picture, and may restore it to normal. The physician is then faced with a disease of the central nervous system, the misdiagnosis of which is likely, as subacute combined degeneration of the cord without anaemia is very uncommon. (2) The relief of the general symptoms of pernicious anaemia often reassures the patient and the doctor, and masks the deterioration of the nervous system. (3) Folic acid deficiency occurs infrequently, and there is no need for this substance in multivitamin or iron preparations. (4) The question whether folic acid actually precipitates cord degeneration is still uncertain.

Summary

A case is described in which a proprietary preparation of iron containing folic acid was given to a patient with an anaemia which had not been accurately diagnosed. In fact, the patient was suffering from Addisonian anaemia. Deceptive improvement in the blood condition occurred, but was accompanied by the rapid development of combined degeneration of the cord.

My thanks are due to Dr. J. A. W. McCluskie, in whose ward the patient was treated; to Dr. S. Lazarus for encouragement and helpful suggestions; and to Miss N. Johnston for secretarial aid.

Medical Memoranda

Carbon Dioxide Retention Simulating Curarization

Numerous reports have appeared of persistent curarization after the use of one or other of the relaxants; the following case therefore seems worthy of description.

CASE REPORT

The patient, a child aged 6, weighing 42 lb. (19 kg.), had undergone a laparotomy for the removal of a polyp from the sigmoid colon.

The premedication consisted of pentobarbitone sodium, 2 gr. (0.13 g.), and atropine, 1/100 gr. (0.65 mg.), following which the child arrived at the theatre asleep. Anaesthesia was maintained with nitrous oxide and oxygen and a trace of ether, a size 3 endotracheal tube having been inserted. The flow was at the rate of 3 litres of nitrous oxide and 2 litres of oxygen a minute. No absorber was incorporated. Just before opening the peritoneum 2 mg. of decamethonium iodide was given intravenously. After a brief period of apnoea respiration returned and was accompanied by a satisfactory degree of relaxation. (The respiration was assisted throughout.) Some 15 minutes after the first dose a second injection of 2 mg. of decamethonium iodide was given. This time the apnoea persisted for 15 minutes, and at the time of the skin closure only minimal diaphragmatic respiration was present.

After an interval of five minutes, respiratory activity, although minimal, appeared just sufficient to keep the child a good colour, provided pure oxygen was given through a T-piece connected to the endotracheal tube. The child was therefore returned to bed with a flow of 5 litres of oxygen a minute passing through the T-piece, and inflation by means of a bag was carried out for one-minute periods every five minutes.

Respiratory activity did not increase, although the child at all times remained a very good colour, there being no evidence of suboxygenation. After two hours it was noted that, if anything, respiratory activity was decreasing again, but that there was some improvement after each period of ventilation. There was no response at all to an intravenous dose of 2 ml. of nikethamide. The delay in recovery of respiration had until this time been attributed to a residual effect of the decamethonium iodide; but it was noted that such respiratory effort as was present was not marked by any urgency, neither was it accompanied by a tracheal tug, both of which features are usually present in cases of residual curarization.

Three hours after the injection of the second dose of decamethonium iodide, on the supposition that carbon dioxide accumulation might be the underlying cause of the respiratory depression, the child was vigorously hyperventilated through an absorber for a period of three minutes. The absorber very rapidly became intensely hot, indicating considerable elimination of carbon dioxide. Promptly following this hyperventilation the child's respiration was noted

to be greatly increased in depth, and therefore a further three-minute period of hyperventilation through the canister was undertaken. At the end of this the child's respiration was noted to be normal in depth and character. The endotracheal tube was therefore removed, and an airway was substituted. No further oxygen administration was required.

COMMENT

The remarkable features of this case appear to be: (1) Persistent respiratory paralysis, apparently due to the residual effect of a relaxant, seems to have been caused by carbon dioxide retention. Possibly an increased carbon dioxide tension is capable of producing myoneural block. (2) The child did not recover consciousness for some four hours, although recovery would normally have been anticipated within one hour after operation; it therefore seems likely that the degree of carbon dioxide retention was sufficient to produce narcosis.

It is unfortunate that carbon dioxide estimations were not possible in this case. The difficulty of the treatment of prolonged respiratory depression is illustrated. Such depression has been attributed to hyperventilation; it now appears that underventilation also may perpetuate respiratory depression. It is possible that an electronic apparatus may in future be devised which, by means of an electrode inserted into the tissues, may give continuous measurement either of pH or of carbon dioxide concentration. Such an instrument would obviously be of the greatest value in cases requiring controlled ventilation.

A Possible Method of Pre-operative Anticipation of Thrombo-Embolic Episodes

In recent years major advances have been made in the preparation of patients for the stress and eventualities of surgical procedures, and many previously fatal secondary factors can now be evaluated and corrected pre-operatively to prevent a fatal outcome. Not so post-operative thrombo-embolic episodes: the majority still occur apparently unexpectedly and in spite of increasing awareness of the condition and diligent attempts to anticipate its occurrence.

Ochsner has shown that approximately 50% of pulmonary emboli occur in patients without recognizable preceding peripheral stigmata. Sulamaa and Pentti (1949) reported 170 cases of thrombo-embolic disease, 20 being fatal pulmonary emboli: of the latter, 14 were not diagnosed or were not suspected before their occurrence. Felder (1949) reported 27 cases of pulmonary emboli; in 10 the chest and peripheral signs occurred simultaneously and in 11 cases the chest signs were the first indication. In 78% of his cases treatment began after the chest signs were manifest.

Active prophylactic therapy, excluding routine use of anticoagulants, has not lowered the incidence; 0.57% of patients are liable to pulmonary infarction and 0.22% to fatal pulmonary emboli. A perusal of gastrectomy fatalities shows that about 20% are due to pulmonary emboli.

It is thus the more apparent that pre-operative diagnosis of the thrombophilic type of patient would present a major advance in the selection of those patients who require post-operative anticoagulant therapy. At present it would be unwise to adopt routine anticoagulant treatment owing to its cost, its sequelae, and the labour involved.

It seems reasonable to postulate that clotting *per se* is a normal physiological accompaniment to wound-healing, and that in association with any trauma, definitive or accidental, there is a general and a local mechanism which ensures clotting at the breaches in vascular continuity; likewise, this process is graded in degree to meet the local requirement, and its duration should be proportional to the initial lesion. This effector mechanism has already been discussed in detail by many authors, and no useful purpose will be served by repeating their observations.

Previous attempts have been made to prevent patients from developing thrombo-embolic episodes—the construction of a coagulation graph post-operatively and detection of fibrinogen B in the plasma (Cummine and Lyons, 1948). Ochsner also propounded the theory of a lowered anti-thrombin titre, and advocated the use of alpha-tocopherol and intravenous injections of calcium to raise a lowered titre. No case selection was made, and such a method, even if it proved to be effective, would be costly and, like coagulation-graph charting, could be conducted only in well-staffed institutions. If it could be foreseen which patients were liable to thrombo-embolic phenomena, active measures could be taken with this smaller group.

It is possible that an increased post-operative clotting tendency is a function of the general response of the body to the strain applied to it by a surgical operation and that the degree of clotting is an indication of adrenal cortical function. During recent years there have been increasing records of spontaneous thromboses and embolic phenomena occurring during cortisone therapy. Cosgriff (1951) recorded the increased coagulability of the blood during treatment and an unexpectedly high incidence of thrombo-embolic complications. The patient liable to post-operative thrombotic episodes may thus respond abnormally to stress or prolongation of the post-operative state.

Godlowski (1951) demonstrated that changes in the eosinophil count could be modified by the administration of heparin, and this suggested that such changes may bear some relation to blood coagulability. Post-operative eosinophil counts were charted on several cases, but the results were not uniform.

An effective reproduction of stress to the body can be secured by the adrenaline test, as used extensively in America to ascertain the resistance to stress of a patient about to undergo a given major operation.

Adrenaline hydrochloride, 0.3 mg., was given to pre-operative patients, and their clotting-times and eosinophil counts were recorded half-hourly during the next four hours. It was found that varying results were obtained. These same patients had coagulation graphs taken post-operatively and were examined clinically for thrombotic stigmata. In all, about 50 patients have been examined and a certain pattern is developing.

The majority of those patients examined showed a rapid shortening of their coagulation time during the first hour and then a fairly quick return to normal time inside the four-hour period of examination. Six of them showed a shortened coagulation time, but it persisted at a low level and was still present after six hours. They also were followed up post-operatively, and all six developed thrombotic episodes, two of a major nature and one fatal. The other patients demonstrated shortening of their coagulation time for four days and then elongation to normal.

All patients were treated identically: pre-operative and post-operative physiotherapy, early rising, and routine examination for tender calf muscles and calf-muscle spasms. The duration of stay on the operating table was almost identical, and the operative procedures were of a similar magnitude and location.

Application.—Given forewarning of subjects who are likely to develop post-operative thrombotic episodes, it is possible to provide selective treatment with anticoagulants 24–48 hours after operation; and, in the event of the discovery of a more innocuous replacement therapy on the lines of the antithrombin hypothesis, treatment could be given post-operatively to those subjects showing a suggestive adrenaline response and liable to undergo major surgery.

Reviews

DISEASES OF MUSCLE

Diseases of Muscle: A Study in Pathology. By Raymond D. Adams, M.A., M.D., D. Denny-Brown, M.D., D.Phil., F.R.C.P., and Carl M. Pearson, M.D. (Pp. 556; 347 illustrations. £5 18s. 6d.) London: Cassell and Company. 1953.

It is quite surprising that before this monograph was written there was no comprehensive and critical account of the diseases of skeletal muscle in the medical, surgical, or neurological literature of this country or America. The deficiency becomes all the more remarkable when, after even a brief perusal of this almost encyclopaedic volume, one appreciates how fascinating the study of skeletal muscle can be made when its development, structure, and function are skilfully related to its behaviour in the wide variety of diseases and injuries in which it participates.

The monograph is divided into two parts. The first is on the nature of skeletal muscle, including its embryology, anatomy, and histology, the chemistry and physiology of muscular contraction, and its general pathology. This last section must be unique in pathological literature. It deals with the large volume of widely scattered observations relating to the experimental pathology of muscle and is followed by a description of the basic pathology of human muscle.

This first part on anatomy, physiology, and general pathology serves as an introduction to the second. This covers the special pathology of myopathic diseases, and, though it is primarily concerned with pathology, informative and concise surveys of the clinical background clearly define the disease entities. There are several useful chapters in this well-illustrated section, which includes the pathology of the muscular dystrophies, myositis in general, the effects of ischaemia, spinal and neuronal atrophy, and toxic metabolic and endocrine disorders, and a remarkably informative chapter on disorders of excitability and contraction. The account of myasthenia gravis is outstanding.

Taken as a whole, the book contains a large number of reviews of subjects which have not yet reached the orthodox textbooks. Among these reviews are accounts of haemopoiesis in skeletal muscle, fibril structures of muscle by electron microscopy, the part played by venous occlusion in obliterative vascular disease, the remarkable resistance of muscle to several poisons and to irradiation, and its equally remarkable susceptibility to certain quinoline compounds, to Cocksackie virus, vitamin-E deficiency, and variations in the potassium content of the plasma.

Workers in many fields will be indebted to the authors for the thoroughness with which they have collected and skilfully analysed an enormous amount of relevant information. There are many references; the illustrations are of the highest standard, and a large proportion will be new to most general readers. The substantial contributions to the subject made by the authors themselves stamp their monograph with authority. This is certainly a book which every serious student of disease must acquire.

GEOFFREY HADFIELD.

INDUSTRIAL PHYSIOLOGY

Praktische Arbeitsphysiologie. By Professor Gunter Lehmann. (Pp. 352; 145 figures. M.33.) Stuttgart: Georg Thieme. 1953.

Analysis of human endeavour, and study of the conditions of human endurance and comfort, in peace and in war, at work or at sport, has often engaged the attention of physiologists. It is especially in the highly industrialized countries that the scientific study of the conditions of human labour is of high importance, for, in the author's opening words, "Working man is the most important and valuable factor in production." This book, by the distinguished director of a world-famous institute for the study of working conditions, is written not only for physiologists but for all who have the responsibility for the scientific organization and amelioration

of the conditions under which all sorts of work is done. It is of importance, therefore, for those with managerial responsibilities. Physiological theory as commonly understood has little place in it, for the outlook is rather that of an *ad hoc* approach to the many problems which affect conditions of effort, gainful or otherwise.

Problems discussed include those of the purely mechanical type, such as static and dynamic effort, co-ordination, fatigue, rest, accommodation, age and sex, climate, energetics, and the adaptation of machines to the individual. Most of the illustrative material is derived from studies in which the author or his colleagues have been engaged. As the recent inauguration and subsequent rapid growth of the Ergonomics Research Society in this country shows, these subjects now engage the attention of numerous experts, and there is already good progress to report. This book will set them a high standard to live up to, and will do much to disseminate useful information. Author and publishers are to be congratulated on having done a service in the interest of good industrial relations, as well as in the interests of science.

C. LOVATT EVANS.

PROBLEMS OF OLD AGE

Our Advancing Years: An Essay on Modern Problems of Old Age. By T. H. Howell, M.R.C.P.Ed. (Pp. 192; 28 illustrations. 16s.) London: Phoenix House Ltd. 1953.

This essay on the problems of old age is intended to encourage and stimulate our efforts in the medical care of the aged and to focus the attention of the public on their problems and needs. The author has had a wide and prolonged experience in the care of the aged and chronic sick, and this sensitively written book is welcomed as a record of his findings and his philosophy. The keynote here is the assistance of people in their search for happiness in old age. The author wisely points out that "happiness in elderly people is more closely associated with their psychological condition than their bodily health." This is a simple and profound truth applicable to all of us. The author suggests that in the aged, on the whole, cancer does not cause a great deal of pain. It is to be hoped that this is true, and, if indeed it is, the more widely this truth is known the happier many people will be. La Rochefoucauld is quoted: "Old age is a tyrant who forbids all the pleasures of youth, under pain of death"; to which some who are happily growing old might reply that they are well content.

Dr. Howell notes with approval that one London teaching hospital has broken with tradition and has established a geriatric unit. He would perform a valuable service if he could persuade all the other teaching hospitals to do likewise—perhaps this book may assist in their enlightenment.

There is but one small criticism. Dr. Howell with characteristic diffidence apologizes for mentioning by name some of his colleagues in geriatric practice. He is clearly right to discuss them and their work, but perhaps it would have been better to omit the adulatory adjectives. The superlatives, if any, are best left to after-dinner speakers, movers of votes of thanks, book reviewers, and writers of obituary notices.

This is a good book and worthy of careful study by everyone who is or may be concerned with the care of the aged and chronic sick—and that embraces everyone.

C. METCALFE BROWN.

INTRODUCTION TO OPHTHALMOLOGY

Parsons' Diseases of the Eye. By Sir Stewart Duke-Elder, K.C.V.O., Ph.D., D.Sc., LL.D., M.D., F.R.C.S., F.A.C.S. 12th edition. (Pp. 606; 22 coloured plates and 465 text figures. 42s.) London: J. and A. Churchill. 1954.

This is the best introduction to ophthalmology in English, and its value has been increased by changes made since the previous edition. Useful facts about modern therapy have been assembled in Chapter 10, and the new illustrations are excellent. Although rare conditions cannot all find room, many have been briefly surveyed. Moreover, Sir Stewart has helpfully described topics of recent interest, including

maternal rubella, toxoplasmosis, retrolental fibroplasia, and corneal grafting. How could so much new material be inserted without enlarging the book? Expert production gives the answer. The type is closer, and many paragraphs are set small. Publishers and printers deserve praise for arranging more words in fewer pages without sacrificing legibility, and the spacing of illustrations is vastly improved.

Certain treatments recommended for conjunctivitis and blepharitis are old-fashioned. Few would advise daily lid-painting with silver nitrate (p. 137) for gonococcal conjunctivitis. Bicarbonate of soda (p. 522) is inferior to hydrogen peroxide for removal of lid-crusts, and aniline dye painting is more effective than inunction of mercury in blepharitis. Haloes (p. 235) are not pathognomonic of glaucoma, and is it true that prophylactic iridectomy on a quiet eye (p. 241) "invariably results in a complete cessation of the disease"? Greeves's operation for ptosis, commended on p. 535, often produces gross hypertropia. On p. 473 Fig. 383 correctly indicates that the right superior rectus and left inferior oblique are the muscles chiefly concerned in looking up and to the right, but the text does not tally. Just below Fig. 383 the words *adducted* and *abducted* should be transposed; and in the next sentence the relevant muscles should be the *right* superior rectus and the *left* inferior oblique.

These defects are mentioned because the book's merits transcend them. Chapters 18 and 19, on fundus abnormality, abound in clinical wisdom, but young ophthalmologists should read the whole book six times to get acquainted with their subject. Thus will they learn to profit from larger books, of which Sir Stewart's six-volume system is easily the best.

J. H. DOGGART.

VITAMINS

The Vitamins in Medicine. By Franklin Bicknell, D.M., M.R.C.P., and Frederick Prescott, M.Sc., Ph.D., F.R.I.C., M.R.C.P. 3rd edition, revised and enlarged. (Pp. 784; 245 figures. 70s.) London: William Heinemann Medical Books, 1953.

The 11 years which have elapsed since the appearance of the first edition of this valuable book have seen great advances in our knowledge of many of the vitamins. In preparing its third edition Drs. Bicknell and Prescott have kept in step with this progress, both in describing new discoveries and in removing from their text references to work which has failed to stand the test of time. Their claim that their labours amounted to little short of complete rewriting can be accepted without question. Our gratitude and congratulations are due for the high standards which they have maintained, both in literary presentation and in the accuracy of their statements, in a volume which includes over 5,000 references to sources of information and nearly 250 illustrations.

As in previous editions, each vitamin has been considered under the headings of history, chemistry, sources, physiology, pharmacology, human requirements, deficiency diseases, methods used for detecting deficiency, and clinical applications. The emphasis is on human rather than on animal aspects, but experiments on animals which have a bearing on human vitamin requirements receive adequate mention. The chemistry and biochemistry of the vitamins and the details of their significance in medicine have seldom been so ably and clearly treated in the same book. As an aid to the diagnosis of vitamin deficiencies the clinician can refer to an excellent collection of photographs, which often show the appearance of the same patient before and after treatment with the appropriate vitamin.

The industry and understanding with which the authors have recorded the progress of research on every vitamin deserve high praise. Their obvious determination that nothing of importance should be missed out, however, may bring some risk of questionable material being included. The specialist in nutrition, and doubtless the authors themselves, will have no difficulty in distinguishing between established facts and claims still requiring confirmation, but the general practitioner may find it less easy to discriminate. Thus,

an excellent chapter on vitamin P, which is claimed to be necessary for the control of capillary fragility, does not perhaps sufficiently emphasize that many authorities would resist the classification of substances having this activity as vitamins. Similarly the cautious account of the possible significance of vitamin-E deficiency in the aetiology of human muscular dystrophy might give rise to some confusion between speculation and fact in a less cautious reader. However, we must congratulate the authors on producing a book which will serve the clinician well when he is confronted with patients in whom vitamin deficiency may be suspected.

T. MOORE.

ADRENOCORTICAL STEROIDS

Ciba Foundation Colloquia on Endocrinology, Volume VII: Synthesis and Metabolism of Adrenocortical Steroids. Consulting editor for this volume, W. Klyne, M.A., B.Sc., Ph.D. General editor, G. E. W. Wolstenholme, O.B.E., M.A., M.B., B.Ch., assisted by Margaret P. Cameron, M.A., A.B.L.S. (Pp. 297; 375 structural formulae and 27 illustrations. 30s.) London: J. and A. Churchill, 1953.

This volume follows the same general form as its predecessors in this series and maintains the same high standard. It reports the proceedings of two conferences.

The first, on synthesis of adrenocortical and related steroids, has a largely chemical emphasis. One section on substances present in cholesterol includes an account of lathosterol. Another describes briefly the synthesis of adrenal cortical hormones from ergosterol, and a further one on cortisone production from sarmenotogenin includes an account of the distribution of this raw material in Africa. Other sections describe the synthesis of 11-oxygenated steroids from ergosterol, the infra-red spectroscopy of tri-substituted steroidal olefins, the stereochemistry of C-20, and the effects of x rays on steroids.

In the second conference the emphasis is on biochemistry. In a review of adrenal perfusion work at the Worcester Foundation an account is given of attempts to produce C¹⁴ labelled compound F. A.C.T.H. is shown to increase formation of compounds B and F from C¹⁴-labelled cholesterol. Studies of the enzymes involved in the synthesis and breakdown of adrenal hormones have analysed specially the oxidation of 3 β hydroxy-steroids to $\alpha\beta$ unsaturated ketones. Separate enzyme systems for hydroxylation at 11, 17, and 21 positions seem to exist, and the substrate requirements of some of these are outlined. Species differences in adrenal secretion are reviewed and some data are given on the new adrenal hormone influencing salt excretion and now called electrocortin. A section on corticosteroid metabolism in man reveals that some 33 "corticoids" can be found in urine and about 40 in human adrenal gland perfusates. A polarographic method is offered for estimating some of these steroids in blood.

The field of steroid metabolism has already become so complex that few can follow all its developments. The present volume should help workers in one field to learn what fellow workers in neighbouring fields of steroid work are doing and thinking.

C. L. COPE.

Dr. Henry E. Sigerist's *Grosse Ärzte* first appeared in 1932, to be followed by an English translation in 1933. It contained biographical sketches of fifty-five of the most important men in medical history, ranging from Imhotep to Osler. Written against a background of knowledge acquired during a lifetime devoted to the study of the history of medicine, the book was recognized as a major contribution to medical biography. A new German edition has now been published (J. F. Lehmanns Verlag, Paul-Heyse-Str. 26, Munich 15, price DM.24), in which Dr. Sigerist has taken the opportunity to revise his work in the light of further information that has come to hand during the past twenty years. He has also added five new biographies (Ramón y Cajal, Pavlov, Cushing, Friedrich von Müller, and Sauerbruch). Excellent portraits round off this finely produced volume, and it is to be hoped that a new English translation will soon be available for those whose unfamiliarity with German prevents their full enjoyment of a delightful book.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MARCH 6 1954

CHILD LIFE AND HEALTH

No higher tribute could be paid to the child welfare services than that contained in Professor Charles McNeil's Fleming Memorial Lecture, reproduced in the opening pages of this issue. McNeil is of the opinion that success in the promotion of health in childhood in the future rests with the child welfare services, and he submits a plea for a strengthening of the services by providing what he terms "new and better weapons." His views differ from those expressed by Professor A. L. Banks,¹ who suggested that the maternity and child welfare service had largely accomplished its intended purpose and could now be merged with the hospital and paediatric services. It is, incidentally, remarkable that it is the hospital physician who advocates strengthening of the maternity and child welfare service, while the former public health officer recommends its demobilization. These two opposing, and perhaps somewhat extreme, views have in common that they contain little reference to the school health service and to the importance of the family doctor. If, as McNeil emphasizes, it is by education of the mother that child care can best be promoted, what more appropriate place could there be to do so than in the home? And if that be so, has the family doctor no part to play? It is no uncommon experience to hear it said that the general practitioner is not interested in prevention. There may be some foundation for the statement as a generalization. None the less, much of the work of many family doctors is concerned both directly and indirectly with the prevention of disease and with the promotion of health among the children in their practices. Not a few general practitioners give part-time service in local authority clinics. Others have their own organized arrangements specifically intended to cater for the needs of the expectant and the nursing mother and of the infant and child: this trend is one which will almost certainly be favoured by the encouragement being given to group practice. Evidence in some areas suggests that these arrangements are stimulating requests for the periodic examination of 3- and 4-year-old children whose mothers have stopped bringing them to the welfare clinics.

¹ *British Medical Journal*, 1952, 2, 1007.

The family doctor possesses numerous and in many ways unique opportunities to educate parents in child care. (Professor McNeil writes mainly about the education of mothers, but should not fathers have a share of the instruction?) While it is true to say that in the past the general practitioner has not on the whole received very much encouragement in this field, it must be admitted that his attitude has not always invited encouragement. The crux of the present problem is this: Is the family doctor capable of utilizing his opportunities to educate parents, and, if he is, will he find himself in conflict with the statutory child health services? In answering these questions account must be taken of the changes brought about within recent years in the instruction given the medical student in paediatrics and child health. The basis of instruction is the study of health. The student sees the child at home, in the nursery, in the residential home, at the welfare clinic, and in school; and he has opportunities of observing the day-to-day work of the medical and nursing staff of the child welfare and school health services among children, and also the family doctor's work. It is against this background that the student is encouraged to study disease, the restoration of well-being, and the promotion of healthy growth and development. There is already evidence that the young doctor enters practice suitably equipped and anxious to co-operate with the child health services in their work of education. Further progress in this direction would be discouraged, not favoured, by merging the child welfare services with the hospital obstetric and paediatric services. The foundations of child life are in the home. The success of measures to improve child health depends on acceptance of this conception. Sanitation has improved out of all bounds; so also have the general standards among children of cleanliness, clothing, and nutrition. In contrast, despite great improvements, housing and overcrowding remain the most potent deterrents to a nationwide attainment of optimum health in childhood.

Hospital management committees intent upon making provision for the sick are not always successful in interpreting the special requirements of the ailing child and cannot be expected fully to understand the needs or methods of parental education in child health, which should not be weighted in favour of hospital or specialist considerations. The need is for an increasingly close link between the general practitioner and the children's services provided by the local health authorities. With education for child health there might well be combined education in the care of childhood ailments, if only to reduce the number of unnecessary references of children to hospital

and to foster in mothers a confidence in their own ability to tend their sick children. Centres of study and schools of training in child health along the lines advocated by Professor McNeil would serve to co-ordinate the activities of all those working in this field, and would, as he believes, add to the authority and prestige of the child welfare service.

Q FEVER

When Q fever was first recognized in 1937¹ it appeared to be mainly an occupational disease affecting slaughter-house workers and restricted to the vicinity of Brisbane. This idea of the disease changed notably during the 1939-45 war, when it was established that several outbreaks of non-bacterial or atypical pneumonia in Allied and enemy forces in Southern Europe were caused by infection with *R. burneti*, the causative agent of Q fever.^{2,3} Subsequent reports, in addition to confirming the unusual feature of pulmonary involvement seen in man, have drawn attention also to the world-wide distribution of Q fever in animals.^{4,5}

Although a rickettsial disease, Q fever differs in many respects from the rest of this group of infections. Insect vectors, for instance, play little or no part in the spread of the disease to man, and the part they play in transmission of the disease from animal to animal is by no means an essential one. Cutaneous rashes are uncommon, and serum agglutinins to the proteus group do not appear in the patient's blood. Indeed, one of the few findings in Q fever, in common with other rickettsial infections, is the severe headache so frequently present. It now seems well established that infected animals—cows, sheep, and goats in particular—are the main sources of human infection. The organism is excreted in the faeces, the placenta, and the milk of infected animals, and infection is by inhalation of infected excreta or by drinking contaminated milk.⁶ *R. burneti* is a hardy organism, being relatively resistant to inactivation by normal physical and chemical methods. Pasteurization is only just adequate to inactivate the organism if the correct conditions are scrupulously maintained.⁶

The presence of Q fever in Britain was established in 1949,⁷ since when both outbreaks and sporadic cases have been reported.^{8,9} So far cattle appear

to be the only reservoir of infection in this country.¹⁰ A recent survey of Q fever in Britain by Marmion and his colleagues⁹ shows that a large proportion of the observed cases have occurred in the south-eastern counties, where a corresponding higher proportion of infected cattle have also been found. Epidemic Q fever as seen in Italy in 1943-4 is not likely to cause much confusion in diagnosis, but considerable variation is seen from case to case, and asymptomatic infection is by no means uncommon. Harnman,¹⁰ reviewing the clinical features, emphasizes that some of the points in favour of a diagnosis of Q fever are the extremely sudden onset, severe headache, often out of all proportion to the severity of the case, and the lack of upper respiratory or gastro-intestinal symptoms. Later an unproductive cough and radiological evidence of pulmonary infection develop. Serological tests are useful in helping to distinguish Q fever, and in particular the mild or sporadic case, from other forms of pyrexia of unknown origin labelled as influenza or atypical pneumonia. Specific antibodies can be detected by the seventh to twelfth day by the complement-fixation test, which remains positive for a considerable time.^{11,12} Except in old people the prognosis is good, with full recovery in most cases, but there is the possibility that some cases may become chronic and prove resistant to antibiotic treatment.⁹ Fortunately Q fever is not a serious problem in this country, but as the risk of milk-borne infection exists it would seem advisable on general principles to reduce the risk by suitable treatment of raw milk.

MEASURING HOSPITAL EFFICIENCY

The efficient use of the available hospital beds in this country is of special importance because of the meagre allocation of money for building new hospitals and major hospital extensions. When considering the use being made of the existing hospital beds, discussion is apt to centre on certain statistical information, and in particular on bed occupancy rates. Avery Jones¹ believes that a general community hospital should have at least a 90% bed occupancy and that it is feasible to achieve a 93% bed occupancy. The fact that there are many hospitals up and down the country with only 80% bed occupancy, and some substantially lower, he considers to be evidence of extravagance, and he concludes that, on the basis of the bed occupancy figures reported, there cannot be said to be any overall shortage of hospital beds in this country.

In assessing the amount of hospital accommodation required, and the efficiency of a particular hospital,

considerations other than mere figures must be given due weight, though statistical data are essential if the questions are to be fully studied. But the figure of bed occupancy is only one index of efficient bed utilization, and others must be taken into account, such as the average length of stay of patients in the hospital concerned and the "turnover interval." This is the interval which elapses between the discharge of one patient and the admission of another into the same bed. If the bed occupancy figure alone were taken into account in assessing the full utilization of a particular hospital bed, then the figure of 100% bed occupancy could be obtained by keeping one patient throughout the year in that bed. In other words, by increasing the length of stay and reducing the number of patients occupying the bed in one year, the bed occupancy rate will rise, but it cannot be said that the bed has necessarily been efficiently utilized. A hospital which has a low figure for the average length of stay, a minimum turnover interval, and a high bed occupancy rate is statistically a much more efficient hospital than one which has a high static bed occupancy. When these three requirements have been achieved, considerably more patients are being treated in the same number of hospital beds during a given period. As an example of the measurement of this kind of efficiency the figures for the Manchester Region may be taken. There, 20,000 more in-patients were dealt with in 1951 than in 1950 without any increase in the actual number of hospital beds. The alternative to this increase in the turnover would have been to provide a new hospital of 800 beds.

When considering bed utilization, the number of patients who have occupied the beds during the year must therefore be taken into account in addition to the percentage bed occupancy. This figure, known as the bed turnover or bed-use factor, is calculated by dividing the number of patients who were discharged or died during the year by the number of available beds. In the report of the Chief Medical Officer of the Ministry of Health for 1952² it is shown that there is considerable variation in this figure for hospitals which prima facie appear comparable. For example, the average figure for the London undergraduate teaching hospitals for 1952 in general medicine was 12.3 and that for provincial undergraduate teaching hospitals was 19.1, while the corresponding figures for general surgery were 19.4 and 25.0 respectively. Because of these wide variations, the bed occupancy rate taken in isolation can be misleading, for a higher figure of bed occupancy will be obtained

in the hospitals with a longer duration of stay if the turnover interval remains the same. Murley³ has pointed out that an increase in turnover will result in a lower bed occupancy figure, but this is conditional on the turnover interval remaining constant. At present the national figure for the turnover interval is 3.26 days, but there must be a minimum level to which the turnover interval can fall, and when this is reached improved utilization can be effected only by reducing the length of stay, which in turn reduces the rate of bed occupancy. At this point a rise in bed occupancy would in fact indicate that beds were being less efficiently used.

All these indices, therefore, have to be taken into account in considering the use of available hospital beds from a statistical point of view, but even so allowance must be made for the great variety of circumstances in different hospitals. In an acute general hospital it is not possible to obtain a 100% bed occupancy except by crowding in extra beds above the normal bed complement, particularly when wards have to be reserved for separate groups—for example, maternity patients. Indeed, it is undesirable for an acute general hospital to have a 100% bed occupancy, otherwise no reserve beds would be available for the admission of emergency cases. The admission of day cases for operation, variations in bed allocations to individual specialties, differences in hospital requirements in an industrial area as compared with a residential area, and the shortage of ancillary facilities in a hospital will all affect the bed occupancy figure, making it inappropriate for use as the sole yardstick for comparing hospitals of the same size and apparently otherwise comparable. But it can be a useful guide to hospital staffs and administrators in assessing the use which is being made of available resources when taken in conjunction with other factors and over a suitable time.

CANCER REGISTRATION

The development in Britain of cancer recording on a national scale comparable with the Danish system has been beset with difficulties. The Radium Commission, which controlled the supply of radium from 1930 to 1948, was in the fortunate position of being able to insist on the keeping of records wherever radium was used, but the obligation applied only for patients treated by radiotherapy, and it had to be suspended during the war and lapsed altogether in 1948 with the National Health Service Act. In 1939 the Ministry of Health had advised county and county borough councils to provide for the keeping of records of treatment and its results as part of the plans asked for under the Cancer Act, and in 1944 a circular letter was issued on

the subject. The Radium Commission, having devoted much attention to methods of recording, introduced a standard card for use in radiotherapy centres, and in 1947 the General Register Office became the statistical bureau for dealing with the cards. After the repeal of the Cancer Act in 1948 local responsibility for cancer registration passed to the regional hospital boards and teaching hospitals, but not all have acted.

In 1945 some 29,000 cancer cases were registered, and by 1948 the annual number had risen to about 49,000, not yet amounting to half of the estimated total of new cases seen annually in England and Wales, and not properly representative because of overweighting with radiotherapy patients. In the first report issued by the General Register Office¹ the cases registered in 1945 and 1946 were studied with one-year survival rates, these being supplemented later by rates of survival to two and three years.² In a further supplement³ recently published the 1947-8 registrations have been analysed for each cancer site by sex, age, and confirmation of diagnosis, and also by interval before treatment at each hospital centre.

Since 1948 little further progress has been made towards reaching the objective of complete cancer registration, and it is to be hoped that a circular⁴ just issued by the Ministry of Health to regional hospital boards will receive serious attention. It expresses concern at the slow progress and underlines a recommendation of the Minister's Standing Advisory Committee on Cancer and Radiotherapy that registration should be continued on a voluntary basis in all regions, using a simpler follow-up card which has been designed by a special subcommittee of the Registrar-General's Advisory Committee on Medical Nomenclature and Statistics. In revising the standard card great care was taken to eliminate items which experience has shown to be of doubtful value or to present difficulty, and the new abstract card can easily be transcribed by a lay clerk from clinical records. Brought up to date and shorn of resemblance to an official record form, it aims to provide essential information on cancer incidence by site, sex, age, geographical area, interval between first signs and start of treatment, methods of treatment in use, and survival according to extent of disease when first seen. Regional hospital boards are asked to examine the position in their regions in conjunction with the teaching hospitals and to report by June 30 on the projected development of cancer registration.

In some regions the teaching hospitals have shown little enthusiasm for cancer recording, and in others discouragement has been felt because of lack of publication of findings as they concern the region. The United Birmingham Hospitals set a good example by deciding to issue a series of annual reports on survival of cancer patients admitted during the period 1936-49. The first⁵ of the series deals with the methods of treatment and survivals to two and five years of some 6,500

patients with new growths of the alimentary tract and tongue. This report is a model of concise presentation, profusely illustrated by 32 diagrams, and, depressing though many of the facts recorded undoubtedly are, their presentation in a manner such as this can do nothing but good. It is much to be desired that other hospital regions will strive to bring their cancer registration nearer to completeness with a view not only to providing the national information that is needed but also to producing regional studies of this kind on special aspects of the cancer problem.

BURNS AND THE ADRENAL

The weak point in all discussions on stress and the pituitary-adrenal axis is the gross inadequacy of all the methods of assessing the activity of the adrenal cortex, whether in the experimental animal, the live patient, or even at post-mortem examination. Without exact and objective evidence on this point the way lies open to the flood of hypotheses which have swamped and almost discredited this most important field of research. Reliable methods for chemical assay of steroid hormones in the blood are the only final answer, and are slow in appearing. Meanwhile modern histochemical techniques are being used in a promising new attack¹ on the problem of estimating pituitary and adrenal activity from examination of post-mortem specimens; and, as Dr. S. Sevvitt shows elsewhere in this issue, the only technically simple method of approach—the eosinophil count—can still give useful results in a field which has become the province of the well-equipped biochemist. In 1951 Dr. Sevvitt² described the changes in the eosinophil count in burned patients seen at the Birmingham Burns Unit. The eosinophils fall from their normal 200 per c.mm. to below 40 within two hours of the accident and remain low for several days.^{3,4} The period of eosinopenia can be presumed to correspond to a period of increased secretion of cortical steroids. Broadly speaking, the duration of the eosinopenia depends on the severity of the injury, being a day or less in burns involving 10% of the body surface, and four to five days in 50% burns. A moderate "rebound" eosinophilia often follows.

Some patients show less eosinopenia than would be expected from the size of their burns, as Sevvitt and others⁴ have found, and this seems to worsen the prognosis. An inadequate adrenal response to stress is the obvious suggestion. Sevvitt's present work offers new evidence of this and gives some indication of its causation. The eosinophil responses were studied in burned patients who had passed the initial eosinopenic phase. Two drugs were used which have different mechanisms. A.C.T.H. acts directly on the adrenal, and failure to respond to it indicates an unresponsive adrenal. Intravenous adrenaline acts on the pituitary (perhaps through the hypothalamus), stimulating the production of

A.C.T.H. A patient who responds to A.C.T.H. but not to adrenaline must have some defect at the pituitary end of the axis. Two of Sevvitt's patients failed to respond to A.C.T.H., and one of these died: though equivocal, the post-mortem findings were compatible with true adrenal cortical failure. Three other patients were found in whom intravenous adrenaline was ineffective: two had simultaneous mental changes, and the suggestion that a hypothalamic lesion was present seems reasonable. Sevvitt has established the fact that adrenal cortical deficiency can occur in burns, and that at least two wholly distinct mechanisms can be involved. It follows from his work that there is a case for treating some (not more than 10%) of burned patients with cortisone for short periods.

EMOTIONS AND THE NOSE

The primary purposes of the nose are olfaction and conditioning of the air which passes through it, so that when the air reaches the lower respiratory tract it will be suitably filtered, warmed, and moistened. This conditioning of the inspired air includes the filtering-off of unwanted foreign particles and the giving-off of more than a litre of moisture in the course of 24 hours. Such activity is made possible by the nasal mucous membrane, which is rich in blood vessels and mucous glands. The surface area of the nasal mucous membrane is also greatly increased by the turbinates, which project into the nasal cavities and contain erectile tissue enabling them to swell and give off mucus in accordance with the needs of the body. This delicate mechanism is under the control of the parasympathetic system and can be readily invoked by a variety of stimuli, some of which may be quite unconnected with respiration. Nasal obstruction and hypersecretion are part of many emotional experiences—the "honeymoon cold," for instance, being a common phenomenon. Holmes, Goodell, Wolf, and Wolff,¹ in a study of reactions within the nose in human subjects during varying emotional situations, have continued observations which they had previously made by direct observation of the mucosa of the stomach in a patient with a large gastric fistula. They found that circulatory changes in the nose were similar to those in the gastric mucosa. In particular they noted that emotional reactions induced by anxiety, resentment, and feelings of frustration were associated with hyperaemia and hypersecretion in both nasal and gastric mucosae. They concluded that if such reactions were sustained troublesome symptoms would result which might predispose to chronic disease in the nose.

Elsewhere in this issue Mr. P. Reading, Mr. K. Malcomson, and Mr. D. O'Neill give an interesting account of the investigation and treatment of chronic vasomotor rhinitis. When hay fever is excluded they found that there is still a large and troublesome group of sufferers in whom inhaled allergens play little part in the aetiology. These workers believe that chronic vasomotor rhinitis is a disorder associated with emotional tension or stress and is therefore comparable in aetiology

with asthma and duodenal ulcer, in which the cholinergic system seems to play a part. When local and general treatment failed to alleviate the rhinitis, psychological investigation often brought to light a condition of emotional strain, and psychotherapy, sometimes continued for 20 months, had a gratifying success in relieving both paroxysmal rhinorrhoea and chronic nasal oedema.

FOLIC ACID AND PERNICIOUS ANAEMIA

The Addisonian type of macrocytic anaemia is effectively treated with extracts of liver or stomach or with vitamin B₁₂ (cyanocobalamin); on the other hand, hypochromic microcytic anaemia responds only to full doses of suitably administered iron preparations and neither requires nor responds to the other anti-pernicious-anaemia agents. Nevertheless, in spite of these simple therapeutic facts, many elegant and expensive preparations containing iron, vitamins, liver and stomach extracts, yeast, copper, vitamin B₁₂, folic acid, and often other substances, are on the market and recommended by their manufacturers to the doctor for the treatment of his anaemic patients. These polypharmaceutical remedies rarely contain enough of any constituent to deal effectively with any form of anaemia, while their heavy cost sometimes leads the doctor to prescribe them in such small doses as one pill or capsule per day. Anaemic patients still commonly receive some form of treatment with these blunderbuss preparations before their blood has been examined for the purpose of determining the type of anaemia and the appropriate treatment. Then, when a patient does not fully respond to the remedy given, subsequent blood and marrow examinations may fail to give a clear-cut diagnosis. This difficulty is noticed most often in pernicious anaemia—which is still a fatal condition if not properly treated—since the bone marrow rapidly loses its megaloblastic character even after inadequate anti-anaemic treatment, though this does not necessarily lead to a remission of the anaemic state.

Elsewhere in this issue Dr. C. P. Lowther (p. 564) once again draws attention to the dangers of this practice. In the past the worst that could happen to a patient with pernicious anaemia treated with an ineffective remedy was a failure to respond to treatment, the development of a more severely anaemic state, and, consequently, a misdiagnosis of refractory macrocytic anaemia; usually, and fortunately for the patient, this led to subsequent reference to hospital for investigation, diagnosis, and treatment. Now, however, the danger is more serious and may be acute, because so many of the blunderbuss anti-anaemic preparations contain folic acid, though this is not always realized by those who prescribe them. The tablets taken by Dr. Lowther's patient contained this substance. Both Davidson¹ and Wilkinson² clearly showed that folic acid was undesirable for the treatment of pernicious anaemia, while in 1949 Israëls and Wilkinson,³ and others, later concluded that folic acid induces peripheral

neuritis and spinal cord degeneration in patients with pernicious anaemia who had previously shown no signs of such complications, or else makes worse an early peripheral neuritis. The onset of such, often acute, neurological complications may be quite sudden, and in some cases even while liver extracts or vitamin B₁₂ are being given at the same time as folic acid, as was the case with Dr. Lowther's patient, who had been taking 3 mg. of folic acid daily for only 38 days. Fortunately, if the real diagnosis is made early enough, the prompt administration of liver extracts or vitamin B₁₂ and the immediate discontinuance of the folic acid usually reverses this disconcerting and serious complication.

Folic acid has no place in the treatment of pernicious anaemia and is of no value in hypochromic microcytic anaemia. In patients with pernicious anaemia it may mask the development of, or deterioration in, neurological symptoms by bringing about a false sense of improvement in the general symptoms and a variable degree of improvement in the blood count. There is now a strong case against the inclusion of folic acid in polypharmaceutical anti-anaemic preparations, the usefulness of which in the opinion of most haematologists is in any case open to grave doubt.

PYRAZINAMIDE WITH ISONIAZID IN TUBERCULOSIS

Drugs in bewildering variety, falling into several main classes, are now known to possess anti-tuberculous activity, and their use in various combinations and for different forms of the disease bid fair to occupy the attention of investigators for some years to come. One of the latest and least familiar is pyrazinamide ("aldinamide"). This is a derivative of nicotinic acid, as isoniazid is of isonicotinic acid, and was shown to exert moderate anti-tuberculous activity in guinea-pigs by Dessau and his colleagues.¹ In a clinical study² they reported on the treatment of 43 patients, of whom 25 had far advanced disease: the results were generally encouraging, although the authors regarded the usefulness of the drug as limited by the rapid emergence of drug-resistant bacilli, particularly in patients with far advanced tuberculosis with large cavities.

Walsh McDermott and his colleagues³ now report a clinical study of the action of pyrazinamide and isoniazid given together, prefaced by a description of an animal study by McCune and Tompsett of which a fuller account is to appear later. The latter workers used this drug combination in infected mice, and studied its effects by quantitative cultures of the organs. The striking fact which emerged was that the initial fall in the bacillary content of the spleen which follows the use of either drug alone or of other forms of chemotherapy was continued during combined treatment to complete extinction. This apparent sterilization of splenic lesions has never been achieved before, and suggests an "eradicated" action in surprising contrast

to the relative inactivity of pyrazinamide *in vitro*. The clinical study embraced 81 patients, of whom some were treated in New York City and some (presumably Navajo Indians) in the Navajo Medical Centre, Fort Defiance, Arizona. In all but nine the pulmonary lesions were classified as far or moderately advanced. Both drugs were given orally, pyrazinamide in a daily dose of 50 mg./kg. and isoniazid in one of 5 mg./kg., the intention being to continue this treatment for three months and to continue thereafter with isoniazid alone: complete courses were given to 61 patients, early deaths and other causes having prevented completion in the remainder.

The results from all points of view but one were gratifying. An effect comparable to that observed in the mouse spleen was apparently obtained in the disappearance of bacilli from the sputum of 90% of the patients. Substantial radiographic improvement was achieved in 70% and cavity closure in 65% of those with cavitation. On the other hand, unequivocal signs of liver damage developed in six patients, and this complication was fatal in one of them. Jaundice with impairment of liver function was also observed by Yeager, Munroe, and Dessau² in two of their 43 patients. Although this does not mean that the treatment is unjustifiable, it clearly can be used only under strict supervision: its freedom from any tendency to cause gastro-intestinal upset, in contrast with the disturbing effects of P.A.S., had encouraged the hope of domiciliary application. Possibly a modification of dosage may diminish this risk of toxic effect.

THE CLARE WAND FUND

The Conference of Local Medical Committees at its meeting on June 26, 1952, resolved to pay a tribute to Dr. S. Wand and Dr. D. P. Stevenson—chairman and secretary of the General Medical Services Committee—in recognition of their "outstanding services to the profession during the negotiations on remuneration which culminated in the Danckwerts award." An appeal was sent to all local medical committees in which it was suggested that the major portion of the money subscribed should be used to form a fund to provide educational assistance for doctors in general practice. At the wish of Dr. Wand the fund was to be called the "Clare Wand Fund." In the first letter in this week's *Supplement*, the chairman of the Trustees of the Fund puts forward tentative proposals for the use of the sum of £12,000 which has been subscribed. Further suggestions, it says, will be sympathetically examined. Some may well be forthcoming, but the Trustees' own ideas seem to be well designed for their purpose of encouraging "projects which will enhance the prestige of general practice."

We announce with regret the death on February 27 of Dr. T. Jenner Hoskin, senior physician and cardiologist to the Royal Free Hospital. A memoir will be published in next week's *Journal*.

CLINICAL PATHOLOGY IN GENERAL PRACTICE

TESTS FOR VENEREAL DISEASE—I

BY

I. N. ORPWOOD PRICE, M.R.C.S., D.P.H.

Pathologist, Whitechapel Clinic, the London Hospital

Laboratory tests for venereal diseases are mostly concerned with gonorrhoea, non-gonococcal urethritis, chancroid (soft sore), and syphilis. Occasionally laboratory investigation of material from patients suspected of suffering from lymphogranuloma inguinale (lymphogranuloma venereum) or granuloma inguinale is required.

At the outset it must be stressed that before instituting treatment for any of these diseases, laboratory assistance should always be invoked in order to confirm the diagnosis, and when occasion demands the practitioner should telephone the laboratory for the necessary glass slides, culture media, or screw-capped bottles, with containers for transport. If he is uncertain about which test should be employed, the pathologist will give the necessary advice.

Before taking material from the patient it is essential to mark each specimen with an identification name or number, the date, and the source of the material—for example, urethra, vagina, cervix.

Specimens

No laboratory, whatever resources it may have or however experienced its personnel, can give the best advice when supplied with badly harvested specimens.

Smears.—These should be made with a platinum loop, thinly and evenly spread on the glass slides (mix a drop of sterile water or saline with a drop of the discharge, if necessary), and fixed by moderate heat—that is, the slide should not feel uncomfortably hot when placed on the back of the hand.

Cultures.—Specimens for culture should be taken with a platinum loop or the sterile wool swabs supplied by the laboratory.

Blood.—With adults at least 8 ml. should be obtained by venepuncture. In order to avoid haemolysis, which may vitiate the tests, care should be taken that both needle and syringe are free from water or spirit (wash out with sterile normal saline if necessary). The needle should be removed before transferring the blood to the sterile screw-capped blood bottle, care being taken to use no undue force. In the case of adults or small children with "difficult veins" a guarded safety-razor blade can be used. All except the last $\frac{1}{4}$ in. (3 mm.) of one cutting edge is covered with adhesive plaster; a clean-cut nick is inflicted into the surgically cleaned and warmed heel of the patient. If the skin is stretched by the use of the thumb and forefinger of the left hand and the cut made at right angles to the "stretch," the small wound will tend to gape and sufficient blood will usually run into the container (5-ml. bijou screw-capped bottle) held against the skin below the cut. Umbilical cord blood, as will be explained in Part II of this article, is not a suitable specimen to collect.

Cerebrospinal Fluid.—It is, of course, essential that cerebrospinal fluid should not contain any blood.

Serum from Primary Sore.—A capillary tube closed at one end should be used to obtain serum from a suspected syphilitic sore if the presence of *Treponema pallidum* is to be demonstrated. If the sore is covered with a scab, this should be removed, the lesion washed thoroughly with plain tap-water or normal salt solution (soap should not be used), and then dried. The dried surface is gently scari-

fied so as to provoke slight bleeding and the exudation of serum. Wipe away the first few drops of exudation, especially if they contain blood, and wait for a clear drop of serum to appear from the depth of the lesion. Gently heat the closed end of the capillary tube and immediately apply the open end to the drop of clear serum, and as the closed heated end cools allow sufficient serum to be drawn up into the tube so that none is present $\frac{1}{4}$ in. (13 mm.) from either end of the tube. The open end is then sealed by heat.

Clinical Details.—Finally, all specimens should be accompanied by a brief note containing the name and address of the doctor, the patient's name or identification mark, the essentials of the clinical history, the probable diagnosis, and the examination required. It cannot be too strongly stated that "slot-machine" laboratory reports are largely a waste of time and money. If the pathologist and clinician do not collaborate, the latter may well be deprived of vital information.

Transport.—The speedy transport of specimens from the patient to the laboratory is of paramount importance. Time is often the essence of a useful investigation. Fluid specimens may deteriorate rapidly after being taken, and thus the examination of such material would be fruitless. For example, the cells in the cerebrospinal fluid begin to disappear within two hours of lumbar puncture, and in 24 hours few, if any, cells can be seen.

Reports.—Reports on the findings of tests for venereal diseases are intended to be regarded only as part of the evidence required in order to make a diagnosis. Thus a report that no gonococci can be found in the smear from a urethral discharge is no proof that the patient is not suffering from gonorrhoea. Further investigation may be required and the final decision must rest with the clinician.

Identification of Gonococci

When the patient is suspected of suffering from gonorrhoea, three types of test should be employed—namely, smears, cultures, and blood tests.

In acute gonorrhoea in the male smears should be made with a platinum loop from urethral discharge after carefully cleaning up the glans penis and meatus with sterile water or saline. In the female, with the patient in the lithotomy position, smears should be made from the urethra, posterior fornix of the vagina, and the cervical canal. In the case of suspected chronic gonorrhoea in the male smears should be made from the prostatic secretion after massage as well as from the early morning discharge obtained from the urethra after the patient has held his water all night. In the female, examination of smears from the urethra, cervical canal, and the rectum should be made. Satisfactory rectal smears cannot be obtained without the aid of a proctoscope, and unless the practitioner is skilled in the use of this instrument he should obtain the advice of an expert. Strands of mucus on the mucosal wall can often be found (30% cases, C. S. Nicol, personal communication), which on examination may reveal the presence of gonococci.

Most bacteriologists will report that the smears contain Gram-negative intracellular diplococci and/or other organisms such as coliform bacilli, diphtheroid bacilli, or monilia. Further information on the cellular content of the smear will also be given. Polymorphonuclear leucocytes predominate in acute inflammatory conditions, whilst epithelial cells suggest a more chronic infection. Two points must be remembered: (1) that the absence of the relevant organism

is no proof that the patient is not suffering from gonorrhoea, and an examination of another specimen may be indicated; and (2) a report that Gram-negative intracellular organisms morphologically resembling gonococci have been seen will not be accepted in a Court of Law as proof that the patient from whom the specimen came is suffering from gonorrhoea, because other organisms of the Neisseria group may occasionally be present in the genital tract.

In suspected gonorrhoea in the female smears and cultures should be taken just after the menstrual period.

Cultures should be taken immediately after the smears and from the same anatomical sites. Direct inoculation of discharges on to solid media has been largely abandoned in favour of transport media. The sterile cotton-wool swab impregnated with carbon provided by the laboratory should be well rubbed into the discharge and then plunged straight into a bijou bottle containing Stuart's transport medium. The wooden stick is snapped off by pressure against the side of the bottle so that the screw cap can be replaced and tightly screwed up again. Since the success of this transport medium depends on anaerobic conditions, this manoeuvre should be carried out with speed and great care taken to check that the screw cap is not loose when the operation is completed. After receipt at the laboratory, the swab is used to inoculate suitable media, incubated in an atmosphere of carbon dioxide and examined after 24 to 48 hours, depending on the amount of growth obtained. Typical pure gonococcal colonies, if present, are picked off, some examined under the microscope, some tested with the oxidase reactions, and some subcultured for testing with sugar reactions. If gonococci are grown the organism can be isolated in pure culture and "sugared" in 80% of such specimens. These are reported as morphologically and culturally gonococci. The 20% which cannot be obtained in pure culture are reported as "presumptive" gonococci, and warrant the institution of anti-gonococcal treatment, provided the history and clinical condition indicate a strong probability that the patient is suffering from gonorrhoea. If there is any doubt consultation with the bacteriologist is indicated.

Gonococcal Complement-fixation Test

The only blood test at present in routine use is the complement-fixation test for gonorrhoea (G.C.F.T.) and reports on this test are given as negative or positive. Positive reactions are quantitated and reported as positive with neat serum or a dilution thereof. A positive reaction is evidence of a gonococcal focus of infection, but in the absence of any supporting evidence the test should be repeated. A negative reaction, however, does not exclude gonorrhoea, because in the early stages of the disease the body may not have had time to elaborate the antibodies detected by the test. The table shows how soon after exposure to infection one might expect a positive G.C.F.T. in untreated gonorrhoea.

Time after Exposure	No. of Cases	Percentage with Positive G.C.F.T.
1st week	663	9
2nd "	491	16
3rd "	160	34
4th-6th weeks	90	39
7th week	26	50

During the course of treatment of acute gonorrhoea with penicillin the fate of the reaction is as follows: 68% fail to record a positive reaction throughout the course of their illness; 19.2% are positive at first testing before treatment is begun; 6.4% at the end of the first week of treatment; 2.5% at the end of the second week; 0.8% at the end of the third week; and 0.5% at the end of the fourth to eighth weeks. The remaining 2.1% show "oscillating" reactions—that is, on serial testing at intervals the reaction results recorded may be negative, positive, negative, or alternatively positive, negative, positive. This type of serological pattern probably means that the antibody content of the

patient's serum is sometimes over and sometimes under the threshold of recognition by the test. In gonorrhoea this process goes on for a relatively short time, until antibody production recedes, and thereafter negative results are recorded.

Of patients who record a positive reaction at the first testing before treatment, approximately 64% may be expected to become negative after treatment within three months, leaving 36% who will become "oscillators" and revert to negative in due course. Of patients who have a negative test when first tested, and subsequently become positive, 60% will have a positive G.C.F.T. before the end of the first week, when in all probability the treatment has not had time to take effect; 24% will become positive before the end of the second week; and the remaining 16% will become positive during the third to eighth weeks. Complications of gonorrhoea are not common, but at least 66% can be expected to show a positive G.C.F.T.

The value of the G.C.F.T. may be summed up as follows: in early acute gonorrhoea its use is limited; it is of value in subacute or chronic gonorrhoea, particularly in the female, when smears may give little or no help initially; it is of definite value in the diagnosis of complications; it is useful in the management of gonorrhoea; it is unwise to ignore a positive test which has been confirmed by retesting.

Non-gonococcal Urethritis

Non-gonococcal urethritis is a most troublesome condition. According to the latest Ministry of Health returns 11,552 men attended public V.D. clinics with this condition in 1952, as compared with 15,510 new cases of gonorrhoea in the male. The cause of the condition is unknown, though it is thought that it may be due to a virus infection or one of the organisms of the Pleuropneumonia group. Laboratory help is therefore entirely confined to negative findings in excluding a diagnosis of gonorrhoea. In the acute stage of the disease smears from the urethral discharge usually reveal the presence of masses of leucocytes but no organisms. Later many lymphocytic cells and contaminants such as staphylococci and diphtheroid bacilli may also be found. In like manner cultures will either fail to grow any organisms or grow only the contaminants. Blood tests for gonorrhoea are always negative.

Chancroid

Laboratory tests in the diagnosis of chancroid are of some value. Smears taken from the sore usually contain a mass of leucocytes plus a variety of contaminating organisms. Occasionally organisms resembling Ducrey's bacilli (small Gram-negative bacilli, characteristically arranged in chains) may be seen. Cultures can be taken into clotted sterile rabbit's blood which has been heated at 55° C. for five minutes. Fresh medium should be used and a head of discharge is obtained from the base of the ulcer under its undermined edge by means of a platinum loop. The medium is inoculated by the wire being passed several times round the clot so as to ensure even distribution of the inoculum. Two media tubes should be inoculated and examined after 24 to 48 hours. According to Teague and Deibert* if the characteristic chains and tangles of small Gram-negative bacilli are found even in admixture with contaminants the culture may be regarded with confidence as being positive for Ducrey's bacillus. In all cases a cutaneous skin test (dmelcos) should be performed to confirm the diagnosis and standard serum tests should be requested with a view to excluding syphilis. Always remember that the first result of the latter may be negative if the blood is taken during the incubation period of syphilis.

[Part II will appear in our next issue.]

THE JENNER OF AMERICA: A BICENTENARY

Benjamin Waterhouse was essentially and aggressively American—even to the extent of placing after his name on the matriculation roll of the University of Leyden the words *Liberæ Reipublicæ Americanæ Foederatæ Civis* in 1778. He came there, as he said, to acquire "a little of the Dutch phlegm." But, ardent nationalist as he was, he nevertheless lived on to illustrate the truth that political ties, however severed, cannot prevent the permeation of scientific thought from one country to another.

Perhaps his English ancestry helped. Born on March 4, 1754, at Newport, Rhode Island, his mother was a cousin of the Quaker physician John Fothergill, F.R.S., collector of one of the finest botanical gardens in Europe and a great friend of Benjamin Franklin. It was with Fothergill in London that he came to study in the year before the Declaration of Independence, and three years later (varied by nine months in Edinburgh) he moved to Leyden, London, Edinburgh, and Leyden fashioned him so well that a year after he returned to America he was offered, and accepted, the chair of physic in the newly founded medical department at Harvard. Here his most immediate colleague was John Warren, the professor of anatomy and surgery, who was reputed to have taken part in the Boston Tea Party, and who had drafted the plans for the medical department. Warren was a bold and skilful surgeon who had not only performed one of the first abdominal operations recorded in America but also pioneered in amputation at the shoulder-joint. It was Warren's clear outlook, no less than Waterhouse's own English connexions, which were to play so decisive a part in the great event which is for ever associated with the name of Benjamin Waterhouse in medical history—the introduction of vaccination into the United States.

It is hard now to estimate the one-time ravages of smallpox. John Coakley Lettsom, a Quaker like Waterhouse and Fothergill, co-operated in reporting to the House of Commons that it was responsible for the loss, in England, of from 34,000 to 36,000 lives annually. No less severe were its ravages in the United States, for as early as 1721, during the sixth epidemic in Boston, Zabdiel Boylston had courageously inoculated his son and two negro slaves and some 244 other persons, risking death by hanging in doing so. Fifty-seven years later, in the same place, a subsequent epidemic led John Warren to establish a hospital. So when Lettsom sent Waterhouse a copy of Edward Jenner's *Inquiry into the Causes and Effects of the Variolæ Vaccinæ* early in 1799 the immense advantage of cowpox vaccinations over smallpox inoculations was immediately appreciated by Waterhouse, who on March 16 in that year published an account of it in the *Columbian Centinel*, following it up a few weeks later by showing Jenner's book to the members of the American Academy of Arts and Sciences assembled at Boston.

He did more. Although England was at war with Napoleon at the time, he secured some vaccine from England in the form of infected threads, and on May 8, 1800, used his son Daniel Oliver Waterhouse, then 5 years old, as a subject. As the vaccine pustule reacted on Jennerian lines, he then vaccinated a servant boy. Then, at his request, William Aspinwall, of the smallpox hospital at Brookline, inoculated one of the boys to test the theory that the subject would now be immune from the general disease. And so the boy was. For, though his arms became infected, nothing else was manifest, and Waterhouse could justifiably write, "One fact, in such cases, is worth a thousand arguments," and within six weeks his report, *A Prospect of Exterminating the Small Pox*, was published.

Success was so dramatic and so sudden that it temporarily eclipsed the discovery. For the quacks and charlatans, who are ever on the watch to exploit such things, leapt to administer vaccine. And since their cowpox matter was often

impure, sometimes being even mixed with smallpox, yet another epidemic occurred in Boston and a number of people died. Waterhouse then had to endure much the same kind of abuse meted out to early inoculators, and in the end asked the Boston Board of Health to make an investigation. This was duly carried out by a committee of seven practitioners (of whom Waterhouse was one) on 19 subjects, and served to vindicate him completely. Waterhouse followed this up by publishing a second part to his original report, which included letters from Jenner himself, Benjamin Rush, and the President of the United States, who had had his family vaccinated at Monticello in 1801.

From now on Waterhouse continued to stress the importance of inoculating with pure vaccine virus, not with that taken from the vaccine virus after the efflorescence had formed around the pustule. But the effort impoverished him. Professional jealousies and academic intrigues wore him down so much that he resigned his chair when he was only 56 years old. He was able to support his family only by the gift of the medical superintendency of nine New England medical posts, a gift made to him by President Madison. He also campaigned with some success against the use of tobacco, and his *Cautions to Young Persons Concerning Health*, embodying his doctrines, ran to six editions and several translations from its first delivery in 1804. He died, aged 92, in 1846, and lives on in history as the Jenner of America.

W. H. G. ARMYTAGE.

Reports of Societies

RELATION OF FAMILY AND CONSULTANT SERVICES

A meeting of the Sections of Medicine and General Practice of the Royal Society of Medicine on February 23, under the chairmanship of Sir Henry Cohen, devoted itself to a discussion on the relation of family and consultant services.

Changing Relations

Dr. GEOFFREY BARBER, who opened from the point of view of the general practitioner, referred to the changes in relationship between general practitioners and consultants which had taken place during his own experience of practice since 1930. In his early days when he encountered, for example, an acute appendix, he would ring up a fellow practitioner who did surgery and if necessary an operation would be arranged at which he himself gave the anaesthetic. That co-operation was of enormous advantage to the young practitioner because "his bluff was called every time. He knew when he had made an incorrect diagnosis and how he came to make it, and repartees cracked like small-arms fire." That had all been changed. The surgeons who were also general practitioners had largely disappeared. The distance between the general practitioner and the consultant had widened. There were those who appeared to think that the work of the general practitioner must be increasingly to direct his patient to the proper department in which his ailment could be treated. But many still felt that human illness was an intangible affair, and that the general practitioner, with his knowledge of the patient and of his mentality and background, should initiate the medical sequence of events and only when he came up against his own limitations should shepherd his patient to the consultant.

He had found to his horror that he did not always know the consultant to whom he was sending his patient. Unless the personality of the consultant was known one could not confidently choose the right one. Two equally good men, each proficient in his specialty, might be poles apart in their personality. A proper consultation, in his view, was one in which the patient, in his absence, was first discussed between the practitioner and consultant, afterwards in the presence of the patient his case was discussed by them together, and again was discussed between themselves after

the patient had retired. In that way he had continued his own postgraduate education. One form of self-discipline to which he had subjected himself was to put himself in the consultant's place in dealing with some poor old chronic patient who had borne a label for perhaps 15 years, to look at the patient again with the consultant's eye, as if he saw him for the first time, and it was astonishing how often one could detect something fresh to modify the label and to suggest something new in treatment.

To narrow the gulf between the general practitioner and the consultant he suggested that general practitioners should follow their cases into hospital, maintaining continuing responsibility for them. From the personal point of view there was a pathetic pride and gratitude in a patient when his general practitioner walked into the ward and he could say to his fellow patients, "This is my doctor." Secondly, the general practitioner must have sufficient pathological and x-ray facilities to take the patient up to a certain stage before he sent him to the consultant. Thirdly, he must regard the consultant as his friend and provide him with all the essential information which he had obtained by virtue of being the family doctor.

The Right Use of Hospital Beds

Dr. E. BULMER, who spoke for the consultants, asked that the problem be looked at from the point of view of the right use of hospital beds. The consultant nowadays was always on the hospital staff; formerly many respected family doctors were consultants; those days were gone. Mistakes were often made in hospital in keeping interesting patients for too long; in not admitting early enough that a case was incurable; in admitting patients only for them to die. He viewed with extreme alarm the competition for priorities for hospital beds. Why should cancer always have priority, second only to acute surgical emergency? Could not special hospitals be built for the surgical treatment of the humdrum—piles, hernias, prolapse, tonsils, etc.—and so avoid such competition? In the General Hospital, Birmingham, the number of beds in the medical department was 322, and the number of patients waiting 375, or 1.1 waiting patients for each bed. In the surgical department there were 5.7 waiting patients for each bed. A duty was placed upon the consultant to use his beds properly. Hospitals were too often regarded as dumping grounds for nuisances. The question whether the hospital was the right place for the patient to go to was seldom considered as it should be. No one yet had the courage to say what type of patient should be admitted to hospital, and it was very difficult to deal with situations in which the patient's medical condition was not suitable for in-patient treatment and yet socially admission was imperative. Many forms of illness could be dealt with by the family doctor, with interest to himself and benefit to his patients.

Dr. Bulmer gave a restricted list of conditions which demanded admission on medical grounds. After mentioning that some patients were admitted to hospital for rest and care, he said that care in the modern hospital was certainly excellent, but rest was apt to be non-existent. The decrease in the size of families, the employment of women in industry, and the lamentable ignorance of most young women of the elementary principles of home nursing made it seem to many that the only place to be ill in was the hospital. To-day almost everyone was born in hospital, or their parents would like them to be, and there seemed to be a demand that everyone should die there also. He thought that people should die in their beds at home if that was socially possible.

There should be hand-picking of patients for admission to hospital, Dr. Bulmer continued, but hand-picking was possible only by consultation. The teaching hospitals were in a unique position. In his own hospital about 85% of the patients were hand-picked; the remaining 15% came in through the bed-bureau or by order of the regional hospital board or in some other way.

How popular was consultation? It was popular with part-time consultants, but less so with full-time, who had

routine work to do. How popular it was with the family doctor he had no means of knowing. For his own part he wished to see the general practitioner visit his patient in hospital. He was now notifying every doctor when his patient was admitted and had offered him a welcome. This scheme was to be run for a year, and it remained to be seen what the response would be. Ward rounds with general practitioners were growing in popularity. Sunday morning was perhaps the least inconvenient time for the purpose.

The Patient Speaks

Miss ROSE HEILBRON, Q.C. (the first woman to do so and herself the wife of a doctor), said that after listening to the discussion so far she thought that the only person who had come really well out of it was the patient. Much was heard about the convenience of the doctor, but illness did not always fit into the schedule. The need to call a doctor sometimes occurred on a Sunday or even on Christmas Day. As the mother of a young child she had suffered from the frustration of wanting to call a doctor at some inconvenient hour and being told that she had better wait. The child had a temperature at night and so she called up the doctor at 11 p.m. and braved his wrath. She was not to know that by the next morning the child would be laughing in the doctor's face. She also criticized doctors for not explaining sufficiently to the patient and his family what was wrong. With broadcasting and television and newspapers even the most ignorant lay people nowadays had a little knowledge of medicine and could be entrusted with more explanation. Some health education would also lessen the queues in the waiting-room.

In further discussion Dr. L. W. BATTEN said that he agreed that the home and not the hospital was a good place to be ill in so long as the illness could be managed there, and he rather thought that when he came to die he would like to die at home if possible. Many patients who went into hospital now would be better off at home. But there was a corollary to this, that if the family doctor was to deal with many more types of illness he must have a greatly increased nursing service at his command.

Hospital Beds for the General Practitioner

Dr. H. GUY DAIN spoke of his experience in the war of 1914-18 when he was placed in charge of a Territorial General Hospital to which convoys of sick and wounded were brought straight from the front, and he was responsible for saying what should be done with them. He had behind him surgical specialists and any material aid he required. That was the ideal practice of medicine. The general practitioner should have hospital beds under his control, with the facilities of modern medicine, so that he could be responsible for patients right through their stay in hospital.

Sir HENRY COHEN said that in the discussion a speaker had observed that one of the openers had been looking back and the other forward, but he would remind them of Sir Winston Churchill's comment on history: "The farther back you look the farther forward can you see."

Figures for bed-occupancy unless related to the special circumstances—for example, the type of case, use for teaching or research, or for prolonged observation—could be misleading. In his own wards, three years ago, he had found that patients referred from other consultants had, over a period, a stay on an average of 12 to 13 days, but he would refrain from drawing any specific inference from that fact. It must never be forgotten that the research worker rightly isolated one facet of a problem and studied it intensively. Consequently, he was able to make major contributions to the prevention and control of disease. But the patient, in and out of hospital, was greater than the sum of these scientific isolates and must be studied as a whole personality.

Finally, Sir Henry doubted the validity of economic advantage as the sole criterion of the hospitals' contribution to human welfare. There were imponderables in human happiness and pleasure which, in his view, were of at least equal value.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

The Place of Forceps in Present-day Obstetrics

SIR, I expected my article on the above subject (*Journal*, October 31, 1953, p. 951) to arouse criticism if only because it was prepared deliberately to provoke discussion at the Cardiff meeting of the Section of Obstetrics and Gynaecology of the British Medical Association. I was therefore surprised and more than a little gratified to find that what I had thought might be viewed as heresy met with such a large measure of approval, not only at the meeting itself and amongst contributors to your correspondence columns, but also amongst a large number of general practitioners and obstetricians in this and other countries who have written or spoken to me privately.

Dr. M. W. Fordham (*Journal*, November 21, 1953, p. 1159) and Dr. A. H. Morley (*Journal*, December 12, 1953, p. 1324, and February 13, 1954, p. 396) appear to be your only correspondents who have been provoked to what could be regarded as adverse comment, although the technical points which they raise impress me as being reasonable and deserving attention if not acceptance. When attempting to cover a large subject within a strictly limited number of words it is difficult to avoid a semblance of dogmatism, but I am sorry that Dr. Morley should have gained the impression that I was writing "majestically"; for humility is essential to good midwifery and any attempt to dictate technique to others is a sign of ignorance.

In regard to axis traction forceps, I only stated that they had been discarded in the hospital whose results I was reporting and that I regarded this development as merely one of many factors contributing to the improvement in these results. It was not suggested that all who practise obstetrics should immediately abandon axis traction forceps; on the contrary, anyone who is trained and experienced in the use of this or any other particular instrument should adhere to it unless he is convinced that a change would improve his results. The pattern of forceps does not matter so much as the judgment and skill of the obstetrician; the good workman can adapt a well-tried and trusted tool or method to meet all manner of circumstances.

Unswerving lifelong loyalty of apprentices to their master, admirable though it may be, can, however, hinder progress, and in this case it ought not to prevent us from recognizing that with the recent rapid evolution of obstetric technique, and from the standpoint of rising generations of obstetricians, the place of forceps having axis traction handles is becoming historical rather than utilitarian. They were introduced for delivery of the head from a high station in the pelvis, and at a time when the mechanism of labour was generally misunderstood. In designing and using them the older obstetricians often sacrificed an accurate cephalic application, or rotated a head from a normal to an abnormal position, in the interests of a pull in the right direction. If it be accepted that caesarean section is now generally preferable to difficult mid-forceps delivery, and that forceps should not be applied (at least in domiciliary practice) until the foetal head has already passed along the greater part of the birth canal, the need is not for an axis traction mechanism but for a simple pattern of forceps which makes for easy observance of the more important principle of an accurate cephalic application. Although axis traction instruments can readily be used on the head arrested at the pelvic outlet, they have no advantage in such a situation. Their potential dangers are that they lure the less experienced operator to reach for a head which is too high to be extracted safely, and they put emphasis on a factor which in these days is not the most important.

Dr. Morley is correct in assuming that the lithotomy position was used in the majority of the forceps deliveries reported in my article, including those in which the mother died from inhalation asphyxia. Space does not permit discussion of the various reasons why the lithotomy position is referred by nearly all obstetricians throughout the world. Dr. Morley will find them stated in detail in *Operative Obstetrics* by J. Munro Kerr and J. Moir. His rather naive explanation that it is

because gynaecologists have invaded the realm of obstetrics cannot be accepted, if only because the lithotomy position was widely adopted long before there were any gynaecologists, and some of its strongest advocates to-day are specialists in obstetrics alone. Even if Dr. Morley's suggestion were correct, however, it remains to be asked why the gynaecologist prefers the patient in the lithotomy position for operating.

Nevertheless, it must be recognized that the left lateral position has some advantages, at least in certain circumstances, and that the lithotomy position may have some disadvantages, among which Dr. Morley very properly emphasizes that, according to the type of anaesthesia employed, it may increase the risk of inhalation asphyxia. Here again it is unreasonable to lay down hard and fast rules, and, even if it is generally accepted that the advantages of the lithotomy position ordinarily far outweigh its disadvantages, it does not mean that every obstetrician must use it or that any obstetrician should use it in every case.

Just as Dr. Morley was taught to use axis traction forceps with the patient lying on her left side and has found the method to his liking, I was, soon after qualifying, advised to avoid engaging in public correspondence as far as possible. This explains why I did not reply to Dr. Morley's letters of June 4, 1950 (p. 1319), and December, 1953, letters in which he made his points well and which could safely be left to rest on their own merits. I reply now only because to leave a third letter unanswered might appear discourteous, and because I should like him and Dr. Fordham, as well as other contributors to this discussion, to know that I appreciate their observations, which have helped to fill in some of the many gaps in the original paper. We can certainly ill afford to neglect any suggestion which might reduce the present risks of general anaesthesia in midwifery.—I am, etc.,

Liverpool.

Rh Antibodies and Domiciliary Midwifery

SIR, I am sure all general-practitioner obstetricians will be grateful to Dr. M. Chalk (*Journal*, February 20, p. 457) for bringing the subject of Rh antibodies and domiciliary midwifery up for discussion. All who practise domiciliary midwifery are familiar with this problem and will admire the soundness of Dr. Chalk's methods in dealing with these cases, but how many are fortunate enough to have a laboratory with 24-hour facilities close at hand?

First, I would like to underline the need for reassurance to the Rh-negative mothers, most of whom have exaggerated ideas on the gravity of the condition. In this connexion, as well as a precaution should need for transfusions arise later, it is wise to determine the paternal blood group—and a certain number of patients can have their minds put at rest immediately. In the case of a primigravida without a history of miscarriages in whom antibodies are found at the thirty-second week, domiciliary confinement can be permitted, for the risks of an affected baby, let alone a severely affected baby, are negligible. A sample of blood is sent for a Coombs test as a routine. In a subsequent pregnancy arrangements should be made for admission to hospital.

The case of the multigravida is somewhat different, and if antibodies are present she should certainly be confined in hospital. Anybody who has seen an affected baby turn yellow within a few seconds of cutting the cord will surely agree. Even the best-equipped hospital likes to have some notice that a replacement transfusion may be required. It takes some time to mobilize the equipment, paediatrician, and haematologist, and to obtain the correct blood, cross-match and alter the P.C.V., etc. There are no reliable tests to determine in utero if the foetus is affected (the presence of antibodies puts us on guard). Until there are, let us of general practitioners, who have a lot of other problems, leave this one to those whose intimate concern it is, for they need all the research material they can obtain.

Unlike your correspondent, I am only too willing to receive instruction on such a complicated and important matter.—I am, etc.,

Southwold.

R. H. REYNOLDS.

SIR,—Dr. M. Chalk (*Journal*, February 20, p. 457) raises an important problem. I have notes of over 600 confinements from 1945. Three patients were Rh-negative with antibodies with following results in four confinements. All the children were affected with erythroblastosis.

(1) Mrs. X, 3rd para, confined in hospital. Child was transfused and died after a few hours from cerebral haemorrhage. (2) Mrs. Y, 2nd para, confined in private nursing home. Child alive, not anaemic (Hb 13.6 g.), required transfusion 230 ml. at 3/52. Alive and well. (3) Mrs. Z, 2nd para, confined in private nursing home. Child (cord blood, Hb 9.1 g.) given replacement transfusion immediately after birth in hospital, returned to mother in home the same evening alive and well. (4) Mrs. Z, 3rd para, confined in hospital January, 1952. Stillborn.

I am satisfied that with the help of the paediatrician and the haematologist there was no more delay in case No. 3 than would have occurred in hospital. I am convinced that this help must be laid on for all women with antibodies. In this small series the hospital results were poor, although no blame could be attached to anyone for the result in case No. 4, as the foetus was dead before labour started. I believe that case No. 1 would have had an easier labour at home, as I should not have allowed her to struggle so long with an occipito-posterior without rotating manually. The nursing homes concerned were no better equipped than a decent house.

I conclude, therefore, that these women may be confined at home provided: (1) the home is of reasonable standard; (2) the mother really wants to be delivered at home; (3) the general practitioner is willing to take precautions and enlist the help of the paediatrician and haematologist. I agree with Dr. Chalk that pregnant women should be surrounded with all modern care and attention, but this care should not be so blatant, not to say strident, as is found in many hospitals. The women just get worried to death.—I am, etc.,

Cambridge.

C. W. WALKER.

SIR,—As a general practitioner, I agree wholeheartedly with Dr. M. Chalk (*Journal*, February 20, p. 457) that domiciliary midwifery provides distinct advantages over hospital midwifery. If, however, one concedes that 45% of Rh-negative women with antibodies bear affected children,¹ and that exchange transfusion undertaken within the first nine hours of life has been found to be the best remedy for preventing the development of kernicterus,² then, I submit, there are grave disadvantages in their delivery at home.

First, the general practitioner must be at the delivery to obtain umbilical cord blood for a Coombs test, to do a haemoglobin estimation, and to make a detailed physical examination of the neonate for signs of haemolytic disease. All general practitioners know what such an implacable "must" implies. Secondly, a reassuring negative Coombs may be unobtainable within nine hours of birth. Many laboratories do close at night. Thirdly, hospitals may be loth to take in a neonate for blood tests and observation only, and rightly so, for a case from outside is for them technically not clean. On the other hand, to put a clean baby in a nursery in which it might possibly become infected is hardly fair. Breast troubles in the mother and feeding difficulties in the baby on its return home may be increased.

After one experience of having to leave a busy evening surgery to attend the confinement of a Rh-negative woman with strong antibodies, who refused categorically to enter hospital, of finding that pre-natal arrangements for hospital admission of the suspect neonate had come unstuck, and of finally getting its admission to hospital after three further refusals from other hospitals, I am, for myself, quite certain where Rh-negative women with antibodies ought to be confined.—I am, etc.,

Manchester.

Papilloedema in Emphysema

SIR,—I was interested in the very instructive article by Dr. T. Simpson on acute respiratory infections in emphysema (*Journal*, February 6, p. 297). I have examined the fundi of a considerable number of cases of emphysema with severe cyanosis and the findings are quite characteristic. In gross cases the veins are enormously dilated and the tortuous, black sausage-like appearance is very striking. The arteries are often quite normal, although they usually share in the tortuosity. I feel, however, that a word of caution is necessary in interpreting the appearance of the disk as a true papilloedema. It is the rule rather than the exception that the margin of the disk appears to be indistinct in these severe cases, but I think that marked swelling is very uncommon. It would seem that this appearance is due to the dilated veins displacing the tissues of the disk and obliterating the physiological cup, but there is often little or no forward displacement, and when one tries to measure the swelling this is found to be impossible. No case of optic atrophy has been reported, although, of course, papilloedema can subside without this occurring.

I have no doubt that true papilloedema can occur, as Drs. Westlake and Kaye (p. 302) have shown that the C.S.F. pressure can be raised in certain cases and quote an example in which actual retinal haemorrhages were seen with papilloedema, but this type of case must be very rare. In his article Dr. Simpson is aware of the difficulty of interpretation of the disk findings and has only included a few cases in the large number of acute emphysema cases in which he has been certain of the swelling of the disk.

I mention the above points to avoid the diagnosis of papilloedema in cases of emphysema more often than it is actually present.—I am, etc.,

London, W.1.

J. GIBSON MOORE.

Medical Needs in the Gold Coast

SIR,—The letter from "Senior Registrar" (*Journal*, February 27, p. 519) raises important questions for all men and women contemplating service in the overseas territories with which the Colonial Office is concerned, and perhaps I may be permitted to offer some comments on the points which he mentions in view of the connexions which I have had with the Colonial Service.

On the issue of a career overseas, it must be admitted that, in the past, officers could look forward without apprehension to a life's work and, on its conclusion, to a pension. While that may not seem so to-day in those territories which are rapidly approaching self-governing status, we must not overlook, for example, the declared statement of the Prime Minister of the Gold Coast that a fully self-governing Gold Coast would need and want the services of overseas officers and that their interests would be fully safeguarded. Is it realistic to expect that any employer of labour could say more than this without inviting a sense of overstatement in the minds of the readers of that statement?

In considering what alternative employment would be open to officers who were no longer required by a territory on attaining self-government, it can reasonably be assumed that in the negotiations leading up to the grant of self-government the question of compensation for loss of career would be one of the important issues to be settled at that date. In 1930, when constitutional changes were agreed upon for Ceylon, officers were given the right to leave the service with compensation for loss of career, and when Ceylon became independent in 1948 an agreement was signed guaranteeing the pensions and salaries of existing and retired public servants. When the mandate for Palestine was given up, arrangements for compensation were made. For those officers who would wish to continue in service overseas, every effort would be made to find suitable employment for them, and it should be noted that all medical officers serving in Palestine who wished to continue in service overseas were allocated to suitable posts in the Colonial Service.

While a guarantee clearly cannot be given in advance that it will be possible to follow some precise course on a particular occasion, it is certain that, taking the overseas territories as a whole, British officers will be needed for many years to come and no keen and efficient officer should be apprehensive about his chances of continuing in employment.

Colonial pensions are not paid by the United Kingdom Government, since that Government is not the employer of officers in the Colonial Service. The payment of pensions is a liability of the Colonial Government which employs the officer. As was mentioned above in connexion with compensation for loss of career, the negotiations leading up to the grant of self-governing status would also cover the payment of pensions. There is no evidence, so far, to suggest that this aspect also would not be settled satisfactorily or that the terms of settlement would not be honoured. Your correspondent asks whether there is any guarantee that pensions would continue to be paid. One can only answer this by asking another question: What evidence of any default is there, so far, which would justify apprehension on this score?

I hope that your correspondent and others who will read this letter will appreciate that there are really no grounds for apprehension, either about the payment of reasonable compensation if careers are cut short, or about the payment of pensions when an overseas territory achieves self-government. Where this has happened to date, satisfactory arrangements have been made and there is no reason to suppose that the same will not be the case in the future.—I am, etc.,

Cardiff.

FREDERICK HEAF.

Lumbar Puncture

SIR,—It is unfortunate that Dr. J. N. Cumings in his article on "The Cerebrospinal Fluid in Diagnosis" (*Journal*, February 20, p. 449) should advocate anew the procedure of lumbar puncture in cases of intracranial and spinal tumour. The majority of the younger generation of neurologists and general physicians are alive to the danger of this investigation producing tentorial or medullary pressure cones and realize that very little information of value accrues from its use. This enlightened view was well put forward by Dr. W. Gooddy in your issue of November 7, 1953 (p. 1040). Once the suspicion of space-occupying lesion within the skull has arisen upon clinical grounds the appropriate investigations are those of radiography of the skull, air study of the ventricular system and/or angiography, the aim being to localize the expanding lesion in order to give the neurosurgeon the best chance of making a radical cure, if this be possible.

Lumbar puncture disturbs the pressure relationships within the skull and spine, frequently produces an aggravation of symptoms or signs and occasionally death within 24 to 48 hours as a result of slow seepage of cerebrospinal fluid into the extradural spinal tissues, with the precipitation of a medullary or tentorial pressure cone. Once this vicious circle has been established the chances of a successful result from surgery are gravely prejudiced. Lumbar puncture is dangerous enough, but the added insult of jugular compression is the one measure calculated to initiate pressure coning at the tentorium or foramen magnum. Similarly, lumbar puncture in cases of spinal compression is highly dangerous and often the cause of sudden onset of bladder and bowel complications or of rapid worsening of the clinical picture. When necessary to aid in the diagnosis of spinal tumour, lumbar puncture should be performed on the same day as, and as a preliminary to, myelography and laminectomy in an attempt to relieve the compression.

Lumbar puncture has a use when properly employed in suspected cases of spinal tumour, but it has no place, or value, in the investigation of patients suffering from suspected intracranial tumour.—I am, etc.,

London, W.C.1.

WYLIE MCKISSOCK.

Sterilization of Ampoules

SIR,—It is evident that I owe an apology to Dr. D. Reckless (*Journal*, February 20, p. 455) for the ambiguity in my letter (*Journal*, February 6, p. 355). Lignocaine ("xylocaine"), which I use for practically every extradural block that I do, is supplied in ampoules (or possibly they are better described as phials) made of thick glass and closed by a small rubber plug. This latter can be removed without the slightest risk of any glass being broken. Bacteriological examination of the ampoules' contents has never shown contamination having occurred through the thick glass. So I can assure Dr. Reckless that the technique is absolutely safe, and I am sorry that the lack of clarity in my letter should have happened.

Concerning his admonition to examine the contents of ampoules prior to intrathecal injection, this is advice I am unable to take for the simple reason that I abandoned spinals in favour of the very satisfactory and, I suggest, safer extradural block, six years ago. There is an abundance of good advice in the literature on how to find the extradural space: if Dr. Reckless is still content to encounter the "only disaster" of a fruitless entry into the theca, then I suggest that these are the words of wisdom that have fallen on stony ground.—I am, etc.,

London, S.W.15.

G. C. STEEL.

Reaction to Blood Transfusion

SIR,—I suggest that the fears expressed by Dr. R. D. Barnard (*Journal*, February 6, p. 332) are unjustified because he does not take into account the indications which serve to show when dextran is likely to benefit the patient. The principal indication for dextran is oligæmic shock due to haemorrhage, whether evident or concealed as in crush injuries, or in concealed accidental haemorrhage of pregnancy; and the purpose of its administration is to increase blood volume so that the circulation again becomes effective. Dextran is, in fact, a plasma volume expander and we use it as such, either alone or as a stop-gap, until properly grouped and cross-matched blood can be obtained. We have administered about 1,300 bottles to about 600 patients, and encountered only one reaction sufficiently severe to warrant our stopping the infusion. We do not often administer more than 1,000 ml. 6% dextran to one patient, but we have given 1,500–2,000 ml. occasionally without any serious reactions; all these infusions have been given to patients with haemorrhage or crush injury, and a few have saved lives.

If dextran is used in this way its "conglutinin" powers do not matter. Even were it to increase anti-A or anti-D titres a thousandfold, the patient would not suffer provided that ABO and D homologous blood were administered. In England to-day few transfusionists consider group O blood to be "universal donor" blood, and even in America I believe it is usual to add Wittebsky's group-specific substances to neutralize the agglutinins of group O blood which is to be used as "universal donor" blood. Anyone knowing of the "conglutinate" powers of dextran would expect that if a sufficient quantity of dextran were administered to patients whose blood contained high titres of auto-antibodies an episode of acute intravascular haemolysis would follow. Fortunately, auto-antibodies are fairly uncommon except in acquired haemolytic anaemia, atypical pneumonia, and leukaemia, and are rare in neoplastic disease. It is very unusual for patients with these diseases to require treatment with a plasma volume expander, and I am a little surprised that Dr. Barnard has been able to obtain experimental confirmation that dextran given to such patients causes haemagglutination and (presumably) haemolysis.

In the patient with severe oligæmic shock, treatment must be directed to restoring blood volume. In many patients the *vis medicatrix naturae*, with warmth and fluids by mouth, will suffice; others can tolerate a few hours' delay while blood is obtained; but there remain some who need blood volume restoration as soon as possible. In this last group one must choose between plasma—which carries a 1% risk of hepatitis—and dextran, the dangers of which appear to be theoretical

—unless, of course, one is to fly to the blood bank and demand blood at once, thus increasing the risk of incompatibility. Dr. Barnard's fears seem to be based mainly on work *in vitro*. I agree that when dextran is mixed with blood in the test-tube many peculiar things happen; but if dextran is mixed with the blood remaining in an exsanguinated patient the patient gets better.

I have never done "dextran compatibility tests" and I do not intend to start until it is shown that they would serve a useful purpose; nor do I propose to allow Dr. Barnard's largely theoretical fears to overwhelm my practical experience, which is that patients who have had a sudden severe haemorrhage can usually be revived by dextran infusion, and that in such circumstances dextran is safer than plasma or whole blood.—I am, etc.,

London, N.W.10.

GEORGE DISCOMBE.

"Status Lymphaticus"

SIR,—In his article on "Status Lymphaticus" (*Journal*, January 16, p. 149) Dr. H. B. Dodwell, presumably in support of his views, quotes from Boyd's *Textbook of Pathology* the author's statement that "there is no proof that the thymus gland has anything to do with stoppage of the heart." A few lines above this Boyd writes: "There is no doubt that the diagnosis of status lymphaticus or enlarged thymus has been much misused at coroners' inquests, but on the other hand there does appear to be some relationship between lowered constitutional resistance to certain otherwise trivial injuries and a condition of lymphatic hyperplasia. I may quote the following case from the medico-legal practice of my colleague Dr. Erb, which is surely sufficient proof that the concept of death from status lymphaticus is not a pure myth. One of a group of children who were playing on the road was struck down by a motor car and injured. He did not die, but a little lad watching the accident from an adjoining lawn fell dead. At post mortem the child was found to have an enlarged thymus, a thin-walled hypoplastic aorta, and marked hyperplasia of the lymphoid tissue throughout the body."

I submit that if the above illustrates the way in which Dr. Dodwell has made use of the subject-matter reviewed then his researches on the subject of status lymphaticus, which appear to be entirely literary, must be regarded with misgiving.—I am, etc.,

Alloa.

W. B. LAING.

REFERENCE

¹ *Textbook of Pathology*, 1947, 5th ed., London.

SIR,—May I reply to the letters criticizing my article on the above subject (*Journal*, January 16, p. 149) which have appeared in the *Journal*? Dr. H. Ucko (*Journal*, February 13, p. 398) would appear to be discussing an entirely different pathological condition; no report of any case of status lymphaticus that I have ever read has described a patient who, prior to unexpected sudden death, displayed anatomical anomalies, recurrent asthma, lymphocytosis, and evidence of the breaking down of the nuclei of lymphocytes. Had this syndrome been associated in this country with sudden death surely a few cases among the two hundred odd deaths per annum would have been described.

Dr. C. Langton Hewer (*Journal*, January 30, p. 274) raises two points of objection to my views—the late Sir Bernard Spilsbury's expressed opinions, and my denial of Dr. Kemp's case records. With regard to Sir Bernard's view, there is no supporting published evidence, the Medical Research Council's Committee found no association between enlarged thymus glands and enlarged lymphatic glands, the only writers to publish a series of narrowed aortae in unexpected deaths found no enlargement of the thymus gland, and I have failed to find any collection of cases of fatty infiltration of the myocardium in sudden death in the young. As to Dr. Hewer's view that it is incredible that Sir Bernard could have pursued a chimera for so many years, surely it is equally incredible that the twelve distinguished members of the Medical Research Council's Committee should have

been thoroughly misled after such painstaking collecting and weighing of evidence?

Turning to Dr. Hewer's second point, I certainly owe Dr. Kemp an apology for stating that he did not cite any cases; he did not do so in the article originally quoted by Dr. Hewer but did cite five cases in his article (which I overlooked) in the *Canadian Medical Association Journal* for 1933 and which, together with two other cases, were reported again in *Elementary Anaesthesia*.¹ I cannot agree with Dr. Hewer in regarding this article as an excellent account, since only a bare majority of the cases have the weights of the thymus glands recorded and all "the" aortas are capable of another explanation—thus, of the two tonsillotomies, that with the really large thymus gland was found after death to have some blood in the lower trachea, and that with the slightly enlarged thymus some venous congestion of the lungs. Of the five non-operative cases, in only two is the weight of the thymus gland stated; both infants found dead showed cardiac petechiae and the other three cases had been ill for from fifteen hours to two days, one of them having a "chest full of rales" shortly before death.

Finally, in his historical account of status lymphaticus Dr. Kemp, in dealing with the article published in Vienna in 1889 from which Osler took his account,² states that Dr. Paltauf had "access to a vast quantity of clinical pathological material and from his wide experience advanced the view . . ."; Dr. Kemp is obviously confusing the author with his elder brother, since the author Arnold Paltauf died in his thirty-third year, four years after the article was published, while it was his elder brother Richard Paltauf who subsequently became in 1898 professor of pathology in Vienna, dying in 1924.—I am, etc.,

London, N.7.

H. B. DODWELL.

SIR,—The cycles of the old, and some of the new, arguments for and against "status lymphaticus" have been moving again in your correspondence. The observations of Dr. H. Ucko (*Journal*, February 13, p. 398) are not only interesting but seem to relate reasonably thymic hyperplasia with adrenal, or pituitary adrenocortical, deficiency in a lack of resistance to stress.

In gross morbid anatomical study of cases of "status lymphaticus" 25 years ago I noticed that a common finding was peculiarly small adrenals. I am now therefore quite interested in Dr. Ucko's final observation that the hypothesis (adrenocortical deficiency) could easily be verified by investigations into the adrenal cortical reserve of cases with suspected status thymo-lymphaticus. Perhaps some specially skilled team will take up this well-worth-while study.—I am, etc.,

Bristol.

A. V. NEALE.

Cortisone and Manipulation of Knee-joint

SIR,—With all due deference to the distinguished members of the Medical Research Council subcommittee, I would like to make a few comments on their recent report (*Journal*, January 30, p. 233) concerning the effect of cortisone as an adjuvant to manipulation in rheumatoid arthritis. No one to-day would use systemic cortisone in preference to topical hydrocortisone to cover the manipulation required to straighten a knee-joint fixed in flexion. It is presumed that when these therapeutic trials were initiated hydrocortisone was either not readily available or its advantages in this situation were not recognized; in either event, it would be interesting to observe the result of further studies, similarly controlled, using intra-articular hydrocortisone.

It is noted that in all cases in this series the contralateral knee was also affected, though less severely than the one selected for manipulation; however, there was no significant difference between the cortisone-treated and codeine-treated groups, the contralateral knee in each group showing some slight improvement. To anyone not entirely familiar with the indications for cortisone therapy, these results might

seem surprisingly negative; but it should be recalled that patients with "severe disease activity" were excluded from this study, and it is only in so far as active inflammation exists in a joint that cortisone can be of temporary benefit. Since in these patients deformities had been present for a minimum of six months, it is reasonable to assume, in the absence of any information to the contrary, that in most of them the arthritis had reached the chronic fibrotic stage in which little if any inflammatory reaction persisted.—I am, etc.,

J. H. LAURIE.

Medical Director, Merck & Co., Ltd.

Whither Anaesthesia?

SIR,—The letter of Dr. Charles E. Sykes (*Journal*, February 6, p. 336) expresses the view of most anaesthetists. The race to be first with the news could be laughable were it not so dangerous, because false facts often endure for a long time. The confidence and comparative ease with which barbiturates and relaxants were so successfully introduced into anaesthesia became presumptuous in the case of hypotension and the bloodless field, even though the dangers were obvious. Doubtless the very highly skilled escaped disaster or confined its use to those cases where the risk is justified, but others were either not so skilled or so lucky. It should be a sobering thought that the majority of these misfortunes could have been avoided if well-established methods had been employed, since, if there is sufficient skill and experience available, the patient unfit for anaesthesia scarcely exists to-day. There was some lack of discernment in the conclusions of many of the research workers in this field.

Our profession very properly defends and encourages the right of freedom of action among its members. It holds, however, that this right implies a responsibility, and the opportunity an obligation. The introduction of every new anaesthetic agent results in a flood of reports of strange reactions, most of which fortunately appear to happen only to a few, and which, after a while, no longer seem to happen at all. Such reports only cause confusion or amusement, since errors of technique and judgment are always possible. Otherwise why are the majority of anaesthetists spared these dramatic experiences when the drugs are in daily use?

Hypothermia is now in the news. Is it too much to ask whether the promised benefits are sufficiently great to justify haste in its use, and if it is not possible that research should be carried out by those with the experience and the facilities to do it adequately? Surely some control is justifiable to ensure that the hypotensive debacle is not repeated, and that our inevitable progress is sane, safe, and satisfactory.—I am, etc.,

Deal

G. DONAL MCGRATH

Controlled Hypothermia

SIR,—Drs. P. R. Mesham and W. E. B. Scott (*Journal*, February 20, p. 455), while discussing the possible site of action of chlorpromazine, state, "We include in our conception of the autonomic system those centres in the hypothalamus and elsewhere which co-ordinate and integrate the functions of this system." Such a wide interpretation of the autonomic nervous system may well justify the claims of the above authors (together with Drs. J. W. Dundee and T. Cecil Gray) in a previous paper entitled "Hypothermia with Autonomic Block in Man,"¹ but it opens the term "autonomic blocking-agent" to include practically every known anaesthetic agent.

No one would question the close association of the hypothalamus with the autonomic system, but are we justified in describing any drug which interrupts the normal mechanism of thermo-regulation as an autonomic blocking-agent? Any anaesthetic drug which produces unconsciousness disrupts the heat-regulating mechanism, and, provided shivering is prevented, the patient's body temperature rapidly approaches that of his environment. Chlorpromazine, therefore, is but one of a multitude of drugs available for lowering the body temperature, and it remains to be proved that

it possesses any advantage over routine and established anaesthetic techniques.

Professor G. A. G. Mitchell, in his excellent book *Anatomy of the Autonomic Nervous System*,² classifies this system into "a central part which includes centres located in the cerebrum, cerebellum, brain stem, and cord," and "a peripheral part which consists of two paravertebral ganglionated trunks and various prevertebral, visceral and vascular nerve plexuses. . . ." If we are to name any drug that acts on this vast network as an "autonomic blocking-agent," then the confusion will be great.

In the interests of clarity, therefore, may I suggest that we should abandon the term "autonomic blocking-agent" at its birth, and return to the parental term from which it obviously sprang—that is, "autonomic ganglion-blocking drug"—a name which has a specific meaning in both physiology and pharmacology?—I am, etc.,

London, S.E.1.

The Unsaturated Fatty Acids

SIR,—In answer to Dr. Eric Lodge's inquiry (*Journal*, February 13, p. 395), one of my partners and I have had some experience of the unsaturated fatty acids in the treatment of leg ulcers in elderly women. These cases healed up well on the treatment. We also found that if the ulcer is infected with *B. pyocyaneus* the ointment was not successful until the *B. pyocyaneus* was killed off; and we found dibromopropylamine isethionate ("brulidine") the most useful cream for this purpose.

We also tried this treatment in two cases of psoriasis. One healed in the course of three months and has not relapsed as far as we know (18 months). The other did not respond to the treatment until ung. dithranol was applied at night. It is now responding very well.

In conclusion we found this treatment most efficacious in the treatment of bedsores.—I am, etc.,

New Malden, Surrey.

CHRISTOPHER PETT.

Intravenous Iron

SIR,—I very much enjoyed Dr. J. A. Nissim's article on intravenous iron (*Journal*, February 13, p. 352). I would appreciate the hospitality of your columns to reply to some of the points raised. I entirely agree that the question of iron precipitation is of great, if not fundamental, importance. Although it has been shown to occur in animals, there is as yet no evidence, as Dr. Nissim himself admits, that it occurs in man with normal dosage, which means, I think he will agree, a maximum of 100 mg. Fe per injection. I am prepared to admit that the iron moiety may not be involved and that my tuberculous cases¹ were not strictly normal cases of iron-deficiency anaemia. Nevertheless, I do not think that impurities in the saccharated component are fundamental causes of reactions. After all, many thousands of injections must be given annually, and only a small fraction cause reactions severe enough to be talked or written of. Surely one should expect more. Betty Holt² has told us that in India reactions are rare despite the fact that the same compounds are used there. Although not strictly apposite, intravenous glucose and glucose saline are given very frequently, but little is heard of painful reactions from this cause. I have no doubt, however, that the compound is locally irritating, for maladministration in my hands has produced some painful and swollen arms from intravenous extravasation. I have tried, without success, to get some saccharated component itself, as I felt that investigation of this moiety would yield interesting information.

It is my experience with the use of antisera, especially anti-diphtheria, that has led me to stress the importance of an altered antigen-antibody reaction in these cases. Landsteiner's³ classical experiments with *para*-arsanilic acid showed that it was its combination with protein, and not the compound itself, which was important. Combinations of bacterial polysaccharides with protein similarly act as

happens. Protein is therefore essential in the production of antigenic effects. This does not seem to me to be incompatible with any theory of the cause of these iron reactions, for either the iron or the saccharated components could combine with the subject's protein to act as an antigen. With regard to paroxysmal haemoglobinuria, this is another example of a violent and abnormal antigen-antibody response—namely, an abnormal cold haemolysin. The reticulo-endothelial system activity can therefore be invoked not as a cause but as an effect of this abnormal reaction.

As to the age of the patient, my limited experience of its use in the old was encouraging in that I thought injections were tolerated better or as well as in younger subjects. There were no reactions in my cases. I have had no experience of injections in children, but the fact that reactions are commoner among them and young adults may be linked with their increased susceptibility to abnormal antigen-antibody effects—e.g., asthma, serum sickness, and so on—just as such effects are rarer in the old.—I am, etc.,

Romford, Essex.

I. M. LIBRACH.

SIR,—I hope that the possibility of toxic reactions reported in Dr. J. A. Nissim's interesting paper (*Journal*, February 13, p. 352) will not dissuade others from the use of this valuable remedy. We have used saccharated iron oxide, mainly for anaemia in rheumatoid arthritis, for four years, and in the last two years or so have been impressed by the lack of toxic reactions. We have used "neoferrum" throughout this latter period. Complete figures are only available since the beginning of 1953. Since then, 117 patients have been given 899 injections (107 of the patients had rheumatoid arthritis). No serious toxic effects and no venous thrombosis occurred; the only "complications" seen were the following: One nervous girl complained of "tingling fingers and a faint feeling" shortly after the first two injections, lasting about 15 minutes. She completed the course without further upset. Two women, given injections during menstruation, thought their loss was heavier for a day after the injections.

Clinical evidence of visceral arteriosclerosis is an indication for caution and the maximal dose may need to be restricted to 100 mg. I do not now think that age of itself, however, is a contraindication. During the period in question, 14 patients over 65 years of age were treated without any ill effects; the eldest was 79 and was treated as an out-patient.

The following practical points may be worth mentioning. Injections are given thrice weekly as a rule, but sometimes daily, using hypodermic needles (size 12), the injection of 10 ml. taking about one minute. These small needles limit the rate of injection and enable veins on the back of the hand to be used when elbows are fixed in flexion. Total dosage is calculated to raise the haemoglobin to 100% (on the basis that 100 mg. iron raises the Hb by 4%), with 50% of the dose added. The initial dose is usually 50 mg., followed by 100 mg., and then 200 mg. injections to the required amount. In frail patients the first dose may be reduced to 40 mg. or less. Care must of course be taken that the injection is wholly intravenous. After injection the arm is raised for a few minutes without any local pressure and the patient rests for a few minutes more (we insist that patients must be recumbent); out-patients are detained for at least 15 minutes.

At least in anaemic cases of rheumatoid arthritis, intravenous iron appears to be a safe remedy, though not, of course, invariably effective.—I am, etc.,

Bath.

M. R. JEFFREY.

The Thyroid

SIR,—Dr. I. Doniach (*Journal*, February 27, p. 503) ends his review of my book, *The Thyroid, a Physiological, Pathological, Clinical, and Surgical Study*, with the remark, "But I am afraid that the work as a whole would irritate the serious student beyond measure." The perceptive reader

will have gathered from the tone and substance of the review that Dr. Doniach, who is a pathologist, does not agree with the conclusions that I have reached from a study of the material obtained from 2,114 consecutive thyroidectomies. Though we must agree to differ I see no reason why there should be any feeling of irritation on either side: time will show where the truth lies.

In fairness to prospective readers may I be allowed to point out that more than 400 out of the 600 pages of the book deal with the anatomy and physiology of the gland, and with the clinical aspects of thyroid diseases and their medical, radiotherapeutic, and surgical treatment. And as to the pathology of the thyroid, if Dr. Doniach will be good enough to re-read my book more carefully he will find that his queries are fully dealt with.—I am, etc.,

London, W.1.

T. LEVILL.

Diagnosis of Thyrotoxicosis

SIR,—I read with great interest Professor E. J. Wayne's paper on the diagnosis of thyrotoxicosis (*Journal*, February 20, p. 411). Some time ago, while following up a number of thyrotoxic patients treated with methythiouracil, I noticed that as they became euthyroid a sinus arrhythmia appeared. It occurred to me that it was perhaps possible that hyperthyroidism with its increased sympathetic tone abolishes sinus arrhythmia, and therefore one could exclude, in most cases, a diagnosis of hyperthyroidism if sinus arrhythmia is found. Once aware of this possibility, I have looked for this sign in a number of cases in which a suspicion of hyperthyroidism was raised by the presence of palpitations, sweating, tachycardia, etc.,

So far I have been satisfied that no cases showing sinus arrhythmia have proved, after further investigation, to have thyrotoxicosis. As I have seen no references to this matter in the literature, I venture to make this observation known, as it may be of help in doubtful cases.—I am, etc.,

London, N.19.

E. MONTUSCHÉ.

SIR,—We feel that the article by Professor E. J. Wayne (*Journal*, February 20, p. 411) and the leading article of the same issue (p. 443) contain certain experimental and bibliographical inaccuracies which deserve comment.

It was Robertson and Reid¹ and not Robertson² who "pointed out that a specially careful technique and standards derived from normal persons in Great Britain should be used" for estimation of the B.M.R. Robertson³ drew attention to the value of the effect of iodine on the B.M.R. as a diagnostic test for thyrotoxicosis, of great value when the thyrotoxicosis is mild and the B.M.R., though raised for the patient, yet may fall within the normal range, and Means⁴ stated this a year previously. It is not our experience that B.M.R. "observations on out-patients are often unsatisfactory" or that "the test can be conducted satisfactorily only on the in-patient." To quote from a previous paper by Robertson,⁵ "this is an entirely false conception without any experimental evidence to support it." Around 1930 both Benedict and DuBois told one of us (J.D.R.) that B.M.R. tests on ambulatory patients were as accurate and reliable as those carried out at the bedside, if half an hour's rest on a comfortable bed in a warm room at a temperature around 20° C. precedes the determination. Full details are given in the paper just quoted, in which paper Benedict and DuBois's views were amply confirmed.

With regard to the determination of serum protein-bound iodine, the pessimistic note struck by both Professor Wayne and your leader writer is contrary to our experience. One of us (Kirkpatrick⁶) has recently discussed the practical aspects of a method somewhat different in principle to that used by Professor Wayne, and has indicated the precautions needed to avoid the most serious of the difficulties that may arise. We have employed this method routinely in this department during the past two years, and have found it of great assistance in the assessment of thyroid status, the time and cost involved comparing favourably with those of a determination such as the 17-ketosteroids in urine which is now a more or less familiar feature in clinical bio-

chemical work. We feel justified, therefore, in having a more hopeful outlook regarding the extension of availability of the determination to clinicians, especially as stimulation of interest is prerequisite to improvements in accuracy and technique.—We are, etc.,

H. F. W. KIRKPATRICK.

College of General Practitioners

SIR,—In answer to Dr. D. G. Berry (*Journal*, February 27, p. 520), we would like to say that the arrangement to send the College's Research Newsletters to members on the Research Register only (before publishing them in the *Practitioner* and subsequently in the Annual Report) is a Council decision which could be changed if the expense of circulating nearly 3,000 members and associates with frequent letters was considered justifiable. During the past year you have kindly published in your *Journal* more than a dozen notices about the activities of the College which many members have seen.

The time for lectures delivered to undergraduates last autumn (5.30 p.m.) was deliberately chosen, after discussion with medical schools, as being that most suitable for medical students. Any similar course of lectures for postgraduates will clearly be arranged at times which will not clash with normal surgery hours.

Some regional faculties have already been formed in the provinces and overseas, which, with others now being developed in London and elsewhere, will provide information on all College activities for those members and associates who wish to play an active part.—We are, etc.,

G. F. ARERCROMBIE,
Chairman of Council.J. H. HUNT,
Honorary Secretary.College of General Practitioners,
London, E.C.4.

The Feeble-minded

SIR,—The paper by Drs. N. O'Connor and J. Tizard (*Journal*, January 2, p. 16) was welcome as a piece of factual information, especially where it depended on the observations over a wide range of hospitals of one team of workers. This kind of knowledge is hard to come by. It is a pity that it made a text for the unhelpful suggestions in the annotation (p. 35) and, apparently, elsewhere to which Dr. J. M. Crawford refers so wisely and so clearly (*Journal*, February 13, p. 395). I endorse his every word, particularly about the treatment of the feeble-minded.

It is true that there is some variation in policy between one hospital and another—we have not reached the dullness of certainty that there is only one best way—but to his statement from Botley's Park I can add one on the practice of the hospital for which, until recently, I had been responsible for 20 years. Each patient was regarded as an individual rather than as a member of a group, and none was "detained for an indefinite period" because he "might become" difficult. The aim was to develop and train each one as far towards life in the community as it seemed possible for him to go. Apart from such psychiatric adjustment as was necessary, the stages were freedom of movement within the hospital, parole in the neighbourhood, short leaves, long leaves, full licence, and possible discharge. At the same time there was social and occupational training within the hospital leading to daily work outside the hospital, usually of progressive responsibility and importance, and then to useful employment on licence in employable cases. The process took only a short time for a few patients, even when admitted with a lurid history; for some it took years and several trials and failures; and for many the full grade could never be made. But the hope and the effort

were always there, and the patient's capacity and ability were estimated and his treatment and progress judged—in fact he was fathered and mothered by the team of doctors, nurses, trainers, teachers, and other staff, the social workers and, when possible, the parent or friend outside under the guidance of the psychiatrist.

The fallacy in the annotation, and it was suggested in Tizard and O'Connor's earlier paper¹ on the factory experiment at Darenth, is that employment is the main object and employability the criterion. As Dr. Crawford makes clear, the long aim of all treatment is the wider one of social rehabilitation, to enable the feeble-minded person to live in the community with reasonable success and with comfort to himself and his neighbours.—I am, etc.,

Wimbledon, S.W.19.

Eli Lilly Medical Research Fellowship (South Africa)

SIR,—May I, through the courtesy of your columns, draw the attention of medical practitioners registered in South Africa, who may at present be in the United Kingdom, to the fact that applications may be submitted for the 1954 award of this Fellowship? The value of the Fellowship is \$250 a month for 12 months, plus return travelling expenses to the point of study in the United States of America. Further details can be obtained from the undersigned. The closing date for applications is June 15, 1954.—I am, etc.,

Capetown.

H. A. SHAPIRO.

Honorary Chairman, Selection Committee,
Eli Lilly Medical Research Fellowship (South Africa).

A New Oral Diuretic

SIR,—Referring to Dr. Myer Cohen's letter (*Journal*, February 13, p. 394) under the above title, I too found your annotator's arguments regarding "mercloran" unconvincing if not actually misleading, and with no other information than from your annotation would have dismissed the preparation as unreliable as previous oral mercurials. I had, however, used mercloran in a number of cases, both before and after your annotation appeared, both under hospital conditions, with measured fluid intake and output, and also in the home. My technique has, however, been that suggested by the manufacturers—the administration of one tablet, three or four times daily, supplementary injections of a mercurial being given once weekly or less frequently. The results have been entirely satisfactory, the basal output being in most cases greatly increased, with no gastro-intestinal upset, a result I have never achieved with previous oral preparations.

Given as recommended above, mercloran should prove a most valuable aid to the general practitioner, in keeping his cardiac cases oedema free, without unpleasant side-effect.—I am, etc.,

Tiverton, Devon.

T. N. RUDD.

Westminster Abbey Appeal

SIR,—During the course of last year you were good enough to draw the attention of your readers to the Westminster Abbey Appeal Fund. I shall be grateful if you will now allow me through your columns to thank all the members of the medical profession who so kindly responded to the Appeal. It has proved impossible to write to all contributors personally, beyond sending them an official receipt, but I hope that these few words will serve to assure them one and all of the sincere gratitude of the Dean and Chapter of Westminster. There is good hope that before the Fund finally closes down the target of a million pounds will have been reached.—I am, etc.,

London, S.W.1.

ALAN C. DON,
Dean of Westminster.

Obituary

K. H. DIGBY, O.B.E., M.B., F.R.C.S.

We record with regret the death of Professor Kenelm Digby in London on February 23 at the age of 69. For many years he was professor of surgery in the University of Hong Kong, and since his return to England he had been doing surgical research work at the Royal College of Surgeons.

Kenelm Hutchinson Digby, the son of the late William Digby, C.I.E., was born at Ealing on August 4, 1884. From Quernmore School, in Kent, he entered Guy's Hospital Medical School, where he had a distinguished career as a student, winning the Michael Harris, the Hilton, and the Beaney prizes. After graduation in 1907 he held a number of resident posts at Guy's, and was surgical registrar there from 1909 to 1911. Meanwhile he had taken the F.R.C.S., and in 1912 he was appointed principal medical officer of the Great Central Railway. He held this post for only one year, however, for in 1913 began his long association with the Colony of Hong Kong, where he took up the appointment of professor of anatomy in the university which had been opened the previous year. He occupied the chair until 1923, when he became professor of surgery; since 1915 he had also been Ho Tung professor of clinical surgery in the university. He relinquished both surgical chairs in 1945, when he was appointed emeritus professor. From 1915 to 1948 he was honorary consultant in surgery to the Government of Hong Kong and from 1930 to 1948 surgeon at the Queen Mary Hospital in the island. In the Birthday Honours in 1939 he was appointed O.B.E. for his medical services in Hong Kong. Interned in the Stanley Camp, by the Japanese during the last war, he returned to this country in 1949 and had since been engaged in research work at the Royal College of Surgeons of England's surgical research farm at Downe, in Kent.

Professor Digby's medical interests were wide, and he turned his inquiring mind to problems both within and outside the scope of clinical surgery. He published many papers on a great variety of subjects and, in 1919, a book entitled *Immunity in Health: the Functions of the Tonsils and the Appendix*. His ingenuity and versatility were remarkable, and he enjoyed devising his own equipment. At the Scientific Exhibition at the Annual Meeting of the B.M.A. in Cardiff last year he demonstrated methods of investigating the functions of the subepithelial lymphatic glands.

A member of the British Medical Association for many years, Professor Digby was president of the Hong Kong and China Branch in 1946, and after his return to England served on the Council of the Association from 1952 until January of this year (when he resigned) as the representative of the Borneo, Ceylon, Hong Kong and China, and Malayan Branches, and on the Overseas Committee during the same period. He married Miss Selina D. Law in 1913, and there were two daughters of the marriage.

We are indebted to Professor L. J. DAVIS for the following appreciation: As a man, Digby was remarkable for his integrity, his honesty of purpose, his enthusiastic attitude to life, and his complete absence of smallmindedness. His colleagues in committee sometimes found him somewhat intransigent when there were differences of opinion, but his opinions were often vindicated by time, and he never

nourished rancour. If he did disagree with people he never spoke ill of them. He had no enemies, but many friends among people of all positions and races.

As a teacher, he was remarkable for his zeal, which never flagged notwithstanding advancing age and adverse climatic conditions. Many hundreds of medical students who have passed through his hands owe much to him for his sound teaching of the principles and practice of surgery. As a surgeon he was quite first-rate. He neglected no opportunity of extending his knowledge of new developments, and during his leaves of absence from Hong Kong he visited most of the leading surgical centres in Europe and the U.S.A. Despite his heavy commitments as a teacher and a practitioner of surgery, he took a lively interest in research. He wrote papers himself and stimulated his associates to do likewise. Throughout his life he maintained his interest in the role of lymphatic tissues in immunity. Only just recently he demonstrated an exhibition of this subject before a scientific society in this country. News of his death will be learnt with great sorrow by his former colleagues, patients, and students in the Far East and elsewhere.

F. R. SELBIE, M.D., Ph.D., D.Sc.

Professor F. R. Selbie, professor of bacteriology at the Middlesex Hospital Medical School since 1949, died suddenly in London on February 22 at the age of 49.

Frederick Robert Selbie early gave evidence that he was destined for high academic honours. He had a brilliant career at Aberdeen University, gaining gold medals for anatomy and one for being adjudged the most distinguished student of his year. He graduated M.B., Ch.B. in 1928, and four years later his thesis for the M.D. brought him the Thursfield Award, which is given for the best thesis of the year. Resolved on a research career in some branch of pathology he went to Paris to continue his training at the Pasteur Institute. Here he worked in the department of Professor Levaditi, studying rat-bite fever and relapsing fever. From Paris he went to the University of Munich to work with Professor Borst, and, returning to this country, he joined the staff of the Imperial Cancer Research Fund, then under the directorship of the late Dr. J. A. Murray. For the first few years that he spent there he made a study of transplantable tumours, a subject which was still in its infancy at that time, but later he joined forces with the late Dr. W. E. Gye, who succeeded Murray as director, and together they tackled the problem of virus-induced tumours. This work he continued after his move to the Middlesex Hospital in 1936, where with the late Professor James McIntosh he was responsible for some outstanding achievements on the nature of virus neoplasia.

The next phase of his work included the war years, and at this time Selbie turned his attention to the urgent problems arising from the discovery of the sulphonamides and the antibiotics. On this subject he made some first-class contributions to the medical literature, among which may be mentioned his work on infective endocarditis and on gas gangrene. In this, close collaboration with the clinician was essential, and his co-operation with the clinical staff of the Middlesex Hospital was an important contributing factor to the great value of this work.

After the war Selbie was called upon to take charge of the bacteriology department of the Middlesex Hospital, and while still continuing with research work his activities found a much wider scope in the assistance he gave to the staff of the Middlesex Hospital and in his great service to the students. He was a brilliant

exponent of his subject and a sympathetic teacher with a full realization of the students' difficulties. He took the degrees of Ph.D. (London) in 1944 and D.Sc. in 1949.

Apart from his contributions to research and his work in the school and hospital, his ability and personality led to his being invited to undertake numerous outside responsibilities. These he carried out with enthusiasm and the same high standard which characterized all his work. He was secretary of the Pathological Section of the Royal Society of Medicine, and latterly was the representative of that Section on the editorial committee. He was also secretary of the Board of Studies in Pathology for four years and acted as examiner in pathology for the final degree. He had been editor of the *British Journal of Experimental Pathology* and of the *British Journal of Cancer*. He gave lectures to the nurses of the Middlesex Hospital and also, for the Royal College of Nursing, to the sister tutors; he was in the middle of a course of these lectures at the time of his death. He was an energetic member of the Royal Microscopical Society, of which he was a vice-president, and attended most of its meetings. He was also a member of the Medical Research Club and of the Pathological Society of Great Britain and Ireland. In these numerous activities Selbie was unsparing of himself and rendered considerable service to the world of pathology in general.

His apparent reserve on early acquaintance soon melted on better knowledge of him, and his colleagues have cause to appreciate his great helpfulness and loyalty to them. To his fellows his outstanding characteristic was one of unselfish helpfulness, but he could be very forthright in denouncing slipshod work or specious assertions made with little foundation. He made an excellent companion both in his work and elsewhere. At the height of a brilliant career the tragic death of Selbie at the age of 49 leaves gaps in many circles.—R. W. S. and S. P. B.

EUGENE WOLFF, M.B., F.R.C.S.

Mr. Eugene Wolff, ophthalmic surgeon to the Royal Northern Hospital and to the Moorfields, Westminster, and Central Eye Hospital, died suddenly in London on February 28. He was 57 years of age.

Eugene Wolff was born at Oudtshoorn, Cape Province, South Africa, on March 11, 1896. He was educated in London at University College School and then at University College Hospital. Graduating M.B., B.S. in 1918, he won the Lister medal for clinical surgery in the same year, and was appointed ophthalmic registrar at University College Hospital after he had held the post of house-surgeon there. From 1918-19 he served in France as a captain in the South African Medical Corps, and then returned to University College as demonstrator of anatomy, a post which he held until 1930. Meanwhile he was developing his interest in ophthalmic surgery, and held the post of chief clinical assistant at the Royal London Ophthalmic Hospital. In 1928 he was appointed ophthalmic surgeon to the Royal Northern Hospital. Eight years later he joined the staff of the Royal Westminster Ophthalmic Hospital. He was also at one time ophthalmic surgeon to the Metropolitan Hospital in London.

Besides building up a big practice in his specialty he played an important part in ophthalmological affairs generally, and in 1950 he was appointed by the University of London as a teacher in ophthalmology at the

Institute of Ophthalmology. He had held office as vice-president of the Ophthalmological Society of the United Kingdom and also the Ophthalmic Section of the Royal Society of Medicine; and the Belgian and Greek Ophthalmological Societies had honoured him by awarding him honorary membership. Since 1950 he had been a member of the North-west Metropolitan Regional Hospital Board.

Wolff was not only a first-class ophthalmological surgeon, but he had a keen, inquiring mind and an enviable ability to express himself clearly. His early interest in anatomy never left him. One of the earliest of his publications was a book entitled *Anatomy for Artists*, which reached its third edition in 1947. He was also the author of *An Anatomy of the Eye and Orbit* (fourth edition, 1953), *Pathology of the Eye* (third edition, 1951), and *Diseases of the Eye* (fourth edition, 1952). In 1923 he married Lydia Abravanel; she and a daughter survive him.

We are indebted to Mr. P. MCG. MOFFATT for the following appreciation: The sudden and unexpected death of Eugene Wolff has deprived ophthalmology of one of its most distinguished exponents. I had the privilege of knowing him from the time of his first association with the then Royal Westminster Ophthalmic Hospital in 1930. His career had already taken shape. A brilliant studentship at U.C.H. had been followed by ten years' study of, and demonstrating, anatomy, pursued at the same time as the study of ophthalmology at his parent hospital and at Moorfields. His love of anatomical detail and the influence of Elliot Smith, Percy Flemming, and Sir John Parsons give the clue to his early devotion to the study of the anatomy, histology, and pathology of the eye. In these fields he earned an international reputation by his original observations and the publication of *An Anatomy of the Eye and Orbit* and *A Pathology of the Eye*: both are accepted standard works to-day. He was a lucid lecturer and a great teacher, possessing infinite patience, anxious and able to impart his knowledge to others. I enjoyed many demonstrations of slides and specimens in the pathological laboratory, where he spent much of his time, and where many of the illustrations for his books were prepared. He had an immensely wide knowledge of ophthalmic literature, a fact well known to his colleagues, who often brought their problems to him and rarely did so in vain. To his juniors he was always encouraging and imbued them with the spirit of enthusiasm to advance the knowledge of their specialty. He used to say that he could read French and German but could not speak either language. On one occasion when he was due to read a paper before the French Ophthalmological Congress he confessed to his friends that it was possible to read the paper in French but that answering questions afterwards was a very different matter. As expected, he acquitted himself with distinction. He wrote a great many papers on subjects of histological, pathological, and clinical interest, and in addition to the two books already mentioned he wrote *An Anatomy for Artists* in 1926, *A Shorter Anatomy* in 1928, and *Diseases of the Eye* in 1937. All his books have gone into several editions. He was for ten years lecturer in anatomy at the Slade School of Art.

To his friends who knew him well, his outstanding qualities were his modesty about himself and his very considerable achievements, his enthusiasm and indefatigable industry, and his kindness. As a recognition of his valuable contributions to ophthalmology he was awarded the William Mackenzie Memorial Medal at Glasgow in 1947. In the preface to his books he paid tribute to the help afforded him by his wife. To her and their daughter we extend our deepest sympathy. Wherever ophthalmologists gather together the name of Eugene Wolff will be remembered.

H. E. L. writes: I should like to add a small tribute to the late Mr. Eugene Wolff. It was my great privilege to have his friendship soon after I arrived in Britain and came

to work at University College. I shall always remember with affection the time spent with the Wolffs at their beautiful home in Wimpole Street. To us—postgraduate students and junior academic people—these were wonderful evenings, full of warmth, human kindness, and cultured conversation. Sir Arthur Keith, in his *Autobiography*, recalls as a young man, living in "digs," how much he appreciated the visits he made to certain friends of his, and that they kept him in touch with "how life should be lived." I felt the same appreciation of Mr. Wolff's hospitality, but he was always embarrassed when I quoted Sir Arthur Keith. One was often tempted to stretch one of their invitations and include a colleague or two who might be currently depressed by impending examinations, or home sickness, or the general physical discomforts of lodgings in Bloomsbury, Notting Hill Gate, or Camden Town. A few hours spent in the lively sympathetic company of Mr. Wolff and his family would restore morale for a long time. Their generosity seemed inexhaustible; they never boggled at the troop that I brought, and somehow or other I was always asked again. An adequate tribute is very difficult, coming from me: it tends to sound trite, and I shall respect his memory by avoiding what he abhorred. I speak on behalf of many of my friends when I extend our deepest sympathies to his family.

H. W. POOLER, M.D.

We record with regret the death on February 28 of Dr. H. W. Pooler at the age of 88. He was elected a Vice-president of the British Medical Association in 1947. In his autobiography, *My Life in General Practice*, he described himself as "an ordinary general practitioner." He certainly showed in that volume that the life of the busy family doctor, ordinary or otherwise, was not lacking in human interest or drama or colourful incident. He showed also that it had its deep and abiding satisfactions.

Henry William Pooler was born at Wellington, Shropshire, on January 30, 1866. His father was a tailor and draper in that town. One of his earliest recollections was of seeing Captain Webb, of Channel-swimming fame, who was the son of a doctor in the neighbourhood, arrive at Wellington, where the people took the horses out of his carriage and dragged it to his hotel. At the age of 10 Pooler was sent to the traditional school of his family, Adams' Grammar School, Newport, in the same county. At 17, having passed the London matriculation, he was firmly resolved on medicine as his career. The difficulty was ways and means. His father had no money to spare. It was arranged that Pooler should become a pupil of his uncle, Dr. George Hollies, a man of sterling character—when approaching his 80th year he went up to Cambridge to take his M.A. degree at the same time as his grand-nephew. This pupilage allowed Pooler to register as a medical student eighteen months before entering a medical school proper, and it gave him an insight into medical practice. In those days there were no telephones and no cars. The doctor, if a call came at night, had to saddle and bridle his horse for riding or harness it to his vehicle for driving, and whatever complications he found when he got to his case he had to deal with them himself. Pooler never ceased to be grateful for an insight into general practice in the country under those conditions. After about eighteen months with Hollies he was entered as a student at Queen's College, Birmingham, in 1885. Later on he returned as a qualified assistant, spending six months with his uncle before taking up a succession of resident hospital posts. During those six months he helped his uncle amputate a

thigh and a forearm, while finger amputations, strangulated hernias, and the like were all in the day's work. He would start out on horseback on his country round at about ten in the morning, lunch at a convenient inn, and return home about four in the afternoon; and then perhaps he might have to saddle another horse to visit a patient some miles away. Midwifery calls were frequent. Pooler himself declared much later that he had done every operation in midwifery except caesarean section.

During his student career in Birmingham he served as a dispenser to a doctor in the city. His wages began at 15s. a week and rose to 50s., together with the offer of a partnership by the time he had qualified, but, having his eye at that time on the Indian Medical Service, he declined the offer. He was accustomed to do his dispensing each morning until ten or later, then to rush to the hospital for clinical lectures and ward work, and, in the afternoon, lectures at the college.

He qualified L.S.A. in 1889, and before going up for the last part of his final he obtained the most valuable prize open to senior students at the General Hospital, that of resident medical assistantship. Later he became house-surgeon in the obstetric and ophthalmic department at Queen's, and subsequently was elected to the post of house-physician. Dr. Guy Dain was one of those who, as clinical clerks, came under his more or less paternal eye. It was while at Queen's that Pooler met Sybil Woodward, a nurse, whom he married in 1894, and thus began the happiest of married partnerships, which continued for more than 50 years. Mrs. Pooler died on November 5, 1951. He obtained the London Conjoint diploma in 1890 and took the degrees of M.B., B.Ch. of the University of Birmingham in 1901, proceeding M.D. in 1952, over 50 years later.

On leaving hospital Dr. Pooler bought a practice at Ashted, a district in the east end of Birmingham, for £700, and received in the first twelve months £412. Eventually, however, he made a good income, but the work was very hard—morning and evening surgery at home and at a branch surgery from 8 to 9 p.m. or later, after a long day's visiting, and there were many night calls. Midwifery was essential in those days to the general practitioner, and he averaged over 200 cases a year. After 15 years, tired of the round of practice, he took up a whole-time position as district medical officer and public vaccinator, but when the National Health Insurance Act came in he resolved to get back into private practice. Practice in the east end of Birmingham was not exactly a bed of roses, but one thing on which he always looked back with great satisfaction was the formation of the Birmingham Infant Health Society, of which he was appointed honorary medical officer. It was a gratification to him, many years after he had left Birmingham, to have his old centre chosen on the occasion of a royal visit as a representative example of pioneer child welfare work. For some years Pooler was a member of the Birmingham City Council, and undertook as a member of the housing committee two extensive tours to inspect Continental housing. He also represented the city at international conferences on child welfare at Berlin and Dresden.

His connexion with Birmingham came to an end in 1916, when he took up a practice in the attractive village of Stonebroom, near Alfreton, in Derbyshire. Here the income was small, but the work, though heavy, was congenial and the people friendly and pleasant to serve. After twenty happy years he left this village for the

neighbouring one of Ashover, while his son Alan carried on at Stonebroom, the father still continuing to do some work in the practice. To the great grief of his family and friends, Alan Pooler, always delicate in health as the result of rheumatic fever in early life, died as the result of overstrain during the second world war. Dr. Pooler's other three sons are all members of the medical profession, and his daughter is married to a doctor. The later years of Dr. H. W. Pooler were spent in retirement at Ashover, where his hobbies were alpine gardening, the collection of old English watercolours, music, and the game of chess.

While in practice in Birmingham Pooler was made honorary secretary of the Central Division. There his first duty was to issue 350 confidential circulars to members informing them that certain practitioners had come under the ban of the Association for conduct held not to be in accordance with the honour of the medical profession by acting as medical officers of a certain dispensary in Coventry. That affair ended in a writ for conspiracy, libel, and slander, and heavy damages were awarded against the Association.

On moving to Derbyshire he was again made honorary secretary of the Division, where he found himself plunged into a series of fights with miners' clubs—clubs formed for the purpose of providing miners' dependants with medical treatment—and in a fight with the county council over the salaries of district medical officers. He was elected president of the Midland Branch, and later, when Derbyshire became a Branch by itself, of that Branch also. He was a member and the treasurer of the Derbyshire Panel Committee, and the moving spirit of a benevolent trust, the object of which was to make grants to needy Derbyshire insurance practitioners or their dependants, particularly for educational purposes. For many years he was a familiar figure in the Representative Body, and in 1930 he became a member of the Council, where he sat on many committees, but did his chief work as chairman of the subcommittee concerned with maternity and child welfare. He was one of a small committee which went to South Wales to investigate the well-remembered Llanelly dispute in 1934. His term as member of Council ended in 1943, and in 1946 he gave up the local secretaryship. He had then been in the medical profession as student and practitioner for more than sixty years. At the Annual Representative Meeting held in London in July, 1947, he was elected a Vice-President of the British Medical Association as an appreciation of the exceptional services he had rendered to the Association.

Pooler will be recalled as a friendly, vivacious companion, a man with a great faith in his profession and its ideals, and an "ordinary general practitioner" who managed to fill out his length of days with the most devoted service to his fellow-beings and thereby with an amplitude of quiet happiness for himself.

Dr. GEORGE COOPER, who died on November 24, 1953, at Budleigh Salterton, where he had spent many years in retirement, was at one time director of the department of radiotherapy at the General Infirmary at Leeds. He was 75 years of age. Born at Belfast on June 22, 1878, he had a distinguished academic career at Queen's University. He took an arts degree at the Old Royal University of Ireland in 1909, and in 1911 graduated M.B., Ch.B. at Queen's University, gaining not only first-class honours but obtaining first place and being awarded a special exhibition. Two years later he

proceeded to the degree of M.D. He held resident appointments at Worcester General Infirmary and at the National Hospital for Nervous Diseases before, during the first world war, he became medical officer in charge of the electrotherapeutic department of the Royal Victoria Hospital at Netley. This appointment was followed, in 1921, by a similar one at the General Infirmary at Leeds, where he was placed in charge of the electro- and radiotherapeutic departments. The following year he obtained the Cambridge D.M.R.E. Dr. Cooper was one of the pioneers of deep x-ray therapy, and was unremitting in his efforts to obtain the most up-to-date and powerful apparatus available. His enthusiasm often induced interested philanthropists to buy new apparatus for his department. In 1920 less than 100 patients attended the department, and by 1925 the number of new patients had increased tenfold. He was appointed lecturer in radiology and electrotherapy at Leeds University in 1924. When the British Medical Association held its Annual Meeting at Oxford in 1936 he served as a vice-president of the Section of Physical Medicine. He retired in 1937. George Cooper did his work with a thoroughness and care which were a feature of every aspect of his life. His specialty brought him into contact with large numbers of patients, many of whom were gravely, and often hopelessly, afflicted. He felt deeply for these people, and invariably extended to them a kindness and sympathy which were as sincere as they were spontaneous; for his quiet, sometimes almost whimsically shy bearing concealed a warm and generous humanity, which was itself the product of a refined and cultured mind. A wide and avid reader, he was keenly devoted to both music and painting, and was as well a true countryman, deeply interested in his garden, and indeed in all aspects of natural beauty. He will be remembered as a delightful professional colleague, a refined and courteous gentleman, and a loyal and trusted friend.—A.W.G.

Dr. ROBERT WILLIAM BOLLANS, who died in hospital at Glossop, Derbyshire, on January 29 at the age of 81, was well known in the district for over half a century. He was born at York and educated at the Yorkshire College, Leeds, graduating M.B., Ch.B. at the Victoria University of Manchester in 1897. Having lived in Derbyshire since boyhood he came to regard Glossop as his home town, although he actually practised from the neighbouring village of Hadfield. From the time he returned to Derbyshire in 1898 as a qualified medical practitioner until his death he was liked and respected by his patients and colleagues as a real family doctor. Always immaculately dressed, and quiet and courteous in manner, he quickly built up a large practice. He was an admirable choice for a justice of the peace, his tolerance and common sense being particularly appreciated in the juvenile court. For many years he was surgeon to Woods Hospital, Glossop, and medical officer to the Hadfield district of the Glossop Union. He had the distinction of being a hereditary freeman of the City of York, his birthplace. A member of the British Medical Association for 53 years, he was secretary of the Glossop Division from 1922 to 1925 and chairman of the Division from 1940 until the time of his death. He had a heart attack on Christmas night last year and was admitted to Woods Hospital, where he died. He leaves a widow, one son, and one daughter.

Dr. DOROTHY STOPFORD PRICE, consulting physician to St. Ultan's Infant Hospital, Dublin, died at her home at Dublin on January 30 at the age of 63. Elinor Dorothy Stopford was born at Dublin in 1890, the daughter of the late Mr. J. J. Stopford, and was educated at St. Paul's Girls' School, London, and at Trinity College, Dublin, graduating M.B., B.Ch. in 1921. She proceeded to the M.D. in 1935. Shortly after graduation she became dispensary medical officer at Kilbrittain, Co. Cork, where she figured prominently during the "troubled times" as the medical officer to a brigade of the I.R.A. When all other means of transport were denied, Dr. Stopford reached her more distant patients in West Cork

on horseback. Early in her career she became associated with St. Ultan's Infant Hospital, Dublin. Other appointments which she held were those of clinical assistant to the children's department, Royal City of Dublin Hospital, consulting physician to the Royal National Hospital for Consumption for Ireland, and consulting physician to the Children's Sunshine Home, Stillorgan, Co. Dublin. In 1925 she married Mr. Liam Price, D.J., who survives her.

J. St. P. C. writes: It was for her work as consultant physician at St. Ultan's Hospital that Dr. Price earned for herself an international reputation. She became attracted by the problem of childhood tuberculosis and devoted herself more and more to this specialty. Directly through her efforts there was built in 1945 at St. Ultan's a unit specially for the treatment of primary tuberculosis. Four years later, in 1949, the B.C.G. unit, another monument to her endeavour, was formally opened at the same hospital. In the City of Dublin to-day and throughout the Irish countryside there are many who owe their lives to her enlightened care of them when, as children, they were brought to her wards at St. Ultan's suffering from the effects of childhood tuberculosis. Her vast experience of the treatment of childhood tuberculosis was frequently drawn upon by Dr. Price for her many scientific contributions to British and Irish medical journals; it was synthesized and published in 1942 in her book, *Tuberculosis in Childhood*, a classic in its subject and a book which to-day enjoys world-wide circulation. In 1937 she began to use B.C.G. vaccine at St. Ultan's Hospital. Advocating its use more widely, she met, inevitably, with considerable opposition, but in the subsequent years she stuck fast to her faith in its powers of prevention and her work did not go unnoticed. In 1949 the Irish Government, as part of a vigorous drive against tuberculosis, decided to launch a national campaign for the use of B.C.G. vaccine. In deference to her pioneering work and to her accumulated experience at St. Ultan's Hospital, the Government centred its campaign on her hospital, and the Minister for Health nominated Dr. Price as chairman of the National B.C.G. Committee. She pursued this work with renewed vigour and enthusiasm. Indeed, her illness, which began in 1950, was undoubtedly the result of so much overwork. In the years since 1950, Dr. Price, although physically incapacitated, kept in constant touch with the development of the use of B.C.G. vaccine at home and abroad. From time to time she published results of the work in Ireland, and indeed, until a fortnight before her death, was engaged in the preparation of a paper for publication. In 1951 Dr. Price was nominated by the executive committee of the Irish Medical Association as a candidate for the award of the Leon Bernhard Foundation prize, given by the World Health Organization for practical achievement in social medicine. Her loss will be widely mourned.

Dr. BALFOUR MCKEAN, who was in practice at Sheffield for over 40 years, died suddenly on February 12 at the age of 66. He was educated at Glasgow High School and Glasgow University, where, after a distinguished career as an undergraduate, he graduated M.B., Ch.B. in 1910. Three years later he proceeded to the M.D., being awarded a high commendation for his thesis. His first appointment was that of house-surgeon at Glasgow Royal Infirmary. In 1911 he was for a time assistant medical officer at the Park Hospital, Hither Green, London, when that institution was being used as a hospital for sick children, and then he returned to Glasgow as house-physician at the Western Infirmary. In 1912 he moved to Sheffield, where he held the appointments of assistant medical officer and, later, deputy medical superintendent at Fir Vale Hospital, known since 1930 as the City General Hospital, Sheffield. During the first world war he held a commission as a captain in the R.A.M.C. and was attached to the 3rd Northern General Hospital, of which the 550 military beds at his hospital were a part. After 13 years of whole-time hospital work he decided to enter private practice. He was an active member of the British Medical Association all his profes-

sional life and served on the executive committee of the Sheffield Division. He was a medical referee for the Ministry of Health and chairman of No. 2 medical board of the Ministry of Labour and National Service. He also served for a time on the board of governors of the United Sheffield Hospitals. In December, 1940, during the first major air raids on Sheffield, his house suffered a direct hit, and he, his wife, and his daughter were buried under the debris. Fortunately he was a strong man, and was able to lift a girder which lay across his wife's chest and to extricate her and his daughter. A less powerful man would probably have failed and all would have perished, as the debris was then on fire. In spite of severe shock he carried on his work as a practitioner. He was an athlete in his younger days, his favourite sports being tennis and swimming, but in later years pressure of work left him little time for recreation. Eventually work at such high pressure took its toll, and in 1951 he suffered a severe vascular lesion from which he slowly recovered. He was advised to take things easy, but it was not his nature to relax, and soon he was working as hard as ever. On the day of his death he had a very full list of professional engagements, and was on his way home when he collapsed. He was able to drive his car to the side of the road and stop the engine before he died, as he wished, in harness. Dr. McKean was a clinician of exceptional ability and wide experience who never spared himself in any circumstances. He was a staunch friend and loyal colleague and will be sadly missed by his patients, his friends, and his fellow practitioners. Our sympathy goes out to his widow and daughter in their loss.—J. C. and R. C. B.

Medical Notes in Parliament

MEDICAL AUXILIARIES' QUALIFICATIONS

The new regulations governing the employment of medical auxiliaries, which come into operation on April 1, were discussed in the House of Commons on February 23. The debate, which arose on a prayer for the annulment of the regulations, was primarily designed to seek information of the Minister's intentions, and to ventilate some doubts, and the motion was withdrawn at the end of it.

Mr. IAIN MACLEOD, Minister of Health, did not offer an enthusiastic defence of the regulations, presenting the procedure adopted as no more than the least undesirable of the courses open to him. He recounted the failure to get agreement on the 1951 suggestions, which were more favourable to medical auxiliaries than the Cope Report from which they originated, and the necessity for taking a decision which faced him at the end of 1952. He could have pushed ahead on the lines of the Cope Report, either on its original basis or as modified, but in face of the known hostility of many of the bodies concerned, including some of the most important, that would have been disastrous. He could, assuming time was available for the necessary legislation, have established statutory registration for each of the groups concerned; the overwhelming objections to that were the necessity for consultation between the groups, and the practical difficulty that many were too small to justify or support financially such a proposal. He could have done nothing, but government by circular was bad, and cases of unfairness were arising as a result of the 1951 circular. So he was left to exercise his powers under Section 66 of the Health Act to lay down qualifications. It was undesirable that the Minister should have to concern himself with qualifications of this kind, and the whole basis of his case was that the regulations were only a temporary measure. He had sent his "rough ideas" to the organizations concerned, and had told them in recent correspondence of his intention to set up a working party to continue the probe to get agreement. He was hopeful of the results. It was important to note that a solution did emerge from

the organizations concerned, partly no doubt as a result of the catalyst of these regulations.

Approval had to be given before April 1 to existing courses of training that were adequate. All the bodies had been asked to send him before the end of February particulars of their courses and examinations. He intended, for the future, to invite those who advised him, assisted by his consultant advisers, to examine the courses and examinations of the representative training schools. Since the discussion had been most closely concerned with physiotherapists, he added that on this he would ask the advice of his consultant adviser, Dr. Cooksey, director of the department of physical medicine at King's, and also of Sir Harry Platt, emeritus professor of orthopaedics at Manchester.

He repeated the assurance that standards that were too low would not be accepted, and quoted from the *British Medical Journal* annotation of February 6 (p. 325):

"There is now undoubtedly an opportunity for the Minister to achieve a piece of constructive statesmanship which will bring the position of medical auxiliaries into line with the other professions in the National Health Service."

This is what he would like to achieve. This was a temporary measure. He would do his best to reach a final solution. In the consideration of standards he would first be guided by the findings of the Cope Committee, and would then act on the best advice available to him.

Dollars for Cardiac Delegation

Lord CROOK asked on February 23 whether the Treasury had reconsidered the application of the British Cardiac Society for permission to send a larger number of delegates to the World Conference on Cardiology in Washington next September, and, if so, with what result. Lord HAWKE, Lord-in-Waiting, replied that after full consideration the Treasury had allowed currency for the full number of delegates applied for—namely, 32.

Prescription Charge Claims

Mr. OSBERT PEAKE, Minister of Pensions and National Insurance, informed Mr. A. BLENKINSOP on February 22 that it was estimated that in the calendar year 1953 Assistance Board grants in respect of Health Service charges amounted to about £1,060,000, of which prescription charges account for about £445,000 and dental charges about £235,000.

Typhoid-Infected Cream

Mr. IAIN MACLEOD, Minister of Health, in a statement on February 22 on the search for tins of cream suspected of being infected with typhoid, said that from information supplied by the manufacturers and importers medical officers of health were informed of the location of wholesalers and retailers as soon as their names could be ascertained. Although at that stage he could obviously make no predictions, he could say that up to that date no case of typhoid attributable to this cream had been notified.

Mr. T. STEPLE asked on February 25 if the Minister was prepared to use his powers to prevent the import of tinned foods from Ireland pending proper investigations. Miss PAT HORNSBY-SMITH, the Parliamentary Secretary, replied that the Minister did not think the circumstances called for this.

Supplementary Ophthalmic Services

Mr. SOMERVILLE HASTINGS asked the Minister of Health on February 25 whether, in order to save time, he would give instructions to ophthalmic opticians providing supplementary ophthalmic services under the National Health Service Act to refer cases needing further investigation direct to ophthalmic surgeons, at the same time notifying the general practitioner in charge of the case. Miss PAT HORNSBY-SMITH, Parliamentary Secretary, replied "No." It was for the general practitioner to decide whether a

patient required specialist treatment, which would not always be that of an ophthalmologist. The Minister had no evidence that this caused needless delay.

Medico-Legal

PLOT TO DEFRAUD HEALTH SERVICE

A doctor and a chemist were each sentenced to prison for one year by Mr. Justice Sellers at Essex Assizes on March 1. They had been found guilty of conspiring together to defraud the Essex Executive Council of the National Health Service, and causing to be paid to the firm of which the chemist was managing director, by false pretences with intent to defraud, cheques for £1,121 6s. 8d., £1,392 18s. 1d., and £826 16s. 7d. The doctor was Archibald Luke Basham, aged 49, of Rayleigh, Essex, and the chemist Geoffrey William Unwin, aged 38, managing director of Yardley (Rayleigh), Ltd. They had pleaded not guilty.

The prosecution contended that Basham wrote out some prescriptions, and that Unwin collected the money from the paying authority of the National Health Service on the basis that the articles mentioned on the prescription had been supplied from his shop, whereas in some cases the articles had not been received by the patients. It was not suggested that the whole of the large sums mentioned in the charges represented drugs that were not supplied, but that a portion represented drugs and other articles not supplied. It was said for Unwin that only 2% of the sums mentioned in the charges were actually involved.

Both men gave evidence strongly denying any dishonest intent. They said that, although there might have been some irregularities, there was certainly no dishonesty or any attempt to obtain any money by false pretences.

Patients of Dr. Basham were called, one of whom described him as "a thoroughly satisfactory and painstaking doctor."

Detective-Sergeant L. H. Chaplin stated that in 1941 Basham, then an R.A.F. medical officer, had been convicted at a court martial for drawing drugs for his own use and neglecting to record prescriptions. He was sentenced to be dismissed the Service, but this was commuted to a severe reprimand. He afterwards resigned from the Service. Before the war he had been a house-surgeon at several hospitals. Sergeant Chaplin agreed that the doctor had been a voluntary patient in a mental hospital for seven weeks last autumn, and that he was now practically penniless. He was unmarried. He first went into practice on his own in 1950.

Unwin, married, with one child, had no previous convictions.

The Judge said it was apparent that the National Health scheme required the utmost honesty on the part of those engaged in it as medical practitioners or chemists, because the prescription was a thing of value. If the ingredients on it were dishonestly increased, the value was increased, and this increased the amount to be paid to the chemist. While the increases might be small in relation to this particular case, it opened up an avenue of continued and successive fraud against the system, and this had to be paid for by the public.

The Judge said that he would take into consideration the fact that Basham had been in a mental hospital, and had been in custody since December, and treat both men equally. The basis of the allegation against the two men, he said, was that they had used bogus prescriptions. He told the jury that Dr. Basham appeared to be a quite skilled, qualified doctor who attended to his duties quite diligently, and no one was suggesting that Unwin was not a qualified chemist or that he was unskilled or careless. The allegation was that they had been dishonest. The heart of the case was that the prescriptions were at times for drugs which were never dispensed and never supplied. Therefore there was a demand for money to which the chemist was

not entitled. Or perhaps there might be a lesser view, the Judge continued, that at times part, but not all, of the drugs prescribed were dispensed. The defence had said that the doctor had dispensed drugs at his surgery and later sent prescriptions to the chemist to replenish his stock, and they asked the jury to say that they might have been irregular and careless. If the jury thought that was all, and nothing more, then they would acquit them.

Vital Statistics

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in January, 1954, was 132, compared with 116 in the previous month and 100 (revised figure) in January, 1953.

The number of cases of industrial diseases in the United Kingdom reported during January was as follows: lead-poisoning, 4; other poisoning, 0; anthrax, 2; epitheliomatous ulceration, 6; and chrome ulceration, 28; total, 40. There was one death from anthrax.

The number of persons killed during the 13 weeks ending December 26, 1953, as a result of accidents occurring in that period at mines as defined by the Coal Mines Act, 1911, in Great Britain was 87, compared with 86 in the 13 weeks ending September 26, 1953, and 107 (revised figure) in the 13 weeks ending December 27, 1952. The corresponding numbers of persons seriously injured at such mines were 475, 445, and 598 (revised figure).—*Ministry of Labour Gazette*, February, 1954.

Week Ending February 20

The notifications of infectious diseases in England and Wales during the week included pneumonia 932, scarlet fever 1,223, whooping-cough 2,099, diphtheria 19, measles 1,944, dysentery 754, acute poliomyelitis 19, paratyphoid fever 10, and typhoid fever 1.

Infectious Diseases

Only relatively small changes occurred in the trends of the notifications of infectious diseases in England and Wales during the week ending February 13. The largest fluctuations were increases of 359 for measles, from 1,487 to 1,846, 146 for scarlet fever, from 1,015 to 1,161, and 45 for dysentery, from 624 to 669, and a decrease of 68 for whooping-cough, from 1,984 to 1,916.

The increase in the incidence of measles was concentrated in the northern section of the country. The largest rises were 103 in Lancashire, from 262 to 365, 47 in Yorkshire West Riding, from 61 to 108, and 40 in Cumberland, from 160 to 200. The rise in scarlet fever was mainly contributed by the south-eastern and midland counties; the largest rise was 30 in Kent, from 35 to 65. The largest rises in the local trends of whooping-cough were 31 in London, from 45 to 76, and 31 in Yorkshire West Riding, from 141 to 172. 11 cases of diphtheria were notified, being 8 fewer than in the preceding week. The chief features of the returns of diphtheria were a rise of 0 to 3 in Middlesex and a fall from 3 to 0 in Warwickshire.

21 cases of acute poliomyelitis were notified, and these were 2 fewer for paralytic and 2 more for non-paralytic cases than in the preceding week. The largest returns were London 3 and Gloucestershire 3 (Bristol C.B. 3).

For the fifth consecutive week the incidence of dysentery has risen and the number of notifications is now double what it was five weeks ago. The largest centres of infection during the week were Lancashire 132 (Preston C.B. 37, Bolton C.B. 13, Oldham C.B. 10, Eccles M.B. 10), Yorkshire West Riding 114 (Leeds C.B. 47, Bradford C.B. 37), London 100 (Islington 34, Hackney 26, Wandsworth 10), Middlesex 61 (Enfield U.D. 19, Ealing M.B. 10), Stafford-

shire 33 (Cannock U.D. 26), Nottinghamshire 24 (Worksop M.B. 16), Norfolk 23 (Norwich C.B. 22), Warwickshire 21 (Birmingham C.B. 20), Essex 18, Kent 17, Durham 17, Leicestershire 17 (Leicester C.B. 12), and Sussex 16 (Brighton C.B. 16).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1945-53 are shown thus -----, the figures for 1954 thus ————. Except for the curves showing notifications in 1954, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending February 13 (No. 6) and corresponding week 1953.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Medical News

"The London" at Home.—During the last six years the London Hospital, Whitechapel, has expended much thought and money on reorganizing its out-patient department. With 700,000 attendances each year—some 2,000 a day—the London has the largest out-patient department in the country. The whole building, with its 40 departments, has been modernized and redecorated. The new departments—the genito-urinary and gynaecological in particular—are models from the staff point of view of designed efficiency and give greater comfort and privacy for the patients. An appointments system has been arranged and the medical records department has been reorganized. A questionnaire was sent out recently to 800 general-practitioner "clients" to obtain their criticisms and suggestions from the consumer angle. This was followed up on Wednesday, February 24, when these doctors were invited to an evening At Home in the out-patients department. In addition, members of the lay press were present. Here in an informal atmosphere the hospital staff—consultants, sisters, registrars, and residents—talked with their guests and showed them round. Many who had till then been but a voice on the 'phone or a signature on a letter became realities to each other and, as is usual after such human contacts, felt the better for it.

Poliomyelitis Vaccine.—According to a report last week in the *New York Times*, Dr. J. E. Salk and his colleagues from Pittsburg University, U.S.A., have started to inoculate local schoolchildren against poliomyelitis. This is said to be the first large-scale trial of Dr. Salk's vaccine (see *Journal*, April 11, 1953, page 826), which is said to contain the three main types of poliomyelitis virus. The children are between the ages of 6 and 9 years, and the aim is to inoculate 5,000 of them. From Australia comes the report that the Queen and the Duke of Edinburgh have also been inoculated against the disease, though whether with gamma globulin or a virus-containing vaccine has not been stated.

Medical Education in Manchester.—The ripples caused by last year's World Conference on Medical Education are now becoming apparent. The February issue of the *Manchester University Medical School Gazette* is devoted to a symposium on the education of the medical student, to which a general practitioner and no fewer than seven of the faculty's professors have contributed. In addition there are accounts of medical education in Australia and Sweden, and as an introduction to the symposium a brief summary of the proceedings of the First World Conference is given. What lends special cogency to these essays is the fact that the Manchester curriculum is just now about to be extensively revised, and medical educators elsewhere will welcome the views of their Mancunian colleagues on this very thorny problem. The *Gazette* is obtainable from the Treasurer, *Manchester University Medical School Gazette*, the University, Manchester, 13.

Report on Homosexuality.—The Church of England Moral Welfare Council has issued for private circulation and comment an interim report on homosexuality. The report is the work of a small group of Anglican clergy and doctors, with legal advice, and they alone are responsible for the views expressed in it. Limited to a consideration of the male homosexual, the report discusses the clinical patterns, predisposing and precipitating causes, moral and religious aspects, and the law. At the end are tables of police statistics from 1926 to 1952. That current public anxiety might lead to ill-conceived measures of repression is recognized, and the report seeks to clear the air by a calm statement and examination of the facts. These, in the view of its authors, are of sufficient importance to deserve a full official inquiry. The report is available from the Church of England Moral Welfare Council (price 2s. 6d.) to all concerned with the problem of homosexuality, and com-

ments on it should be sent to Canon H. C. Warner, Church of England Moral Welfare Council, Room 252, Church House, Westminster, London, S.W.1.

B.M.A. Film Library.—The Association is seeking to enlarge and improve its Film Library. The Film Committee would therefore be glad to have details of any recently produced medical films, and to know whether they may be borrowed for appraisal. Information should be sent to the secretary of the Film Committee, B.M.A. House, Tavistock Square, London, W.C.1.

Dr. David Nabarro.—Dr. David Nabarro was 80 years old on February 27. On Monday evening this week Dr. Bernard Schlesinger, the senior physician at the Hospital for Sick Children, Great Ormond Street, presented Dr. Nabarro with a pair of eighteenth century Sheffield plate tea-caddies, an eighteenth century Nanking teapot, an eighteenth century Crown Derby cup and saucer of exquisite design, and a modern tea alarm. Dr. Nabarro was appointed bacteriologist in 1912 and later director of the pathological department, being the first so named in any department of the hospital. He started the first V.D. clinic in the hospital in 1917 and later initiated the biochemical laboratory. His contribution in 1903 in Uganda to the discovery of the trypanosome as a cause of sleeping sickness is now commemorated in the annals of the history of medicine. His book on congenital syphilis, to be published soon, will add further laurels to a name so long held in esteem among paediatricians and pathologists.

Dr. Douglas Guthrie, lecturer on history of medicine, University of Edinburgh, who is returning home from New Zealand and Australia, will deliver the Clendening Memorial Lectures at Kansas City on March 24 and 25, and the Woodward Lecture at the Medical School of Yale University on May 5.

Dr. J. P. M. Tizard, assistant director at the paediatric unit at St. Mary's Hospital Medical School, has been appointed to the University Readership in Child Health tenable at the Institute of Child Health.

Dr. H. J. Gibson, at present medical officer to that part of the University of St. Andrews which is in Dundee, has been appointed to the new post of assistant to the Dean of the Faculty of Medicine, Edinburgh University. Dr. Gibson, who is 43, was previously in the Indian Medical Service.

Dr. J. W. Thompson, research assistant in the department of applied pharmacology at University College Hospital Medical School, London, has been appointed lecturer in the department of pharmacology of the Royal College of Surgeons.

COMING EVENTS

Willesden General Hospital Medical Society.—The inaugural meeting of this society will be held on March 17 at 8.45 p.m. in the department of physical medicine. The meeting is open to all practitioners in the neighbourhood. The subject for discussion will be "The Medical and Surgical Aspects of Thyrotoxicosis." Further information may be obtained from the honorary secretary of the society, Dr. Alec Wingfield, the Willesden General Hospital, Harlesden Road, London, N.W.10.

Ergonomics Research Society.—The fourth annual conference will be held from April 5 to 8 at Ashorne Hill, near Leamington Spa. The theme of the conference will be "The Scientific Study of Human Work in Industry." Sir George P. Barnett, H.M. Chief Inspector of Factories, will speak at the opening session, at which Sir Frederic Bartlett, F.R.S., will be chairman. Further information may be obtained from Miss B. G. Murrell, Slaters Cottage, Peppard Common, near Henley-on-Thames, Oxfordshire.

International Poliomyelitis Congress.—The third international poliomyelitis conference will be held in Rome from September 6 to 10. Further information may be obtained from the secretariat of the conference, Via Lucullo 6, Rome.

British Association of Sport and Medicine.—The annual general meeting will be held on March 19 at 5 p.m. at the Westminster Hospital Medical School, Horseferry Road, London, S.W.1. This will be followed by a paper by Dr. J. L. Blonstein on "Some Medical Aspects of Boxing."

St. Thomas's Hospital Musical Society.—A concert will be held on March 15 at 8.15 p.m. at St. Sepulchre's Church, Holborn Viaduct. No tickets are required.

C.M.F./M.E.F. Physicians' Reunion.—The annual dinner will be held at Simpson's-in-the-Strand on April 10, with Dr. D. Evan Bedford in the chair. Further information may be obtained from the honorary secretary, Dr. A. Willcox, 59, Harley Street, London, W.1.

Dr. A. H. Douthwaite will deliver the Harveian Lecture to the Harveian Society of London at the Royal College of Surgeons on March 16 at 8 p.m. The title of the lecture is "The Problem of Duodenal Ulceration."

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Monday, March 8

INSTITUTE OF NEUROLOGY.—5 p.m., Dr. W. R. Bell: Preparation and Writing of Papers for the Medical Journals.

INSTITUTE OF PSYCHIATRY.—5.30 p.m., lecture-demonstration by Dr. E. Stengel.

MEDICAL SOCIETY OF LONDON.—8.30 p.m., meeting of Fellows. Clinico-pathological Meeting.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.—At Physiology Theatre, 4.45 p.m., public lecture by Professor F. Lynen (Munich): Participation of Coenzyme A in the Metabolism of Fat.

Tuesday, March 9

CHLSEA CLINICAL SOCIETY.—At South Kensington Hotel, 7.30 p.m., annual general meeting, followed by a discussion: The Royal Hospital and the Chelsea Pensioners, to be opened by Captain C. J. T. Denn.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. P. J. Hare: Xanthoma Necrobiosis Lipoidica and Granuloma Annulare.

LONDON UNIVERSITY.—At University College Hospital Medical School, 5 p.m., special university lecture in Dentistry by Professor J. Dankmeyer (Leyden): Early Differentiation of Nasal and Buccal Cavities in Relation to Tooth Development.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Mr. A. J. Wrigley: Problem of Postmaturity.

WEST END HOSPITAL FOR NERVOUS DISEASES.—5.30 p.m., Mr. J. Minton: Ocular Manifestations in Nervous Disease. Part II.

Wednesday, March 10

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Treatment of Mycotic Diseases.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—6 p.m., Professor Gösta Dahlman (Lund): Mechanism of Vestibular Fistula Reaction.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Dr. S. B. Osborn: Radiotherapy.

LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.15 p.m., special university lecture in Physiology by Professor E. A. Müller (Dortmund): Man at Work, a Physiological Analysis.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Sir Cecil P. G. Wakeley, F.R.S., F.R.C.S.: Health of a Nation.

ROYAL SANITARY INSTITUTE.—2.30 p.m., discussion: Tuberculosis: Problems of Notification and Rehabilitation. To be opened by Dr. H. J. Trenchard and Dr. P. W. Edwards.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. S. A. MacKeith: Lecture-demonstration in Psychiatry.

Thursday, March 11

ALFRED ADLER MEDICAL SOCIETY.—At 11, Chandos Street, W., 8 p.m., Dr. R. R. Bomford: A General Practitioner Looks at Psychosomatic Medicine.

INSTITUTE OF CHILD HEALTH.—5.30 p.m., Dr. D. A. Pond: The E.E.G. in the Neuro-psychiatry of Childhood.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. O. Oliver: Animal Parasites of the Skin.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5 p.m., Professor F. C. Ormerod: Types of Deafness.

LIVERPOOL MEDICAL INSTITUTION.—8 p.m., Professor D. T. Robinson: Duct as a Possible Source of Infection in Neonatal and Post-operative Tetanus: Dr. T. Black: Role of the Spleen in Thrombocytopenic Purpura.

LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.15 p.m., special university lecture in Physiology by Professor E. A. Müller (Dortmund): Man at Work, a Physiological Analysis.

NUFFIELD ORTHOPAEDIC CENTRE.—At Wingfield-Morris Orthopaedic Hospital, Headington, Oxford, 8.30 p.m., Mr. H. Osmond-Clarke: Cervical Spondylosis.

OXFORD UNIVERSITY.—At Southfield School, Glanville Road, Cowley Road, Oxford, 8 p.m., Dr. A. G. M. Weddell: Science and Medicine.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor F. W. Holdsworth: Traumatic Paraplegia.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Professor G. L. Montgomery: Biology of Repair.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., neurology demonstration by Dr. J. H. Paterson.

Friday, March 12

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. P. J. Hare: Xanthoma Necrobiosis Lipoidica and Granuloma Annulare.

LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.15 p.m., special university lecture in Physiology by Professor E. A. Müller (Dortmund): Man at Work, a Physiological Analysis.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.—At Royal Army Medical College, 5.30 p.m., address to Metropolitan Branch, Society of Medical Officers of Health: Non-specific Urethritis. Opening speakers, Mr. A. H. Harkness and Dr. C. S. Nicol.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Mr. N. C. Tanner: Present Position of Definitive Surgery for Peptic Ulcer.

ROYAL MEDICAL SOCIETY, Edinburgh.—8 p.m., Valedictory Address by the Senior President.

Saturday, March 13

INSTITUTE OF ORTHOPAEDICS, Royal National Orthopaedic Hospital, Stanmore.—10 a.m., Mr. J. A. Cholmeley: Teaching Ward Round.

MIDLAND TUBERCULOSIS SOCIETY.—At Birmingham Chest Clinic, 3 p.m., Dr. J. Pepys: Relationship of Non-specific and Specific Factors in the Tuberculin Reaction.

APPOINTMENTS

BOIZ, ISTVAN ANDRAS, M.D., D.P.H., Medical Officer of Health, Maesteg Urban District Council.

JACK, JOHN B., M.B., Ch.B., Assistant Medical Officer of Health, County of Perth.

NORTH-WEST METROPOLITAN REGIONAL HOSPITAL BOARD.—A. S. Walker, L.R.C.P.Ed., D.L.O., Ear, Nose, and Throat Surgeon (Consultant), Royal London Homoeopathic Hospital, Great Ormond Street; R. L. G. Dawson, F.R.C.S., Assistant Plastic Surgeon (Consultant), Mount Vernon Centre for Plastic Surgery, Northwood; P. E. Baldry, M.B., B.S., M.R.C.P., Physician (Consultant), Ashford Chest Clinic, Ashford, Middlesex; M. W. Hutchings, M.B., Ch.B., Assistant Pathologist (S.H.M.O.), St. Charles' Hospital, Ladbroke Grove; S. K. Ganczakowski, M.B., Ch.B., Assistant Anaesthetist (S.H.M.O.), Bedford General Hospital; Faith C. Poles, M.B., B.S., M.R.C.P., Assistant Chest Physician (S.H.M.O.), Pinewood Hospital, Wokingham; B. Bradley, M.D., D.O.M.S., Assistant Ophthalmologist (S.H.M.O.), Central Middlesex Hospital, Acton Lane, N.W.; D. H. Bodger, M.B., B.S., D.M.R.D., Diagnostic Radiologist (Consultant), West Middlesex Hospital, Isleworth; Mildred I. Port, M.B., Ch.B., D.C.H., D.P.M., Psychiatrist-in-charge (Consultant), "High Wick" Centre, St. Albans; A. T. Frapp, M.B., B.Ch., F.R.C.S., Orthopaedic Surgeon (Consultant), Heatherwood Hospital, Ascot; Margaret T. Collins, M.B., B.S., D.C.H., D.P.M., Psychiatrist (Consultant), Child Guidance Training Centre, Osnaburgh Street; E. Zwielfach, M.D., F.R.C.S., D.L.O., Ear, Nose, and Throat Surgeon (Consultant), West Middlesex Hospital, Isleworth; P. R. N. Kerr, M.B., B.S., F.R.C.S., Assistant Orthopaedic and Accident Surgeon (Consultant), Luton and Dunstable Hospital; H. D. L. Campton, M.B., B.Chir., Resident Medical Officer (S.H.M.O.), Mount Vernon Hospital, Northwood; C. E. Bagg, M.R.C.S., L.R.C.P., D.P.M., Assistant Psychiatrist (S.H.M.O.), Three Counties Hospital, Arlesey; Ruth A. Cohen, M.B., Ch.B., D.P.M., Assistant Child Psychiatrist (S.H.M.O.), Hill End Clinic, St. Albans; Olive N. Roper, M.B., B.S., Assistant Child Psychiatrist (S.H.M.O.), Hill End Clinic, St. Albans; C. A. G. Cook, M.C., G.M., F.R.C.S., D.O.M.S., Ophthalmic Surgeon (Consultant), West Middlesex Hospital; N. S. Slater, M.B., B.S., F.R.C.S., Assistant Surgeon (Consultant), Edgware General Hospital; J. F. Azzopardi, M.D., Assistant Physician in Geriatrics (S.H.M.O.), Barnet General Hospital; G. W. Csonka, M.D., M.R.C.P., Venereologist (Consultant), Male V.D. Clinic, at Shrodel's Hospital, Watford; J. C. Ballantyne, F.R.C.S., D.L.O., Ear, Nose, and Throat Surgeon (Consultant), Royal Northern and Highlands Hospital; J. R. Hudson, F.R.C.S., D.O.M.S., Ophthalmic Surgeon (Consultant), Mount Vernon Hospital, Northwood; Jean M. Laidlaw, M.B., Ch.B., D.P.M., Assistant Psychiatrist (S.H.M.O.), St. Bernard's Hospital; W. K. Schnarr, M.R.C.S., L.R.C.P., D.P.H., D.P.M., Assistant Psychiatrist (S.H.M.O.), Priern Hospital.

TATLOW, W. F. T., M.D., F.R.C.P.C., M.R.C.P., Clinical Assistant, Montreal Neurological Institute, and Lecturer in Neurology, McGill University.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Brown.—On February 26, 1954, to Ruth (formerly Richardson), F.R.C.S.Ed., wife of Dr. R. W. W. Brown, South Collingham, Newark, Notts, twin sons.

Gordon.—On February 20, 1954, at 27, Arlington Drive, Ruislip, Middlesex, to Valerie, wife of Neil Gordon, M.D., M.R.C.P., a son—Keith Gray.

Jones.—On January 21, 1954, at the Royal Infirmary, Cardiff, to Dr. Vera Jones, wife of Dr. Idris G. Jones, a daughter.

Law.—On February 23, 1954, at the London Hospital, London, E., to Beryl (formerly Dyson), wife of W. Alexander Law, F.R.C.S., a sister for Bruce—Aileen Margaret.

DEATHS

Brown.—On February 14, 1954, at his home, Buckland House, Esher, Surrey, William Brown, M.B., Ch.B., aged 64.

Crawford.—On February 9, 1954, at Gamlingay, Cambs, Jane Crawford, L.M.S.S.A., of Angmering-on-Sea, Sussex, late of Knebworth, Herts, aged 71.

Croucher.—On February 1, 1954, at his home, Chiltern Rise, Woodcote, Reading, Berks, Alexander Henry Croucher, M.D., F.R.C.S.Ed., aged 90.

Curran.—On February 6, 1954, at The Vicarage, Saxton, Yorks, Patrick Joseph Curran, M.B., B.Ch., late of Pudsey, Yorks, aged 57.

Dalling.—On February 1, 1954, Reginald Ramsdale Dalling, M.R.C.S., L.R.C.P., M.R.C.V.S., Major, R.A.V.C., T.A., of Bryn Castell, Caernarfon, North Wales, aged 60.

Emerson.—On January 28, 1954, at his home, Chalet Alpina, Venne-sur-Lausanne, Switzerland, Ambrose Emerson, M.D., aged 78.

Fraser.—On February 8, 1954, at 91, Back Hilton Road, Aberdeen, George Hudson Fraser, M.B., Ch.B., D.P.M., Colonel, I.M.S., retired, aged 63.

Haydon.—On February 2, 1954, at Kingston Hospital, Kingston-on-Thames, Surrey, Walter Turner Haydon, M.R.C.S., L.R.C.P., Surgeon-Captain, R.N., retired, of 221, Sheen Lane, London, S.W., aged 77.

Hill.—On January 29, 1954, at his home, "Dalestead," Caterham, Surrey, Frederick Teophilus Hill, M.C., M.R.C.S., L.R.C.P.

Hoskin.—On February 27, 1954, at his home, London, W., Theo Jenner Hooper Hoskin, M.D., F.R.C.P., aged 65. A memorial service will be held on Thursday, March 11, at Holy Trinity Church, Marylebone Road, at 12.30 p.m.

Klasley.—On January 29, 1954, Sylvia Victoria Klasley (formerly Elman), M.R.C.S., L.R.C.P., D.P.H., of Brighton, Sussex.

Stevenson.—On February 3, 1954, at "Redcroft," Meols Drive, Hoylake, Cheshire, Edgar Stevenson, M.D., aged 85.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Straight Leg Raising Test

Q.—What exactly does the straight leg raising test measure, and how should it be interpreted? How should the test be performed?

A.—Straight leg raising tests the mobility of the fifth lumbar or first sacral nerve root: thus, if a disk prolapse lies under it, stretching the leg would pull the nerve down and cause pain by increasing the tension. It is therefore a very good diagnostic test for the presence of a disk prolapse, and also a very good measure of the size of the prolapse. It is found that very limited straight leg raising is almost pathognomonic of a large disk prolapse. Clearly, however, adhesions of the nerve root due to inflammation or scarring from an old disk prolapse or post-operative adhesions will also cause pain on stretching. Finally, some patients have tight hamstrings and this will limit straight leg raising, but that does not usually cause severe pain, and is the same on both sides.

The straight leg raising test is usually performed with the patient lying on the back, and each leg is elevated with the knee straight until pain is just caused. It is essential to watch the pelvis, as this may rotate and give a false impression of the freedom of elevation. A refinement of the test is that, when pain just begins, if the foot is dorsiflexed pain will be increased, as this causes further pull on the nerve roots.

Metal Containers for Chloroform

Q.—Are there any objections to storing chloroform in metal containers similar to those in which trichlorethylene is supplied?

A.—The manufacturers of one well-known brand of chloroform recommend that chloroform should not be stored in tins. The tins are affected and the chloroform is therefore suspect so far as anaesthetic use is concerned. For this reason, chloroform, including that for export to the Tropics, is packed in bottles.

Boy with a Small Penis

Q.—The penis of a boy of 12 has hardly increased in size since babyhood, and it is very small. Puberty has not begun. What treatment is recommended? Should treatment be started before puberty, or is it better to wait until then?

A.—Assuming that the penis is really small and not hidden by fat and that the testes are smaller than one might expect at this age, the more obvious diagnosis would rest between infantilism (of pituitary origin) or eunuchoidism. In the absence of assays of F.S.H. (follicle-stimulating hormone) the differential diagnosis at this age may be difficult, but a positive response to gonadotrophins—for example, chorionic gonadotrophin, 500 units twice weekly for six weeks—would indicate a primary pituitary defect. There would be no response in the case of eunuchoidism, and the appropriate treatment for this latter condition is testosterone or methyl testosterone.

No information is given about height, bone age, muscular development, or adiposity, all of which are relevant to diagnosis and treatment. The age of 12 is near enough to chronological puberty to justify therapy if such is sought by the patient or his parents.

Oestrogens for Prostatic Cancer

Q.—What is the optimum dosage of stilboestrol in cases of carcinoma of the prostate, and is there any advantage or danger in giving such massive doses as 100 mg. thrice daily? What survival rates are usual after treatment with stilboestrol, and how do they compare with untreated cases?

A.—There is no general optimum dose of stilboestrol for carcinoma of the prostate; it varies with the individual. It is a good practice to start with 1 mg. three times daily, increasing by 1 mg. each day up to 5 mg. thrice daily by the fifth day. Thereafter the dose is continued, increased, or diminished according to the response. Doses up to 100 mg. thrice daily are usually well tolerated and often have a better effect than smaller doses in refractory cases. There appears to be no danger. It is always better to do a subcapsular orchidectomy as well as giving stilboestrol, and smaller doses may then suffice.

Patients have survived for from 5 to 10 years when oestrogens are combined with surgical measures. Before stilboestrol a survival of three years was considered good.

Severe Myopia in Motorists

Q.—Do persons with moderate or severe myopia have difficulty in judging distances and thus become potentially dangerous drivers? Is this disability entirely eliminated by correcting glasses?

A.—There is no sharp dividing-line between moderate and severe myopia, but it is generally true that anything up to 10 dioptres is unlikely to be a severe handicap in driving, provided that appropriate spectacles are worn and the eyes are healthy in other respects. When the myopia exceeds 10 dioptres in amount, peripheral vision is necessarily curtailed by the powerful correcting lenses, but, even so, many high myopes manage to drive well by exercising special care. One source of confusion in driving arises from sensitivity to the glare of headlights, and there is no doubt that the average myope is more readily dazzled than are those who are not short-sighted; and macular disturbances afflict many high myopes, especially in later life. Mobile vitreous opacities are also prevalent. Any of these three pathological states can of course lead to intense confusion in driving, but their detailed consideration is beyond the scope of the query.

Dating the Menopause by the Menstrual Cycle

Q.—Is there any correlation between the length of a woman's menstrual cycle and her reproductive period of life? For example, does a woman who menstruates every 23 days or so have an earlier menopause than the average?

A.—The idea behind this question, presumably, is that if a woman uses up her allotted number of ova more quickly than average the menopause will occur earlier. Another popular notion with a similar background is that each pregnancy (during which ovulation is suppressed) postpones the age of the menopause. The basis for such views is unsound, because it is doubtful whether the menopause is the result of the ovary coming to the end of its supply of ova. And, even if this is the case, then it has to be recognized that ovulation plays an insignificant part in the disappearance of ova, and a few more or a few less follicular cycles in any one year make no material difference to the duration of reproductive life. Of the 30,000 to 50,000 ova generally estimated to be present in the ovaries at puberty not more than 450 are destined to be lost by way of ovulation.

Statistical inquiries into matters raised in this question are difficult because they depend so much on the patient's memory of past events—and this tends to be unreliable. Nevertheless, they have been attempted from time to time, and the results go to show that the age of the menopause is not significantly related to either previous menstrual or previous reproductive function. Nor is it related to the age of the menarche. Of all the possible factors which have

been considered, the only ones (other than disease) which most authorities would accept as likely to have any bearing on the age of the menopause are an inherited disposition manifested among races and families, and possibly social and economic status.

Male and Female Symbols

Q.—What is the origin of the symbols ♂ and ♀?

A.—The origin of ♂ for male and ♀ for female is from the well-known symbols of the planets, ♂ being for Mars and ♀ for Venus. Thus they come to indicate masculine and feminine qualities respectively. Very early—perhaps before the Christian era, but certainly soon after—the planetary symbols became associated also with certain metals, ♂ standing for iron and ♀ for copper. Thus they entered alchemy, where we need not follow them. How much older than the Christian era are these signs for planets it is hard to say. The association of deities with planets was borrowed from Mesopotamia by the Greeks in the 4th–5th century B.C., and later by the Romans. Thus Roman Venus corresponded to Greek Aphrodite, who corresponded to Babylonian Ishtar, the Ashtaroth of the Bible. It would therefore not be surprising if these planetary (and sexual) signs, or something like them, were ultimately traced to the second millennium B.C. In any event they are extremely ancient. One idea is that ♀ represented a hand-mirror—the “looking-glass of Venus”—and corresponded to the Egyptian *ankh*, ♀ “the handled cross,” the sun's gift of life, but all such stories—and there are many—are mere fancies, unverified and perhaps unverifiable.

Borax for Cholera

Q.—Is there any authority for the belief that borax is effective in the treatment of cholera?

A.—There is no reliable evidence that borax is of any value in the treatment of cholera.

Testosterone into the Scrotum

Q.—Is there any valid reason why small injections of testosterone propionate (5 mg. in 1 ml. of oil) should not be given into the scrotum? It seems to me that there might be economy by this procedure. I have a case of testicular atrophy following mumps, and the cost of normally disposed treatment is high.

A.—There is no advantage in injecting testosterone propionate into the scrotum. The dose would not be diminished by giving it by this route, since the amount provided in a case of testicular atrophy should be roughly equivalent to the amount of testosterone produced by the normal testis. Testosterone has no effect on the atrophic testis itself.

“Any Questions?” Book.—The second book of selected “Any Questions?” is available, price 7s. 6d. (postage 6d.). Copies may be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY MARCH 13 1954

A CRITICAL ANALYSIS OF CATION-EXCHANGE THERAPY

BY

A. G. SPENCER, M.D., M.R.C.P.

AND

H. G. L. LLOYD-THOMAS, M.B., M.R.C.P.

(From the Medical Unit, University College Hospital Medical School, London)

It is now established that cation-exchange resins are sometimes an effective adjuvant to a low-salt diet in the treatment of oedema. The early hope that the use of ion-exchange resins would allow patients with cardiac oedema to take a more liberal diet and an increased intake of salt has not been realized (Greenman *et al.*, 1953). The main advantages now appear to be these: first, resin treatment may succeed when other methods have failed; secondly, by preventing the absorption of sodium and the reaccumulation of oedema fluid, the patient may be spared much discomfort, and the periodic use of mercurial diuretics becomes unnecessary.

It is often difficult to assess the contribution of ion-exchange resins to the successful results that have been reported. This is because a preliminary control period has not always been obtained, and because resin therapy has been used simultaneously with other forms of treatment, such as mercurial diuretics (Elkinton *et al.*, 1952), A.C.T.H. (Greenman *et al.*, 1951b), and abdominal paracentesis (Payne and Wilkinson, 1951). In addition, the published results show a great variation in the response of individual patients; in some a negative sodium balance was not obtained (Danowski *et al.*, 1951; Klingensmith and Elkinton, 1952), and it seems certain that these patients failed to benefit from ion-exchange therapy. Serious complications such as acidosis and potassium depletion are common to many reports (Dock and Frank, 1950; Greenman *et al.*, 1953) and were encountered in the present series. Although resins are now available in a palatable form, the large bulk that must be ingested, the relatively high cost, and the close chemical control that is necessary during treatment are practical reasons for restricting their use. Moreover, the response of many patients to rest in bed, a low-salt diet, digitalis, and mercurial diuretics is so good that no other treatment is needed.

It is clear that the selection and management of patients require considerable experience and care. Despite an abundance of biochemical data, there is little information to guide the practitioner in the safe and effective use of cation-exchange resins. The purpose of the present paper, therefore, is to present and analyse the results obtained over the past three years with special reference to the selection of patients, the methods by which dangerous complications can be avoided, and the most effective use of the resins now available.

Material and Methods

Observations were made on 39 patients with peripheral oedema due to cardiac (30) or renal (9) disease (Table II). The patients were not specially selected, and included those with all degrees of oedema from gross anasarca to minimal ankle-swelling; but many (32) had persistent chronic oedema which had failed to respond to intensive treatment by all the standard methods.

The patients were treated in bed on a constant regime, taking a low-salt diet with a restricted fluid intake of 40 oz. (1,140 ml.) a day. Six diets were analysed in duplicate, and the cation content is given in Table I.

TABLE I.—Daily Cation Content of the Low-salt Diet; Data Obtained by Analysis

	Mean	Range
Sodium ..	15 mEq	11–23 mEq
Potassium ..	48 "	41–65 "
Calcium ..	631 mg.	614–654 mg.
Magnesium ..	312 "	305–344 "
Iron ..	11 "	10–12.5 mg.

Metabolic balance studies for sodium and potassium were obtained on 12 patients during 42 three-day collection periods, and for calcium, magnesium, and iron on six patients. The diet and stools were homogenized and aliquots ashed at 550° C. in a muffle furnace. The methods of analysis were the standard techniques previously described from this laboratory (Spencer, 1950; Nabarro *et al.*, 1952); inorganic iron and calcium were determined by the methods described by Hawk *et al.* (1947). Frequent observations were made on the plasma electrolyte concentrations and on the patients' weights.

A sulphonated polystyrene cation-exchange resin was administered as a 3:1 mixture of the ammonium and potassium phases (kationium), except for four patients who were given hydrogen-phase resin (“zeo-karb 225 H”) and four who received a mixed cation-anion exchanger 29% in the potassium phase (“carbo-resin”). The usual dose was 20 g. thrice daily suspended in a liquid vehicle, taken after meals. Treatment lasted from two to eight weeks, with an average of 3.6 weeks. A special watch was kept for clinical and chemical complications, and records were kept of the patients' complaints.

There can be no doubt about the successful treatment of oedema: there is a rapid loss of weight, a water diuresis, and the swelling is grossly diminished.

Our results have been classified on the following basis:

	Excellent Over 14 lb. (6.4 kg.) +++	Moderate 14-7 lb. (6.4-3.2 kg.) ++	Failure 0-7 lb. (0-3.2 kg.) +→0
Loss in weight ..	Over 7 litres	7-3 litres	<3 litres
Excess urine volume over fluid intake (Total)	Over 7 litres	7-3 litres	<3 litres

Seven of the 39 patients had insufficient oedema to permit classification of their response in this way, and these are grouped in Table II as "not assessed." They are included in the series to give a true overall account of the patients and of the incidence of complications during treatment.

Whereas the effective treatment of oedema is obvious, the credit is easily allotted to one particular form of therapy when it should be given to a combination of several, or, more correctly, recognized as a spontaneous improvement independent of any. To reduce this error, all patients were observed during a preliminary period of at least three weeks' (average five weeks) treatment by rest in bed, a low-salt diet, and fluid restriction; digitalis and mercurial diuretics were given when indicated. Except for the diuretics, this basal treatment was continued during the administration of the cation-exchange resins, and the results obtained are not considered as an unaided response to resin therapy.

Results

The clinical results obtained in 39 patients during the administration of ion-exchange resins are summarized in Table II. In 34% of the patients there was an excellent response, with clearing of massive oedema. Considerable

TABLE II.—Clinical Response of 39 Patients to Ion-exchange Resins, Classified According to the Standards Given in the Text

	Total	Clinical Response			
		Excellent	Moderate	Failure	Not Assessed
Heart disease:					
Rheumatic ..	8	3	3	2	0
Ischaemic ..	19	4	3	5	7
Cor pulmonale ..	3	1	1	1	0
Renal disease:					
Type II nephritis ..	7	4	0	3	0
Chronic ..	2	1	1	0	0
Total ..	39	13	8	11	7

improvement was obtained in a further 21%, with loss of oedema and weight up to 14 lb. (6.4 kg.); but in 45% no definite benefit resulted. If the seven patients with minimal oedema are excluded, an excellent response or considerable improvement was obtained in 65%. The resins were most effective in type II nephritis in the absence of uraemia, and in chronic rheumatic heart disease without cardiac cirrhosis. Poor results were obtained in patients with very chronic or recurrent congestive cardiac failure, whether due to advanced disease of the coronary arteries or to rheumatic heart disease; in those with renal failure; and in oedematous patients with a plasma sodium below 130 mEq/l. after long-continued treatment by salt depletion. Three seriously ill patients died during treatment—the first from a large pulmonary embolus, the second and third from advanced coronary artery disease.

Patients' Complaints

The frequency and type of complaints induced by the ingestion of resins were similar to those reported by Klingensmith and Elkinton (1952), and are summarized in Table III. In 67% there was discomfort, mainly related to the gastro-intestinal tract, and in 11% this was severe enough to cause the treatment to be abandoned. In 10% the complaints were moderately severe but were relieved by adjust-

TABLE III.—Incidence of Complaints During Cation-exchange Therapy

Incidence of Complaints		Severity	
Anorexia ..	12	Weakness ..	7
Constipation ..	11	Paraesthesia ..	4
Nausea ..	9	Sore mouth ..	4
Vomiting ..	4	Haematemesis ..	1
Abdominal pain ..	6	Alopecia ..	1
Diarrhoea ..	4		
		Nil ..	33%
		Mild ..	46%
		Moderate ..	10%
		Severe ..	11%

ments to the regime; while in 46% symptoms were slight. Although only 33% of these patients were entirely free from symptoms, severe gastro-intestinal complaints such as stomatitis and vomiting were confined to four subjects who were given the 100% hydrogen-phase resin in the early stages of this investigation. Resin preparations which were more palatable soon became available; these could be taken by most patients over periods of several weeks. Despite these improvements, patients still objected to the large bulk of resin that was required for effective treatment.

Biochemical disorders frequently developed during treatment with cation-exchange resins, but were not often serious. A characteristic metabolic response to resin therapy is illustrated in Fig. 1, which summarizes the data obtained in the following patient.

Case 4.—A woman aged 44 had type II nephritis, with gross anasarca, ascites, and pleural effusions. B.P. 110/70; serum albumin, 1.8 g./100 ml.; plasma cholesterol, 710 mg./100 ml.; blood urea, 24 mg./100 ml., with a maximum urea clearance of 83% of normal; albuminuria 16 parts per 1,000 (1.6 g./100 ml.). There was no improvement during three weeks' treatment with rest in bed and a low-salt diet containing 15 mEq of sodium. The ingestion of 60 g. a day of a cation-exchange resin was followed by complete relief of the oedema in four weeks, a weight loss of 16 kg. and a negative sodium balance totalling 1,860 mEq. The bowels were opened twice daily by a laxative. The faecal excretion of sodium was the greatest obtained in this series of patients, but an increased renal loss of water and salt accounted for 67% of the negative sodium balance. The stool potassium increased from 8 to 96 mEq a day, and the patient developed a negative potassium balance, hypokalaemia, and a compensated hyperchloraemic acidosis. These were corrected by supplements of potassium citrate, 2 g. three times daily. As the oedema disappeared the albuminuria decreased from 16 parts to 1 part per 1,000, the serum albumin gradually rose from 1.8 to 4.8 g./100 ml., and the plasma cholesterol fell from 710 to 265 mg. per 100 ml. One year later the patient was free of oedema and in good health, with normal renal function and normal urine.

FIG. 1.—Metabolic balance chart of Case 4, type II nephritis, during treatment with ion-exchange resin. The black columns represent the stool electrolytes, while the renal excretion is unshaded. The intake is at the level of the interrupted lines, and the output is plotted upwards from zero. A negative balance is shown when the columns extend above the interrupted lines.

The frequency and type of complaints induced by the ingestion of resins were similar to those reported by Klingensmith and Elkinton (1952), and are summarized in Table III. In 67% there was discomfort, mainly related to the gastro-intestinal tract, and in 11% this was severe enough to cause the treatment to be abandoned. In 10% the complaints were moderately severe but were relieved by adjust-

Sodium Depletion

The object of resin therapy was, of course, to deplete the body of excess sodium contained in the oedema fluid, and this was achieved in 8 out of 12 patients on whom balance studies were obtained (Table IV). The mean nega-

12	34	18	-37	35	-1,295	-9	-12

tive balance of sodium in these eight subjects was 48 mEq a day, and the total sodium depletion was very great in patients relieved of gross oedema. These studies demonstrate that the action of cation-exchange resins is not confined to the removal of dietary sodium as suggested by Dock and Frank (1950) and Danowski *et al.* (1951); but also show that they extract sodium from the body fluids, thus confirming the results of Duncan (1953). The faecal excretion of sodium varied greatly in different patients, and

often declined during prolonged treatment, as it did in the studies of Cobbe *et al.* (1949), Emerson *et al.* (1951), and Barker and Mackay (1951).

A major factor, however, in the relief of oedema during resin therapy was an increased renal excretion of water and salt as noted by Greenman *et al.* (1951a). Thus the increment of sodium excretion generally had two components, an increased faecal excretion accounting for 42%, and that in the urine for the remaining 58% (Figs. 2 and 3).

The salt-depletion syndrome characterized by

FIG. 2.—Mean daily excretion of cations in the urine of 12 oedematous patients before and during the administration of a cation-exchange resin and a low-salt diet.

FIG. 3.—Mean daily excretion of cations in the stools of 12 oedematous patients before and during the administration of a cation-exchange resin and a low-salt diet.

weakness, anorexia, nausea, muscular cramps, a fall in blood pressure, oliguria, and uraemia, together with a low plasma sodium, was not observed in any of our patients. In nine a complaint of anorexia and nausea was not associated with any other indication of salt depletion, and possibly resulted from the local action of the resin on the gastro-intestinal

tract. Weakness was observed in seven subjects, but this was accompanied by a low plasma potassium. A normal blood urea and a plasma sodium over 130 mEq/l. is strong evidence against the existence of a serious degree of salt depletion.

The plasma sodium concentration did not fall significantly in any of the patients (Fig. 4), the mean sodium concentration remaining unchanged at 137-138 mEq/l. (81 observations). These results are similar to those reported by Kraus (1950) and by Klingensmith and Elkinton (1952); but a fall in plasma sodium during resin therapy was observed by Greenman *et al.* (1953) and Weston *et al.* (1953). The initial plasma sodium concentration was usually lower in oedematous patients (mean, 137 mEq/l.) than in normal subjects (mean, 142 mEq/l.). In six it was below 130 mEq/l., but during administration of the ion-exchange resin it did not fall any lower. The blood urea did not rise during resin treatment except in those patients with pre-existing renal failure.

Potassium Depletion

Significant potassium depletion developed in 19 out of 39 patients, as shown by the incidence of muscular weakness (7), paraesthesiae (4), electrocardiographic changes (4), digitalis sensitization (4). The plasma potassium concentration fell below 4 mEq/l. in 26 out of 83 observations. Kraus (1950) and Greenman *et al.* (1953) experienced a comparable incidence. Potassium depletion results from a gross increase in the faecal excretion of potassium, mean 70 mEq a day (Fig. 3). The renal excretion of this ion usually decreased during resin therapy, except when potassium supplements were given (Fig. 2). The deficiency was closely related to the total intake of potassium, as it was less commonly found in patients taking a resin mixture 25% in the potassium phase, and was reduced still further by supplements of potassium citrate, 2 g. three times daily (Table V). Kling-

TABLE V.—Effect of Potassium Intake on the Plasma Concentration and Balance of Potassium of Patients Taking 60 g. a Day of a Cation-exchange Resin

Total Potassium Intake (mEq/day)	Potassium Balance (mEq/week)	Plasma Potassium After 2 Weeks
41-65 (diet + 100% hydrogen-phase resin)	-270	2.1-2.9 mEq/l.
70-98 (diet + 25% potassium-phase resin)	-80	3.2-5.1 ..
90-108 (diet + 25% potassium-phase resin + 20 m.mols potassium citrate)	+20	4.3-7.5 ..

ensmith and Elkinton (1952) avoided potassium depletion by administering resin 30% in the potassium phase, while Weston *et al.* (1953) recommended supplements of potassium salts for this purpose. Potassium depletion was not always avoided by these means, and occurred whenever our patients failed, through lack of appetite, to eat all their diet.

Potassium Retention

Potassium retention occurred in two oedematous patients with impaired renal function during treatment with 25% potassium-phase resin, the plasma concentration rising to 7.5 and 7.8 mEq/l. This has also been described by Peel and Semple (1953).

FIG. 4.—Plasma concentration of sodium and chloride ions before and during cation-exchange therapy. Means and ranges of 141 determinations on 28 patients. The graph is drawn through the means, while the vertical lines represent the ranges.

Depletion of Calcium, Magnesium, and Iron

There was no clinical evidence of depletion of calcium, although tetany (Dock and Frank, 1950; Martz *et al.*, 1952), and a low serum calcium (Greenblatt and Gilwood, 1948; Greenman *et al.*, 1953) have been reported during prolonged treatment with ion-exchange resins. The mean faecal calcium excretion increased from 405 to 518 mg. a day, but renal losses decreased from an average of 251 to 106 mg. a day (Figs. 2 and 3), and a small negative balance was found in only two patients. The mean faecal excretion of magnesium rose from 215 to 311 mg. a day and renal losses fell from 152 to 64 mg. a day, producing a mean negative balance of 46 mg. a day. No changes were observed in the serum calcium, but in five subjects the plasma magnesium was low, the mean being 2.4 mg./100 ml. (normal 4 mg./100 ml.). The faecal excretion of iron was not altered by resin therapy, and the patients remained in balance. Apart from the experiments of McChesney *et al.* (1951) and McChesney (1952), little is known about the effects of resin therapy on the metabolism of magnesium and iron.

Acidosis

It was unusual for clinical signs of acidosis to appear during treatment with cation-exchange resins. The plasma chloride usually rose, the mean increasing from 98 to 105 mEq/l. (Fig. 4). This hyperchloraemia was associated with a decrease in the plasma bicarbonate, the mean falling from 25 to 16 mEq/l. (Fig. 5). These changes were more apparent when a hydrogen-cycle resin was used. Similar observations were made by Elkinton *et al.* (1952).

FIG. 5.—Plasma concentrations of potassium and bicarbonate ions before and during cation-exchange therapy. Means and ranges of 146 determinations on 28 patients. The graphs are drawn through the means while the vertical lines represent the ranges. A=Patients taking 60 g. of a 3:1 $\text{NH}_4^+:\text{K}^+$ -phase resin and a dietary intake of 68 mEq K. B=Patients taking 60 g. of a 3:1 $\text{NH}_4^+:\text{K}^+$ -phase resin and a dietary intake of 48 mEq K. C=Patients taking 60 g. of a 100% H-phase resin and a dietary intake of 48 mEq K.

deficient in early renal failure, and six patients developed clinical signs of acidosis, with the plasma chloride rising to 115 mEq/l. and the bicarbonate falling to 8 mEq/l. Acidosis was less apparent in four patients with renal disease who were treated with a mixed anion-cation exchanger, the mean plasma chloride being 106 mEq/l., and the bicarbonate 18 mEq/l.

Renal Failure

There was no evidence that renal failure ever resulted from resin therapy, but uraemia, acidosis, and electrolyte disorders were usually increased by this treatment. Serial determinations of the blood urea were made in 21 patients,

and in 15 these were normal throughout. Six subjects had a raised blood urea before treatment; in one of these the blood urea fell, but in the other five it increased rapidly, and treatment by exchange resins was abandoned on this account.

Factors Relating to the Effectiveness of Exchange Resins

The efficiency with which cation-exchange resins increase the loss of sodium in the stools when the diet is constant appears to be related to the intestinal motility, to the body sodium content, and to the total intake of potassium in relation to the dose of resin.

Intestinal Motility.—On the same intake of sodium and resin the faecal excretion of sodium varied greatly from one patient to another (12 to 64 mEq a day, Table IV), but when measured over a period of several days was relatively constant for the same individual. In only 4 of 12 patients taking resins did the stool sodium (mean, 48 mEq a day) clearly exceed the intake, and these had loose motions; whereas in eight constipated patients the mean daily faecal excretion of sodium was 17 mEq a day. Laxatives consistently increased the loss of sodium in the stool, in part because of the extra quantity of resin passed and of the electrolytes contained in the larger volume of stool water, but largely due to the increment in sodium bound per gramme of resin. Potassium excretion also rose, but to a smaller degree, and the ratio of Na/K ions on the resin was greatly increased whenever the bowel motility was rapid. The stool sodium of four subjects taking resins was constantly very low, and, although this was increased by laxatives, the absolute loss of sodium was still comparatively small. The significance of these observations in relation to the dynamics of cation-exchange resins in the intestines is considered in detail by Spencer, Ross, and Lloyd-Thomas (p. 603 of this issue).

Total Body Sodium.—During prolonged treatment the mean faecal excretion of sodium declined from 38 mEq a day during the first week to 22 mEq a day after six to eight weeks, but at the same time the oedema became less extensive. Stool sodium was also greater in the first week of treatment in grossly oedematous patients (mean 46 mEq a day) than in those with slight oedema (mean 27 mEq a day). However, in four patients with extensive oedema associated with a plasma sodium between 126 and 130 mEq/l. the faecal excretion of sodium in response to resins was only 14 mEq a day. The ion-exchange resins are therefore more efficient when the total body sodium is increased, except when the plasma sodium concentration is low.

Dietary Potassium.—The faecal excretion of sodium was decreased by increasing the dietary intake of potassium. With a combined potassium intake in the diet and on the resin of 88 mEq a day the mean excretion of sodium in a group of eight patients was 32 mEq a day. When extra potassium was given to a total of 108 mEq a day, the mean stool sodium declined to 24 mEq a day.

Discussion

The value of ion-exchange resins in the treatment of oedema is seriously limited by their small exchange capacity, and even more by the complete lack of specificity for the sodium ion. For example, the resin mainly used in the present study has a maximum capacity of only 3.1 mEq/g. and combines with three to four times as much potassium as sodium when in equilibrium with solutions containing equal proportions of these ions. Whereas resins are available with an *in vitro* capacity of up to 10 mEq/g. (Duncan, 1953), this has not been achieved at the hydron concentration of the intestines. Moreover, all these resins exhibit a descending order of affinities for cations, $\text{Ca}^{++} > \text{Mg}^{++} > \text{K}^{+} > \text{Na}^{+} > \text{NH}_4^{+} > \text{H}^{+}$ (Nachod, 1949).

Considering the high concentration of sodium in the small-intestinal juices, the failure of cation-exchange resins to extract large amounts of this ion from the alimentary

tract of all subjects ingesting the resin has occasioned surprise (Dock and Frank, 1950). This has led to statements that ingested exchange resins extract sodium only from the diet and the upper small intestine (Hegsted *et al.*, 1951), or that increased secretory activity of the adrenal cortex in response to sodium depletion grossly alters the sodium content of the alimentary secretions (Berger *et al.*, 1951; Berger and Steele, 1952). Such conceptions of the action of exchange resins in the body are at variance with their known physical properties. Moreover, studies from this department, using the radioactive tracers Na^{24} and K^{42} have demonstrated that cation-exchange resins establish a dynamic equilibrium with the intestinal contents throughout the alimentary tract. There is a continuous interchange of ions to and from the resin and the body pool of sodium and potassium, with a rate of turnover at least equal to the total body content of these electrolytes every 24 hours. Large quantities of sodium are taken up by the resin in the small intestine even when there is only a small excretion of this ion bound to the resin in the stools. Most of the sodium taken up in the small intestine is exchanged for potassium in the colon (Spencer, Ross, and Lloyd-Thomas, p. 603).

From these observations, it appears that the efficiency of ion-exchange resins in the treatment of oedema could be increased in at least three different ways: first, by avoiding constipation; secondly, by developing resins which have a high exchange capacity and a special affinity for sodium; thirdly, by influencing cation exchange across the mucosa of the small intestine and colon, as by the use of specific enzyme inhibitors.

In their present stage of development cation-exchange resins cannot be recommended for general use in the treatment of oedema. Most oedematous patients respond well to treatment by rest in bed, a low-salt diet, digitalis, and mercurial diuretics. These measures are generally so simple, effective, and safe that cation-exchange therapy is not likely to replace them. Some patients, however, remain oedematous despite vigorous treatment by these standard methods, and in others mercurial diuretics are contraindicated. It is in these patients that resin therapy finds its most useful application; but not all of these benefit, and in others serious complications may occur. An attempt has been made to define these two groups from an analysis of the results obtained in the present series and from those previously published. It now seems possible to select patients and manage their treatment with ion-exchange resins so that the majority become free of oedema without the risk of grave metabolic disorders.

Indications

1. **Cardiovascular Disease.**—In the absence of contraindications, treatment by ion-exchange resins is advised: (a) in persistent congestive cardiac failure of all types when pitting oedema remains after two to three weeks' treatment by standard methods; (b) when mercurial diuretics or digitalis are contraindicated because of sensitivity, toxicity, or failure to respond; and (c) during the convalescence from heart failure to prevent the recurrence of oedema. A satisfactory response is less often obtained in the presence of extensive disease of the coronary arteries, chronic congestive heart failure with cirrhosis of the liver and ascites, and whenever intensive salt depletion by other means has failed to relieve oedema. Two points merit further consideration. When the routine treatment of oedema has failed, resin therapy should not be delayed. Prolonged immobilization in bed leads to a steady deterioration, and greatly increases the risk of venous thrombosis and pulmonary embolism. Although the relief of oedema is highly desirable, it does not necessarily indicate any considerable improvement in cardiac function. In fact, treatment by resins or by other methods of salt depletion often removes many of the cardinal signs of heart failure.

Hypertensive Disease.—The use of cation-exchange resins together with a low-salt diet has been advocated as a more practical alternative to the rice diet in the treatment of

hypertension (Page, 1951; Gill and Duncan, 1952). However, six of our patients with a high blood pressure were treated in this way, and in only one was there an appreciable fall of blood pressure. The most useful application of resin therapy in hypertensive disease therefore seems to be in cardiac failure. Little information is available concerning the value of exchange resins in patients with cardiac asthma or with hypertensive encephalopathy.

Renal Disease.—An excellent response may be obtained in type II nephritis and in early diabetic nephrosclerosis, provided that the blood urea is not raised. Patients with chronic nephritis and oedema commonly have advanced renal failure and are made worse by resin therapy. Sodium-phase resins have been successfully used in the management of hyperkalaemia occurring in anuria (Merrill *et al.*, 1950; Bull, 1952).

Contraindications

Gastro-intestinal Disorders.—A poor appetite, nausea, and dyspepsia interfere with the continued ingestion of the resin or, by causing gross fluctuations in the dietary intake, precipitate potassium depletion. Anorexia and nausea are among the symptoms of sodium depletion, and are often indications for an estimation of the plasma sodium and the blood urea.

Renal Failure.—The absence of an effective renal compensation for electrolyte disorders should generally be an absolute contraindication to treatment by ion-exchange resins. Metabolic complications such as severe hyperchloraemic acidosis, potassium retention or depletion, and a rapid elevation of the blood urea are common; whereas relief from oedema is seldom achieved. The ammonium-phase resins contribute significantly to the nitrogen intake, and the usual dose is equivalent to the ingestion of 5 g. of urea a day. This extra load on the kidney would, if not excreted, raise the blood urea by 100 mg. per 100 ml. in ten days.

Advanced Liver Disease.—Ammonium phase resins may precipitate coma from ammonia intoxication in patients with advanced liver disease (Phillips *et al.*, 1952; Gabuzda *et al.*, 1952). Since effective sodium depletion can be achieved only by resins in the ammonium or hydrogen phases, and as the latter are unpalatable and likely to cause oesophageal erosions, resin treatment should not be used when liver function is severely impaired. Some excellent responses have been reported, however, in patients with cirrhosis of the liver (Gabuzda *et al.*, 1952).

Cation Depletion.—If in patients with heart failure the plasma sodium is consistently below 130 mEq/l., the daily urine volume is less than 500 ml., or the blood urea is over 60 mg./100 ml., treatment with cation-exchange resins is contraindicated. Uncorrected potassium depletion should be an absolute bar to cation-exchange therapy. This most commonly results from an inadequate intake of food associated with disease or operations on the gastro-intestinal tract, diarrhoea, and the previous use of exchange resins.

Management of Cation-exchange Treatment

The principles of management are these: to use exchange resins as an adjuvant to salt restriction, with digitalis, mercurial diuretics, and rest in bed when necessary; and to avoid complications by the exclusion of unsuitable patients, close supervision of the potassium intake, and the early detection of biochemical disorders.

Chemical Control.—Before treatment is begun it is advisable to measure the blood urea and the plasma concentration of sodium, potassium, and bicarbonate ions. The plasma potassium should be measured at intervals of one week. The treatment of patients with renal failure is not recommended, but, should there be doubt about the renal function, resin therapy may be tried, provided that weekly estimations of the blood urea, plasma bicarbonate, and potassium concentrations are available. It is helpful to keep a record of the weight, degree of oedema, urine volume, and bowel action.

Diet.—There is abundant evidence that the ingestion of exchange resins allows little increase in the intake of sodium (Greenman *et al.*, 1951a; Greenman *et al.*, 1953), and at first this should not exceed 20 mEq a day (1 g. salt). To avoid potassium depletion the intake needs to be maintained at 75 mEq (3 g.) potassium a day, in addition to that on the resin. The low-salt diet may not contain this amount of potassium, and the addition of fresh fruit will then form an acceptable supplement of this ion. Since a constant and relatively high intake of potassium is the chief safeguard against potassium depletion, close supervision of the patients' meals is required. Any failure to eat the diet should be recorded by the nurse and reported to the physician in charge. The addition of 1 pint (570 ml.) of milk a day makes the diet more palatable, and helps to prevent depletion of calcium and magnesium during prolonged therapy. Although exchange resins absorb thiamine (Nachod, 1949; McChesney and McAuliff, 1950), no evidence of vitamin deficiency has been observed during treatment (Greenman *et al.*, 1953). Nevertheless it may be advisable to provide a compound vitamin supplement. In the treatment of type II nephritis the introduction of up to 150 g. of protein into the diet is made more effective by the administration of exchange resins, which take up the increment in sodium.

Selection and Administration of the Resin.—Of the available preparations those containing a 3:1 mixture of the ammonium and potassium phases of a sulphonic or carboxylic cation-exchange resin are most generally useful. Ammonium-phase resins are contraindicated in advanced liver disease (Phillips *et al.*, 1952). The resins now in common use in this country have an effective combining capacity of about 3 mEq/g., and in adults the effective dose is 45–75 g. a day. These preparations are pleasantly flavoured, making them easy to take as a suspension in water or in fruit juices. It is immaterial whether the resins are given before or after meals (Martz *et al.*, 1952). The intermittent use of resins has been advocated by Weston *et al.* (1953). This reduces the risk of potassium depletion, the resin being given on five days a week with intervals of two days, in which potassium citrate, 2 g. three times a day, is provided in a simple mixture. There may be little response in the first ten days of treatment, but some of these patients rapidly improve thereafter. Resin therapy should therefore not be abandoned for this reason in less than two to three weeks.

Domiciliary Treatment.—In selected patients, treatment with ion-exchange resins and a modified low-salt diet (2 g. salt) has been continued at home for many months. This has successfully prevented the reaccumulation of oedema, and in this way has reduced the frequency of readmissions to hospital. These patients attend the follow-up clinic at intervals of two to four weeks for clinical supervision and estimation of the plasma electrolytes and the blood urea. Voyles and Orgain (1951) and Aaron and Weston (1952) have reported their experience of long-continued resin therapy.

Care of the Bowels.—Many patients have become constipated during the administration of exchange resins, and this may give rise to abdominal swelling and discomfort (Arnold, 1951). In the present study it has been demonstrated that the efficiency with which resins remove sodium from the gastro-intestinal tract was decreased by constipation and increased by the use of aperients. For this reason it is recommended that the bowels should be opened once or twice a day, obtaining soft stools by any laxative which suits the patient. Salts should not be used for this purpose, and diarrhoea must be avoided.

Administration of Digitalis.—An increased incidence of digitalis toxicity has been reported during treatment with cation-exchange resins (Kraus, 1950; Weston *et al.*, 1953). Gross disturbances of this kind were seen in 3 out of 28 patients in this series who were taking maintenance doses (0.25 to 0.75 mg. a day) of digoxin (Fig. 6). These occurred when the plasma potassium was reduced, and were relieved by the administration of potassium citrate. Special care

FIG. 6.—Digitalis toxicity associated with potassium depletion during the course of cation-exchange therapy. (a) Multiple ventricular extrasystoles. E.C.G. Lead I (rate 150 per minute). Plasma potassium, 3.6 mEq/l. (b) Auriculo-ventricular dissociation. E.C.G. Lead III (ventricular rate 79, auricular rate 130 per minute). Plasma potassium, 4.1 mEq/l.

should therefore be taken to avoid potassium depletion in patients taking both digitalis and ion-exchange resins. The maintenance dose of digitalis may be halved when the resin is begun, and increased later as indicated. The relation between potassium metabolism and the action of digitalis on the heart has been reviewed by Enselberg *et al.* (1950) and Lown *et al.* (1951).

Mercurial Diuretics.—Martz *et al.* (1952) and Elkinton *et al.* (1952) have reported that the efficiency of mercurial diuretics was increased during the administration of cation-exchange resins, and our recent experience confirms this observation.

Paracentesis.—When patients lose their oedema, effusions into the pleural and peritoneal cavities commonly persist. These are best removed by paracentesis in the early days of resin treatment.

Summary

Cation-exchange resins were administered to 39 patients with chronic oedema resulting from cardiac or renal disease.

A satisfactory response was obtained in 65% of those with gross oedema. Minor complaints induced by resin therapy occurred in 67%, but serious chemical disorders were uncommon.

Metabolic balance data were obtained in 12 patients, and the results are discussed and analysed in relation to the incidence of biochemical complications and to the clinical effectiveness of cation-exchange therapy.

Recommendations are made on the use of cation-exchange resins, with particular reference to the selection and management of patients and the methods by which dangerous complications can be avoided.

We gratefully acknowledge the help given by Professor M. L. Rosenheim and the physicians of University College Hospital. Our thanks are due to Professor M. Maizels for the routine clinical chemistry; to Miss C. F. Harris, the advisory dietitian; to Dr. R. J. Calvert, who provided some of the patients; and to the nursing staff for their great help and co-operation.

CATION EXCHANGE IN THE GASTRO-INTESTINAL TRACT

BY

A. G. SPENCER, M.D., M.R.C.P.

E. J. ROSS, Ph.D., M.B.

AND

H. G. L. LLOYD-THOMAS, M.B., M.R.C.P.

(From the Medical Unit, University College Hospital Medical School, London, W.C.1)

Cation-exchange resins are surprisingly inefficient at removing sodium from the gastro-intestinal tract. It had been anticipated from *in vitro* studies (Morton, 1951) that the large preponderance of sodium over other cations in the fluids of the small intestine would more than compensate for the greater affinity which such resins exhibit for potassium. In practice, when cation-exchange resins are administered to patients on a low-salt diet they remove far more potassium than sodium (Dock and Frank, 1950; Barker and Mackay, 1951; Greenman *et al.*, 1951). It has been suggested, therefore, that exchange resins extract sodium only from the diet, their activity being confined to the upper small intestine (Hegsted *et al.*, 1951). This concept is opposed by McChesney (1952) and seems to be at variance with the physical and chemical properties of the resins.

Despite the abundance of clinical and experimental studies there appears to be little direct evidence concerning the action of ion-exchange resins at various levels in the intestinal tract. Data of this kind have been obtained in the present investigation. The rates of turnover of sodium and potassium ions to and from the exchange resin have also been measured with the radioactive tracers Na^{24} and K^{42} . From these results the activity of cation-exchange resin has been interpreted

in terms of a constantly changing series of dynamic equilibria between the cations on the resin and those in the intestinal fluids. Through this medium all the cations in the body continually exchange with those on the resin. The activity of the exchange resin is not confined to one region of the intestinal tract. On the contrary, cation exchange is continuous throughout the length of the gut. The rates of turnover of cations to and from the resin are not constant, however, but undergo a regular sequence of change as the resin passes from the stomach onwards to the rectum. One result of this complex cycle of activity is that when cation-exchange resins are administered in the ammonium or hydrogen phase there is a predominant uptake of sodium in the small intestine. Most of this sodium is exchanged for potassium and other ions in the colon.

Materials and Methods

These have largely been described in the previous paper (Spencer and Lloyd-Thomas, p. 597 of this issue). The resin used in these studies was a sulphonated polystyrene of equivalence 3.1 mEq per g. of resin. The phase and mesh size is given separately in the accounts of the individual experiments.

The total electrolyte contents of the stools, intestinal contents, and enema samples were obtained by flame photometry of dilute solutions prepared from ashed aliquots of the entire specimen. The resin was isolated by flotation from aliquots of the homogenized intestinal fluid. This was facilitated by administering part or all of the resin as a coarse (40–80 mesh) powder. The resin so obtained was dried at 60° C and weighed. The cations were eluted with 4N HCl and estimated as before. The radioactivity of the acid extract was determined in a liquid counter.

Composition of Ion-exchange Resin in the Small and Large Intestines

Samples of fluid and exchange resin were obtained from the small intestine by Miller-Abbott tube (2), from a fresh ileostomy (7), and at post-mortem examination from three patients who had died suddenly from coronary thrombosis (2) or pulmonary embolism (1). In the necropsy studies samples were also taken from the proximal colon and rectum. The subjects had all been taking a low-salt diet and a cation-exchange resin, as previously described by Spencer and Lloyd-Thomas at p. 597. Their plasma sodium concentrations were in the range 137–141 mEq per litre.

SITE	SMALL INTESTINE RESIN	PROXIMAL COLON RESIN	DISTAL COLON RESIN
No. Obs.	11	3	15
Na mEq/g.	1.4	0.9	0.4
K "	0.5	0.8	1.1
Na:K	2.8	1.1	0.36

FIG. 1.—Mean concentration and relative proportions of sodium and potassium ions bound to a cation-exchange resin at different levels of the human gastro-intestinal tract.

Results.—Resin taken from the small intestine had a similar composition in all the subjects. The results of these analyses, together with those for the resin from the colon, are summarized in Fig. 1. From these data it was apparent that the exchange resin had taken up large amounts of sodium in the small intestine even though the patients were on a low-salt diet. In the distal part of the colon there was more potassium bound to the resin than sodium, while

in the proximal colon the composition of the resin was intermediate between these two. These results suggested that most of the sodium ions taken up by the resin in the small intestine were exchanged for potassium in the colon. A study was therefore made of the transfer of ions between the mucosa of the colon and the cation exchange resin.

Observations on Cation-exchange Resin in the Colon

Three experiments were completed on patients taking a low-salt diet, without exchange resin by mouth. The colon was washed out with water. Two hours later approximately 5 g. of a 40-80 mesh sulphonic acid cation-exchange resin 100% in the sodium phase was introduced into the bowel through a high rectal tube. The foot of the bed was raised, and at intervals of 60-120 minutes samples of resin were removed via the tube or were obtained as the bowels were opened. In one group of experiments the sodium-phase resin was labelled with Na^{24} , and in another K^{42}Cl was injected intravenously two hours before the enema was given.

Results.—The composition of the exchange resin as put into the lower bowel and as removed 60-120 minutes later is given in Table I. Although samples of resin removed

TABLE I

Cation	In (mEq/g. of Resin)	Out (mEq/g. of Resin)	
		Mean	Range
Na	2.8-3.1	1.4	2.5-0.8
K	0	1.1	1.9-0.3
Ca	0	0.14	0.21-0.06
Mg	0	0.18	0.24-0.08

from the colon varied in composition the results were qualitatively similar. The exchange resin regularly lost sodium in the colon, and this was replaced by potassium and to a smaller extent by calcium and magnesium. The duration of these experiments was comparatively brief, and the results of these analyses do not represent the ultimate distribution of cations on the exchange resin. The net rates of exchange as measured by the radioactive isotopes were similar to those found by chemical analysis. It was impracticable to obtain frequent samples of resin from the colon, and for this reason it was not possible to compute the rates of ion exchange both to and from the resin. Data of this kind were therefore obtained by experiments on rats.

Effect of Laxatives

It had previously been observed that, of patients taking a low-salt diet and a cation-exchange resin, those with loose motions lost more sodium in the stools than did the subjects who were constipated (Spencer and Lloyd-Thomas, p. 597). From seven patients who were constipated on such a regime the stools were collected and analysed before, during, and after a period of 48 hours in which the motions were kept fluid by the administration of castor oil or cascara.

Results.—The effect of laxatives was to increase the mean faecal excretion of sodium from 21 to 63 mEq a day, and that of potassium from 69 to 103 mEq a day, as shown in Table II. It was apparent that the faecal excretion of sodium

TABLE II.—Daily Excretion of Cations in the Stools

	Total (mEq)		Bound to Resin (mEq/g.)		
	Na	K	Na	K	Na/K
Resin only	21 (13-37)	69 (58-106)	0.32	1.2	0.26
Resin and purge	63 (39-114)	103 (73-127)	0.68	0.93	0.73

had increased for three different reasons: first, the greater quantity of stool and resin passed; secondly, the electrolytes in the extra volume of stool water; and, lastly, because of the increment in sodium bound to each gramme of resin. The method of analysis permitted the separation of these components. When the bowels were freely open the mean

excretion of sodium bound to resin increased from 0.32 to 0.68 mEq/g. and the Na/K ratio rose from 0.26 to 0.73. It was thought that laxatives had modified the uptake of cations on the resin by changing the composition of the intestinal fluids and by accelerating the passage of exchange resin from the small intestine through the colon into the stools.

Experiments with Isolated Loops of Rat Intestine

Methods.—Loops of small intestine and colon of 250-g. rats were isolated by ligature, under ether anaesthesia. Special care was taken to preserve the blood supply. Small quantities of a 40-80 mesh carboxylic cation-exchange resin were introduced into the loops with the minimum amount of water, and the loops were then returned to the abdomen. At timed intervals (20-30 minutes) 2-cm. lengths of gut were excised and their content of resin recovered and analysed as described above. In one group of rats, Na^{24}Cl or K^{42}Cl (1 μC . in 1 ml. of isotonic carrier) was injected subcutaneously two hours before the resin (100% hydrogen phase) was introduced into the gut. The data obtained permitted the calculation of the rates of transfer of sodium or potassium from the body fluids to the resin. In a second group, resin labelled with Na^{24} or K^{42} was introduced into the gut so that the rates of exchange in the direction resin to body fluid could be calculated. In a third group, resin which had equilibrated with the contents of the small intestine was transferred to the large intestine and samples of resin were removed at intervals and analysed as before. The analysis and interpretation of the data obtained follows the methods developed by Visscher *et al.* (1944) in their studies of cation transport across the intestinal mucosa. Details of these experiments will be reported elsewhere.

Results.—There is a continuous transfer of cations on and off the resin. The change in concentration of cations on the resin over a period of time is merely the net rate of transport, which is the algebraic sum of the rates of transport of cations on and off the resin. The net uptake of sodium and potassium by resin in the gut is shown in Fig. 2.

FIG. 2.—Net uptake of sodium potassium by a cation-exchange resin in the small and large intestine of the rat.

In the small intestine, 1 g. of resin took up 1.2-1.5 mEq of sodium and 0.3-0.45 mEq of potassium. When the resin in this state was transferred from the small to the large intestine it gradually lost sodium ions, but continued to take up potassium. The total Na^+ and K^+ bound to the resin fell, owing to the uptake of Mg^{++} and Ca^{++} . The ratio of sodium to potassium was 3-4:1 in the small intestine, 1:1 in the large intestine, and 0.4:1 in the faeces. The rates at which sodium and potassium were exchanged in the small intestine between the resin and its surrounding fluid after the attainment of a dynamic equilibrium were also determined. From these results it was calculated that all the sodium on the resin was turned over once every 60-75 minutes. With 5 g. of resin in the rat's small intestine, the turnover of sodium ions to and from the resin would

approximately equal the exchangeable body sodium every two hours. The turnover rate of potassium was one-half to one-third that of sodium.

Discussion

When a cation exchange resin is shaken up with an electrolyte solution in a simple container, such as a test-tube, an equilibrium distribution of ions between the resin and the solution is quickly reached. In the present experiments more than 90 minutes was required before a steady state was reached between the resin and the fluid in the rat's small intestine. The presence of resin in the gut introduces, in effect, a further electrolyte-containing compartment into the organism, the sodium and potassium of which require time to come into equilibrium with the exchangeable sodium and potassium of the body.

Even when the concentration of cations on the resin has reached the maximum for that section of the intestinal tract, there is a constant exchange of ions to and from the resin and the surrounding fluid. A series of dynamic equilibria are established between the cations on the exchange resin, those in the intestinal fluids, and eventually with those in the total exchangeable pool of cations in the body. In the rat the total exchange of sodium to and from the resin in two hours was found to be approximately equal to the entire sodium content of the body. The turnover rate for sodium was about three times greater than that for potassium. Exchange rates in the colon were slower and more variable than those in the small intestine.

However, the final concentration of cations on the exchange resin in the gut appears to depend only on the type of resin, the pH, and the concentration and physical properties of the different ions in the surrounding fluid. When an exchange resin was placed in solutions of the same pH and electrolyte concentration as the fluids of the small intestine and the colon, it took up cations in approximately the same proportions as those found on resin actually removed from these sections of the intestinal tract.

As the cation-exchange resin passes along the intestinal tract it undergoes a sequence of changes (Fig. 3). These net changes in the concentration of ions on the resin are the resultant of the simultaneous movement of cations on and off the resin.

In the fasting stomach, at a pH of 2 or less, the resin remains largely in the hydrogen phase. If ingested in the ammonium and potassium forms some of these ions are exchanged for hydrogen ions. When there is a simultaneous ingestion of exchange resin and food, the net uptake of cations by the resin will vary greatly according to the electrolyte content of the diet and the pH of the stomach. The hydrogen-ion concentration is important for two reasons. First, the uptake of cations by carboxylic resins, and to a much smaller extent by sulphonic acid resins, is dependent on the pH (Nachod, 1949). Secondly, in the presence of phosphate ions the availability of calcium and magnesium ions for exchange is greatly increased in acid solutions. Under these conditions there is a considerable uptake of calcium and magnesium from the diet of an acid stomach (pH 3-6). Because of the great affinity of exchange resins for these ions, they are not subsequently displaced to any considerable extent by sodium or potassium ions.

In the small intestine there is a net uptake of sodium reaching up to 1.5 mEq/g. of resin in our experiments, and of potassium 0.3-0.5 mEq/g. of resin. Here the concentration of sodium in the intestinal fluid (86-134 mEq/l.) is much greater than that of potassium (6-17 mEq/l.), and this more than compensates for the smaller affinity of the resin for sodium as compared with potassium. If the ingested resin contains more potassium than 0.5 mEq/g. of resin the excess is exchanged for sodium. The concentration of electrolytes in the jejunal fluids is altered by ingested food, and this factor influences the net uptake of cations by the resin at this level of the intestinal tract. With a low-sodium, high-potassium diet, the resin takes up a preponderance of potassium ions in the jejunum, most of which is displaced by sodium lower down in the small intestine. Resin ingested in the ammonium phase continues to lose this ion.

By the time the resin has reached the proximal colon a net loss of sodium is already apparent, largely in exchange for potassium ions. This process continues as the resin passes along the colon to the rectum, the concentration of cations on the resin in the proximal colon being 0.9 mEq of sodium per g. of resin, and 0.8 mEq of potassium per g. of resin; and in the stools 0.4 mEq of sodium and 1.1 mEq of potassium per g. of resin. The concentration of electrolytes, expressed as mEq/l. of water of the gut contents, gradually changes along the course of the large intestine. In the caecum the values were similar to those in the small intestine—sodium 93-118 mEq/l., potassium 12-21 mEq/l. In the sigmoid colon and in the stool water, however, there was generally more potassium than sodium, the concentrations being sodium 6-38 mEq/l., potassium 14-44 mEq/l. Throughout the length of the gut the cations in the intestinal fluids compete for the free valencies in the resin. In the colon the net exchange of sodium ions bound to the resin for potassium and other ions merely results from the change in concentration and relative proportions of these ions in the fluids of the large bowel. It is possible that this exchange of sodium for potassium may begin in the distal part of the small intestine. When resin is ingested in the ammonium phase some 10-20% of the resin in the stools is still in this phase. The low-salt diet used in these studies was also comparatively low in calcium and magnesium, but resin in the stool contained up to 0.3 mEq/g. of resin of both these ions, the quantity actually bound to the resin varying with the pH of the stools when analysed.

When dietary sodium is low there is a reduction in the excretion of sodium bound to exchange resin in the stool (Dock and Frank, 1950; Greenman *et al.*, 1951; Martz *et al.*, 1952), and this decrease is most conspicuous in salt-depleted subjects (Emerson *et al.*, 1951). Berger and Steele (1952) have suggested, therefore, that the electrolyte content of the intestinal fluids is altered by salt depletion, in response to increased secretory activity of the adrenal cortex. The observation that injections of deoxycortone acetate decrease the faecal excretion of sodium bound to resin (Berger *et al.*, 1951) appears to support this concept. While it is true that McCance (1938) has reported change in the electrolyte content of the salivary and gastric juices during severe salt depletion, there does not appear to be any direct evidence of similar alterations in the composition of the fluids in the small and large intestines.

In the present studies the patients were maintained on a low-salt diet, but were not seriously depleted of sodium. Under these conditions, exchange resin removed from the small intestine was still predominantly bound to sodium. Salt restriction did not materially alter the sodium content of the fluid in the small intestine. In the same patients the excretion of sodium bound to resin in the stool was low. It would therefore seem that the effect of salt restriction was to make the colon more efficient at removing sodium from the resin. The reabsorption of sodium is a normal function of the colon, and the increased efficiency of this mechanism during salt restriction is comparable to that exhibited by the sweat glands and the kidneys.

FIG. 3.—Mean concentration of cations bound to an exchange resin during its passage along the human gastro-intestinal tract.

By the use of laxatives it was possible to increase the faecal excretion of sodium during the ingestion of cation-exchange resins. However, a great increment in sodium excretion was obtained only when the stools were kept fluid. Vigorous treatment of this kind is not recommended, as, besides the discomfort, purgatives greatly augment the excretion of potassium in the stool water. During treatment with cation-exchange resins the aim should be to keep the motions loose but not actually fluid, and to supplement the dietary intake of potassium. Saline laxatives, the cations of which become bound to the resin, and liquid paraffin, which coats the resin with a water-repellent film, must of course be avoided.

Summary

The net uptake of cations by an exchange resin was determined at different levels of the intestinal tract in man. The rates of turnover of Na^{24} and K^{42} to and from the resin were also measured in the small and large intestines of the rat.

A series of dynamic equilibria are established between the cations on the exchange resin and those in the intestinal fluids. These transfers are continuous throughout the gut, but the rates of turnover and the net uptake of cations by the resin change as it passes onwards from the stomach to the rectum.

Cations throughout the body continually exchange with those on the resin by way of the intestinal fluids.

These concepts have been used to interpret the results obtained during the treatment of patients with cation-exchange resins.

The Minister of Food, Major Gwilym Lloyd-George, M.P., has approved for publication a report presented to the Food Standards Committee by its Metallic Contamination Subcommittee on the amount of zinc that should be permitted in food. The report recommends that no exception need be taken to the presence of traces of zinc in foods in amounts not exceeding, in "beverages ready to drink," 5 parts per million (p.p.m.), and in other foods 50 p.p.m. This recommendation is subject to a few exceptions; thus a limit of 100 p.p.m. has already been prescribed for edible gelatin, and the subcommittee sees no objection to the sale of certain animal and vegetable products with a high natural zinc content—even when it exceeds 50 p.p.m. Attention is drawn in the report to the undesirability of using zinc and galvanized iron containers in the preparation or storage of foods. The subcommittee states that zinc, like copper, has a definite physiological function in the human organism. The normal daily intake of an adult is estimated at 12 mg. It considers that public health requirements would be met by observance of the limits proposed, and that, in the absence of any new developments, statutory effect need not be given to the limits recommended.

CARCINOMA COMPLICATED BY PROXIMAL MOTOR NEUROPATHY DUE TO VITAMIN-B DEFICIENCY

BY

P. L. de V. HART, M.D., M.R.C.P.

Senior Medical Registrar, Royal Cancer Hospital, London

Though the number of cases of neuropathy associated with cancer is not so far very great, it is probable that many are overlooked, and that patients who might otherwise have lived useful lives for months or years suffer unnecessarily or come to an untimely end. The general practitioner must usually undertake the care of the patient with incurable malignant disease, and he is unlikely to be aware of this particular complication, still less that it responds well to the correct treatment if given promptly.

The Literature

Spillane (1947) reviewed the effects on the central nervous system of deficiencies of the various members of the vitamin-B group. Cases of neuropathy associated with carcinoma, including many cases of true peripheral neuropathy with sensory disturbances, are reviewed by Denny-Brown (1948) and by Lennox and Prichard (1950). The cases of true peripheral neuropathy are not dealt with here.

Five cases of neuropathy associated with carcinoma of the bronchus were reported by Lennox and Prichard. Two actually under their care (Cases 1 and 2) were typical of peripheral neuropathy with motor and sensory phenomena. The other three (Cases 3, 4, and 5) seem quite different, and may have been similar to the cases reported below from the Royal Cancer Hospital. The points of difference which stand out include:

Cases 1 and 2

1. Sensory symptoms early.
2. True peripheral weakness—for example, foot-drop.

Cases 3, 4, and 5

1. Absent or minimal sensory phenomena, subjective and objective.
2. An early symptom, at any rate in Cases 3 and 5, was inability to sit up in bed; perusal of the clinical description leaves a very real doubt regarding the main sites of weakness. The evidence suggests that the proximal musculature bore the main brunt. In Case 4 the details given are insufficient to throw light on this aspect.
3. Palatal weakness, dysphagia, and, in Case 5, facial weakness were involved—that is, the brain-stem was rapidly and severely affected.

Heathfield and Aldren-Turner (1952) described a case of neuropathy associated with presumed carcinoma of the bronchus. In this case no sensory symptoms and few sensory signs were elicited, and the weakness seems to have involved the hips and knees as well as the ankles and, only slightly, the

grip. Here, therefore, the proximal muscles were involved significantly. It is of note that a pyruvate-tolerance test done before treatment was abnormal, and returned to normal later. The sensory abnormalities and the peripheral element of the weakness responded to aneurine, nicotinic acid, and riboflavine therapy, though some weakness, especially of the hips, remained. No pantothenic acid or pyridoxine was used.

It is worth recalling that Spies *et al.* (1940) reported that patients who recovered from pellagra after treatment which did not include pyridoxine were significantly helped by the intravenous administration of this substance; the symptoms relieved included muscular weakness and difficulty in walking.

Experimental Work

With regard to experimental work on animals, Follis and Wintrobe (1945) reported peripheral nerve lesions without posterior root ganglion damage in pigs deficient in pyridoxine. With pantothenic acid deficiency, however, the posterior root ganglia were early affected. An interesting description is given of the gait of pigs affected. With pyridoxine deficiency "a swaying of the hindquarters and twisting of the legs with a broad base" was seen, but with pantothenic acid deficiency "a jerky military goose-step" with no twisting was observed. Follis and Wintrobe failed to produce nerve lesions with aneurine deficiency alone.

Swank and Adams (1948) confirm the above to a large extent, particularly the twisting movements of the hind legs, and later the forelegs, with pyridoxine deficiency, and the stiff "goose-step" gait with pantothenic acid deficiency. They also demonstrated with rough tests the preservation of sensation in pyridoxine deficiency, at any rate in the early stages. The final pictures of both deficiencies when prolonged are reported to be similar.

This peculiar swaying gait of the pigs I would interpret as due to weakness of the proximal musculature and comparable with the trick movements noticed so often in true myopathies. The "military goose-step" is presumably due to peripheral weakness with, possibly, tenderness and paraesthesiae contributing; but other explanations are equally plausible and cannot be excluded.

Meiklejohn (1940) and Wintrobe *et al.* (1944) reviewed the evidence on the part played by aneurine in neuritis, and concluded, in brief, that its deficiency was not the cause. Swank and Adams reviewed the evidence again, and concluded that aneurine did have an antineuritic property. This point seems to be far from settled, and further experimental work will be needed before a definite decision can be made. Similar doubts exist about the role of nicotinic acid and riboflavine in the pathology of neuritis.

Two Distinct Types

There does not appear to be any previous record which distinguishes two distinct types of neuropathy associated with cancer—one primarily affecting the proximal musculature and the other primarily peripheral and associated with sensory disturbances. An account is given of two cases of the former seen at the Royal Cancer Hospital.

Case 1

A painter aged 61 had had pain in the left side of the face for seven months before admission, and for six weeks had noticed swelling of the left cheek and a discharge from the left nostril. Ten days previously an x-ray examination at the Royal National Throat, Nose, and Ear Hospital had revealed destruction of the bony walls of the left antrum, and a fenestration of the palate had been performed by Mr. Maxwell Ellis. A biopsy taken then was reported by Dr. J. W. Whittick as showing very active, poorly keratinizing squamous-cell carcinoma. The patient had noticed weakness, of fairly sudden onset, particularly of the spine and arms, about a week before admission to hospital, and had developed oedema of the arms and a rash. Prior to this the only neurological symptoms were those attributable to pressure of the growth on the floor of the orbit—namely, slight proptosis of the left eye with diplopia; numbness to pinprick and cotton-wool of the first and second divisions of the left fifth nerve but sparing the upper branches of the first division which supply the scalp and forehead; and diminution of the left corneal reflex. A slightly lower motor neurone weakness of the left facial nerve affecting the mouth may also have been due to local involvement.

Examination on the fifth day showed gross weakness of the axial spinal muscles, including the sternomastoids, trapezius, pectoral girdle, and ilio-psoas muscles, but little or no weakness of grip, or dorsiflexion of the ankle or other peripheral muscles. The patient was unable to sit up in bed, to hold his arms horizontally in front of him, or to raise a leg off the bed unaided; only with difficulty could he lift his head off the pillow. No sensory changes could be detected, except those mentioned above in the first two divisions of the left fifth nerve. There was no significant wasting, and the reflexes were present in the right arm but not in the left. The knee-jerks were diminished, the ankle-jerks brisk, and the plantar flexor. There was slight oedema of both arms, the left more than the right; at the time this was attributed to drooping of the shoulders leading to compression of the venous return from the arms. Undoubtedly this was part of the truth.

The skin eruption was described by Dr. H. W. Gordon as "curious telangiectatic papular areas on the back of the neck behind the ears, on the sides of the neck, on the outer side of the left arm, and on the right side of the face, which appeared about two weeks before admission. I am at a loss for an exact diagnosis." It was also noticed that there was a mucopurulent conjunctivitis of the left eye, which recovered with routine treatment.

On the third day his serum globulin was 3.12 g.%, albumin 3.25 g.% (total protein 6.37 g.%), and an x-ray film of the chest showed a normal heart shadow. On the sixth day R.B.C. were 4,520,000; Hb, 77%; W.B.C., 19,000. The day after this a Caldwell-Luc operation was performed by Mr. W. A. Mill, and a swab of the pus obtained at that time showed a profuse growth of coagulase-positive *Staphylococcus aureus*, insensitive to penicillin. On the seventh day a lumbar puncture produced a clear C.S.F. under normal pressure. There was no block, and the total protein was 15.2 mg. per 100 ml., there was no increase in the cell count, and the Lange and Wassermann reactions were negative. Up to this time his weakness and oedema had increased, but there was no other change. He had a temperature each night of 99° F. (37.2° C.) for the first ten weeks, after which it subsided.

He had been receiving, in addition to his food, 5,000 units of vitamin A, 30 mg. of vitamin C, 600 units of vitamin D, 1 mg. of aneurine, 1 mg. of riboflavine, and 15 mg. of nicotinic acid daily, with some ferrous sulphate, this being a routine at the Royal Cancer Hospital. On the 20th day this was supplemented by "becozym" injections, providing in all 11 mg. of aneurine, 5 mg. of riboflavine, 55 mg. of nicotinamide, 4 mg. of pyridoxine, and 6 mg. of pantothenol daily.

From the 21st day a remarkable change began—namely, his weakness rapidly decreased so that he was able to hold up his arms and almost sit upright unaided. The oedema, however, increased and involved the legs, and did not begin to improve until about the 36th day, certainly not earlier. On the 30th day the dose of aneurine was raised to 111 mg. daily, and given intravenously. Owing to a misunderstanding it was omitted on the 31st to 33rd days inclusive, but was continued thereafter until the 39th day. By the 37th day his recovery of power was complete, and he gave a demonstration of shadow boxing in mistaken enthusiasm, before being promptly confined to bed again, as he still had an increased venous pressure and oedema. A brisk diuresis occurred between the 39th and the 46th day, resulting in a fall of 19 lb. (8.6 kg.) in weight, and his venous pressure returned to normal. An x-ray film of the chest on the 31st day showed a slight increase in the diameter of the heart, and an early effusion in each costophrenic angle. On the 48th day the x-ray picture was back to normal. Between the 27th and the 30th day he received 500,000 units of penicillin twice daily, but as the organisms were proved insensitive to this, and it had no effect on his temperature, this may be regarded as ineffective and omitted from the discussion.

Ever since admission he had been receiving regular x-ray treatment to the antrum and secondary nodes in the left side of the neck, the dose increasing almost linearly until on the 59th day he had received a maximum of 5,100 r and a minimum of 3,660 r to the antrum and about half of this amount to the glands.

An electromyographic examination was carried out by Dr. P. Bauwens about seven months later, but nothing abnormal was found. He regarded the diagnosis of myasthenia gravis as excluded by this examination. A fractional test meal done at about the same date showed free acid in the resting juice and a hyperchlorhydric curve after histamine.

There can be no doubt that the patient suffered from a vitamin-B deficiency, leading to cardiac weakness and a proximal motor neuropathy. The time relations strongly suggest that either pyridoxine or pantothenic acid affected the neuropathy beneficially, and that aneurine hydrochloride in large doses intravenously cured the myocardial weakness. The patient was still alive when this report was drafted, and there had been no recurrence of the neuropathy, but further radium treatment for his carcinoma had been necessary.

Case 2

A woman aged 56 had for nine years noticed a lump in her right breast which, two months before attending hospital, ulcerated and was subsequently so typical of an advanced scirrhous carcinoma with secondaries in the axilla that biopsy was omitted as unnecessary. Just before x-ray treatment was started she noticed aching in the upper part of her back and weakness, particularly of the muscles used to hold up her head. There were no sensory symptoms or signs. On examination about one month after starting x-ray treatment there was definite weakness of the sternomastoids, trapezii, the extensors and flexors of the whole spine (but particularly of the cervical spine), deltoids, supraspinati and infraspinati, serratus anterior, and the ilio-psoas groups. The distal limb muscles were not affected at all. The triceps-jerks were absent, but other reflexes were present. She was unable to sit up without using her arms, and exhibited trick movements when extending her neck and thoracic spine. She had a sad "myopathic" facies, but no definite weakness of the facial muscles could be demonstrated. There was considerable generalized loss of subcutaneous fat, attributed to the ulcerating carcinoma.

Two months after starting radiotherapy an x-ray film of the cervical spine showed no evidence of secondary deposits, only early osteoarthritis. At the same time screening of the chest showed marked impairment of movement of the anterior portion of the left diaphragm. A month later a lumbar puncture showed a normal C.S.F. with no block and

under normal pressure: total protein 31 mg. per 100 ml., globulin negative, no increase in cells, Lange and Wassermann reactions negative. Electromyography, performed about the same time, showed no spontaneous activity in the right trapezius, right deltoid, or left trapezius, but, on volition, the pattern of motor unit activity was decreased and the units were broken up as is seen in neurogenic lesions.

Radiotherapy to the breast and associated lymph nodes lasted three months and the maximum total dose approached 6,000 r to the breast and axilla. One month after the end of this treatment the mass of malignant tissue had almost completely disappeared and her muscular weakness began to decrease. At the same time as this was noted she was also given aneurine hydrochloride by mouth, 9 mg. daily. Looking back, one can see that it would have been much more helpful if this had been prescribed two or three months earlier, as, anyway, improvement would be expected with the suppression of the carcinoma; therefore the effect of the aneurine at that particular time cannot be assessed one way or another. This improvement in muscular weakness continued slowly but fairly steadily.

Ten months later her right shoulder had become "frozen," despite physiotherapy, and the right trapezius was seen to be almost totally denervated, owing to local extension of the growth. Her other muscle weakness still existed, but to a less extent. Pyridoxine, 50 mg. intravenously twice weekly, was given until a total of 200 mg. had been reached. The patient stated that she had noticed a great improvement during this period, much more than in any other two weeks; and examination confirmed this: there seemed to have been complete recovery of the ilio-psoas group. The cervical spinal muscles were still detectably weak, however. She has continued to take 50 mg. of pyridoxine daily by mouth since then and has become almost normal, apart from the "frozen" shoulder and right trapezius paralysis.

A fractional test meal showed no free acid in the resting juice or until 30 minutes after an injection of histamine (0.5 mg.), but specimens withdrawn 30 to 50 minutes after the injection contained free acid in normal amounts.

The patient was still alive and reasonably well when this account was written, despite the presence of the carcinoma in the breast, axilla, and supraclavicular region.

Discussion

There seems to be no doubt that both conditions were causally related to the carcinoma, and in one case there is incontrovertible evidence of return to normal following vitamin-B therapy; in the other case the evidence is less strong. In both cases the weakness began before treatment with x rays and therefore cannot be attributed to irradiation. The possibility of erroneous diagnosis seems excluded by electromyography, which showed no evidence of myopathy, myasthenia, or anything other than neuropathy. Fasciculation was not seen in either case, nor was muscle tenderness a feature. It is possible that hypochlorhydria played some part in predisposing to vitamin-B deficiency in Case 2, but it seems more reasonable to suppose that the condition really arose from competition by the tumour for the vitamin, leading to a bodily deficiency.

Taken in conjunction with the other evidence quoted above, these two cases seem to be examples of a nosologically distinct disease due to a deficiency of vitamin B and caused by cancer indirectly. An attempt has been made to combine all these facts by the simplest hypothesis, outlined as follows:

Vitamin-B group deficiency occurs in many forms of carcinoma, but most often in carcinoma of the bronchus. At least two distinct types exist: (1) Proximal motor weakness, often with brain-stem lesions and no sensory component, and no abnormality in the C.S.F. (2) Peripheral mixed motor and sensory neuropathy with sensory phenomena predominating, and often with abnormal C.S.F. (cf. Guillain-Barré syndrome).

The first I would attribute mainly to pyridoxine deficiency; the second to deficiency of some other member of the vitamin-B group, pantothenic acid or riboflavin being the most likely. No doubt mixed types occur, since nearly always when one member of the vitamin-B group is deficient, others are also. It is not surprising, therefore, that pyruvate-tolerance tests are abnormal in most cases. Solely from the point of view of therapy, it follows that the ideal treatment is daily intravenous injections of aneurine, with other members of the vitamin-B group, including pantothenic acid and pyridoxine, in large doses. For the purpose of elucidating these syndromes, however, it would be of great value to treat some cases with pyridoxine or pantothenic acid alone, and to observe the results, being prepared to add the other vitamins if necessary.

With regard to animal experiments, a different approach is indicated. The feeding trials of Follis and Wintrobe and of Swank and Adams need to be repeated, but with the emphasis on function, not histology, and with careful assessment of motor and sensory changes by clinical examination of the living animal and by electromyography. This is really only a special case of the generalization that in medicine, except to the anatomist, details of structure are significant only in their relation to function. Swank and Adams report, for example, that the motor roots of certain pyridoxine-deficient animals were normal, but this gives no information about the presence or absence of muscle weakness, since the motor nerves might well be functionless at some point distal to the motor root, and retrograde degeneration of nerves does not occur to any great extent (though one might have expected chromatolysis of the anterior horn cells to be visible).

Summary

The importance of recognizing neuropathy in cancer patients is mentioned, and two cases of proximal motor neuropathy in association with carcinoma are described. In the first, there was also cardiac weakness similar to the mixed type of beriberi. Both cases subsequently recovered neurologically, and there is definite evidence that vitamin B was responsible, particularly pyridoxine. In both the carcinoma is still present, although it has responded to irradiation. These cases should be differentiated from cases of true peripheral neuropathy. A hypothesis based on competition for the vitamin by the tumour cells is suggested. It is also suggested that pyridoxine should be included when treating these cases in future.

My thanks are due to Mr. Maxwell Ellis, Mr. W. A. Mill, Mr. A. H. Hunt, and Dr. Worster Drought for permission to publish case reports of patients under their care. I am also indebted to Dr. M. Lederman and many of my colleagues for their co-operation, and also to Dr. Frank Sargent, who first suggested to me the theory of substrate competition.

[Since this paper was written an account of eight cases of proximal motor neuropathy in association with carcinoma of the bronchus has been published by R. A. Henson (*Proc. roy. Soc. Med.*, 1953, 46, 859).]

METHOD OF ESTIMATING ISONIAZID IN BIOLOGICAL FLUIDS

BY

W. F. J. CUTHBERTSON, Ph.D., F.R.I.C.

AND

S. W. A. KUPER, M.B., B.Ch., D.C.P.

Clinical Pathologist, Brompton Hospital, London

Several colorimetric methods have been proposed for estimating isoniazid (isonicotinic acid hydrazide) in biological fluids (Kelly and Poet, 1952; Rubin *et al.*, 1952; Ginoulhiac, 1952; Smolarek and Stahl, 1953; Wojahn and Wempe, 1953; Jacobs, 1953).

The following method was developed in an attempt to improve the specificity of isoniazid estimations. It depends on the reaction between isoniazid and picryl chloride (2-chloro, 1,3,5-trinitrobenzene) to form a coloured compound, which may be measured photoelectrically.

While our work was in progress a method for the estimation of isoniazid with picryl chloride was described (Kirschbaum, 1952), but not its application to biological fluids.

Method for Plasma

Reagents.—Whenever available, all reagents used were of analytical reagent grade.

10% (W/V) sodium tungstate.2H₂O

2/3N sulphuric acid

N sodium hydroxide

N/10 hydrochloric acid

Ammonium sulphate

n-butanol 1 part, diethyl ether 3 parts

Phosphate buffer pH 7: 60 ml. of M/5 disodium hydrogen phosphate added to 40 ml. of M/5 potassium dihydrogen phosphate.

Phosphate buffer pH 6.5: 30 ml. of M/5 disodium hydrogen phosphate added to 70 ml. of M/5 potassium dihydrogen phosphate

5N acetic acid

Picryl chloride (Hopkin and Williams). This reagent should be washed twice in distilled water, recrystallized twice from chloroform, and air-dried. It is stored in a dark bottle in the refrigerator.

A freshly prepared solution—35 mg. of picryl chloride in 10 ml. of ethanol—is required for the estimation.

Procedure

Plasma (heparinized) from 10 ml. of blood is required for the estimation.

Protein Precipitation.—8 ml. of distilled water, 4 ml. of plasma, and 2 ml. of sodium tungstate solution are measured into a 1-oz. (30-ml.) screw-capped bottle. After mixing well, 2 ml. of 2/3N sulphuric acid is slowly added, with constant shaking. The lid is screwed lightly in position, and the bottle placed in a boiling-water bath for five minutes, cooled, and centrifuged for 10 to 15 minutes—that is, enough to make possible the withdrawal of 12 ml. of supernatant protein-free fluid.

Extraction of Isoniazid into Butanol-Ether Mixture.—11 g. of ammonium sulphate, 0.5 ml. of N sodium hydroxide

solution, 1 ml. of phosphate buffer pH 7, 40 ml. of butanol-ether mixture, and 12 ml. of supernatant protein-free fluid are measured into a glass-stoppered 2-oz. (60-ml.) bottle. The bottle is shaken vigorously for five minutes (mechanically) and then allowed to stand until the butanol-ether and aqueous phases separate. The butanol-ether phase is transferred as completely as possible to a fresh 2-oz. glass-stoppered bottle.

Extraction of Isoniazid into Hydrochloric Acid.—The butanol-ether extract is shaken for two to three minutes with two separate volumes of 5 ml. of N/10 hydrochloric acid. The combined acid extracts are then placed in a 6 by 1 in. (15 by 2.5 cm.) test-tube.

Colour Reaction.—1 ml. of N sodium hydroxide and then 2 ml. of phosphate buffer pH 6.5 are added to the acid extract. After mixing well, 0.5 ml. of freshly prepared picryl chloride solution is added and the tube heated for 20 minutes in a boiling-water bath. The tube is cooled and 0.4 ml. of 5N acetic acid is added, followed by 6 ml. of *n*-butanol. After being shaken for approximately one minute the tube is centrifuged and the butanol phase transferred to a test-tube, two drops of ethanol being added to prevent any cloudiness due to water droplets.

Colour Measurement.—Readings are made against water in a Hilger absorptiometer, using a 4-cm. (8-ml.) light-path cell and an Ilford blue-green filter No. 603 (absorption maximum 485 m μ).

Standard Curve.—Results are calculated by comparison with a standard curve. This is prepared from readings obtained by applying the method to known freshly prepared solutions of 0, 4 μ g., 8 μ g., and 16 μ g. of isoniazid, each level in 4 ml. of pooled, non-haemolysed plasma from blood transfusion material. The reproducibility of the method is satisfactory: the absorptiometer readings are linearly related to the amounts of isoniazid present within the range 0 to 20 μ g. The standard deviation of a single estimation is about $\pm$ 10%. It is necessary to estimate unknown samples and standard samples concurrently.

Method for Urine

The same method is used as for plasma, but protein precipitation is omitted.

Test samples are read against standard aqueous isoniazid solutions treated in the same way.

Specificity of Method

Metabolic Products of Isoniazid Ingestion

The urine of human subjects after isoniazid ingestion is known to contain isoniazid, isonicotinic acid, and isonicotinoyl glycine (Cuthbertson *et al.*, 1953). Isonicotinamide was not detected, but could have been present undetected in amounts of up to about 5% of the dose. The reactions of these substances with picryl chloride have been described (Cuthbertson *et al.*, 1953). Quantities of 150 μ g. of each of the last three substances do not interfere in the recommended method.

Another metabolic product of isoniazid ingestion is also present in human urine, but its nature is unknown. By paper chromatography of concentrated urine solutions using water-saturated *n*-butanol as developing solvent, this substance has approximately the same *R_F* value as isonicotinamide. It reacts with picryl chloride to form a red-coloured compound at alkaline pH and a yellow-coloured compound at acid pH, but does not react with the cyanogen bromide-pyrazolone or cyanogen bromide-benzidine reagents in the same way as isonicotinamide (Cuthbertson *et al.*, 1953).

Since this substance reacts with picryl chloride similarly to isonicotinic acid and isonicotinamide, it is unlikely to interfere in the determination of isoniazid by our method. This assumption is supported by the fact that after isoniazid ingestion some 24-hour human urine samples contain little or no isoniazid, as shown by this method, but do contain appreciable amounts of the unidentified substance, as shown by chromatography.

Wojahn and Wempe (1953) have shown that isoniazid combines through its hydrazide group with an unknown substance or substances in plasma and urine to form micro-biologically inactive or less active compounds. We have no direct evidence to show whether or not these compounds, if different from the unknown metabolite described above, interfere in our method. Circumstantial evidence indicates that they interfere only slightly, if at all. Smolarek and Stahl (1953), using a method that does not measure this type of "bound" isoniazid, found that the average 24-hour urine excretion of free isoniazid in five human subjects receiving a single 500-mg. oral dose of isoniazid was 17.5% of the dose. The individual values varied between 13.6% and 22.5% of the dose. We found that the 24-hour urine contents of isoniazid in two human subjects each receiving 250 mg. of isoniazid orally every 12 hours were 21% and 22% of the dose. Furthermore, approximate assessments of the isoniazid content of urine samples from chromatographic evidence agree with actual estimations.

Since isonicotinic acid is a metabolic product of isoniazid ingestion in human subjects, hydrazine could also be liberated. Hydrazine reacts with picryl chloride to form hexanitrohydroazobenzene (Kulberg and Cherkosov, 1952), the light absorption of which would be measured by this technique. However, Kelly and Poet (1952) and Kelly *et al.* (1952) have not detected the presence of free hydrazine in the body fluids of the animals they studied. Using their method, we were unable to detect free hydrazine in the plasma of human subjects receiving orally 200 mg. of isoniazid per subject, or in the plasma of guinea-pigs (body weight 380 to 420 g.) receiving orally 10 mg. of isoniazid per guinea-pig, at $\frac{1}{2}$, 1, 2, 4, or 7 hours after the dose. Also 24-hour urine samples from human subjects receiving 500 mg. of isoniazid orally contained no free hydrazine.

Streptomycin and *p*-Aminosalicylic Acid

Experiments were performed to detect any possible interference with the picryl chloride method by streptomycin or *p*-aminosalicylic acid.

In aqueous solutions of isoniazid the addition of 500 μ g. of streptomycin per ml. caused no increase in the readings obtained.

p-Aminosalicylic acid was found to interfere even in relatively low concentrations. For this reason it was possible to perform isoniazid assays only on patients not at the time receiving any *p*-aminosalicylic acid, but streptomycin therapy was not a factor of importance in this connexion.

Results

Plasma

Isoniazid was estimated in the plasma of 24 patients. Twenty-two received 100 mg. and two 150 mg. of isoniazid orally every twelve hours. Table I gives each patient's dose in mg. of isoniazid per kg. body weight.

Blood samples were taken by venepuncture shortly before the morning dose of the drug, and three further samples were withdrawn at intervals of 30, 60, and 120 minutes afterwards. Preliminary tests had soon shown that the picryl chloride method was not sensitive enough to detect any isoniazid in plasma twelve hours after the last dose, and so it was considered permissible to treat the early morning plasma of each patient as a "blank."

Table I shows the results obtained from these patients. In general, the plasma levels are somewhat lower than the figures quoted in previous publications (Elmendorf *et al.*, 1952; Rubin *et al.*, 1952), and the highest level was almost always found 30 or 60 minutes after the dose.

In 10 patients receiving 1.15 to 1.5 mg. of isoniazid per kg. body weight the average level of isoniazid estimated 30 minutes after the dose was 0.7 μ g./ml., 60 minutes after the dose 0.8 μ g./ml., and 120 minutes after the dose 0.4 μ g./ml. For 14 patients receiving 1.55 to 3.65 mg. of isoniazid per kg. body weight the corresponding 30-minute,

10 R	1.50	0.5	0.2	0.0
21 R	1.95	0.0	0.0	0.5

The plasma isoniazid concentration of Cases 10 and 21 were redetermined three months later as shown under 10 R and 21 R.

60-minute, and 120-minute values were 1.0 μ g./ml., 1.3 μ g./ml., and 1.0 μ g./ml.

Three of the 24 patients (Cases 4, 10, and 21) had no detectable isoniazid in any of the blood samples. Nothing in their clinical condition suggested a disturbance of intestinal absorption, and examination of urine for isoniazid and its metabolites was undertaken in Cases 10 U and 21 U (Table II). This subject is considered in the discussion of

TABLE II.—Urinary Excretion of Isoniazid. (a) 100 mg. Isoniazid, Administered Orally 12-hourly; (b) 250 mg. Isoniazid, Administered Orally 12-hourly

Case No.	mg. Isoniazid per kg. Body Weight	μ g./ml. Isoniazid in Urine	Total Isoniazid Excreted in 24 Hours (mg.)	% of Dose Excreted in 24 Hours
(a) 25 U	3.3	13	9.7	4.8
26 U	3.5	20	35.0	17.5
27 U	2.7	18.5	32.0	16
28 U	2.3	6.2	11.5	5.7
29 U	3.2	8.0	17.4	8.7
30 U	3.1	8.4	8.0	4.0
31 U	3.9	4.3	5.3	2.6
10 U	3.0	2.0	3.0	1.5
21 U	3.9	2.6	5.7	2.8
			Average	7.1
(b) 28 U	5.7	61	103	21.0
29 U	8.0	42	110	22.0

results of urine assays. Three months later, blood curves were repeated on two of these patients (Nos. 10 R and 21 R), who were still in hospital. These two curves are very similar to those obtained on the first occasion. In both patients the highest level attained was 0.5 μ g./ml., and this was present in only one specimen from each patient.

Urine

The results shown in Table II (a) were obtained from nine patients receiving 100 mg. of isoniazid 12-hourly. Whenever possible a 24-hour specimen of urine for use as a "blank" was collected before isoniazid therapy was begun, and the test estimations were performed on aliquots of 24-hour specimens of urine collected during treatment.

The amount of the dose excreted as isoniazid during 24 hours varied widely (1.5% to 17.5%, average 7.1%). These values are appreciably lower than those found by Elmendorf *et al.* (1952), using the assay method of Kelly and Poet (1952). In six patients receiving 3 mg. of isoniazid per

kg. body weight, they found the 24-hour urinary excretion of isoniazid lay between 47.8% and 70.7% of the dose. Our results thus confirm that the method of Kelly and Poet measures something besides isoniazid (Smolarek and Stahl, 1953; Wojahn and Wempe, 1953; Cuthbertson *et al.*, 1953). Samples 10 U and 21 U (Table II (a)) are urine samples from the patients whose blood values are shown in Table I as 10 and 21 and 10 R and 21 R. In these two patients the very low excretion values, together with the low blood levels suggested some defect of absorption, but chromatographic analysis (Cuthbertson *et al.*, 1953), of the two urine samples revealed the presence of the metabolites of isoniazid (isonicotinoylglycine, isonicotinic acid, and the unidentified metabolite) in approximately the same amounts as contained in the urine of patients with higher isoniazid levels in blood and urine. Assessment of their clinical response to isoniazid was rendered difficult, for both the patients were also receiving streptomycin.

Patients whose urine samples are given as 28 U and 29 U were subsequently given 250 mg. of isoniazid twelve-hourly. There was an appreciable rise in percentage of the dose excreted as isoniazid during the succeeding 24-hour period (Table II (b)).

Further assessment of the method is desirable and should lead to improved evaluations of results obtained by it. It is hoped that the description given here of both method and results may be of use to those who wish to carry the matter further.

Summary

A colorimetric method is described for estimating isoniazid in biological fluids by means of picryl chloride.

The specificity of the method is assessed with reference to the metabolites of isoniazid.

Results are given for the amounts of isoniazid in plasma and urine from patients receiving the drug.

We wish to thank the physicians and surgeons of the Brompton Hospital for permission to investigate the samples from their patients; Dr. R. N. Johnston, medical registrar, for his great assistance in the collection of samples; and Miss E. Harris and Mr. F. W. Price for technical assistance.

The professor of medicine at Duke University, North Carolina, Dr. James V. Warren, is to visit Kenya to perform research work on giraffes. The object of this research is to aid those who are designing "G-suits" (gravity suits) worn by the pilots of high-speed jet aeroplanes. In pulling out of power dives or other manoeuvres at high speeds pilots are subjected to pressure eight or nine times the force of gravity. It is generally believed that a pressure of 8 G is the maximum that a pilot can withstand. The G-suits are pressurized and designed to offset the violent pressure changes which cause a reduced flow of blood to the brain and consequent black-outs. Dr. Warren believes that the giraffe, with its head a considerable distance from its heart, has at all times to meet the situation that man faces when he is subjected to centrifugal force in military planes making fast turns and dives. "Maybe," Dr. Warren is reported to have said, "the giraffe has some sort of booster mechanism that helps its heart."—*U.S.A. in Review*, February 24, 1954.

VALUE OF STRICT DIETING, DRUGS, AND "ROBADEN" IN PEPTIC ULCERATION

BY

P. R. C. EVANS, M.D., M.R.C.P.

From the Wrexham Group of Hospitals

Recent papers on gastric and duodenal ulceration express conflicting views on the value of many of the therapeutic measures customarily used in the conservative (non-surgical) treatment of the two diseases. Nicol (1939), Ronald (1939), and Lawrence (1952) found that rest in hospital on a light diet or even a normal hospital diet gave results as good as those obtained in hospital on a strict "ulcer" diet with antacids and belladonna, whilst Doll and Pygott (1952) found that cases treated on a "gastric" diet in hospital fared better than those on ambulatory treatment with a "convalescent" diet. They were undecided whether the physical and mental rest or the supervised strict dieting was the important factor, although they showed that phenobarbitone and vitamin C had no influence on the rate of ulcer healing. Martin and Lewis (1949), as a result of a 10-14-year follow-up of cases, concluded that medical treatment had no influence on the natural history of gastric and duodenal ulceration. Morton Gill (1947) found that the treatment of gastric ulcers with subcutaneous injections of sterile water whilst the patients were ambulant and on a normal diet gave results as good as those achieved with orthodox treatment.

The great importance of anxiety and mental stress in the pathogenesis and in the precipitation of relapse of peptic ulceration, and particularly of duodenal ulceration, is now generally accepted (Davies and Wilson, 1937; Nicol, 1939, 1942; Gill, 1947).
