The days are recorded after the first injection. Cases 5 and 10 were females, the rest males.

Damage to Liver (1 case).—In one patient (Case 6) the temperature rose, finally reaching 104° F. (40° C.) after the tenth injection; two days later he vomited repeatedly; and the next day he developed jaundice, with bile and albumin in the urine. He made a satisfactory recovery, and one month later was much improved. It was difficult to assess the cause of the jaundice, as it was possible that there was either previous liver damage or a coincidental infective hepatitis, both of which are fairly common in Gambia. Since the patients previously treated had showed no other toxic features the trial was continued; and subsequently five more cases were treated satisfactorily in the ward.

Albuminuria did not occur in any of the patients, apart from the one case noted above.

Group 3. Cases Treated in a Village

Twenty-one cases of filariasis were selected for treatment in a village which had been previously surveyed. Heavy infections were chosen. Each patient was examined clinically. The projected dose schedule was a daily injection of 5 ml. for 12 days. Since the lowest weight of any patient selected was 50 kg. no patient received a dose greater than 2.5 mg. of arsenamide per kg. daily. After the group had received 10 injections, however, treatment was discontinued because one of the patients died (see below). The injections were given between 6 and 7.30 p.m., after the villagers had returned from their work in the fields. They were given intravenously and slowly with the patients lying down. Urine specimens were examined for albumin before treatment, and 3, 6, 9, and 15 days after the first injection. All patients were weighed before and after the course of injections. On the evening before the injections were begun, measured quantities of blood were taken as described above, between the hours of 10 and 11 p.m. Any information on

toxic features volunteered by the villagers was recorded, and direct questions were asked only after the course was completed.

Results

Table II records the microfilariae counts of these patients. In all the blood samples taken two weeks after the first injection, only a single *bancrofti* microfilaria was found. Sixteen of these patients had received 10 injections of arsenamide, but 2 had 9 injections, 1 had 8, and 1 had only 5. Seven months after treatment the blood of all the patients was free from *bancrofti* microfilariae. Two of these patients also contained appreciable numbers of *perstans* microfilariae in the blood; one patient became negative.

Toxic Features

Vomiting (7 cases, 33%).—One patient vomited after each injection, while the others vomited only occasionally.

Diarrhoea.—Four people complained of occasional loose stools during the course of injections. This feature is difficult to assess; it was not noted in the cases treated in the ward.

Dizziness occurred in two cases.

Generalized Pain.—One person complained of pains all over the body. This is a common complaint in Africans, and was probably associated with yaws.

Signs of Death of Adult Worms or Allergic Reactions.—One person developed a filarial abscess on the medial aspect of the thigh which subsequently broke down and discharged thick creamy pus; one developed a bilateral hydrocele; one had a transient enlargement of the scrotum; one had an enlargement of the epididymis. Several days after the injections had ceased one person developed weals on the skin associated with pruritus which cleared satisfactorily with mepyramine maleate.

Loss of Weight.—One person lost 3 kg. (associated with vomiting) and one lost 3.5 kg. (not associated with vomiting).

Signs of Liver Damage.—One man died from liver damage after receiving only three injections of the drug; this case is described in detail below. Another man developed jaundice four and a half weeks after the last injection; a fresh dry sterilized syringe and needle had been used for each injection, so this jaundice could not have been due to the passage of a virus.

Albuminuria did not occur in any case. The drug did not leak from a vein on any occasion.

The Fatal Case

The patient, a man aged 55, weighed 53 kg. He was given three daily injections of 5 ml. (2.4 mg./kg.). After the third injection he vomited and complained of vague retrosternal pains. The symptoms were mild and hardly seemed sufficient to contraindicate further treatment; but no more injections were given. Two days afterwards he felt well; but later that night developed pain in the back of the neck, staggered, and was unable to stand or sit up. This was reported next day, when the investigator returned to the village and found that the patient was comatose.

On admission to the ward he was still comatose but able to move his limbs. Reflexes were present and normal. Lumbar puncture showed: no increased pressure, Queckenstedt's test normal, Pandy's test positive, 60 lymphocytes per c.mm. No trypanosomes seen. Blood pressure, 230/120 mm. Hg. Urine contained no albumin or bile. There was some doubt whether or not he had a slight icteric tinge, but African observers considered that the colour of his conjunctivae was normal. Dimercaprol and penicillin were given, but he developed the signs of basal pneumonia and died four days later.

Post-mortem Findings.—The liver weighed 880 g. and was stained yellow, the kidneys 170 g. each, and the heart 284 g.; there was some atheroma of the heart and aorta. The urine contained no appreciable amounts of bile salts or pigments. **Histology.**—In the liver were numerous areas of recent focal damage from which most of the parenchymal cells had disappeared; there was considerable proliferation of fibroblasts, but no evidence of pre-existing cirrhosis. In the kidneys, the cells of the cortical nephrons showed the appearance of massive necrosis (part of this appearance could have been due to post-mortem autolysis); many of the medium and small arterioles showed medial fibrosis and irregular intimal thickening. It is concluded that death was due to widespread necrosis of the liver.

Group 4. Cases Treated with Low Doses in Hospital

The experience with the fourth group of patients indicated that although large doses of arsenamide were therapeutically effective they might also have dangerous toxic effects. Accordingly an investigation was made to discover whether a much lower dose, which would be small enough to be safe, might yet be sufficient to produce cure. For this purpose five patients were treated with strict precautions against toxic effects—namely, the dose was 0.3 mg./kg. daily (only one-eighth of that previously used), the patients were kept under careful supervision in hospital, and they were given 50 g. of dry skim-milk daily (protein-rich supplement) in addition to good hospital diet, so as to fortify the liver against the toxic effects of arsenic. No toxic effects were observed; and the therapeutic results are shown in Table III. Reduction of the microfilaria count was much

TABLE III.—Treatment of 5 Cases of Bancroftian Filariasis (Group 4) with 0.3 mg. Arsenamide per kg. Daily

Case 35 was male, the rest females.

slower than it had been with large doses. Of the four patients who could be followed for five months the count was greatly reduced in two cases and probably the microfilariae will eventually disappear; in one case the count fell to a quarter of its original level, and in one case there has been no appreciable change. Thus the filaricidal effect of 0.3 mg./kg. daily, although considerable, is not completely satisfactory. From this small group of patients it might be deduced that 0.6 mg./kg. would be the minimum effective dose.

Treatment with Suramin

Suramin is very effective for the treatment of onchocerciasis, in which it kills the adult worm (Wanson, 1950). As regards its action on *W. bancrofti*, we have not found any reports which include an adequate follow-up of the patients for several months, to see whether the microfilariae disappeared. Such late disappearance would suggest that the adult worms had been killed or sterilized. Accordingly the

opportunity was taken of observing the action of suramin in two patients with trypanosomiasis whose blood also contained *bancrofti* microfilariae.

Case A.—A man aged 45, weight 60 kg., was given 1 g. of suramin intravenously on December 18, 21, and 23 and January 1 and 9 (total 5 g.). At 10 p.m. on December 18 his blood contained 7 microfilariae per 40 c.mm.; on March 7 (79 days after the first dose), 57; and on May 28, 62.

Case B.—A woman aged 35, weight 50 kg., received three intravenous doses of 1 g. of suramin between December 18 and January 4; and on January 9, 1 g. At 9.30 p.m. on January 9 her blood contained 23 microfilariae per 40 c.mm.; on March 7, 11; and on May 28, 10.

In these two cases there was no evidence that suramin was able to kill or sterilize the adult worms of *W. bancrofti*. Wanson (1950) states that it does not kill the adults of *W. bancrofti*, *Loa loa*, *Acanthocheilone perstans*, or *A. streptocerca*, although no evidence is given for this statement. In our laboratory at the National Institute for Medical Research, in London, suramin had no lethal action on *Litomosoides carinii*. Clearly the chemotherapeutic reactions of filarial worms differ according to the different species.

Discussion

The action of a chemotherapeutic drug must be considered from two aspects, that of the parasite and that of the host—that is, therapeutic action and toxicity.

Therapeutic Action

Arsenamide in high doses (2 mg./kg. daily) causes disappearance of the microfilariae of *W. bancrofti* from the blood within two weeks. Since this period is much less than their normal life span, their disappearance must be directly due to a lethal action of the drug. Such an action has been demonstrated *in vitro* in concentrations of approximately one in a million (Hawking, 1950). (The gradual disappearance of the microfilariae after small doses (0.3 mg./kg.) was presumably due to failure of replenishment after death of the adult worms.)

Since the disappearance of microfilariae caused by arsenamide is permanent (more than seven months, at least) there is evidence that death or permanent sterilization of the adult female worms has been brought about: on general grounds, and by analogy with the experimental findings with *Litomosoides* in cotton rats, it is almost certain that the adult worms have been killed. This effect is produced by doses of about 1 to 2.5 mg./kg., usually given daily for 15 days. Thus Thetford *et al.* (1948) and Otto *et al.* (1952, 1953) gave 1 mg./kg. for 15 days. In the present series the number of injections varied from 5 to 12 (9 patients received 12 injections, 17 received 10, 3 received 9, 1 received 8, and 1 received 5). Since the daily amount given was not calculated on a weight basis, the actual dose varied from 1.8 to 2.5 mg./kg., according to the weight of the patient. All the courses of injection were effective in removing microfilariae from the blood. With much smaller doses (0.3 mg./kg.) the antifilarial effect, although considerable, is not complete. Perhaps the minimum curative dose is about 0.6 mg./kg.

Arsenamide also causes considerable reduction in the number of *M. perstans* microfilariae in the blood. It is possible that arsenamide kills many of the adult worms of *A. perstans*, although a long period of observation might be necessary to obtain evidence of this, since these microfilariae may live over two and a half years in the absence of the adult worm (Gönnert, 1942). As this parasite is non-pathogenic, however, such action is of academic interest only.

Toxic Action

As described above, intensive treatment with arsenamide may produce various minor toxic effects—for instance, vomiting, dizziness, headache, loss of weight, and (possibly) diarrhoea. Localized inflammation or allergic reactions due to the death of adult worms may also develop during treatment. All these, however, are overshadowed by the

tendency of arsenamide to cause damage to the liver, which may proceed (as in the case described above) to fatal necrosis. In the present series of 35 patients treated with doses of 1.8 to 2.5 mg./kg. a day one patient developed pyrexia after the tenth dose, and jaundice appeared three days later; one man developed jaundice about four and a half weeks after the last of 10 injections (the relation of this to the treatment is not clear); and one man suffered fatal necrosis of the liver three days after receiving three doses of 2.4 mg./kg., total 7.2 mg./kg. Ampoules from this batch of material were returned to the manufacturers. Chemical examination revealed no alteration of composition, and biological assay showed no increase of toxicity. Therefore the toxic effect on the liver must be due to the unchanged compound, probably to the arsenic part of the molecule; there is no reason for believing that the benzamide part of the molecule has any significant toxic action.

There had been considerable previous experience with this compound, and many patients had tolerated much greater total dosages without ill effects. Thus Murgatroyd (1937) administered it (under the name K324) to eight patients with sleeping sickness in the Gambia in doses as high as 35 mg./kg.; doses greater than 2.5 mg. produced vomiting, abdominal pain, or diarrhoea, and in one case there was severe jaundice. Thetford *et al.* (1948) and Otto *et al.* (1952) treated 18 cases of filariasis with doses of 1 mg./kg. daily intravenously for 15 days and observed only minor toxic reactions. Similarly, Otto *et al.* (1953) treated a further 15 cases with the same dose schedule. The main toxic features observed were diarrhoea and nausea; one case had severe lymphadenitis. Hawking (1950) treated four patients with daily injections of 100 or 150 mg. for seven days—that is, 1.7 to 2.5 mg./kg. The larger doses were followed by vomiting and diarrhoea, but there was no suggestion of liver damage. In East Africa 36 cases have been treated with doses of 1 mg./kg. daily for about 14 days; one case of jaundice occurred (Filariasis Research Annual Report, 1952). We have also heard privately of two cases of non-fatal severe hepatitis with jaundice which occurred in the West Indies after treatment with arsenamide. No evidence of special toxic action on the liver of rabbits, dogs, or monkeys was seen by Otto and Maren (1950), or by Drudge (1952), who gave dogs 2.2 mg. of arsenamide per kg. intravenously daily for 15 days.

Apparently the death described above was another example of the tendency of arsenic compounds to cause extensive necrosis of the liver in a very small proportion of the cases treated with it. Such subjects must be predisposed to damage by accessory factors, but the nature of such factors and the causation of widespread liver necrosis in man are still largely unknown. The possible accessory factors include:

(a) *A Virus Infection, Latent or Incipient.*—Hepatitis, presumably infective, certainly occurs in Gambia, since several Europeans developed it recently. In the present investigation a clean sterile syringe and needle were used for each injection, so there was no possibility of passage of infection by this means; moreover, the incubation period was much too short for viral hepatitis to develop from the patients' injections.

(b) *Lack of Essential Nutrients, Especially Tocopherol and Cysteine.*—This food deficiency causes hepatic necrosis in rats (Himsworth, 1950). Many Africans are certainly malnourished, but there is no evidence that the state of nutrition of the present patient was worse than that of others in the same village who were treated. However, in any further trials with arsenical compounds it would be advisable to take the precaution of fortifying the liver against such toxic action by giving a protein-rich supplement—for example, 50 g. dried milk daily in addition to the usual food.

It is concluded that arsenamide, in daily doses of 1 mg. or more per kg. for 10 to 14 days, is an effective drug for the sterilization of bancroftian infection in patients, and that its use is not devoid of risk. Since filariasis is not a fatal disease, it is accordingly not justifiable to use arsenamide for general treatment. In any further investigation of this drug careful precautions should be taken to avoid damage

to the liver: the dose should be kept low, preferably below 0.6 mg./kg.; the patients should be treated in hospital under strict medical supervision; and the protein content of the patient's diet should be increased—for example, 50 g. of skim-milk powder daily in addition to a good general diet—in order to fortify the liver, the protein supplement being given for three days before, during, and three days after treatment.

Summary

Thirty-two cases of filariasis due to *W. bancrofti* were treated with arsenamide (*p*-bis-(carboxymethyl-mercapto)-arsino-benzamide). The dose was 125 mg. (1.8–2.5 mg./kg.) daily by intravenous injection, usually for 10–12 doses.

This treatment removed most of the microfilariae of *W. bancrofti* from the blood within two weeks after the first dose, and all but two of the patients were free from microfilariae six months later. It is concluded that the treatment killed or sterilized the adult worms; it also killed many of the microfilariae (and the rest disappeared in the absence of adult worms to replenish their numbers). The treatment also caused a significant reduction in the number of *A. perstans* microfilariae present, indicating a filaricidal action on this worm also.

The drug undoubtedly has a toxic effect upon the liver. In two cases the treatment was followed by jaundice, three days and four weeks respectively after the last injection; and one patient developed fatal necrosis of the liver after having received only three injections. Other minor toxic effects included vomiting, dizziness, headache, and loss of weight. A few patients showed localized inflammation or allergic reactions, apparently around worms which had been killed.

Five more patients were treated with much lower doses (0.3 mg./kg.) daily for 14 days under strict medical supervision, and with a protein-rich supplement to fortify the liver. No toxic effects were observed. Among the four patients who were followed for five months the microfilaria count was reduced almost to zero in two, it fell to a quarter in one, and it remained unchanged in one. Perhaps the minimum curative dose is about 0.6 mg./kg.

Arsenamide in doses of 1–2 mg./kg. daily is a potent filaricidal drug against *W. bancrofti*, but the danger of severe toxic action upon the liver is a contraindication to its use except under special conditions.

Two patients were treated with 4 g. and 5 g. respectively of suramin for trypanosomiasis. This treatment had no apparent effect during the next five months on the number of *bancrofti* microfilariae in their blood.

Grateful acknowledgments are made to Professor B. S. Platt for clinical facilities; to the Director of Medical Services, Gambia, for interest and encouragement; to Sisters S. E. Brewer and D. J. Fayers for nursing assistance; and to Dr. J. Niven for advice on morbid histology. The drug was kindly supplied by Eli Lilly & Co., Indianapolis, U.S.A. who also re-examined the material at our request.

A BIOLOGICAL APPROACH TO MEDICAL GEOGRAPHY*

BY

J. R. AUDY, Ph.D., M.B., B.S.

Senior Research Officer, Division of Virus Research and
Medical Zoology, Institute for Medical Research,
Kuala Lumpur, Malaya

Everyone knows that frost-bite occurs at the North Pole and heat exhaustion is more common in the Tropics. There is a tendency to look upon medical geography as merely an elaboration of this simple theme, but it is not merely a descriptive subject: it is a most fascinating part of human ecology or social biology—the vitally important sphere of human natural history to which geography is an essential background.

The method of approach followed in this paper was indicated by studies of the medical geography of scrub-typhus made in India and Burma during the war and followed up in Malaya (Audy, 1947; Audy and Harrison, 1951). An attempt is made to apply the ideas and methods of the biologist to the problem, with the support of facts gained by recent studies of animal parasites. The main object here is to stress the contribution that can be made by studying assemblages of parasites as a whole; it is therefore concerned almost entirely with diseases caused by organisms.

The term "parasite-pattern" is used here to describe the whole assemblage or array of parasites (including all pathogens) which are associated with a host population being discussed. By extension of this meaning, I also speak of the "pattern" of disease caused by some of the parasites. My object is to relate the parasite-patterns of various communities to those elements of human existence and behaviour which themselves reflect the geographical background in one way or another. To complete the associations I here call the relevant elements of existence and behaviour of a community its "social-pattern."

Patterns of Disease in Somaliland

I will first consider the semi-desert and thorn-scrub of Somaliland. There are great stretches of sparse grassy plains or thorny scrub with widely scattered water-holes. This sort of country must evoke a distinct type of response from the primitive community which first occupies it. It sets a low limit to the overall population, which is almost entirely pastoral and supported by drought-resisting beasts of burden and livestock, such as camels and mules, goats and fat-tailed sheep. The community soon learns that it cannot continue grazing its animals in one place. Not only is it forced to discover and use seasonal grazing areas, but this together with the scarcity of water will also encourage a natural tendency to form well-knit tribes, with tribal grazing areas and some sort of portable villages composed of tents or their equivalent, which can easily be folded up and taken elsewhere. Naturally, the use of such portable huts, which in Somaliland are small hemispherical cocoons of matting, encourages sleeping in a compact huddle. In such ways the geography of the place has a tremendous influence in guiding the pattern of existence of the community or what in this paper is referred to as the social pattern.

Linked to this social pattern in response to a particular and exacting environment is the pattern of disease. Relatively few rural diseases occur in Somaliland, but, as would be expected, there is a pattern related directly to the habitat. Malaria is highly seasonal and highly localized, spreading

*Based on a lecture on the geography of disease given at the University of Malaya in January, 1952.

outwards from small foci during the short rainy season. The general standard of nutrition is low and outbreaks of nutritional disorders occur in bad years. The incidence of desert sores following minor injuries, often leading to severe crippling, is high. In addition to the desert sores, there is a moderate incidence of mycetoma (Madura foot), the fungal spores being inoculated into the skin by the thorns and similar parts of plants on which the fungus concerned appears to grow naturally. Cataract and eye infections are associated with the flying sand and glaring sun, as well as with the flies which thrive in villages. The very free breeding of the flies is directly related to the dry climate. The presence of numbers of soft ticks carrying relapsing fever is also related to the climate. So also is the presence of many herds of animals, including packs of jackals and hyenas, among which rabies is permanently established.

Heavy and regular rainfall has a general cleansing effect which has not yet been properly assessed. Its absence in Somaliland may help to account for much of the spread of intestinal and respiratory infections as well as for the zymotic diseases. The intense dryness and frequent sandstorms encourage sore throats, which the Somalis have been led to treat heroically by snipping off the uvula, usually with slender home-made scalpel and a sharp hook made from an umbrella-rib. Respiratory infections, including tuberculosis, are encouraged by the huddling together in the tiny portable huts, while their effects are made worse by malnutrition.

Malaria in Ceylon

It would be desirable to draw parallel pictures of other places, but these pictures rapidly become much too complicated. I now turn to single diseases in particular places. Malaria offers countless illustrations of medical geography. Ceylon has a particularly fascinating malarial history, culminating in the mastery of epidemic malaria in recent years by a well-planned D.D.T. campaign. The vector mosquito is not very efficient and requires to be present in relatively large numbers for successful transmission. It breeds in clean open pools and puddles, especially in stream and river beds. When these biological requirements are imposed on the geography of the island a very distinctive and peculiar malarial pattern results.

A central mountain-mass breasts the prevailing monsoons and encourages heavy rainfall in the south-west quadrant of the island. Most of the island, however, has a very dry season. Malaria in this "dry zone" is perennial and there is a regular malaria season during the rains. By contrast, the lush, densely populated wet zone in the south-west offers little to the vector mosquito and it is curiously free of malaria in ordinary years. Occasionally during exceptionally dry years certain rivers almost dry up, forming extensive chains of pools in which the vector breeds by the million. This led to violent epidemics in the non-immune population—such as that in 1934-5, when over 80,000 deaths were attributed directly to malaria. Man has aggravated this situation by extensive deforestation in the hills, which results in less retention of water in the catchment areas and tends to produce more rapid changes of water-level in the rivers with more frequent pool-formation during dry spells.

The Typhus Fevers

The next example is the typhus fevers, caused by rickettsiae and transmitted by insects, ticks, and mites. These rickettsiae fall into three groups. The two most primitive groups, carried by ticks and mites, cause infections of small mammals and their parasites, and are only accidentally conveyed to man by a few of these parasites when he loiters in infested places. The vectors are restricted in their distribution in two ways: firstly, on a small scale to patches or "islands" such as a particular stretch of a valley or a single field; and, secondly, on a large scale to geographical regions where conditions are generally favourable for the development of the vectors. Ticks abound in drier tracts outside the rain-forest, so that tick-typhus is practically confined to such country. The mites which carry

scrub-typhus have their home in south-east Asia, where they now abound in the rat-infested scrub which follows deforestation. Scrub-typhus is confined by what are probably formidable barriers to the further spread to the vector—by tropical deserts, ice deserts, and great mountain ranges on the mainland, by extensive oceans which have almost stopped spread elsewhere, and by excessive dryness which has hindered all spread beyond a very small part of tropical Australia.

An interesting feature of both tick- and scrub-typhus is that the disease shows definite changes in character and severity from place to place. This can be correlated with serological types of the rickettsiae concerned. This is most pronounced with tick-typhus, in which local characters have given rise to a larger number of place-names for different forms.

The third group of rickettsiae is distinctive by having become adapted to life in the guts of insects. Flea-typhus, the more primitive member, is carried by various rat-parasites and transmitted to man by the same rat-fleas as carry plague. Because the domestic rat and its fleas are concerned, flea-typhus is urban and almost cosmopolitan in its distribution. In the most recently evolved member of this group, the flea-borne rickettsia has become adapted to the human body-louse. This at once results in three things: firstly, a restriction to cold climes or high altitudes, and cold seasons; secondly, a tendency to spread from man to man in the form of a swift epidemic; and, thirdly, an extension into regions where the rat-flea has no influence. Although both flea-typhus and epidemic or louse-typhus are essentially urban, the requirements of the vector have shifted the distribution of louse-typhus away from the equatorial belt and far into and beyond what Marston Bates calls the Intemperate Zones.

Parasite-patterns of Animals

These examples have been treated superficially. A deeper study confirms that there are important relations between the entire disease-pattern of a community and its geographical background. Recent investigations in Malaya have given some useful facts with which to approach this problem. Nearly 20,000 animals and their parasites, from forest, scrub, plantations, and towns, have been studied in Malaya since 1947 (Audy and Harrison, 1953). One of several objects of this study was to investigate the parasite-patterns of these animals and to attempt to use the parasites as "ecological labels" (Audy, 1947). The parasites concerned are all those viruses, bacteria, protozoa, fungi, worms, and arthropods which live on or in or at the expense of higher organisms such as the vertebrates, whether harmlessly or harmfully. At a rough estimate there are perhaps 50,000 known species of these parasites potentially able to parasitize the vertebrates, including man. Although very many parasites are available, the whole population of any host in any locality usually supports only a few dozen. The assemblage of these commoner parasites, of various kinds and in varying numbers, constitutes a pattern. I am concerned with the reasons why these patterns differ among themselves in different communities and why they involve but a fraction of the available parasites.

The tree-living squirrels in the Malayan rain-forest support some 30 species of parasitic mites which together make up a pattern broadly characteristic for these squirrels. Ground-rats which live in the same area have quite different parasite-patterns. There is a rat (*Rattus canus*), however, which has a pattern essentially like that of the tree-squirrels and unlike that of the ground-rats. A correct inference from this is that *R. canus* lives in the trees like the squirrels. The picture is completed by the ground-squirrels, whose parasite-pattern is like that of the ground-rats. There is reason to believe that other groups of parasites would give more or less similar contrasting patterns, and would suggest that the parasite-pattern is directly related to the environment, to the conditions of life, and to the way of living of the host.

This supposition is supported by the parasite-patterns found in certain rats. Three of these rats are very important commensals* of man in Malaya. They are either absent from or rare in the native forest but occur in great numbers in conditions created by man following deforestation and settlement. These three rats are the Malayan wood-rat (*Rattus rattus jalorensis*), the field-rat (*R. r. argentiventer*), and the house-rat (*R. r. diardii*). Although all the parasites of these rats are completely interchangeable, each kind of rat supports a distinct assemblage of parasites; each has a parasite-pattern of its own. This is entirely owing to the fact that these particular rats are living in different conditions—the wood-rat in oil-palms, the field-rat in grassland, and the house-rat in towns. In other words, the differences in parasite-patterns are related to small-scale geographical differences. A fourth rat, *R. r. jarak*, comes from an uninhabited island, Jarak, in the Malacca Straits. This rat is virtually an escaped house-rat, introduced long ago to the island and running wild on the forest floor. In the absence of predators and competition, the Jarak rat has overpopulated the island and is unusually heavily infested by worms and other parasites (Audy *et al.*, 1950). However, the parasite-pattern of the Jarak rat is found to be of the same type as that of a typical forest rat, *R. mulleri*.

Geographical Background and Disease-patterns in Man

The example given by these rodents establishes an important point of view. What has been illustrated by rats applies directly to man. Soil and vegetation are decided originally by climate and geology, and the vegetation and climate together decide the structure of the animal communities that will be found. If man appears on the scene, the climate, vegetation, and soil, and to a varying extent also the animal life, play a great part in deciding for him how his social pattern is to develop; how he will grow or hunt his food; how much clothing he will wear; what sort of shelter or house he will build; whether or not he will be subject to catastrophes such as floods or erosion or drought or the choking up of his clearings by intractable weeds; and whether or not he will wander about or remain to form either compact or scattered settlements. As his social pattern develops, his pattern of parasitism becomes established, and in these early stages the whole complex is related to the geographical background.

Man immediately starts altering the geographical background—for example, by widely destroying the vegetation. So his social-pattern and his pattern of diseases gradually change, but, even so, they are related to the environment. The change is largely one of emphasis.

The disease-patterns are, of course, greatly modified by various purely human social elements. Religious taboos relating to food affect the incidence of tapeworm; religious fasting may add to the effects of undernourishment. Schistosomiasis in the Yemen is almost confined to the ritual ablution pools in mosques (Kuntz, 1952). Social elements have a tremendous influence on the pattern of expression of all the treponematoses. The "civilization" of many communities, or the introduction to them of many outsiders with a higher standard of living, may unmask infections which have hitherto saturated the communities and kept up a general standard of immunity dating from childhood. Poliomyelitis and the viral encephalitides are important examples; in certain circumstances malaria is another example. Finally, a peculiarly human element is introduced by urbanization.

In due course there is always more or less urbanization of the community, and at the same time more frequent and wider traffic with other places. Many diseases, especially epidemic diseases, appear by introduction from areas which may be remote, to be added to a distinct urban pattern of disease. Traffic between urban centres leads to a dispersal

*Commensals include organisms and creatures that "parasitize" the nests of hosts or other parts of the environment which the hosts have characteristically modified, rather than the bodies of individual hosts.

of diseases and a tendency for urban patterns to be similar over very wide areas. Many urban epidemics tend to involve the rural population secondarily. Finally, there may be industrialization, which evokes its own elements in the disease-patterns. These industrial diseases are, like the rural diseases, often very closely related to the geographical background: an example is the pneumoconioses, which are related to the geology.

Conclusion

In developing our approach, the attention to assemblages rather than to individual parasites or diseases is very important—it would be described by the biologists as a synecological approach, concerned with the functional setting of organisms in relation to the other organisms, as opposed to an autecological approach, concerned with a single organism and its relations with the environment. Several workers have drawn attention to the pathology of social groups in their entirety. Ryle (1948) approached social pathology with the experience of a clinician: he rightly looked upon society as an organism which may be approached as such by the clinician as well as by the pathologist, the epidemiologist, and the psychiatrist.

Those who are sympathetic towards the philosophy of holism expounded by General Smuts (1936) will at once see that the synecological approach is also holistic. The lesson is that as soon as components have been sufficiently studied in isolation, they should then be set provisionally into their organized system or pattern and that the system should be studied as an organism in its entirety. Taking the analogous parasite-patterns of rodents, we have been enabled, from anomalies appearing in the patterns, to make inferences and plan investigations which would not otherwise have occurred to us. These anomalies could be detected only by studying the patterns as patterns and not by studying isolated parasites.

Summary

The whole assemblage of diseases from which a community suffers forms a pattern which can profitably be viewed as a whole. Those diseases caused by organisms form part of a general parasite-pattern. With examples of such patterns drawn from studies of rodents in Malaya, the parasite-patterns are considered to be decided largely by environment—that is, by the geographical background (which may be taken on a very small scale).

The distribution of diseases in different communities in different places is approached by a holistic study of the relationship borne by the entire disease-patterns of the communities to the social patterns and the geographical background. As a simple example, it is suggested that the disease-pattern in Somaliland is more or less evoked by the geography of the country. Further illustrations are drawn from malaria in Ceylon and from the typhus fevers.

In the earliest stages of man's occupation the link between geography and the disease-pattern appears to be very close. Man soon alters his environment, but the disease-patterns, while changing also, are still related broadly to the environment, and the change is largely one of emphasis. Urbanization, however, evokes urban patterns of disease, which tend to be widely distributed and uniform in nature, largely by interchange between urban environments, which are essentially the same everywhere. Industrialization evokes new elements, which again may become closely linked to the geographical background.

The methods and aims of medical geography, or medical ecology, are of interest even to those concerned with

preventive medicine in the most urbanized or stereotyped environments. A particular biological approach is here added to those which are already familiar.

HAEMOLYTIC DISEASE OF THE NEWBORN CAUSED BY A NEW Rh ANTIBODY, ANTI-C^x

BY

F. STRATTON, M.D., B.Sc., D.P.H.

Director, Blood Transfusion Service, Manchester;
Special Lecturer in Human Serology, University of Manchester

AND

P. H. RENTON, M.D., B.Sc.

Deputy Director, Blood Transfusion Service, Manchester

Haemolytic disease of the newborn commonly occurs in Rh-negative women who are delivered of Rh-positive children, where the mother has Rh antibodies in her serum. Cases are also seen in which Rh-positive mothers are delivered of children affected with this disease: in the majority of such cases the maternal serum contains Rh antibodies anti-E or anti-c. Antibodies to other blood-group antigens—for example, anti-Kell—may also be present in the maternal serum and give rise to this condition. Occasionally, haemolytic disease of the newborn is caused by antibodies to much rarer blood-group antigens; these may belong to the Rh series—for example, C^w—but a number of cases have been described in which the cause has been a family antigen.

The family antigens appear to be of two kinds—those which have been observed because they have given rise to haemolytic disease of the newborn, and those which have been found within a family but are not associated with the occurrence of this disease. Those which have caused haemolytic disease of the newborn have been described by Levine *et al.* (1951) (Miltenberger); by Holman (1953) (Wright); and by Davidsohn *et al.* (1953) (Berrens). These blood groups are confined to the members of the family in which the case of haemolytic disease of the newborn occurred.

The present case occurred in a third pregnancy, and was originally thought to be due to a family antigen, but subsequent investigations suggested that it was, in fact, a rare Rh agglutinin at the C-c locus, C^x. It is proposed in this paper to describe the clinical history of the case and certain serological findings, and to discuss their importance. Detailed serological work and family studies will be described in full elsewhere.

Clinical History

The mother had had two previous pregnancies: in 1947 a full-term normal male child, who is alive and well; and in 1950 a 7-months pregnancy resulting in a stillbirth.

In 1953 a full-term male child, weighing 8 lb. 2 oz. (3.7 kg.), was delivered normally. The child was jaundiced at birth, but this had faded by the third day. He was artificially fed and gained weight normally. He vomited twice during the first week of life, and on the tenth day was noticeably

paler. When 15 days old he vomited and was noted to be very pale and slightly icteric, and showed reluctance to feed. There was no pyrexia or evidence of infection; stools and urine were normal; there was no external bleeding or any signs of internal bleeding. On the 18th day he was admitted to St. Mary's Hospital under the care of Dr. G. Komrower, when he was found on examination to be pale, slightly icteric, and lethargic.

The umbilicus was healthy, and examination of the abdomen revealed enlargement of the liver and spleen three fingerbreadths below the costal margin. No abnormality was detected in the heart and lungs; eyes, head, ears, mouth, and palate were normal. No abnormality was detected in the central nervous system. There were no congenital abnormalities. The blood count was: red cells, 1,200,000 per c.mm.; Hb, 22% (3.3 g.); C.I., 0.91; white cells, 9,000 per c.mm.; normoblasts, 80 per 100 white cells, some showing mitosis. The direct Coombs test on the child's cells was positive. The Wassermann reaction carried out on the mother's blood was negative, and antenatally her blood had been typed as Rh-positive.

A transfusion of 60 ml. of compatible whole citrated blood was given when the child was admitted, and the haemoglobin rose to 43%. On the 19th day after birth 90 ml. of group A Rh-positive compatible blood was transfused, and the haemoglobin increased to 59% (8.7 g.). On the 20th day the direct Coombs test was negative, and a further 100 ml. of blood was given; on the next day the haemoglobin was 72%, and the child was much improved. By the 26th day the haemoglobin had dropped to 63% (9.3 g.); 120 ml. of blood was given on the 27th day, and again five days later. The haemoglobin was now 93% (13.6 g.), and after this the child progressed well, and when 6 weeks old was in good health, both liver and spleen being impalpable.

Materials and Methods

Blood samples were obtained occasionally as citrated blood, but largely in the form of clotted blood; all random blood samples were obtained as clotted blood.

Methods.—Saline and albumin agglutination tests and titrations and the antiglobulin (Coombs) test were performed according to the techniques suggested by the Medical Research Council (1952). Papainization of the red cells was performed by the method described by Stratton (1953) slightly modified in order to increase the degree of papainization of the erythrocytes.

Serological Findings

Family Blood Groups

Below are shown the blood groups of the mother, the affected child, the father, and the healthy child of the family in which this case of haemolytic disease occurred:

Mother: A₁ R₁R₂ M.S.J P+ Le(a-b+) Lu(a+),K- Fy(a+) Cx- (CDe/cDE)
Affected child: A₁ R₁R₂ M.N.s P- Le(a-b-),Lu(a+),K- Fy(a-) Cx+ (CDe/cDE)
Father: A₁ R₁R₂ M.N.S P+ Le(a-b+) Lu(a+),K- Fy(a+) Cx+ (CDe/cDE)
1st child: A₁ R₁R₂ M.N.S P+ Le(a-b-) Lu(a+),K- Fy(a+) Cx- (CDe/cDE)

All members of the family were tested with the maternal serum. The father and the affected child were positive, but the first child and, of course, the mother were negative. The maternal serum was titrated by various techniques with the father's cells. The results are shown in Table I.

TABLE I.—Results of Titrating the Maternal Serum Against the Father's Cells

Cells	Method				
	Saline Agglutination		Albumin Agglutination	Coombs Test	Papainized Cells
	20° C.	37° C.	37° C.	37° C.	37° C.
Father	Neg.	1:1	1:4	1:8	1:64

Investigations on Maternal Serum

The maternal serum was tested with a series of Group O cells known to contain the antigens C,D,E, c,d,e, C^w, C^u, M,N,S,s,P, Le^a, Le^b, Lu, K, Fy^a, Fy^b, Jk^a, Jk^b, Levay positive cells (Callender and Race, 1946), and Wright positive cells (Holman, 1953). Negative results were obtained, using all techniques. The serum was also similarly tested with:

11 samples of blood of genotype rr	(cDe/cde)
23	R ₁ R ₂ (CDe/cDE)
6	R ₁ R ₂ (CDe/cDE)
7	R ₁ R ₂ (CDe/cDE)
2	R ₁ R ₂ (CDe/cDE)
3	R ₁ R ₂ (CDe/cDE)

and with blood samples of genotype R₁r (CDe/cde), R₂r (CDe/cde), R₁R₂ (C^wDe/cde), R₁R₂ (CDe/cde), R₁r (CD^ue/cde), R₂r (CD^ue/cde), and -D-/-D-.

The maternal serum was further tested with a total of 3,931 blood samples from healthy blood donors. These were selected only by reason of their ABO groups, and they comprised 1,727 Group A, 1,915 Group O, 210 Group B and 79 Group AB.

Initial testing of 267 samples was performed, using the tube albumin technique at 37° C., but the remainder of the tests were made with the papainized-cell technique in capillaries at 37° C. (Stratton, 1953). Control tests were used, each time employing a known positive reactor, and strong agglutination was obtained on each occasion. The Group O and A samples were tested with unabsorbed serum; the Group B and AB samples were tested with serum from which the anti-B agglutinins had been absorbed with papainized Group B Rh-positive cells. Four positive results were obtained when the 3,931 samples of blood were tested with the maternal serum; these were the 820th, 995th, 1,286th, and 1,779th samples tested. In each case the cell gave positive results with the maternal serum, using the albumin and Coombs techniques, as well as by the papainized-cell method. The four cell samples were tested further, with the following results:

Sample 1 (Lo): A₁ R₁R₂ M.S. P+ Le(a-b-) Lu(a-) K- Fy(a+) Cx+
" 2 (Oa): O R₁R₂ M.S. P+ Le(a-b+) Lu(a-) K- Fy(a-) Cx+
" 3 (Ho): O R₁R₂ M.N.S. P+ Le(a-b+) Lu(a-) K- Fy(a-) Cx+
" 4 (Pri): A₁ R₁R₂ M.S. P- Le(a-b-) Lu(a-) K- Fy(a-) Cx+

Each of these cell samples was shown to have a negative direct Coombs reaction. Tests on these samples and the father's cells with 20 fresh normal sera gave negative agglutination reactions in saline at 20° C. and 37° C.; polyagglutinability was thus excluded. The presence of the antigen A₁ was excluded in the case of the Group O propositi by testing them with the sera from Group O persons known to give strong reactions with A₁ cells. The father's cells and one of the propositi also gave a negative result when tested with anti-C^w, anti-Wright (Holman, 1953), anti-Miltenberger (Levine *et al.*, 1951), anti-Black, anti-Berrens (Davidsohn *et al.*, 1953), and anti-Graydon (Graydon, 1946) sera.

Investigation of Cell Samples Giving a Positive Result With the Maternal Serum

The father's cells and the four other cell samples described above were titrated with five anti-C typing sera in saline at 37° C. In Table II are shown the titres which were obtained by testing the sera with these cells, and with a number of cells containing the C agglutinin, the latter giving negative results with the maternal serum of this case. It will be observed that several of the sera give much lower titres than they do with the control cells of genotype R₁r (CDe/cde) or R₁R₂ (CDe/cDE), although with one anti-C serum the results of testing the control cells and those giving a positive result with the maternal serum do not differ from one another. The detailed scoring of the titration of one of these anti-C sera with cells which gave positive results with the maternal serum, and with two control cells which did not, are shown in Table III. It will be seen that not only in certain cases are the titres lower, but the individual reactions between the various dilutions of the serum and the cells are weaker. Hence the titrations

TABLE II.—Titration of Anti-C + Incomplete Anti-D Sera,
Using Various Cells

Cells	Rh Type	Result with Maternal Serum	Sera

with the control cells and with cells containing this special C antigen, as shown in Table III, have a characteristic pattern of reaction. Titration of anti-c showed that the father's cells contained only a single dose of c-agglutinin.

Family Studies

The original family in which the case occurred has been studied as well as four other families. In these families it has been shown that the cells of members of the families which gave positive results with the maternal serum of the above case were all of type R₁r (CDe/cde), R₁R₂ (CDe/cDE), or R₁R₁ (CDe/CDE). Where the members of the families were of type R₁r or R₁R₂ the C antigen showed a similar modification to that described above, but in cases of type R₁R₁ the modification was masked by the presence of a normal C in the red cell. The family studies were consistent with this new Rh antigen (C^x) being inherited as a Mendelian dominant character.

Discussion

When this case first came to our notice it might not have received detailed consideration if it had not been for two factors. The first of these was the fact that the child was a severely affected case of haemolytic disease of the newborn and the diagnosis was not in doubt. The child's cells gave a strongly positive direct Coombs reaction when first examined on the 18th day. The second factor was that it is customary in this laboratory to make direct tests between the husband's cells and the maternal serum in those cases in which there is a suspicious history and in which no antibodies are found in the maternal serum by the usual methods of testing with standard cells. These include tests by saline and albumin agglutination techniques, by the Coombs technique, and using papainized red cells.

Following the direct tests between the husband's cells and the maternal serum the antibody was detected. It was obvious that this was an antibody of very unusual character, and consideration was given to the possibility of its reacting with a family antigen similar to others that had been described. This was thought to be especially likely when it was found that negative results were obtained with the usual test cells that were known to contain all blood-group antigens. The maternal antibody, nevertheless, was

found to give strong positive results with the father's cells when these were treated with papain; the titre in this latter case was 1:64, whereas using the anti-globulin technique it was only 1:8. Several blood-group antibodies are known to give strong positive results with papainized red cells positive for the homologous antigen when they are prepared by the method of Stratton (1953). Since this was an ABO compatible pregnancy, and since Lewis and P antibodies are not known to be associated with haemolytic disease of the newborn, our attention was directed to the possibility of some antibody of the Rh series, or possibly a variety of anti-S or, on the other hand, some unknown antibody, which was responsible for this strong positive result when papainized cells were employed.

Tests for the rare Rh antibody, anti-C^w, proved to be negative, and when the maternal serum was tested with cells of type C^uDe/cde—a very uncommon type of cell (kindly provided by Dr. R. R. Race)—the results were also negative.

Our attention was further directed to the Rh antigen by the fact that when the father's cells were first typed they were routinely typed as R₀r (cDe/cde), and it was only on further examination, using several anti-C typing sera, that they were found to be of type R₁r (CDe/cde). It is not proposed to go into details in this paper concerning the reactions between these cells and various anti-C sera except to say that the cells appeared to have a modified C antigen which gave characteristic reactions. Cells which gave positive results with the maternal serum all gave this characteristic pattern of reaction except where this was masked by the presence of a normal C antigen, as in the genotype CDe/C^xDe. Had it not been for this characteristic pattern of reaction with various anti-C typing sera and the strong reaction which the maternal serum gave with papainized red cells we might not have thought the antibody to be one associated with the Rh blood group, but might have assumed it was reacting with a family antigen. This latter contingency was quite likely, since when testing random cell samples the first positive result was not obtained until 820 blood samples had been tested. These results suggested, therefore, that we were identifying an allele of Rh at the C-c locus. Moreover, family studies suggested that this was inherited as a Mendelian dominant character. That the serum of the mother was recognizing an allelic form of C could no longer be doubted when it was found with the peculiar form of C and the antigen recognized by the maternal serum showed absolute linkage in the family studies.

This antigen, which we proposed to call "C^x," appears to be analogous to C^w and to be a modification or mutation of C at the C-c locus. Unlike C^u, D^u, and E^u, but like C^w, it has an antibody which reacts with it specifically and characteristically. Anti-C^w antibodies occur in persons of genotype R₁r (CDe/cde), and similarly in this case a mother of genotype R₁R₂ (CDe/cDE) was immunized by a father of genotype C^xDe/cde. It is interesting to note that the difference between C^x and C is sufficient to cause immunization of the mother and the child to be affected with haemolytic disease of the newborn. Although this is the first C^x-positive living child that the mother has borne it is not necessarily the first antigenic stimulus, however, since the second pregnancy resulted in a stillbirth.

This case brings to our attention certain important factors. The first is that when a suspicious case of haemolytic disease of the newborn is observed, or where the clinical history suggests this diagnosis—for example, when there is a history of children affected with jaundice or anaemia or hydrops, or of multiple stillbirths—if no atypical maternal antibodies are found by routine methods then a direct test should be made between the father's cells and the mother's serum. The other interesting feature of this case is that the immunization of the mother might so readily have been thought to be due to a family antigen if the testing of a large number of random cell samples had not been undertaken. From our experience in this case it would seem that very large numbers of random tests need to be made before

one can conclude that an antigen is a true family antigen. Particularly is this so if there is the possibility of immunization to an antigen of the Rh series.

This antigen is very infrequent in the English population; it might be that in other populations the frequency would be greater.

Summary

A description is given of a case of haemolytic disease of the newborn due to a new Rh antibody, anti-C^x.

Anti-C^x antibody gives very few positive results when tested with random blood samples from the English population. Out of 3,931 random samples tested, four positive results were obtained.

The C^x antigen is considered to be an allele of Rh at the C-c locus. Its inheritance has been demonstrated.

The desirability of including direct tests between the husband's cells and the maternal serum in suspected cases of haemolytic disease, as well as the need for extensive investigations on antibodies thought to be reacting with family blood groups, is discussed.

Our thanks are due to Dr. G. Komrower, paediatrician, St. Mary's Hospital, Manchester, for permission to publish the clinical details, and to Dr. R. F. Jennison, pathologist, St. Mary's Hospital, Manchester; to Dr. D. M. Parkin, of the Blood Group Reference Laboratory, London, for undertaking certain family groups; and to Dr. R. R. Race, of the Blood Group Research Unit, London, for his advice; also to our colleagues in the National Blood Transfusion Service for obtaining samples of blood for family studies.

PORPHYRIN EXCRETION IN A PATIENT WITH DELAYED LIGHT- SENSITIVE PORPHYRIA

BY

A. BENSON

W. D. FOSTER, M.B., B.Chir.

AND

F. T. G. PRUNTY, M.D., F.R.C.P.

(From the Departments of Chemical Pathology,
St. Thomas's Hospital, and University College
Hospital, London)

Extensive knowledge based on modern techniques is becoming available on the porphyrin excretion in patients with acute porphyria (Nicholas and Rimington, 1953), but the present state of knowledge on the porphyrins of "delayed light-sensitive porphyria" is much less advanced. This term has been used (Prunty, 1952) in a suggested modified classification of porphyria to include cases referred to by previous authors as "porphyria cutanea tarda." The condition usually occurs in men of adult age and is not familial. Amongst the other changes, one important clinical manifestation is a bullous eruption of the skin produced by light and trauma. The present paper concerns additional data obtained from one of the rare cases of this condition seen by chance in this country.

Clinical Description of the Patient

A man aged 54, normally resident in South Africa, was admitted to St. Thomas's Hospital for investigation. He complained that he had had blisters on his hands for the past year. He has also suffered from arthralgia of the left hip, left knee, right ankle, and right shoulder for three years. There was no relevant family history. He had had blackwater fever in 1915, appendicectomy in 1924, and a cholecystectomy in 1945 for an illness accompanied by abdominal pain and jaundice. In 1952 radiological evidence of the presence of colonic diverticula had been obtained; at about this time he had had symptoms of diverticulitis. Apparently the porphyria became manifest a year before admission. Recurrent crops of blisters about 0.5 cm. in diameter occurred on the backs of his hands and fingers. They took four or five days to develop and then burst. They often contained a clear reddish fluid. This blistering did not appear to be related to exposure to sunlight. He had been treated with a sulphonamide for the diverticulitis without influencing the skin condition. There was some evidence that trauma to the skin favoured the production of these blisters. During the year his urine had been the colour of "dark ale," and had occasionally been dark during the last four years.

Physical examination showed a number of small circular scars on the backs of the hands and fingers, with a circular zone of slight pigmentation around some of them. When first seen three weeks before admission he had three blisters about 0.25 cm. in diameter on his hands, containing yellowish fluid, but these had disappeared by the time of his admission. There was a small rodent ulcer on the right cheek. The liver was enlarged one fingerbreadth below the costal margin, and scars from his two abdominal operations were present. There was a minor degree of osteoarthritis in the knees, hips, and right shoulder.

His urine on examination had a rosy hue and not the brownish-purple appearance of acute porphyria urine containing porphobilin. Porphobilinogen was never detected. On three consecutive days his pigment excretion measured:

Day	Urobilinogen mg./day	Total Porphyrin mg./day	Total Porphyrin Minus Uroporphyrin μg./day
1	9.4	2.4	37
2	6.6	4.8	80
3	3.0	4.4	126

The serum and cerebrospinal fluid contained no porphyrin. Faecal urobilinogen excretion was 295 mg. a day—a normal quantity. Serum total protein was 7.7 g. per 100 ml. (albumin 4.3 g. and globulin 3.4 g.). Thymol turbidity was 4 units; serum bilirubin 0.7 mg. per 100 ml.; cholesterol 159 mg. per 100 ml., of which 65% was esterified. The prothrombin time was 12 seconds (normal). The blood urea was 21 mg. per 100 ml., and endogenous creatine clearance 83 ml. a minute. The haemoglobin was 16.2 g. per 100 ml., and the packed cell volume 48%.

Urine Porphyrin

The porphyrin was isolated as previously described (McSwiney, Nicholas, and Prunty, 1950). Chromatography of the esters on columns of Al₂O₃ (Sayory and Moore) and MgO Grade III (Nicholas, 1951) (see Diagram) to clean up the porphyrin gave a single main band (1), which on further chromatography on MgO Grade IV yielded a main band (1a) and traces of two other bands. This main fraction was crystallized, and the product had a melting-point at 211 to 213° C., and its α band at 624.3 mμ. Each band obtained from these three columns was submitted to paper chromatographic analysis, with the results shown in the Diagram. It should be noted that most of the urinary porphyrin was lost during preliminary purification.

There were two very faint bands, 1c and 1e, too little for any paper chromatography at all.

Fractionation of Urine Porphyrins

Urinary porphyrin. 24 mg. total from 6 litres of urine	Results of Paper Chromatographic Analyses		
	Method 1 (Nicholas and Rimington, 1949)	Method 2 (Falk and Benson, 1953)	Method 3 (Chu <i>et al.</i> , 1951)
Non-fluorescent  1 mg.	1. Mainly 8* + trace 6, 5, and 4		
Non-fluorescent  α 625.0 m μ	1. Mainly 8* + some 6 and 7 and trace 4	Like Uro III, but Rf slightly greater	Strong spot be- tween uro and copro I posi- tion
 α 624.3 m μ Crystallized m.p. 211-213° C.	1d. Mainly 4 and trace 3 1b. Mainly 6+7 and trace 8* 1a. Mainly 8* and some 6 and 7	Like Uro III, but Rf slightly greater	Strong spot be- tween uro and copro I posi- tion

* All octacarboxylic spots had relative fronts (Rf's) slightly greater than pure uroporphyrin; the appearance of these spots also was different, and the material cannot be regarded as typical uroporphyrin.
† The numerals indicate that porphyrins bearing this number -COOH groups in side-chains were found by the paper chromatographic method (cf. Nicholas and Rimington, 1949).

Faecal Porphyrin

This was extracted as ester (McSwiney *et al.*, 1950). Paper chromatography in the lutidine-water system (Nicholas and Rimington, 1949) of the crude ester extract showed only an atypical octacarboxylic porphyrin. Chromatography on MgO Grade III gave two small green-brown bands which were discarded and a main band (α band 620.8 m μ). This main fraction, derived from material which originally appeared to contain only octacarboxyl porphyrin, now on paper chromatography showed spots corresponding to a major component with either 6 or 7 carboxyl groups, together with traces of porphyrins with 3, 4, and 5 carboxyl groups. The evidence for degradation on the MgO column to substances with fewer -COOH groups was in this instance very clear. On paper chromatography after Chu, Green, and Chu (1951) there were three spots. The major component ran in the same position as pure coproporphyrin III, and there were two smaller amounts of material, one behaving like protoporphyrin, the other moving slightly slower than coproporphyrin III.

Discussion

The case described was fairly typical, but in relative remission at the time of the examination. The most interesting feature was the apparent absence of light sensitivity, although blisters which almost certainly had contained porphyrin had clearly been present at times. The large urobilinogen excretion in the urine and slight enlargement of the liver suggested hepatic abnormality, and it may be that the attack of jaundice and abdominal pain for which cholecystectomy had been performed was related to the porphyria. The other features worth mention were the rosy colour of the urine, due to increased porphyrin excretion, and the absence of porphobilinogen. Both of these are important points of differentiation from the findings in acute porphyria, in which condition the brown colour is largely due to porphobilin.

Of special interest were the porphyrins found in the urine and faeces. It has been most usual to find uroporphyrin in the urine (Waldenström, 1937), apparently the isomeric uroporphyrins I and III being present together (Macgregor,

Nicholas, and Rimington, 1952). These authors and Canivet and Rimington (1953) have together shown the presence of porphyrins with 2, 3, 4, 5, and 6 carboxyl groups, some of which have been more carefully characterized than others. Gray, Rimington, and Thomson (1948), however, in their case noted a remarkable instability of the ether-insoluble porphyrin fraction, and Macgregor *et al.* (1952) noted an unstable faecal porphyrin. This state of affairs was also apparent in the present case with regard to both urine and faecal porphyrins. The only stable porphyrin which could be isolated from the urine was a substance the ester of which had melting-point 211 to 213° C. and α band at 624.3 m μ . Apart from these two differences it also differed from uroporphyrin on paper chromatograms (see Diagram). It appears to be identical, by all three paper chromatographic methods employed, with the octacarboxylic porphyrin isolated by Canivet and Rimington (1953) for the first time from the pooled urine of five similar patients. Its similarity to the porphyrin of these authors extends to likeness of α band and melting-point. Neither of these porphyrins appears to be a known uroporphyrin.

The faeces of our patient yielded some protoporphyrin and coproporphyrin III, as might be expected. In addition there was plenty of evidence of decomposition of more highly carboxylated porphyrins, and it is impossible to state with any certainty what the original porphyrins were.

Summary

A brief case report of a man with "delayed light-sensitive porphyria" (porphyria cutanea tarda) is presented. The urine porphyrins were very unstable. The only porphyrin which could be isolated was an atypical octacarboxylic porphyrin like that of Canivet and Rimington (1953). The more highly carboxylated faecal porphyrins present underwent decomposition during processing, but an atypical octacarboxylic porphyrin was observed on paper chromatography of an early fraction.

We are greatly indebted to Professor C. Rimington for his interest.

The 54th annual report of the Liverpool School of Tropical Medicine records that a number of cases of leprosy in persons resident in Britain came to light last year. "All these patients had been imported into this country actually with the disease, as a result of the repatriation of British subjects from India and of the immigration of individuals from various parts of the world following the disturbance in populations due to the recent war. Leprosy is a very chronic disease, which may not display itself for many years after its acquisition and which, when unsuspected, may escape diagnosis for years. In spite of the frequent importation of cases of the disease over many years, it does not spread here, and no case of infection acquired in this country has been seen at the school during the last 50 years. Thus the risk to our own population of the presence of such imported cases of the disease can be ignored as a public health problem. Contrary to popular belief, leprosy is the least infectious of all infectious diseases. The results of treatment with the recently introduced sulphone series of drugs have been most encouraging; but the treatment must be sustained under expert supervision over very long periods to prevent relapse."

THE NEUROMUSCULAR ACTIVITY
OF SUCCINYLMONOCHOLINE IODIDE
IN ANAESTHETIZED MAN

BY

JOHN H. BIRCH, M.B.

Resident in Anaesthesia, Mercy Hospital, Pittsburgh

It was reported by Whittaker and Wijesundera (1952) that succinylcholine (succinylidicholine; SDC) is hydrolysed by horse serum cholinesterase in two steps: first one molecule of choline is split off at a fairly rapid rate from the SDC molecule and then the resulting succinylmonocholine (SMC) is hydrolysed more slowly to succinic acid and choline. Subsequently, Tsuji and Foldes (1953) and Lehmann and Silk (1953) have shown that SDC is hydrolysed in the same manner by human plasma and concentrated human plasma cholinesterase respectively. Foldes and Tsuji (1953) and Foldes (1953) also reported that SMC-I in doses of 2 to 2.5 mg. per kg. caused complete neuromuscular block for about 10 to 15 minutes and partial block for about 20 to 30 minutes in the sciatic-gastrocnemius preparations of cats anaesthetized with pentobarbitone. Lehmann and Silk (1953) found that in rabbits SMC (active cation) in doses of 2.5 mg. per kg. and 3.5 mg. per kg. produced paralysis without apnoea for 150 and 550 seconds respectively. Doses higher than 5 mg. per kg. regularly caused respiratory paralysis in rabbits. Ellis *et al.* (1953) investigated the neuromuscular effects of SMC-I in several species and found that on a molar basis its activity varied from 1/24 to 1/62 of that of SDC-Cl₂. They also found that in mice SMC-I is 1/14 as toxic as SDC-Cl₂.

Present Investigation

In view of the fact that SDC-Cl₂ is being used with increasing frequency for the production of muscular relaxation for operative procedures, and that occasionally as much as 12 mg./min. of SDC-Cl₂ has been administered to patients for prolonged periods (Bourne *et al.*, 1952), it seemed worth while to investigate the muscle-relaxant properties of SMC-I in humans to find out whether or not the SMC concentrations resulting from the hydrolysis of the relatively large quantities of SDC-Cl₂ administered to patients in the course of long operative procedures might have any effect on pre-neuromuscular conduction. Since it is not possible to predict from the effects of muscle relaxants observed in one species the effects to be expected on another species (Paton and Zaimis, 1950; Unna *et al.*, 1950) such information could be obtained only by observing the effect of the administration of SMC-I on human volunteers or on patients requiring muscular relaxation for various operative procedures. We chose the latter course.

At first SMC-I was administered in doses of 1 mg. per kg. to patients anaesthetized with combinations of thiopentone sodium/N₂O-O₂/pethidine according to a previously described technique (Foldes *et al.*, 1952). This dose of SMC-I had no discernible neuromuscular effect. Therefore the initial dose of SMC-I was gradually increased in subsequent patients to 5 to 7 mg. per kg. body weight. With this dosage, muscular relaxation developed in three to five minutes and lasted

from eight to twelve minutes. This relaxation could be maintained by the repeated intravenous injections of 3 to 4 mg. per kg. of SMC-I at intervals of eight to twelve minutes. The resulting muscular relaxation was adequate for the performance of various intra-abdominal operations. The respiratory depth of the patients was hardly affected at times when good abdominal relaxation was present. It has been the impression of the anaesthetists and surgeons that increased diaphragmatic activity compensated for the intercostal paralysis in the maintenance of adequate respiratory depth.

The jaw musculature and the vocal cords were not as well relaxed even after 7 mg. per kg. as after the use of some other neuromuscular blocking agents, but the patients could be intubated without major difficulty.

It was observed that SMC-I markedly potentiated the neuromuscular blocking activity of subsequent doses of SDC-Cl₂ at a time when the patients had apparently recovered from the effects of the former. In a 22-year-old woman weighing 75 kg. the injection of 20 mg. of SDC-Cl₂ produced in 40 seconds slight respiratory depression for 225 seconds. Seven minutes after the intravenous administration of 350 mg. of SMC-I, an identical 20-mg. dose of SDC-Cl₂ produced in 25 seconds respiratory arrest for 270 seconds, and some respiratory depression for an additional 210 seconds.

Owing to the limited supply of SMC-I at our disposal, it was used for the production of muscular relaxation in only 10 patients. The operative procedures included 3 appendectomies, 4 cholecystectomies, 2 hysterectomies, and 1 exploratory laparotomy. Satisfactory abdominal relaxation was obtained in all patients without the development of respiratory arrest or more than a moderate degree of respiratory depression. The pulse and blood pressure of the patients remained remarkably constant. The muscular relaxation had a tendency to wear off abruptly unless a fractional dose was administered at the first sign of its fading effect. In general, the relaxation obtained with SMC-I resembled that obtained with decamethonium.

No prolonged post-operative respiratory depression was observed in any patient in this small series. Respirations became normal within 8 to 12 minutes after the administration of the last fractional dose in all instances.

Muscular twitches occasionally seen with decamethonium and more frequently with SDC-Cl₂ were not observed with the use of SMC-I.

The urinary excretion of SMC-I was followed in two patients. Urine was collected during and 15 minutes after the administration of a relaxant dose of SMC-I. The patients excreted 11.8% and 14.5% of the administered SMC-I during this period. In contrast to this less than an average of 3% of the administered SDC-Cl₂ could be recovered from patients under identical circumstances (Foldes and Norton, to be published).

Discussion

The neuromuscular effect of SMC-I represents a transition between that of decamethonium and SDC-Cl₂. The onset and duration of the neuromuscular blockade with SMC-I resembles that seen with the use of decamethonium. On the other hand, its elimination from the body is similar to that of SDC-Cl₂. Whereas decamethonium can be recovered almost quantitatively unchanged in the urine after its administration (Paton and Zaimis, 1952), most of the SMC-I is hydrolysed in the body to succinic acid and choline. However, since the hydrolysis of SMC-I by the plasma cholinesterase is much slower than that of SDC-Cl₂, urinary excretion plays a greater part in the elimination of SMC-I than is the case with SDC-Cl₂.

The findings presented indicate that in the average patient 0.3 to 0.4 mg./kg./min. of SMC-I gave adequate muscular relaxation without the development of undue respiratory depression. It has been our experience that the administration of 0.05 to 0.15 mg./kg./min. of SDC-Cl₂ was necessary in a large group of patients for the production of good

muscular relaxation. Since the ratio of the molecular weights of SMC-I and SDC-Cl₂ is about 0.8, the hydrolysis of 0.05 to 0.15 mg. of SDC-Cl₂ will produce the equivalent of 0.04 to 0.12 mg. of SMC-I. This dose of SMC-I has little or no effect on neuromuscular conduction in patients whose ability to hydrolyse and excrete SMC-I is unimpaired. However, in patients with low cholinesterase activity, especially if their kidney function is also diminished, the administration of relatively large doses of SDC-Cl₂ for prolonged periods might lead to the accumulation of SMC in sufficiently high concentrations to potentiate the neuromuscular action of the unhydrolysed SDC-Cl₂. Such a set of circumstances can arise if muscular relaxation is maintained in patients with low plasma cholinesterase activity with SDC-Cl₂ by the "apnoeic technique."

With this technique the administration of SDC-Cl₂ is carried to a point where the patient's voluntary respiratory movements are completely abolished and gas exchange is maintained by manual compression of the breathing-bag of the anaesthesia machine. Since the administration of SDC-Cl₂ in amounts many times higher than the apnoeic dose has no discernible effect on blood pressure, pulse rate, or any other physiological process, there is no sign that would indicate whether just enough SDC-Cl₂ is administered for production of apnoea or whether large doses of SDC-Cl₂ accumulate in the organism. If the latter of the two possibilities occurs in patients with low plasma cholinesterase activity and with decreased urinary excretion, prolonged post-operative respiratory depression will result. Since adequate muscular relaxation can be obtained with SDC by utilizing the difference in sensitivity to this agent between the diaphragm and intercostals, there seldom is a need for the application of the apnoeic technique.

It is unlikely that SMC plays a similar part in the prolonged respiratory depression occasionally observed after the administration of a single large dose of SDC-Cl₂ (Hewer, 1952; Love, 1952; Harper, 1952; and others). The hydrolysis of as large a dose as 100 mg. of SDC-Cl₂ will yield only about the equivalent of 80 mg. of SMC-I, and this dose is not likely to have any neuromuscular blocking effect. The prolonged apnoea under such circumstances is caused either by an exceptionally low plasma cholinesterase activity of the patient or by the combination of apnoea due to too energetic controlled respiration, and reflex breath-holding arising from the stimulating effect of the endotracheal tube on the larynx and trachea in the patient in whom the level of general anaesthesia was allowed to become too light.

Owing to the relatively large doses in which SMC-I has to be administered, the less satisfactory relaxation obtained, and the lack of rapid and easy controllability of its neuromuscular effect, SMC-I does not seem to offer any advantages in comparison with other available muscle relaxants, especially SDC-Cl₂.

Summary

In man SMC-I in doses of 5-7 mg. per kg. produced in three to five minutes muscular relaxation of 8 to 12 minutes' duration.

Muscular relaxation could be maintained by repeated intravenous injections of SMC-I in doses of 3-5 mg. per kg. 8 to 12 minutes apart.

These doses of SMC-I caused little respiratory depression.

The administration of SMC-I markedly potentiated the neuromuscular action of subsequent doses of SDC-Cl₂.

The possible role of the accumulation of SMC in the development of prolonged apnoea after the use of SDC-Cl₂ is discussed.

This investigation was supported in part by Research Grant No. RG-3585 from the National Institutes of Health, United States Public Health Service. We are indebted for the supply of succinylmonocholine iodide to Dr. E. J. de Beer, of Burroughs Wellcome and Co., Tuckahoe, New York.

BACTERIAL ENDOCARDITIS DUE TO CHROMOBACTERIUM PRODIGIOSUM

REPORT OF A CASE

BY

A. J. HAWE, M.D., F.R.C.P.
Specialist Physician, Gold Coast

AND

M. H. HUGHES, D.M., Dip.Bact.
Pathologist, Gold Coast

Chromobacterium prodigiosum (*Serratia marcescens*) is usually regarded as non-pathogenic for man, and Wilson and Miles (1946) were unable to quote any indubitable report to the contrary. However, Patterson, Banister, and Knight (1952) reported a case of septicaemia due to this organism, and the literature concerning human infection by members of the *Chromobacterium* group. They quoted 21 records of infection by *Chr. prodigiosum*, including their own, only one of which was a case of endocarditis (Wheat, Zuckerman, and Rantz, 1951).

Case Report

An African man aged 38 was admitted to the Gold Coast Hospital, Accra, on April 30, 1953, after a month's sickness; this began with fever and headaches, accompanied by rigors. After taking mepacrine and "phenic" tablets he was able to continue his work as an omnibus inspector. About a week before admission he had had further headaches with fever and pain in the neck. He attended the out-patient department on April 25, when a blood film proved negative for malarial parasites, but the urine was found to contain albumin. He was given an injection of sulphalocine, 5 ml., and another of quinine, 10 gr. (0.65 g.), both intramuscularly, as well as 2 ml. of mersalyl. He was subsequently referred to A. J. H. and was admitted for investigation.

On admission he complained of feverishness and pain in the umbilical region. His temperature was 101° F. (38.3° C.). A blood film was again negative for malarial parasites and there was a heavy cloud of albumin in the urine. He was systematically examined on May 1. It was noticed that he had lost weight. He was obviously a sick man, but in no way distressed. No rash was found on his skin and his temperature was 104.2° F. (40.1° C.). His bowels had been open daily and the stools were semi-solid. His tongue was moist and a little furred. Except for the complaint of pain in the umbilical region no abnormality was found in the alimentary system. The chest was clear and the sinuses appeared to be normal; the respiration rate was 30 a minute. The cardiovascular system showed nothing abnormal beyond a pulse of 120 a minute. The patient complained of a frontal headache, which was worse when the fever was high in the evenings, but a clinical examination

of the central nervous system proved negative. There was no lymphadenitis. The urine was passed freely without pain.

A white blood cell count showed a total of 11,200 leucocytes (70% polymorphs, 25% lymphocytes, 2% eosinophils, 2% monocytes, 1% basophils). Coliform bacteria were cultured from the urine, and were at the time reported as *Bact. coli*, a finding which was later doubted. Serological reactions with *Salmonella* antigens were negative. A Weil-Felix test gave the following result: *Proteus* OX₂ 1/160, X_k 1/40 X₁₉ 1/80. Two successive stool cultures on May 6 and 8 proved negative. Blood culture on May 2 was discarded as sterile 21 days later.

On May 6 treatment was begun with alkalis and "sulphatriad" in full doses. After three days, since there was no response, he was given chloramphenicol, 2 g., as a loading dose and 1 g. every four hours thereafter; after four days, when he had received 25 g., the available supply of chloramphenicol was exhausted, and although there had been a favourable response this was not maintained when the drug was stopped. By this time blood had appeared in the urine. The patient's condition had deteriorated, and he was very weak; he was thought to be too ill for cystoscopy or pyelography, both of which had been considered. Streptomycin was given from May 16 in doses of 1 g. daily, but with no beneficial effect.

On May 20 a further blood culture was taken, by which date the only positive finding had been the growth of coliform bacteria from the urine. On May 11 a re-examination revealed a full appearance of the abdomen; because of general resistance palpation was difficult, but the liver, spleen, and kidneys could not be felt. Rectal examination revealed, generally, tenderness only. The lungs remained free of signs, but an apical systolic cardiac murmur. The significance of the latter finding was overruled by the continued to show a heavy albuminuria with white blood cells. On May 25 a third blood culture was taken which five days later yielded a pure growth of *Chr. prodigiosum*, which was reported as being probably a contaminant. The patient's condition continued to deteriorate, and he died on June 2 without a diagnosis having been made.

Post-mortem Examination

A post-mortem examination was made 19 hours after death by Dr. F. C. Harris. The main finding was a friable vegetation, buff in colour, attached to the free margin of the posterior cusp of the mitral valve; there was some erosion of the cusp. A haemorrhagic nodule, 0.5 cm. in diameter, was found on section of the liver. There were five recent infarcts in the spleen, which was moderately enlarged, and a large white infarct involving the whole of the upper pole of the right kidney.

On the following day the blood cultured on May 20 was found to have produced a belated pure growth of *Chr. prodigiosum*, after 15 days' incubation in a combined liquid and solid medium put up in the same bottle by a technique modified by Hughes (1953) from that described by Castañeda (1947); the important feature of this technique is that it prevents contamination of the culture between the inoculation of the medium and the isolation of the organism, and it is thus quite certain that the growth of *Chr. prodigiosum* in a second blood culture could not have been due to laboratory contamination. The cut surface of the mitral vegetation removed at necropsy was rubbed on the surface of a blood-agar plate, and this also yielded a pure culture of *Chr. prodigiosum*. Thus *Chr. prodigiosum* was isolated from two ante-mortem blood cultures taken on different dates, and also from the mitral vegetation after death.

Bacteriology

The culture of *Chr. prodigiosum* isolated from this case had the following characteristics: Motile Gram-negative coccus-bacillus without a capsule. Good growth on nutrient agar, sheep's blood agar, MacConkey agar, and "bacto" SS agar. Growth at room temperature (about 25° C.) was

slightly better than at 37° C. No haemolysis on blood agar. On nutrient agar the colonies after 24 hours were from 0.5 to 1 mm. in diameter, smooth, shiny, and low convex with entire edge, and bright red in colour. After 48 hours the confluent growth was orange-red, and the single colonies were between 1 and 2 mm. in diameter, umbonate, surface becoming granular, with pink centre and orange-red periphery. After five days the colonies were from 3 to 4 mm. in diameter with a rough appearance.

The pigment was very slightly soluble in water, moderately soluble in absolute alcohol, and completely removed from a peptone water culture by chloroform. In peptone water and in gelatin a red surface ring was formed, but this did not occur in broth or in glucose phosphate medium. The colonies on MacConkey agar were bright red; this appearance, coupled with a red colour in lactose-peptone water simulating that of acidified Andrade's indicator, probably resulted in an erroneous report of *Bact. coli* in the patient's urine, although if *Chr. prodigiosum* had been recognized at that time it is improbable that the finding would have been regarded as significant.

In peptone water "sugar" media, acid and a moderate amount of gas were formed from dextrose, saccharose, maltose, mannitol, and salicin; there was no fermentation of lactose, dulcitol, arabinose, rhamnose, xylose, and inositol. There was no growth in Koser's citrate. Indole was not formed. H₂S was formed on liver infusion agar, but not in peptone water, when tested for by a lead acetate strip in the top of the tube. Catalase was not formed. The methyl red test was negative. In a five-day glucose phosphate culture the Voges-Proskauer test was negative by O'Meara's method but positive by Barritt's modification of the test. Coagulated serum and gelatin were both liquefied.

In vitro sensitivity tests showed the strain to be completely resistant to penicillin and aureomycin, but sensitive to chloramphenicol and streptomycin. White mice died within 12 hours when injected intraperitoneally with 0.5 ml. of a 24-hour broth culture; these mice showed pleural exudates.

The specific identity of the organism described by us as *Chr. prodigiosum* may be open to doubt. Breed, Murray, and Hitchens (1948) used the formation of gas in carbohydrate media as a criterion for the separation of species within the genus *Serratia*, and on this ground our organism could not be *Chr. prodigiosum*. Wilson and Miles (1946), however, stated that some strains of *Chr. prodigiosum* do form gas. Again, Breed *et al.* used acetyl-methyl-carbinol formation as a means of separating species, but without specifying what method they used for testing for this metabolite; the results with our strain were equivocal by this standard also, and it was not possible to classify it according to the criteria of *Bergey's Manual*. Without aspiring to taxonomic authority we have therefore thought fit to call our organism *Chr. prodigiosum*, a course in which we are fortified by the treatment of this group of organisms by Wilson and Miles.

It is of interest to note that both in our own case and in that described by Patterson *et al.* (1952) there was some clinical response to chloramphenicol, although in both cases the treatment with this drug was interrupted by extraneous circumstances. Patterson *et al.* also found that their strain was highly sensitive to neomycin, and one of these two antibiotics would appear to be the treatment of choice in cases of infection by this organism.

Summary

A case of acute endocarditis is described in which *Chr. prodigiosum* was isolated twice from the blood during life and again from an endocardial vegetation after death. The strain was sensitive *in vitro* to streptomycin and chloramphenicol, and slight improvement followed treatment with the latter drug. The characteristics of the organism are described. Chloramphenicol, or perhaps neomycin, may be the

treatment of choice should further cases of this rare infection by a common saprophyte be brought to light.

Our thanks are due to Dr. F. C. Harris for permission to make use of his necropsy report, and to Dr. L. G. Eddey, Chief Medical Officer, for permission to publish this paper.

Medical Memorandum

Congenital Tuberculosis after Pleural Effusion in the Mother

A woman aged 23 was admitted to a general hospital with a left pleural effusion on December 1, 1949, when five months pregnant. There was no family history of tuberculosis or known contact. She did not remember having had any illness until July, 1949, when her husband was at home on leave and she had a cold and lost weight. In the early weeks of her pregnancy she gained weight, but began to get pains in the left chest in October. The findings on aspiration of approximately 500 ml. of straw-coloured fluid were: red cells, moderate numbers; lymphocytes, fairly numerous; polymorphs, nil. The blood picture was: haemoglobin, 64%; leucocytes, 8,000 (polymorphs 66%, lymphocytes 30%, monocytes 3%, eosinophils 1%). There was nothing abnormal on urinary examination. On January 7, 1950, after the illness had run a typical course, she was discharged home, apyrexial, to await admission to a sanatorium.

On February 7, when admitted to a chest hospital, she was symptomless. The physical signs were those of a small pleural effusion, the anaemia persisted, and the sedimentation rate was 18 mm. (Westergren). Radiologically an opacity remained in the left lower zone. Treatment was by rest and haematinics whilst the pregnancy proceeded uneventfully to full term.

On April 17 she complained of generalized aches and pains and there was an evening pyrexia to 99.2° F. (37.3° C.). Next day the symptoms were improved, and on the 19th she went into labour and was delivered of a normal female child the same day, after transfer to the maternity hospital. The child was isolated. The placenta was examined and recorded as "complete." During the puerperium she had an evening pyrexia of 101° F. (38.3° C.) and was readmitted to the chest hospital on April 25, when treatment was begun with streptomycin, 1 g. daily, and 18 g. of para-aminosalicylic acid. On April 27 the baby died, aged 8 days.

FINDINGS AT NECROPSY ON THE BABY

The body was well nourished and of normal colour. About 5 ml. of clear yellow fluid was present in both pleural cavities, and a little less than 5 ml. in the peritoneal cavity. Both lungs showed severe congestion and oedema. Weight, right 62 g., left 58 g. Dispersed throughout the lung substance of both sides and beneath the pleural surfaces were miliary tubercles consisting of grey-yellow areas 2-3 mm. in diameter and some the size of a small pinhead. The tubercles were either one size or the other, there being none of intermediate size.

The heart showed no congenital or acquired abnormality. The peritoneal cavity contained about 10 ml. of free fluid. There was matting together of the structures around the spleen and yellowish-white exudates were present in small amount. The spleen weighed 35 g. and measured 7.5 by 4

by 3 cm. It was engorged and contained tubercles similar in size to those in the lungs. A direct smear from the cut surface revealed many tubercle bacilli. The liver weighed 260 g., and contained tubercles throughout, and beneath its peritoneal surface. The most interesting feature of this organ was the presence of a mass of glands in the hilum. These measured 3 by 2.5 by 2 cm. The cut surface was yellow and caseous-looking. The kidneys, bladder, uterus, and alimentary tract appeared to be normal. The brain was not congested and seemed normal in every respect, no evidence of tubercle being present.

PROGRESS OF MOTHER

The woman continued to have an evening pyrexia until June 15, by which date 50 g. of streptomycin had been given. Apart from the pyrexia the post-puerperal period continued normally, but the reappearance of menstruation was delayed until August 12. No abnormal physical signs were present in the chest, and radiography demonstrated only a clearing of the pleural opacity. Clinical improvement with a gain in weight began with the subsidence of the pyrexia, but chemotherapy was continued until August 28, when 120 g. of streptomycin had been given. At this time no clinical or radiological abnormality could be detected. She was discharged home on October 19, apparently a healthy woman, the sedimentation rate being 4 mm. (Westergren) and her weight 128 lb. (58 kg.).

Subsequent progress during 1950 was uneventful and her weight increased to 143 lb. (64.8 kg.). On February 26, 1951, a laparotomy was performed and section of the Fallopian tubes and appendectomy were carried out. No abnormality of the pelvic organs was detected. Progress was again uneventful until December, 1951, when a fluctuant swelling was detected in the left breast. At incision in February a localized abscess was removed.

Microscopically, non-specific chronic inflammation was reported and culture of the material evacuated remained sterile, but a sinus persists, although the patient remains well three and a half years after the birth of her child.

COMMENT

The primary lesion in the hepatic glands of the infant is consistent with haematogenous infection via the placenta, whilst its size and maturity would suggest that it originated a considerable time before birth, probably coincident with the onset of pleurisy in the mother. The miliary tuberculosis in the lungs, spleen, and liver would seem to be a secondary haematogenous dissemination in which the mother shared infection just before delivery, the usual effects of such dissemination being suppressed by streptomycin.

Any typical primary focus other than the pleural effusion in the mother remains undisclosed, but it has been shown (Kayne *et al.*, 1948) that quite a large proportion of "idiopathic" pleural effusions occur in close time relationship with the primary infection.

This case contrasts with the almost invariable sequel of healthy infants born to mothers suffering from progressive, advanced, or miliary tuberculosis.

I am informed by Mr. L. E. Perkins that in veterinary practice congenital tuberculosis was not so uncommon and was found in association with primary tuberculous infection, usually believed to be in the uterus, rather than in association with established or widely disseminated tuberculosis.

CONCLUSIONS

Treatment by chemotherapy is justified in primary tuberculosis occurring in pregnancy. Routine B.C.G. vaccination at birth of babies born to such tuberculous mothers should be preceded by a Mantoux test.

I am indebted to Dr. J. F. Horley for the necropsy findings.

Reviews

PITUITARY CHROMOPHOBE ADENOMAS

Pituitary Chromophobe Adenomas: Neurology, Metabolism, Therapy. By Professor John I. Nurnberger, M.D., and Saul R. Korey, M.D. (Pp. 282; illustrated. 55s.) New York: Springer Publishing Company Inc. London: Lange, Maxwell and Springer. 1953.

On the first page of the introduction the authors rather shock the conventional by suggesting that the original case of Fröhlich, always thought to be due to craniopharyngioma, and the painful adiposity case of Dercum and McCarthy, 1902, were both probably due to chromophobe adenomas, presumably with involvement of the adjacent hypothalamus. This conclusion may be questioned. In the first chapter the authors consider the anatomy of the pituitary and the detailed main paths of the secretion of the anterior pituitary gland directly entering venous channels. They also discuss the influence of the hypothalamus on the anterior pituitary gland and evidence of mediation by humoral means, such as by hypothalamic hormones or metabolites, being conveyed by the blood stream to the anterior pituitary gland. Diagrams showing the amazing variation in the shape of the sella turcica in normal individuals are of value, as it is not infrequent to meet queries, or wrong interpretations, about sella turcica that do not conform to the usual shape.

Metabolism is discussed along modern lines but with attention to historical landmarks. The authors indicate that a low level of activity of the thyroid gland and of the adrenal cortex persists after complete hypophysectomy. Inactivation of thyrotrophic hormone by the thyroid gland may explain why this hormone may not be found in the blood in thyrotoxicosis by methods that detect an excess in myxoedema. The contrasting effects of pituitary growth hormone and adrenal glucocorticoids on protein metabolism are well brought out, but in considering the mechanisms by which the anterior pituitary causes nitrogen retention the authors mention the production of gonadal testosterone without making clear the importance of adrenal androgens, a contribution which is noteworthy physiologically and pathologically.

The authors give an adequate account of the neurological signs and complications and the metabolic defects that follow destruction of the anterior pituitary gland. Optic atrophy and bilateral hemianopia were frequent, but papilloedema occurred in 7% due to involvement of the third ventricle or to venous compression. Third-nerve involvement was more frequent than fourth or sixth. Large tumours produced a variety of neurological features. Haemorrhage into a cystic tumour was the cause of rapid onset of neurological signs. Detection of hypothalamic compression was made by encephalography, showing distortion of the floor of the third ventricle, and was found to be present in as high as 88% of cases, although in 30% of these there were no referable symptoms. Eighteen of the 68 patients with hypothalamic involvement showed agitation, attacks of drenching perspiration, and occasional hypothermia. A similar number suffered from lethargy, emotional depression, and excessive somnolence. Epileptic phenomena associated with drenching perspiration and peripheral vasodilatation was observed in 6 of the 68 patients with hypothalamic involvement. Obesity with polyphagia occurred only in six.

None of the cases of chromophobe adenoma showed any pigmentation, and this is recorded as being true of another 100 patients observed by German. In contrast with this was the presence of pigmentation in 25% or more of patients with Simmonds's disease and, according to Davidoff, in one-half of the acromegals. The contrast between patients with chromophobe adenoma and with Simmonds's disease is attributed by the authors to the fact that in Simmonds's disease the posterior pituitary usually remains intact. Apart from this, it should be pointed out that occurrence of pigmentation with Cushing's syndrome and with A.C.T.H. or cortisone therapy has complicated our conception of its origin as a deficiency manifestation. A.C.T.H., or an associated substance, seems to be an important factor in explaining the difference between the frequency of pigmentation in Addison's disease and its relative rarity and mildness in Simmonds's disease.

The chapter on radiography indicates how a chromophobe adenoma may enlarge and invade in all directions, and the frequency and extent of invasion and distortion of the third ventricle and hypothalamus, as shown by pneumo-encephalography, comes as a surprise to the endocrinologist (reviewer). Further information on the radiographic differentiation of craniopharyngioma (for example, the frequency of calcification, particularly in children) would be welcome in a subsequent edition of this book.

The section on pathology is a little disappointing, but this may be innate in the problem. Malignant changes are rare, but cystic degeneration and haemorrhage not infrequent. 10% of the tumours showed transitional eosinophil cells, and clinical evidence of mild acromegaly was traced. Transitional basophil cells are recorded as being very rare. It should also be recognized that a typical Cushing syndrome has been recorded, paradoxically and rarely, with a chromophobe pituitary tumour. In most cases in this present study there was no clue to the origin or cause of the chromophobe adenoma. However, the authors draw attention to the fact that oestrogens can cause chromophobe adenoma in rats, and that this may be associated with dwarfism, atrophy of thyroid and gonads, but enlargement of the adrenal cortex. The latter circumstance would hardly support their hypothesis that the pathogenesis of chromophobe adenoma in man is similar. Surgery, radiography, and medical substitution therapy are also ably discussed.

This book is a very valuable and brief summary of present-day knowledge of pituitary chromophobe adenomas, to which knowledge the authors have made careful and important contributions.

HYPERTENSIVE DISEASES

Hypertensive Diseases: Cause and Control. By Henry A. Schroeder, M.D., F.A.C.P. (Pp. 610; 164 illustrations and 3 coloured plates. 75s.) London: Henry Kimpton. 1953.

The author of this book and his colleagues at St. Louis have been studying hypertension for a number of years, and the book contains a vast amount of knowledge derived from their own work and that of others. The index of authors contains some 900 names. The book deals exhaustively with the pathology of hypertension, its biochemistry, diagnosis, and treatment; but, as is not unusual in American books, less attention is paid to natural history and morbid anatomy. Nevertheless there is a case report of what must be one of the longest periods of observation of a patient with hypertension yet recorded. This concerns a woman who was found to have a systolic pressure varying from 160 upwards at age 26 and who was followed till her death from a heart attack at age 67.

Dr. Schroeder does not attempt any final definition of hypertension and hypertensive cardiovascular disease beyond the fact of raised blood pressure, but he devotes a good deal of attention to certain special aspects and clinical types. These are nephrogenic, neurogenic, and endocrine hypertension. He does not think that much can be expected from dietetic treatment except in endocrine disturbances, and, though he gives a fair description of sympathectomy and subtotal adrenalectomy, he quotes with approval the fifth of Loeb's rules of therapeutics—"Keep the patient out of the hands of the surgeon." The numerous drugs used in treatment of hypertension, many of them introduced in the last few years, are fully considered. Finally, Dr. Schroeder lays down a schedule for investigation of patients with hypertension and for their treatment with a combination of 1-hydrazinophthalazine ("apresoline") and hexamethonium by mouth. Apresoline is believed to neutralize the hypertensive factors which are derived from the ischaemic kidney. This is therefore a two-pronged attack on the nephrogenic and neurogenic factors in hypertension. Few cases have been treated for longer than two years and it is therefore too early to appraise the results, but striking improvement has been observed in malignant hypertension. The book is well produced, indeed perhaps too expensively for what is essentially a progress report. Nevertheless it is a mine of information about this common disease.

L. J. WITTS.

TUMOURS OF BONE

Tumors of Bone: A Roentgenographic Atlas. Annals of Roentgenology, Volume XXI. By Bradley L. Coley, M.D., F.A.C.S., and Norman L. Higinbotham, M.D., C.M., F.A.C.S. (Pp. 216; 172 figures. 75s.) London: Cassell and Co. Ltd. 1953.

That the present atlas of radiology has been written by two orthopaedic surgeons, and is being reviewed for these columns by a pathologist, indicates the extent of overlap of interests in the field of diagnosis of bone tumours. This overlap is, in fact, a most desirable thing, and one of the great assets of the present volume, which comes from the Bone Tumour Service of the Memorial Centre for Cancer and Allied Diseases in New York, is the almost equal familiarity with the clinical presentation and behaviour, the radiological appearance, and the pathology of tumours of bone that its authors possess.

Within the confines of a brief atlas it is not possible to present scientifically all the data in each of these fields on the cases selected for illustration. Radiographs have pride of place—as, in a radiographic atlas, they should—though there is usually a brief clinical note with each x-ray picture and occasionally a photograph of the pathological specimen from the case or an appropriate photomicrograph placed beside it.

With few exceptions biopsy examination has been carried out in the cases chosen for illustration, and the radiological diagnosis thus substantiated or modified. While the reader has to take the authors' word for the authenticity of the biopsy reports, he has the feeling that his confidence in them is rarely misplaced. The general classification of the various conditions discussed, and views on the extent of their practical separation from each other, are in keeping with present-day trends in pathology. Among the benign tumours of bone, for example, the conditions discussed and illustrated include "osteoid osteoma," "nonosteogenic fibroma," and "benign chondroblastoma," although it is surprising to find no mention of "chondromyxoid fibroma."

A subject to which repeated reference is made, and one where the authors give an accurate and balanced account, concerns the degree of correlation to be expected between radiological and biopsy diagnosis in the field of bone tumours. With cartilaginous tumours, in particular, when a biopsy diagnosis of "chondroma" is suggested, just emphasis is given to the importance of radiological evidence of possible malignancy in areas of the tumour outside the region of biopsy. Indeed, the authors' general principle should be as acceptable to the pathologist as to the clinician that "where the x-ray film and the clinical setting suggest a malignant tumor and a study of microscopic sections does not corroborate this impression, one must be extremely hesitant about accepting the pathologist's report as the final word." Both radiological and histological diagnosis have their limitations, and the clinician dealing with bone tumours should be aware of them in some detail.

The standard of illustration of the book is good; it is well arranged and well indexed. In short, it is a volume which can be depended on to make its mark as a reliable account of the radiological characteristics of each of the very numerous "entities" with which we are concerned in the diagnosis of tumours of bone.

H. A. SISSONS.

EMOTIONS AND PELVIC SYMPTOMS

Psychosomatic Approach to Gynecology and Obstetrics. By Fritz Wengraf, M.D. American Lecture Series. (Pp. 346. 50s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1953.

The author of this monograph sets out to emphasize the need to recognize the emotional factor in the aetiology of pelvic disease and symptoms if they are to be properly understood and treated. It is clearly intended mainly for general practitioners and for those who specialize in obstetrics and gynaecology, so that abstruse terms are avoided so far as possible, and the main body of the book is introduced by

general psychiatric considerations, with definitions of states such as anxiety and hysteria and explanations of concepts such as conversion and organ language.

In the two sections dealing respectively with gynaecological and obstetrical conditions are to be found the expected favourites such as dysmenorrhoea, amenorrhoea, functional uterine haemorrhage, frigidity, menopausal symptoms, menstrual tension, nausea, and vomiting of pregnancy, and the effect of the emotions on pregnancy, labour, and lactation, and vice versa. There are also others less expected such as leucorrhoea, abortion, and pica in pregnancy, and a helpful section on a woman's mental reactions before and after a gynaecological operation. As is usual in books of this kind, illustrative cases are quoted in detail.

It is all very readable and, if anything, errs on the side of making the subject appear too easy—glib conjectures sometimes masquerading in the guise of explanations of abstruse problems. However, in the section on treatment the author makes a real attempt to guide the general practitioner in the handling of the difficult class of patient concerned. Whether it all be accepted or not, it is an interesting book, and it presents an aspect of obstetrics and gynaecology which the good doctor cannot overlook.

T. N. A. JEFFCOATE.

GUIDE TO PHYSIOTHERAPY

The General Practitioner's Guide to Physiotherapy. By Janet Dennison, M.C.S.P. (Pp. 39. 6s.) London: William Heinemann. 1953.

This little book is agreeably written and contains much good sense. The author comments on the wide scope of physiotherapy and the popularity of these forms of treatment in present-day medicine. The history of the Chartered Society of Physiotherapy is briefly recalled, and she emphasizes the ethical laws of the chartered physiotherapist, which bind her to work only under a registered medical practitioner. She makes a plea for the close co-operation of the doctor and the physiotherapist. In the following chapters she outlines the various forms of treatment which the chartered physiotherapist is trained to give, rightly emphasizing the value of active movement. She advocates massage and various forms of electrotherapy with the keenness of one who is an expert practitioner of these arts, and, while there is a welcome tendency to make it clear that there are things that such forms of treatment cannot be expected to do, their positive effects are naturally advanced with some enthusiasm. The chapter on "Manipulation by the Physiotherapist" will not be accepted with equanimity by all the medical profession.

Finally, we are presented with a list of conditions for which certain forms of physiotherapy are advocated. This covers more than 200 conditions, ranging from purulent keratitis to haemorrhoids. We are told that in mucous colitis galvanism to each iliac fossa and salicylic ionization of the rectum have proved useful. Such statements will undo much of the good impression given by the early chapters, and the addition of the list of conditions containing such extraordinary prescriptions detracts from the value of the book.

WILLIAM TEGNER.

Artrite Reumatóide, by Jacques Houli (Rio de Janeiro: Tese do Concurso de Livre Docência de Clínica Médica; N.P., 1953), is a study of rheumatoid arthritis and is based on 100 patients. In these days of big battalions of cases this may seem a small number, but the work has been done thoroughly and much consideration given to most points: nevertheless, in a disease so variable and so widespread, numbers tell. There is not much information about cardiovascular complications, for instance. The remarks on Still's disease are based on two examples. The syndrome of Felty likewise has been treated very briefly. The author has studied the literature of the subject thoroughly; there are over 500 references; some are just apt quotations, reaching back to Garrod one hundred years ago. Perhaps the quotations from the literature outweigh the personal observations. The photomicrographs are good; the skiagrams less so. Unfortunately there is no index.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY APRIL 24 1954

FAT AND THROMBOSIS

The suggestion that there may be some association between lipaemia and thrombosis is not new, and evidence that such an association is at least possible has been accumulating for many years. Most of the evidence has been rather indefinite, and consequently the subject has not received as much attention as it would now appear to deserve. Information about thrombosis in general and about coronary thrombosis in particular is of special interest to all medical men, for the death rate from coronary thrombosis is high among members of the profession. It is little comfort to reflect that the apparently high incidence may be partly due to better diagnosis; the risk is still a grave one.

It has long been known that there are a number of conditions in which both lipaemia and thrombosis are commonly found. These include acute blood loss, pregnancy, diabetes mellitus, leukaemia, and ether anaesthesia.¹⁻³ In all these conditions, however, other factors might well be responsible for thrombosis, and on evidence of this kind alone it would be unjustifiable to infer that there is any causal connexion with lipaemia. Rather less indirect evidence pointing the same way comes from some studies linking thrombosis with dietary fat intake. Dock⁴ maintained that men who are neither diabetic nor hypertensive but who subsequently develop myocardial infarction often consume diets rich in butter, cream, and eggs. Malmros⁵ and Closs and Dedichen⁶ have both called attention to a striking difference between Norway and Denmark during the war. In Norway there was a great reduction in dietary fat intake and a marked fall in the incidence of myocardial infarction. In Denmark both fat consumption and the prevalence of myocardial infarction continued at their usual high level.

One serious difficulty in studying the pathology of coronary occlusion seems to have been cleared away by the work of Professor Duguid and his colleagues. At necropsy gross coronary atherosclerosis is an invariable finding, whereas evidence of recent thrombosis is sometimes not obvious. Hitherto the orthodox teaching has been that atherosclerosis is a degenerative process arising within the arterial wall. This was Virchow's contention, and it has gone un-

challenged for many decades. But in fact Rokitsky had previously taught that an atheromatous plaque developed from something deposited on the inner wall of the vessel, and it now seems that Rokitsky was right. Professor Duguid has shown in a careful series of histological studies that a thrombus adherent to the inner arterial wall becomes organized and covered with a cellular layer morphologically indistinguishable from the normal intimal lining. As the process of organization continues, the deposit becomes flattened and the lumen resumes more or less its circular outline. Thus, if the earlier stages have not been observed, the ultimate appearance suggests the development of something within the wall of the artery rather than the organization of a deposit originally lying wholly within the lumen. Many of these organized mural thrombi undergo fatty change and come to show the characteristic appearance of an atheromatous plaque. Such a process has been reported by Duguid in the coronary arteries⁷ and in the aorta,⁸ by Harrison in the pulmonary arteries,⁹ and by Duguid and Anderson in arterioles in cases of hypertension and diabetes.¹⁰ The observations on aortic atheroma have been confirmed by Crawford and Levene,¹¹ who carefully followed the changes by histochemical methods. It therefore seems reasonable to look for a common cause or group of causes for both thrombosis and atherosclerosis.

In view of these facts evidence of an association between lipaemia and atherosclerosis is relevant in discussing the relationship between lipaemia and thrombosis. A strong suggestion that such an association exists has been one outcome of work on plasma cholesterol levels in atherosclerosis. Anitschkow¹² showed that rabbits fed with large amounts of cholesterol develop arterial lesions resembling human atheroma. In man there seems to be no connexion between dietary cholesterol intake and atherosclerosis,¹³ but on the other hand high plasma cholesterol levels are undoubtedly associated with atherosclerosis.¹⁴⁻²⁰ Variations in plasma cholesterol levels seem to be closely associated with

alterations in dietary fat intake, and moreover in populations living on a high-fat diet the average plasma cholesterol level increases steadily with age.¹³ Thus the most likely explanation of these observations is that a high dietary fat intake is linked with atherosclerosis.

Studies on the part played by fatty substances in blood coagulation provide yet another approach to the same problem. Macfarlane and his colleagues²¹ showed that plasma freed from fat by high-speed centrifuging or by carbon tetrachloride extraction lost its power of coagulation in the presence of Russell's viper venom. The defect could be restored by a number of fatty substances, including even cream from the top of a milk bottle. A distinction of importance is that blood coagulation and thrombosis are different processes: the only undoubted similarity between them is the final formation of fibrin. Nevertheless, the efficacy of anticoagulant drugs in thrombotic conditions suggests that at least part of the mechanism is common to both processes. Therefore the paper in this *Journal* last year by Fullerton, Davie, and Anastasopoulos²² showing that fat ingestion has a direct effect on blood coagulation reported an advance of fundamental importance. They found that a breakfast of bacon and eggs and bread-and-butter was followed by a shortening of the accelerated plasma clotting time with Russell's viper venom, and a shortening of the whole-blood clotting time in siliconed tubes. Similar results had been reported following cream ingestion by Duncan and Waldron²³ and by Waldron *et al.*,²⁴ but Tulloch *et al.*²⁵ have shown that part at least of the change reported was due to failure to use clean syringes for successive venepunctures. However, Tulloch and his colleagues seem to have gone too far in concluding that "the blood clotting time is not altered by the oral administration of cream." They decided quite arbitrarily that any shortening of the clotting time by less than 30% would be disregarded. In fact, by the usual criteria of statistical significance they have convincingly demonstrated that a change occurs.

Thus there is a considerable body of evidence which seems to show that lipaemia is a factor in the causation of thrombosis. It is clearly not the only factor of importance. Morris²⁶ claimed that coronary atherosclerosis was if anything less common than formerly, while deaths from myocardial infarction appear to be on the increase. Some different explanation is required for this observation. Again, the higher incidence of myocardial infarction in bus drivers than in bus conductors is most unlikely to be associated with any difference in fat consumption. But at least it is evident that a number of promising lines of inquiry are opening up in what has appeared until recently to be a depressingly unrewarding field for investigation.

CIVIL SERVICE DOCTORS

The pay increases for three grades of medical officer in the Civil Service which have just been agreed (see *Supplement*, p. 194) are the outcome of over four years' protracted negotiation. It was in August, 1949, that a joint committee of the B.M.A. and the Institution of Professional Civil Servants first lodged a pay claim with the Treasury on behalf of Civil Service M.O.s. This claim was turned down in the following February. In the summer of 1950, however, anxiety over recruitment, already at an increasingly low ebb, and a serious shortage of doctors in the Civil Service, forced the Treasury to take some action, and it moved in the natural way of things towards setting up a committee of inquiry (the Howitt Committee¹). If the 650-odd doctors in eighteen Government departments expected anything from this committee their expectations were rudely shattered by the trifling increases which it recommended in November, 1951. As we said in a leading article at the time,² "It [the Howitt Committee] is content to advocate salaries that are second-best when the Civil Service ought to be attracting men of the highest quality for these important posts." The B.M.A. supported the joint committee in its refusal to advise Government medical officers to accept the Howitt Committee recommendations, and in February, 1952, the Council of the Association decided to refuse to advertise Civil Service medical appointments in the *Journal*. This decision was ratified by the Representative Meeting of that year. Reluctantly the Treasury in due course entered into direct negotiations with the Joint Committee, which, in its turn, has kept the Council of the B.M.A. fully informed at every stage.

The conditions of the agreement are fully set out in this week's *Supplement*. It will be seen that both sides will be free to make representations to the Royal Commission on the Civil Service, which is now sitting, particularly on the rates of pay for senior and principal medical officers, whose increases in the present agreement are regarded by both sides as purely token. Furthermore, the Joint Committee, which will continue to act for the Civil Service M.O.s on behalf of the B.M.A. and the Institution of Professional Civil Servants, is free to ask the Royal Commission to consider its full claim for the medical officer grade or, for that matter, any grade. Whatever recommendations may come from the Royal Commission—and there can be no doubt that the need for attracting recruits of high quality to this small but important branch of our profession will be well in its mind—the B.M.A., working through the Joint Committee, has in its persistence in a right cause achieved a

notable feat in moving an unyielding Treasury on behalf of a minority of its members, even though it did not move it all the way.

STRUCTURE AND LIFE

Scientific knowledge of proteins indirectly influences practical medicine at many points. The preparation of immunizing toxoids from toxins is a manoeuvre of protein chemistry; the use of plasma transfusion substitutes rests on appreciation of the nature and role of the natural plasma proteins; and some hormones, such as A.C.T.H. and insulin, are proteins, and their manufacture and the possibility of synthetic substitutes depend on protein chemists. Collagen is a protein fibre, and full knowledge of its structure might shed light on "collagen diseases," on the puckering of scars, and on keloids. Myosin and actin are the "contractile" proteins of muscle, and even if the treatment of myopathies were not helped by such study it would still be interesting to know precisely how a muscle contracts, or what happens when a spermatozoon lashes its tail. The genes on the chromosomes of the cell nucleus are made of nucleic acid; the treatment of many diseases might be changed if it was known how the nucleic acid molecules reproduce themselves at each cell division and how they exert their genetic influence. It is therefore not surprising that the research on the structure of proteins and nucleic acids is a big part of the programme of post-war science.

Chemists are beginning now to be able to say how all the amino-acids are arranged in sequence in the peptide chains which form a protein molecule. Sanger at Cambridge was recently able to do this for insulin. But how the peptide chains are arranged together in the three dimensions of insulin, or any other protein molecule, is altogether a more complex unsolved problem. Physicists, however, are beginning to find an answer with the help of x rays. Just before the first world war it was found that a single inorganic crystal, such as that of common salt, reflected and diffracted a beam of x rays, so that little beams emerged from the crystal in many directions to give a pattern of spots on a photographic film arranged round it. This was entirely analogous to the way a diamond (a crystal of carbon) or cut glass breaks up a light beam into a number of sparkles. But, whereas the directions and intensities of the light sparkles depend on the cut of the crystal surfaces, the emergent spots of x rays depend on the arrangement of atoms inside the crystal. With simple crystals it is fairly easy from measurement of the directions and intensities of the emergent beams to deduce what the atomic structure of the crystal must be to give such

a diffraction pattern. With a complex crystal, such as that of insulin or haemoglobin, containing perhaps 10,000 atoms in each molecule (as against the two of common salt), a pattern is certainly obtained, indicating that the crystal has an ordered, repeating, atomic structure, but it is a very complex one, with over 2,500 reflections, which so far defies complete mathematical analysis. There are various ways of tackling this problem. One is purely mathematical, seeking new descriptive analytic methods. Another is theoretical: one formulates a possible structure for the molecule, deduces what kind of pattern such a structure would give, and compares this pattern with the one actually obtained. The structure of penicillin was settled thus by x-ray diffraction study, since the pattern obtained agreed with only one of the several possible formulae put forward by organic chemists. A third approach is experimental, studying how the diffraction pattern changes when the crystal is gently dried, or when mercury atoms are combined with the free sulphhydryl groups in the protein.¹

Such methods have been extended to substances not obviously crystalline, such as hair, muscle, and collagen. These do give diffraction patterns of a kind with x rays, which means that they must have some degree of order or arrangement within them on an atomic or molecular scale. From the pattern obtained it is possible to say that there are regularities which repeat themselves every 1.5 Å, 2.86 Å, or 5.1 Å (or whatever it may be: 1 Å = 10⁻⁸ cm.), and the problem is to decide what it is which repeats with this regularity in the molecular structure. There have been various theories, but Pauling and Corey's proposal that fibrous proteins are peptide chains coiled in a tight spiral known as an α -helix at present holds the field.² Thus in collagen the chain would make one complete turn every 3.7 amino-acid lengths along it, and each turn would be 1.5 Å from the next. Nucleic acids also appear to be fibrous in the natural state. Members of the Medical Research Council's Biophysics Research Unit at King's College, on the basis of x-ray diffraction pictures, have proposed³ a special ribbon structure, the two edges formed by chains of alternating desoxyribose (sugar) and phosphate radicles held together by cross-links of purine and pyrimidine units. Their theory is not only in accord with x-ray and chemical data, but explains how variations in the same general structure could give rise to different nucleic acids, specific genes, and mutants, and how the gene may reproduce itself. It may suggest, too, how a virus reproduces itself, and therefore the kind of chemical to destroy it.

THE TREATMENT OF VOMITING

Even healthy people after mild dietary indiscretion find nausea and vomiting unpleasant. How much more distressing it is when it occurs as part of some general disease, or, as so often, during recovery from the combined effects of an operation and anaesthetic. Efforts to prevent or treat vomiting have not been lacking through the centuries. The literature of the last fifty years in particular reports a large number of remedies, each one, in the opinion of its sponsor, a certain specific. The substances which appear in this list are as diverse as iodine, insulin, glucose, olive oil, chloretone, and dimenhydrinate ("dramamine"). The causes of vomiting are many, and most approaches to its treatment in the past have been along the rational line of diagnosis and treatment of the causal factor. In some papers the blame is laid on the temperament of the patient, and such "vomiting-prone" patients receive little more than a shrug of the shoulders. In others, it is the fault of the disease, of the surgeon, of the anaesthetist, or of something else. There is truth in all these observations, for there is little doubt that some people are nauseated more easily than others. Many operations on the abdominal viscera are more likely to be followed by vomiting than operations on, say, the foot; ether is more apt to cause vomiting than nitrous oxide.

Two recent papers on this vexing problem advocate drugs structurally belonging to the general group of antihistaminics. The first¹ reports diphenhydramine hydrochloride ("benadryl") given intravenously. The authors consider it to be a good prophylactic against post-operative nausea and vomiting when administered intravenously just before the induction of anaesthesia, and also a good method of stopping vomiting when given in the post-operative period. It has also been reported that the vomiting associated with general disorders such as chronic nephritis, chronic pyelonephritis, subarachnoid haemorrhage, pregnancy, and gastroenteritis is relieved for varying times. The well-known major side-effect of diphenhydramine—namely, drowsiness—occurred in some cases; in others stupor, visual hallucinations, muscular twitchings, dryness of the mouth, and phlebitis were also seen, although they were not considered to be serious disadvantages. This paper confirms the anti-emetic properties of diphenhydramine already demonstrated by many others, notably Glaser and Hervey.²

The other recent report³ concerns the controversial substance chlorpromazine, known commercially as "largactil." It has already been shown that this substance could overcome the emetic effect of apomorphine.⁴ Now it is reported as being used successfully in a wide variety of conditions in which vomiting is a prominent feature. These include carcinomatosis, labyrinthitis, lymphomatosis, and uraemia. Chlorpromazine was also apparently effective in preventing or controlling vomiting caused by "antabuse" administration to alcoholics

and that associated with therapy by aureomycin, codeine, morphine substitutes, and morphine itself. The only side-effects reported are dryness of the mouth, mild sedation, and occasional faintness, palpitation, and flushing of the face.

There seems, therefore, to have been some change of opinion on the prevention and treatment of nausea and vomiting. The attempt to distinguish specific aetiological factors and to treat them seems to be giving way to the practice of administering drugs believed to have an anti-emetic effect independently of the cause of the vomiting. Another observation on this subject may be timely. The evaluation of an anti-emetic drug is not an easy matter and should not be lightly undertaken without careful preparation. Of the many reports through the years, most are of little value because the design of the experiments has been poor and statistical treatment of the data either suspect or not carried out. Two papers within recent years might be cited as examples of the way anti-emetics should be studied. In both the design and tests of significance were adequate. One paper, by Gordh and Rydin,⁵ described an investigation into cerium oxalate, the other, by Mushin and Wood,⁶ an investigation into the effect of nicotinic acid on post-operative vomiting. Both showed that the drugs in question had no significant effect on the incidence of vomiting. The latest reports on diphenhydramine and chlorpromazine do not indicate that the experimental observations were planned along these lines.

SYNTHETIC DETERGENTS

Synthetic detergents, though overcoming some of the imperfections of soaps and alkalis used as cleansing agents, especially in hard water, have introduced some new difficulties of their own. Last year the Minister of Housing and Local Government appointed a committee under the chairmanship of Sir Harry Jephcott "to examine and report on the effects of the increasing use of synthetic detergents and to make any recommendations that seem desirable with particular reference to the functioning of the public health services." The committee's full report on the subject will not appear until further extensive investigations have been carried out, but an interim report¹ has now been published which contains some fairly reassuring information. It seems that despite the widespread use of detergents the incidence of dermatitis of the hands has not increased—a finding supported by recent evidence² from the U.S.A. But these substances may irritate some skins—for instance, the washing of babies' napkins in strong detergents can cause a contact dermatitis of the napkin area—and the committee advises that, after their use, the hands should be thoroughly rinsed in fresh water and dried. The wearing of household rubber gloves is a sensible precaution which should be taken by housewives whose hands become rough and sore from constant immersion in water—which, as the committee points out, often contains much more detergent than is really necessary. So far there has been no evidence of any

ill effects from the possible ingestion of minute traces of synthetic detergents left on crockery, but it is a good hygienic practice to rinse all utensils in hot water before draining.

Housewives as a whole are said to prefer the types of detergents which produce foam, though this quality is unrelated to degreasing and cleaning power. Unfortunately foaming is persistent, and at sewage disposal works, especially where the activated sludge method is used, foam may rise to several feet. This is a serious inconvenience and actual danger to the operators, and the foam may drift and be offensive to the neighbourhood because of contained particles of unpurified sewage matter. Drifting foam can also have a blanketing effect on vegetation. The committee views with concern the possibility that the increasing use of detergents may make it more difficult for sewage works to produce effluents up to the required standard of purification. Since some of the constituents of detergent preparations are only partially removed or destroyed during sewage treatment, further investigation is being carried out to assess how far the presence of these materials is likely to harm river life or river-drawn water supplies. However, the committee thinks that the problem of foaming at sewage works, though calling for speedy solution, is not sufficiently serious to warrant alarm.

FAITHFUL SERVICE

It is a happy characteristic of medicine that its tradition of service readily infects all who come in intimate contact with its work. This is particularly noticeable in that devoted band of lay helpers—yearly increasing—who without regard for the clock, day in day out, smooth the doctor's burden for him and ease his lot. It is true to say that these people, secretaries, receptionists, and surgery assistants, can make or mar a practice, and it is very seldom that they do the latter. It is good news in this week's *Supplement* (p. 194) that the B.M.A., through the Medical Insurance Agency, has sponsored a pension and sickness scheme for doctors' employees. It will satisfy a long-felt need and will enable medical men and women to fulfil in a business-like way obligations which they have always sincerely felt but have been at a loss to know how to carry out.

BIRDS AND VIRAL ENCEPHALITIS

Birds have long been recognized as the source from which man is occasionally infected with psittacosis, or with other viruses of the ornithosis group, usually by the inhalation of infective material. Recent reports from Japan,¹ Australia,^{2,3} and Malaya suggest that birds may also be the carriers of certain viruses which cause encephalitis in man. West Nile viruses and those causing St. Louis encephalitis, Japanese B encephalitis, and Murray Valley encephalitis (M.V.E.) are serologically related: no information is available on the epidemiology of West Nile virus infections, but the other three viruses have several features in common in addition to their

similar size and shared antigens. For example, the proportion of subclinical to clinical infections in man is high; they are transmitted by culicine mosquitoes; and birds are highly susceptible to infection with the viruses, and usually show a transient high-titre viraemia, but no clinical symptoms.

The most obscure feature of the epidemiology of all these diseases is the reservoir of the virus during the winter, or, in the case of M.V.E. virus and Japanese B encephalitis virus in Japan, the reservoir from which the virus periodically invades areas in the temperate zones. Investigation of this problem demands what Dr. J. R. Audy, in a paper appearing elsewhere in this issue, describes as a biological approach to medical geography. Two hypotheses have been suggested, both of which bring birds into the foreground of the picture. Australian workers have suggested that persistence of M.V.E. virus is confined to areas near the Tropics where vector mosquitoes are present throughout the year. The appearance of the disease in temperate regions during the summer is thought, on this hypothesis, to be due to bird movement through a region in which vector mosquitoes were present. A migratory bird might well be infected in one place and develop viraemia a week later in another place hundreds of miles away, and thus infect local mosquitoes with the virus. These mosquitoes could then infect local birds and establish a new focus of infection. The appearance of M.V.E. in southern Australia at long intervals of time might then be due to exceptional meteorological conditions which may cause exceptional bird movements.

The other view derives from the isolation⁴ of St. Louis encephalitis virus from chicken mites (*Dermanyssus gallinae*) collected in St. Louis County during a non-epidemic period. In contrast to the negative results obtained with mosquitoes, the transmission of infection through the eggs of ticks and mites (and hence the possibility of indefinite survival apart from vertebrate hosts) has been reported with several viruses, and Smith and his colleagues⁵ have shown that the eggs of *Dermanyssus gallinae* can harbour the virus of St. Louis encephalitis and that larvae hatched from the eggs can transmit the infection. Thus St. Louis encephalitis virus may survive the winter in the mites of domestic fowls and other birds. In view of the close similarities in the biological behaviour of the other three related viruses, it is possible that a similar cycle may occur with them also.

Both hypotheses may ultimately prove correct. A mite-bird cycle may provide the reservoir of some of these infections in tropical regions: bird migration, annual or exceptional, could then result in the infection of birds in more temperate areas, with a consequent overflow of infection into the susceptible local human populations. The ultimate reservoir of Japanese B encephalitis and Murray Valley encephalitis may be best sought in tropical regions such as Malaya rather than in Japan and Australia, where the clinical diseases were first recognized.

Sir Russell Brain was re-elected President of the Royal College of Physicians of London on April 12. He was first elected President of the College in 1950.

CLINICAL PATHOLOGY IN GENERAL PRACTICE

LABORATORY INVESTIGATIONS IN SUSPECTED INDUSTRIAL POISONING

BY

RONALD E. LANE, M.D., M.Sc., F.R.C.P.
Nuffield Professor of Occupational Health, University of Manchester

There are two situations in which a general practitioner may need the help of the laboratory in dealing with patients he suspects to be suffering from industrial poisoning: (1) When the history and clinical picture point to industrial poisoning but he has no direct evidence of such exposure, nor of its magnitude; here both doctor and patient may be unaware of any danger in the patient's work, and a laboratory investigation may be the only way of establishing that exposure has occurred. (2) When the doctor is supervising (as an industrial medical officer) the health of a group of work-people; here the fact of their exposure is known to him, but laboratory tests are required to estimate its degree and identify individuals who are running into danger.

Only a few industrial poisons give rise to specific laboratory findings. The toxic metals can be detected in the body fluids, and carbon monoxide gives rise to a characteristic change in the haemoglobin. Investigations of this nature require not so much an experienced biochemist as a biochemist experienced in the particular technique, as well as a laboratory set aside for the work (the determination of lead in biological fluids provides a good example). These conditions can rarely be fulfilled in general hospital laboratories. In consequence it has been the practice in some regions to attempt to concentrate work of this nature in one or two special laboratories. Unless special facilities of this type are available results may be inaccurate, and it cannot be too strongly emphasized that incorrect results are worse than no results at all. The clinician, therefore, should explore the facilities available to him before requesting unusual investigations to assist him in diagnosis.

The more important use of laboratory investigations in those exposed to industrial poisons lies in prevention. Unfortunately, this work does not fall within the ambit of laboratories associated with the National Health Service, and the practitioner requiring these examinations will have to make special arrangements. Large firms usually establish a laboratory to deal with their own particular health problems, but difficulty arises where the numbers of workmen involved make such provision uneconomical.

It is often possible for the research biochemist to devise tests which will enable a check to be kept on workers exposed to particular poisons. But the methods to be used and the interpretation of results in the prophylactic field raise special problems, and general practitioners wishing to institute this type of routine supervision would be well advised to seek the advice of an expert in industrial medicine.

Whether the laboratory test is to be used for diagnostic or prophylactic purposes it must be carried out with due care, and this may involve much labour in the laboratory. Equal care is necessary, however, in

the collection of specimens, and the practitioner would be wise to consult the laboratory about their tests and the times at which unusual specimens should be submitted.

Details of some of the industrial poisons giving rise to specific changes are briefly discussed below.

Lead-Poisoning

Lead-poisoning still continues to occur and the diagnosis is often missed. Help can be obtained from laboratory investigations provided these have been carried out in a suitable laboratory. In detecting minute quantities of lead in body fluids the biochemist has to take the greatest care: reagents must be "delead" and special glassware used. The latter is prepared by washing with pure hydrochloric acid and rinsing with water twice distilled from all-"pyrex" apparatus. All these time-consuming precautions in the laboratory, however, are of no avail if proper care has not been observed in the collection of samples by the practitioner.

Lead in Urine.—A true and uncontaminated 24-hour sample would theoretically be most suitable, but in practice the collection of spot samples of at least 200 ml. is to be preferred. The urine should be passed direct into all-glass stoppered pyrex flasks (with or without the use of a pyrex funnel). Great care must be taken to avoid contamination of the specimen from lead on the clothing. To avoid the addition of trace metals no preservatives must be added. The normal lead content of urine ranges up to 100 µg. per litre. Values in excess of this are found in nearly all lead-workers and no particular level can be taken as indicating poisoning. Raised urinary excretion of lead merely indicates raised absorption and confirms what may be already known, that the patient is a lead-worker. Low-grade absorption will give a urinary figure of up to 150 µg. per litre and suggests good working conditions. Repeated values of 200 µg. indicate substantial absorption. If values are frequently found above 300 µg. absorption is excessive and poisoning may occur at any time. There is considerable daily variation in urinary lead output and reliance should not be placed on single observations. In the supervision of lead-workers the importance of group trends cannot be overemphasized. A high lead level in urine in an individual does not indicate poisoning, nor does a low one completely rule it out. Diagnosis must rest upon the clinical picture taken in conjunction with all laboratory findings.

Lead in Faeces.—This investigation has no place in the detection of individual cases of industrial lead-poisoning and is of little value in assessing an industrial hazard.

Lead in Blood.—This determination has been widely used in the United States. Ten millilitres of blood should be collected in a dry all-glass syringe, cleaned as described above, with a stainless steel needle. The blood should be transferred to a similarly cleaned test-tube and allowed to clot. The normal range of values is 0-80 µg. per 100 ml. of blood.

Coproporphyrin in Urine.—While urinary coproporphyrin concentration is a useful index of the lead hazard in groups of lead-workers in industry, the excretion of this substance is also raised in a number of other diseases and the test has little diagnostic importance.

Blood Examination

While by no means entirely specific, blood examination for punctate basophilia offers a useful test for certain types of lead absorption (not lead tetraethyl). Blood for this purpose is most easily obtained from the lobe of the ear. Films should be spread on thin glass slides (to facilitate the use of dark-ground technique in the laboratory). The film should be thin—in a person not markedly anaemic the spreading slide should be at an angle not greater than 20 degrees. It is easier to judge the quality of the film if the slide lies on a white background—a piece of white blotting-paper is very suitable. Several films should be prepared and these should be allowed to dry in air.

Results must be interpreted with care. Actual counts will depend on factors such as the stain used and the experience of the technician. Many laboratory workers content themselves with reporting "punctates per field"; others use even more cryptic remarks such as "numerous." In the absence of other disease likely to produce this condition (pernicious anaemia, malignant disease) punctate basophilia suggests lead absorption. It is observed in minor degrees in most lead-workers, but large numbers of stippled cells—three or four per field, especially if the granules are large—suggest excessive absorption and the possibility of poisoning. Associated with a haemoglobin estimation, and a limited number of lead-in-urine determinations, this method provides a cheap and objective method of supervising lead-workers.

Mercury

The level of mercury in the urine gives a useful indication of the quantity being absorbed. The collection of the specimen is carried out with the same precautions as for lead.

The normal range of urinary mercury is up to 80 µg. per litre and values in excess of 100 µg. are abnormal. Very high values are often found in those exposed to metallic mercury; for instance, values exceeding 1,000 µg. have been found in such a group of workers, and in isolated cases values exceeded 2,000 µg. These men were all at work, but many showed the rather indefinite clinical picture associated with chronic mercury poisoning. Symptoms should be looked for when the value persistently exceeds 300 µg. per litre.

Arsenic

The patient should be sent to the laboratory so that a fresh specimen of urine can be obtained for examination by the molybdenum-blue colour method. Normal urinary arsenic has been given as 170 µg. of arsenious anhydride per litre.

Carbon Monoxide

Carbon monoxide is one of the commoner poisons, both in industry and in the home, and its detection in the blood is often important for medico-legal purposes. The percentage of carboxyhaemoglobin can readily be measured in the laboratory either by the use of reversion spectroscopy or by the sensitive palladium-ammonium molybdate method.

Ten millilitres of blood should be collected with a sterile dry syringe and oxalated.* The blood should be transferred under paraffin to a test-tube and more paraffin should be added to fill the tube, which should be securely corked. Shaking should be avoided, the tube wrapped to exclude light, and the specimen taken to the laboratory without delay so that the analysis can be carried out as soon as possible.

The blood takes up carbon monoxide very readily and minor quantities are not noticed. For instance, the blood may contain as much as 5% carboxyhaemoglobin after

*The oxalate anticoagulant should preferably be Heller and Paul's solution, which is prepared from 1.2 g. of ammonium oxalate, 0.3 g. of potassium oxalate, and 1 ml. of 40% formaldehyde, the solution being made up to 100 ml. with water: 1 ml. of this solution is suitable for 10 ml. of blood.

smoking cigarettes. In a healthy person at rest concentrations up to 15-20% may remain undetected. When the carboxyhaemoglobin reaches 30% a throbbing headache and dizziness are likely to appear, at 50-60% the patient becomes unconscious. If 80% of the haemoglobin is combined with carbon monoxide death occurs rapidly.

Aromatic Amino- and Nitro-Compounds

Aniline, nitrobenzene, and related aromatic compounds give rise to the formation of abnormal haemoglobin derivatives in blood. The erythrocytes of patients who are cyanosed may contain sulphaemoglobin and methaemoglobin, and methaemalbumin may be present in the plasma.

To examine for these, 10 ml. of blood should be withdrawn by syringe and transferred to a tube, where it must be preserved with a mixture of sodium fluoride and thymol,† which acts as a preservative and anticoagulant. Air should be excluded by filling to the stopper with liquid paraffin and the estimation should be made as soon as possible. Sodium citrate should not be used as an anticoagulant as it interferes with the methaemoglobin determination.

Probably about 1% of the total haemoglobin in the red blood cells is normally present as methaemoglobin. It is only when the methaemoglobin concentration reaches levels of approximately 40% that dyspnoea occurs on exertion, although obvious cyanosis may be present at much lower levels. The cyanosis from methaemoglobin clears in a day or two, but that resulting from sulphaemoglobin may persist for several weeks.

Trinitrotoluene

Workers exposed to trinitrotoluene excrete metabolites in the urine which give a positive Webster test. This consists in adding alcoholic potash to an ethereal extract of the acidified urine, when a violet colour appears. This test is of value only in demonstrating—what is usually well-known—that the patient is working with T.N.T.

Benzene

Blood changes following benzene absorption are important but not specific. Leukopenia, anaemia, or even leukaemia may be observed.

New Chemicals

New chemicals are continually being developed for use in industry. When there is any suspicion of their being poisonous it is one of the duties of the research biochemist to devise methods for their detection and estimation in body fluids. If this is impossible he should attempt to devise an indirect method for assessing the degree of intoxication. Some of the newer chemicals used in agriculture illustrate this.

Selective Weedkillers

Dinitro-ortho-cresol (D.N.O.C.), which is used as a selective weedkiller, gives rise to poisoning in man. The clinical picture in mild cases is not clear cut, though help in diagnosis can be obtained from the estimation of this substance in the blood. This is a comparatively simple procedure and can be carried out on small samples of blood. It is particularly useful in supervising the health of those whose work involves exposure to the poison.

The practitioner should submit a sample of 2 ml. of blood to the laboratory. This allows of duplicate tests. The sample is best withdrawn from a vein and must not be allowed to clot. A 2-ml. syringe with a fine hypodermic needle serves well. The best anticoagulant is heparin, and suitably prepared tubes can usually be obtained from the laboratory. If such a prepared tube is not available, any clean dry tube may be used; clotting should then be prevented by the previous addition of a few crystals of sodium

†One gramme of sodium fluoride mixed with 0.1 g. of thymol crystals: 0.1 g. of this mixture is taken for 10 ml. of blood.

citrate. Accidental contamination of the sample by chemicals on the skin must be carefully avoided by thorough cleansing of the site of venepuncture with spirit. In order to avoid false peak values, samples should not be taken within eight hours of the patient's last exposure. It is not necessary to add any preservative, as D.N.O.C. determinations can readily be carried out on whole blood which is over a week old.

Normal values are usually supplied by the laboratory doing the test. Since D.N.O.C. is a cumulative poison and is only slowly excreted, Bidstrup and her colleagues* recommended that a man should be removed from further contact for at least six weeks, if the blood level, eight hours after his last exposure, is 20 µg. per g. or higher.

Organic Phosphorus Insecticides

The organic phosphorus insecticides are now being widely used all over the world. These substances are toxic to man and produce their effects by inhibiting cholinesterase. In order to detect excessive absorption in workmen using these insecticides, it is necessary to estimate the quantity of this enzyme in the blood. This is not a simple procedure but arrangements have been made for it to be carried out in certain National Health Service Laboratories in suspected cases of poisoning.†

There are micro-methods for this determination, but the practitioner would be wise (unless advised to the contrary by his laboratory) to submit a blood sample of at least 2 ml. and preferably 5 ml. Should a micro-method be in use and the practitioner be advised to submit small samples such as can be obtained from a finger prick, it is most important to see that the site is adequately cleaned before pricking, since traces of the insecticide in the sample lead to false low cholinesterase readings. Clotting should be prevented by the use of a heparinized tube or sodium citrate (as for D.N.O.C.); oxalate should not be used. No preservative is required, as enzyme activity of the blood is unimpaired even after a few weeks.

In the absence of an agreed international unit of cholinesterase activity, the amount of enzyme is expressed as a "number."‡ The normal range in healthy adults for whole blood is 80-130 units. Signs of systemic poisoning occur when this figure drops to 20-30 units, though a few patients have shown symptoms when the "number" was in the normal range. The results will almost certainly be interpreted for the practitioner by the laboratory according to the scale in use locally.

The greatest value of this test lies in prevention. In this work the wide range in the normal makes it advisable to have pre-employment determinations carried out on men who are about to be exposed to this poison, and they should subsequently be tested at weekly intervals. A marked fall in a man's cholinesterase number should be regarded as a danger sign and he should be removed from further exposure until his enzyme activity has returned to normal. This recovery is not rapid and may well take six to eight weeks.

Reports of Societies

THE CRIMINAL AND THE DOCTOR

The contemporary crowding of our prisons and the frequency with which young men and women are turning to crime for a living have shocked modern society. Lately, also, the publicity accorded to cases of homosexuality and other sexual offences has heightened the demand that vigorous steps should be taken to mend matters. Unfortunately, no two people agree about what should be done. The psychiatrist has one remedy, the police another, and utterances on the subject from the Bench are conflicting. All are agreed, however, on two things: the urgency of reclaiming all those who can be saved from a life of crime, and the need to protect society from those who cannot.

It is against this background that the International Society of Criminology, with the help of Unesco and the British Council, arranged a two-weeks course in London on "Recent Advances in the Study and Treatment of Offenders." The course ran from March 24 to April 13, and brought together lawyers, magistrates, doctors, psychiatrists, police, prison administrators, sociologists, and other interested people. It consisted of lectures and discussions, and visits to prisons, Borstals, approved schools, and other institutions. The course was directed by Dr. DENIS CARROLL, president of the International Society of Criminology, and Dr. HERMANN MANNHEIM, reader in criminology at London University. Below are reported four of the medical contributions. They deal with electroencephalographic studies, hormone treatment of sex offenders, psychotherapy in prison, and "typological" research on adolescents sent to Borstal institutions.

Electroencephalographic Studies

Speaking on "Electroencephalographic Studies of Offenders," Dr. DENIS HILL (senior lecturer in clinical neurophysiology, Institute of Psychiatry, London University) gave a general survey of work in this field. While the electrical patterns found in epilepsy, brain tumour, and other structural brain disorders were different in kind from the normal record, 10% of the general population showed minor differences in degree, and the study of these was only just beginning. These "variant" records did not indicate any gross structural abnormality, and would be considered normal for children or adolescents in whom, under experimental conditions, they could be produced occasionally by emotional frustration. As the personality trait most often accompanying these aberrant records was undue aggressiveness, it was reasonable to suppose they indicated some failure of the brain to mature and reach integrated functioning, with a resulting imbalance and lack of emotional control. Individuals showing such patterns were more susceptible to physiological stresses, such as a low blood sugar, oxygen lack, and alcohol, and they were also less able to tolerate emotional frustration.

Turning to studies of offenders, Dr. Hill emphasized that no connexion could be found between the E.E.G. tracing and antisocial behaviour as such. Nevertheless, in a recent study of young delinquents, only 16% showed normal recordings. In the prison population, 80% of psychopathic personalities showed variant recordings, a similar proportion to psychopaths in mental hospitals, but among the remainder of the prisoners variant recordings were also abnormally frequent, and these variant patterns were related to aggressiveness. Studies of murderers had been negative in those cases where killing was incidental to another offence, but in those cases where there appeared to be no motive, or where the motive was trivial, three-quarters showed variant records, a fact which indicated the need for close investigation in such cases. There was also a surprisingly high incidence of epilepsy among the

murderers studied, though no case had been found in which the crime was related to a seizure. No explanation for this could be given, but there was evidence suggesting that both epilepsy and an abnormal personality could result from brain damage from anoxia or trauma at birth, probably to the temporal lobes, the last part of the brain to mature. Recent studies showed that where slow waves were obtained from this region there was a 50% chance of a general personality disorder, chiefly shown by irritability, aggressiveness, and antisocial behaviour. Apart from such possible birth trauma and other forms of brain disease, all evidence at present indicated that E.E.G. patterns were primarily determined by heredity.

Treatment of Sex Offenders

Discussing the hormone treatment of sex offenders, Dr. R. SESSIONS HODGE (consultant psychiatrist to the South-western Regional Hospital Board) said that sexual offences could be regarded as due to a lack of balance between primitive drives, probably originating in the hypothalamus and other lower brain centres, and the inhibitory effect of the cerebral cortex which normally regulated them and ensured that they received only socially and ethically acceptable outlets. Drugs could be used either to diminish the drives or to increase the cortical control. Amphetamine "alerted" cortical function via the thalamo-reticular diffusion system and probably diminished enuresis or aggressiveness for this reason. Alternatively, one could depress the drives. In cases of aberrant sexual activity, oestrogens could reduce the sexual impulse to a point where the cortex could control it. Progesterone had a similar effect on women, and could also abolish the outbursts of aggressive behaviour that sometimes occurred premenstrually. In treating the homosexual, Dr. Sessions Hodge felt that the best results occurred when the effects of the drug were frankly discussed with the patient, it being made clear that the responsibility for taking the drug, and so for controlling aberrant behaviour, rested with him.

Though hormones could diminish the drive, they could not alter its direction, and the homosexual remained homosexual when the drug was stopped. Psychotherapy therefore remained the most important form of treatment, though if it was to be effective it would need to be given much earlier in life than was the rule at present.

Psychotherapy in Prison

Dr. H. K. SNELL (director of the Prison Medical Service), dealing with administrative aspects of the psychiatric treatment of prisoners, said that where such treatment was recommended by the courts, or later by medical officers of prisons, prisoners were sent to selected establishments such as Wormwood Scrubs, Wakefield, or Holloway. At Wormwood Scrubs most forms of psychiatric treatment were available, and analytic treatment was given by two visiting psychotherapists. This method was time-consuming, and therefore allowed few to benefit. Group therapy was more promising, and perhaps more suited to the type of case met with. At Wormwood Scrubs the 10 men forming the nucleus of those receiving this treatment lived together in a special ward between group sessions, and there was a full programme of activity, including painting and psychodrama, supplementing the prison routine. Though prison discipline was always in the background, the group was encouraged to develop responsibility for disciplining itself, and the standard was high.

Dr. Snell pointed out that only a small proportion of offenders were suitable for psychotherapy, for reasonable intelligence was needed, and there must be a strong and genuine desire for change; this was often not sufficiently recognized by the courts recommending treatment. It was unfortunate that, because of the time involved, little could be done where the sentence was less than six months, for this group might be expected to include men who would

benefit most from psychotherapy. But, as in many cases much could be achieved in only a few interviews by a doctor with psychological insight, prison medical officers should be able to give simple psychotherapy. The practice of N.H.S. psychiatrists visiting short-term offenders in prison, who could then continue to attend as out-patients on release, was another way of overcoming this difficulty.

Prognosis after Borstal

Speaking on "Typological Research on Adolescent Offenders," Dr. D. A. OGDEN (medical officer, H.M. Borstal Institution, Portland) said that he had been struck by the errors that were often made in predicting how lads would turn out when they left Borstal institutions. He had therefore taken a sample of 250 lads and divided them into 10 groups according to the predominant reaction to Borstal training they showed. The grouping of the cases was performed by several officials at the institution after a discussion. Medical opinion counted as one vote equal with the others except in one category which included all cases showing mental abnormality high enough to affect normal reaction to training. The lads had been followed up for four years after their discharge, and analysis of the number of reconvictions in each group had shown significant differences. The "adolescent" and "emotionally unstable" types, which gave so much trouble during training, did well in the long run, though the reconviction rate was high during the first year. By contrast the "submissive," who gave little trouble, had a bad prognosis, as did the "ego-centric," "the hysterical swindler," and "unethical" types. However, the "shiftless" type, which had done very badly soon after release, had recovered very well over the longer period. Although there was a marked connexion between broken homes and chronic delinquency, it was interesting that the "unethical" type lads who took to crime deliberately, regarding it as a gamble worth the risk, showed good home backgrounds and high mental stability and ability, perhaps indicating a criminal type. Possibly the most striking performance by any of the types was by the one containing the "abnormals," showing only a 30% rate for more than one reconviction. This was markedly better than many other types and strongly encouraged the view that such "abnormal" adolescents could be trained under close medical and administrative co-operation.

THE BIBLE AND MEDICINE

The Bible and Modern Medicine: A Survey of Health and Healing in the Old and New Testaments. By A. Rendle Short, M.D., F.R.C.S. The Second Thoughts Library, No. 9. (Pp. 142. 6s.) London: The Paternoster Press. 1953.

Mr. Rendle Short is widely known as a teacher and writer on surgery and as one of the editors of the *Medical Annual*. His devout little book discusses the differences between the medicine of the Old and the New Testament—which can be summarized by saying that "possession" is very rare in the former and very common in the latter. He considers also the linguistic evidence on whether St. Luke was a trained physician, the nature of possession and of the miracles of healing, the sanitary code of the Old Testament, the interpretation of the word translated as "leprosy," the physical cause of the death of Christ, and the Biblical conception of disease. His treatment throughout is along lines that may reasonably be described as moderately though definitely conservative. His readable and tolerant pages will be of use to the many, like-minded to him, who must often be seeking such a summary.

CHARLES SINGER.

Correspondence

Perforation of the Colon

SIR.—I was very interested to read Mr. Roger Brearley's medical memorandum (*Journal*, March 27, p. 743) on "Spontaneous Perforation of the Colon due to Alkaline Medication" and his ingenious explanation of the perforation. A paper on unusual perforations of the large bowel is in preparation, but it may be of interest to record here a personal case, rather similar to Mr. Brearley's in that perforation of an otherwise normal colon occurred in a patient who had recently developed constipation and who was receiving alkaline treatment for a suspected duodenal ulcer.

A 41-year-old labourer was admitted to hospital in November, 1953, with a six-hour history of very severe pain, sudden in onset, in the lower abdomen. This was preceded for 24 hours by lower abdominal colic and tenesmus. Five weeks prior to this emergency he had had diarrhoea lasting three days. For several years he had had symptoms very suggestive of duodenal ulceration, for which he had been in the habit of taking a self-prescribed bismuth preparation, and during the few months previous to this hospital admission he had developed increasing constipation. General examination showed a very ill man; his abdomen was silent and rigid throughout with diffuse tenderness and release tenderness, both of the latter being most marked just below the umbilicus and in the suprapubic region. No confident diagnosis could be made other than generalized peritonitis, but in view of the maximum median tenderness the possibility of a perforated Meckel's diverticulum was entertained.

At laparotomy purulent free fluid and liquid faeces were found in the peritoneal cavity and a perforation 3.5 cm. by 1.75 cm. was found on the anti-mesenteric border of the apex of the sigmoid colon loop; protruding through the perforation was a hard faecal mass. Many similar faecal masses were present in the rest of the pelvic colon and rectum, but in no sense could the term faecal impaction be applied. The bowel wall adjacent to the perforation was involved in the generalized inflammation but appeared otherwise normal, as did the remainder of the colon and rectum. Treatment, as in Mr. Brearley's case, was by exteriorization of the affected loop through a muscle-split incision in the left iliac fossa using the perforation as a colostomy and drainage of the pelvis. He received aureomycin during his post-operative course, which was satisfactory, and subsequent sigmoidoscopic and radiological examinations of the colon and rectum failed to demonstrate any abnormality. Two months later his colostomy was closed intraperitoneally and to date he has had no further symptoms; barium enema examination has been repeated and shows no lesion in the large bowel. A biopsy specimen from the edge of the perforated ulcer suggested that the ulcer was a chronic one with continued activity rather than acute, and in view of this histology and the operative findings the ulcer was cast on to the scrap-heap of chronic ulcer pathology—the simple solitary ulcer—although perhaps wrongly.

There is little doubt that diarrhoea due to faecal impaction is a not infrequent occurrence after any operation for peptic ulcer, including simple closure of a peptic perforation, and in my experience, limited to acute surgical practice, faecal impaction occurs by far most commonly under those circumstances. As certain alkalis tend to produce dry hard stools, their use may well lead to faecal impaction, as Mr. Brearley has pointed out. Yet, with constipation very common, faecal impaction relatively so, and a large proportion of the population, constipated and otherwise, taking alkaline medicaments over long periods, it is a little surprising that the complication of perforation of the bowel, if due to faecal impaction, does not in fact occur more often. The complication is an exceptional rarity, and Mr. Brearley reports his case as "almost unique." It would have been interesting to know the histology of the edge of the perforation in Mr. Brearley's case.—I am, etc.,

London, W.3.

A. J. M. MATHIESON.

SIR.—An interesting account has recently been published by Mr. R. Brearley of large bowel perforation associated

with alkaline medication (*Journal*, March 27, p. 743); we wonder if this is as rare as the author claims. A similar case occurred at this hospital in 1951.

A man aged 55, known to have a chronic duodenal ulcer for which he consumed large amounts of bismuth, was admitted because of recent onset of constipation and colicky abdominal pain, superimposed on his ulcer symptoms. While in hospital, on the day of admission, he suddenly developed agonizing pain in the left iliac fossa, with shock and abdominal rigidity. At laparotomy, the stomach and duodenum were intact, but free in the abdominal cavity were large, odourless concretions and free fluid. No site of intestinal perforation was found, but the patient's general condition was too poor to allow an extensive search, and in fact the patient only survived the operation for a short period. At necropsy a small perforation of the sigmoid colon was found, the wall of the intestine being intact throughout.

Perhaps the most striking features of this case were the rapidly developing severe shock, and the failure of treatment, despite early operation.—We are, etc.,

M. PEMBERTON.
N. F. KIRKMAN.

Manchester, 20.

Whither Neurophysiology?

SIR.—The study of neurophysiology is now recognized as a basic subject in the training of psychiatrists. It might appear logical that those concerned in the treatment of mental illnesses should have a fair knowledge of the normal functions of the nervous system, and perhaps be confident to diagnose neurological disorders on clinical examination. Yet too many psychiatrists are content to leave the organic field to their colleagues, and have little time for the academic approach to nervous function.

Modern ideas on the brain that have resulted from scientific experiment, including the application of electronic techniques, indicate quite clearly that the existence of a "functional" field must be seriously challenged. It is only one step from the activity of the sense organs to the mental experiences of perception, and the neurophysiologist is finding himself in a sphere that was formerly the undisputed territory of philosophers, psychologists, and psychiatrists. A physical basis has now been established for many aspects of emotional behaviour, and in selected lesions of the brain the type of behavioural disturbance can actually be predicted. Psycho-surgery has been accepted as a useful therapeutic tool without any real understanding of its physiological effect; but its acceptance must be regarded as an admission of a mind-body relationship that is only too plainly material. It might be argued that the brain is merely a medium for the expression of mental activity, which itself belongs to some non-material dimension and cannot be dissected by instruments of science. If this view is correct, it is surely an invitation to psychologists and others to join in this problem of the borderline, discard unwanted theories and speculation, and contribute in some practical way by the use of a common terminology.—I am, etc.,

Leeds.

P. P. NEWMAN.

Short-term Use of A.C.T.H. in Rheumatoid Arthritis

SIR.—Much has been written about the long-term use of cortisone and A.C.T.H.—some in favour and perhaps more against. Less has appeared in the literature on the value of short courses of these hormones.

There are five main ways in which short courses can perhaps advantageously be applied in this chronic disease: (1) when surgery is necessary during an active phase of the disease; in those cases that flare up after surgery a short course of A.C.T.H. or cortisone may be very helpful; (2) in connexion with the correction of deformity by manipulation, but here intra-articular injection of hydrocortisone is often to be preferred; (3) in tiding over an emergency in a patient with rheumatoid arthritis more or less under control, to cover a period of shock or fatigue, or in convalescence after a severe infection; (4) for the patient that is nearly, but not quite, capable of work, or recently bedridden as the after-effect of an illness, in order to assist rehabilitation to a

slightly higher but vital grade; and (5) for the patient whose condition in spite of all other treatment, rest, gold, etc., continues to deteriorate.

A questionnaire has recently been sent to 30 such cases who have received a course of injections of A.C.T.H. gel 20–30 mg. or A.C.T.H. 60 mg. daily for an average period of three weeks, the dose being gradually tailed off. The patients were asked in retrospect their opinions of the effect of their injections on their "rheumatism" and their general health. While realizing that this is an uncontrolled series of cases and only subjective criteria have been used, the results summarized in the table appear of some interest. In assessing these results it must, however, be remembered that all these cases were deteriorating before treatment in spite of several weeks' rest in hospital and having received all other accepted forms of treatment.

	Much Improved	Slightly Improved	Same	Worse	Total
<i>Joint and Rheumatic Pains</i>					
Directly after treatment	16	9	5	0	30
6 weeks after stopping treatment	8	8	6	8	30
3 months later	2	6	6	6	20
6 " "	2	3	5	4	14
<i>General Health</i>					
Directly after treatment	11	12	5	0	28
6 weeks after stopping treatment	11	6	9	2	28
3 months later	5	5	8	2	20
6 " "	4	2	6	2	14

The results from the questionnaire, from the point of view of general health and feeling of well-being, on the whole ran in parallel with the answers about rheumatic pain and disability. While feeling that the indiscriminate use of hormonal treatment in rheumatoid arthritis is to be condemned, these figures help to bear out a clinical impression that A.C.T.H. in small dosage for a short time may be of value in some of those cases that are progressively getting worse in spite of, and after utilizing, all other accepted methods of treatment.—I am, etc.,

Bath.

G. D. KERSLEY.

Treatment of Pernicious Anaemia

SIR.—A short while ago in this *Journal*,^{1,2} and later in the *Practitioner*,³ I drew attention to a small group of cases resistant to vitamin B₁₂ injections and parenteral liver extracts, which can be satisfactorily treated with oral proteolysed liver. Recently I have studied a further similar patient, and, as I think that these cases are important and have a bearing on research into the treatment of pernicious anaemia, I am now reporting the relevant clinical details of this case.

A female aged 41 first reported ill in May, 1953, giving a short history of diarrhoea, vomiting, lower abdominal pain, pallor, weakness, and dyspnoea on exertion. After admission to hospital it was found that there was slight pigmentation of the conjunctivae with pallor of the mucous membranes. No other physical signs were discovered. The following investigations were carried out to establish the diagnosis: red blood cells 1,920,000 per c.mm.; haemoglobin 44%; white blood cells 4,400 per c.mm. The differential white cell count being: polymorphonuclear cells 66%; lymphocytes 23%; monocytes 1%; eosinophils 10%. The marrow was extremely cellular. The red cell precursors consisted almost entirely of megaloblasts, while the myeloid series showed bizarre formation with atypical mitosis and giant metamyelocytes. The megakaryocytes appeared normal. Red cell fragility, within normal limits; direct Coombs test, negative; barium meal, negative; fractional test meal, no acid was found in the stomach, but after an injection of histamine traces of acid appeared; serum bilirubin, 0.5 mg.%; fat balance test, within normal limits.

A diagnosis of pernicious anaemia in relapse was made. Treatment was started with 100 µg. of vitamin B₁₂ given by intramuscular injection three times a week, and there was no response after 19 days. The red cell count and haemoglobin concentration continued to fall, so a potent intramuscular liver extract was given in doses of 2 ml. every third day, and within

six days a satisfactory reticulocyte peak of 21.4% occurred followed by a steady rise in the red cell count and haemoglobin concentration until the figures reached were 3,500,000 red cells per c.mm. and 60% haemoglobin. She continued to have weekly injections of this preparation and reported at regular intervals to the haematological clinic, where a gradual deterioration in the red cell count and haemoglobin concentration occurred during the next 15 weeks, until the figures reached were 1,540,000 per c.mm. and 38% respectively.

She was readmitted to hospital and fully reinvestigated and similar results were obtained as previously. A diagnosis of megaloblastic anaemia of the Addisonian type refractory to vitamin B₁₂ and parenteral liver extracts was made. Shortly after admission to hospital she was saturated with 1 mg. of vitamin B₁₂, followed by 100 µg. three times a week for 14 days, with no haematological response whatever. Proteolysed liver was substituted in doses of ½ oz. four times a day. On the fourth day there was a dramatic reticulocyte response, the figure remaining between 27% and 22% for the next three days. The marrow reverted to a normoblastic state and there was a gradual rise in the red cell count and haemoglobin concentration, and they are now within normal limits.

From a study of these brief clinical details it must be concluded that this is another example of megaloblastic anaemia distinguishable from Addisonian anaemia which is refractory to both vitamin B₁₂ and parenteral liver extracts and only responds to proteolysed liver by mouth.—I am, etc.,

Birmingham, 18.

Clergy and Doctors

SIR.—I wonder if I may, as an ordinary working clergyman of the Church of England, make a humble request for a far greater measure of co-operation betwixt the general practitioner and the parochial clergy. There seems little doubt that of late there has been an increasing awareness of the importance of the spiritual element in the human psyche, and the part it plays in a properly integrated physical and mental life. Yet so often one still encounters those old antagonisms on the part of medical men which are to my mind redolent rather of the 19th than the 20th century. Scathing comments about "the parson" are still made to patients, and letters addressed to them seeking help and co-operation remain unanswered.

If, of course, such conduct is based on a personal knowledge of the inadequacy of the minister and his lack of professional qualifications, much could be forgiven, but too often it is taken for granted that "the parson" is an incompetent without any effort being made to ascertain either who he is or what he is. I respectfully submit that the rift between the Church and the medical profession is one which must be removed if either is to do its appointed work in the healing of "the whole man." As in all "oecumenical movements," however, progress can only be made by a general willingness to take seriously the essential contributions of each to the common task. Similarly it must begin where the bulk of the work is done, in the hurly-burly of parish and practice.—I am, etc.,

Dorset.

TONY CLEMENS.

Animal Technicians

SIR.—With regard to your statement in the annotation (*Journal*, April 3, p. 808) that the animal technician should be of equal status with the medical laboratory technologist, while I have great respect for the animal technicians, and much sympathy with their efforts to increase their status, may I point out that they are after all only an offshoot of my profession? You yourself point out that for such workers to have a high standard of education is not important. The medical laboratory technologist must, however, have such an education before being even admitted as a student.

You refer also to the animal technician as "a new type of scientific assistant." The days when the medical laboratory technologist was merely an assistant are long gone—except perhaps in certain university laboratories. The work performed by the technologist nowadays is nearly always done without direction, and the subsequent reports are sent out on his responsibility. In fact he may surely, by now, be regarded as a scientist in his own right—albeit a junior one. A further relevant point is that the care of animals is included as an important part of the syllabus of the intermediate examination of the Institute of Medical Laboratory Technology, and I think it is true to say that the animal technician has only come into being because of the increased status of the medical laboratory technologist. Therefore I think that it must be admitted that, if a careful and unbiased study is made of the work and examinations of the medical laboratory technologist, it will be realized that he is of far higher status than a thwarted "groom or kennel maid."—I am, etc.,

St. Helens, Lancs.

A. E. BROWN.

SIR,—With regard to the annotation dealing with "Animal Technicians" (*Journal*, April 3, p. 808), I was staggered by its postulations and inference. To compare the status and training of these no doubt useful people to that of the medical laboratory technologist shows a most ill-informed and, to my mind, ridiculous conception of the work performed in pathological departments.

It must be obvious to all but the most conservative and die-hard of medical men that an extremely large proportion of all laboratory investigations and, in many cases, the interpretation of findings have passed, or are passing, from the domain of the pathologist to that of the technician. It will be found, particularly in the field of blood transfusion serology, that some of the greatest authorities in the country are not medical men but technologists. Doubtless these men would be astounded to learn that the knowledge of a subject which occupies so small a part of their intermediate examination entitles animal technicians to be considered co-equal to themselves. A cursory inspection of the requirements of the Institute of Medical Laboratory Technology would reveal a world of difference to those of the Animal Technicians' Association—a point not overlooked by the Minister of Health in his recent survey of auxiliary services.

Part of the duties of the senior grade technologist is to instruct those duly qualified medical officers who wish to become pathologists. It would seem, therefore, to be more justifiable to state that in many respects the technologist has, or should have, equal status to the pathologist. Since, however, we appear to have taken a retrograde step, after 40 years of progress, it can be taken as an example of the maxim "*Facilis descensus Averno*,"—I am, etc.,

F. MATHER.

Intravenous Iron

SIR,—Recent correspondence (*Journal*, March 6, pp. 583-4) suggests that Dr. J. A. Nissim's article (*Journal*, February 13, p. 352) on reactions following intravenous iron therapy was both timely and stimulating. Since 1947, one of us (F. F.) has given approximately 3,000 injections of iron saccharate, mainly in doses of 100 to 200 mg. Fe. The incidence of early, mild reactions was 0.2%, but we endorse Dr. Jeffrey's comments on the importance of an adequate injection technique. The pH of iron saccharate solutions is about 9.5 or greater, and they are hypertonic, which explains their thrombogenic and locally irritant properties. Slow administration is desirable, and dilution of the solution in the syringe with blood assists in this respect and reduces the risk of paravenous injection.

Dr. Nissim states that these solutions are stable in blood or plasma *in vitro*, although he has previously observed precipitation on lowering the pH of the mixtures.^{1,2} We found that rabbits' plasma containing the equivalent of 0.1% Fe as iron saccharate

immediately precipitated in the pH range of 7.5-7.7, and showed slight turbidity between pH 7.8 and 8.2. A plasma iron concentration of 0.005%, similar to that achieved immediately following a single intravenous dose of 200 mg. Fe (as iron saccharate) to an adult, resulted in initial turbidity over the pH range 6.5 to 7.0 and marked precipitation between pH 6.0 and 6.5. Similar results were obtained at 25° C. and 37° C. These findings might explain the higher incidence of reactions following rapid injection of doses exceeding the recommended maximum of 200 mg. Fe. We suggest that the relative instability of the complex in plasma, as the physiological pH is approached, contributes to *in vivo* precipitation in animals and reactions in man.

Nissim refers to Ramsey's³ suggestion that a sudden increase in reticulo-endothelial activity results in reactions. Although it is true that the administration of certain colloids in large doses to patients is frequently unattended by reactions, we feel that the rate of removal of the colloid, or some fraction of it, by the reticulo-endothelial system might be an important factor. Thus, when an iron complex tends to be unstable in the circulation, its removal is rapid compared with more stable preparations, and the rate of its disappearance is related to toxicity in animals. Since reactions sometimes follow the first administration of saccharated oxide of iron, it is difficult to believe that antigenicity alone is always responsible.

The mean LD₅₀ of 313 batches of iron saccharate solution was found to be 238 mg. Fe per kg. of body weight in mice (standard deviation ± 72). A standard batch repeatedly tested for five years was found to possess a mean LD₅₀ of 231 mg. Fe (standard deviation ± 64). It would appear, therefore, that the LD₅₀ values of Dr. Nissim's solutions (LD₅₀ 180 and 300 mg. Fe/kg. respectively) do not necessarily indicate a significant difference in toxicity and clinical safety. A heated, iron-free, sucrose solution (non-analar) treated as in the preparation of the iron complex, possessed an LD₅₀ > 17.5 g. sucrose/kg. in mice. It would therefore appear that this component does not contribute significantly to reactions, although acute lethal effects in animals are not always related to factors producing reactions in man.

Finally, we believe that this problem will be overcome by the discovery of more stable iron complexes, and especially solutions suitable for intramuscular administration. Since 1951 we have prepared several new iron complexes, one of which is approximately one-third as toxic in mice as iron saccharate solutions. It also possesses increased *in vivo* and *in vitro* stability and does not precipitate in plasma over a very wide pH range. The solution has a pH of 6.0 to 7.0 and is isotonic with tissue fluids, whilst containing the equivalent of 5% Fe. It is well tolerated intravenously or intramuscularly and well absorbed by the latter route, producing satisfactory remissions in hypochromic anaemia in animals and man. The detailed results of these investigations will be reported shortly.—We are, etc.,

FRANK FLETCHER.

Physical Signs of Mesenteric Vascular Occlusion

SIR,—I have recently had under my care two cases of thrombosis of the superior mesenteric artery, which later came to necropsy. In both cases, on examining the abdomen before death, there was a dullness to percussion in the left iliac fossa and resonance in the right iliac fossa and hypochondrium. Although one might expect to find the abdominal wall covering the small bowel dull on percussion due to exudation of fluid into the cavity of the small bowel, it is less easy to explain why the caecum and ascending colon should remain resonant though gangrenous in both these cases. Perhaps it may be merely a question of the greater size and rigidity of the colon.

I should be interested to know whether others have found this a useful physical sign in differentiating the condition from perforated peptic ulcer or general peritonitis.—I am, etc.,

Carshalton, Surrey.

J. F. H. BULMAN.

Ferrous Sulphate Poisoning

SIR,—Following the recent cases of pyloric stenosis after ferrous sulphate poisoning, reported in the *Journal* (August 2, 1952, p. 285; November 28, 1953, p. 1200; and January 16, 1954, p. 156), the following case may be of interest.

On December 23, 1946, a boy aged 2½ was admitted to hospital with a history that he had swallowed approximately 25 of his mother's "fersolate" tablets at 12 noon that day. About one hour later he was screaming with severe abdominal pain which doubled him up. Two hours later he became semi-comatose and was brought to hospital. On examination he was very drowsy but could be roused. His stomach was washed out and a brownish fluid obtained. He subsequently had haematemesis at 3 p.m., 4 p.m., and 9 p.m. He then gradually improved, but on January 14, 1947, began to vomit again and peristalsis was observed in the epigastrium. He became dehydrated. He failed to improve on intravenous saline, suction from an indwelling gastric catheter, lavage with sodium bicarbonate, and atropine methonitrate ("eumydrin"). Accordingly, on January 29, 1947, the child was operated on and a posterior gastro-enterostomy performed. The surgeon noticed a dark blue, semi-necrotic mass of mucous membrane occupying only the distal third of the stomach; the upper two-thirds of the gastric mucosa seemed to be fairly normal. He made an uninterupted recovery. Five years later, March 4, 1952, a barium meal showed that no barium passed the pylorus and that all emptying was taking place by the stoma. I last examined him on January 29, 1953, when he was keeping very well, had no digestive symptoms, and his height and weight were within normal limits. He has also a congenital heart lesion (subaortic stenosis).

This case is similar to those mentioned at the beginning of this letter in that the pyloric end of the stomach was mainly involved, leading to stenosis. I wish to support others who have written to emphasize the need to try and prevent these cases of poisoning with ferrous sulphate. I note that Professor A. G. Watkins and Drs. P. T. Bray and O. P. Gray have seen 15 cases in their department in the past 7 years (*Journal*, February 6, p. 335). It is not sufficient safeguard to state on the label of the bottle that the tablets are dangerous to young children. Dr. I. O. B. Spencer in his excellent article on the subject (*Journal*, November 10, 1951, p. 1112) has suggested wrapping the tablets separately and securely in small packets, and he daily dose separately and securely in small packets, and he mentions that in the German Army Medical Service nearly all tablets were supplied in packets of five. This suggestion seems to have passed unheeded so far by the manufacturers. An alternative suggestion is to make the pills less palatable for children. Some manufacturers now incorporate a bitter substance in the coating of their pills—for example, some of the antihistamine drugs. This practice could be extended to all such pills which have the appearance of children's sweets, and I do not believe this will stop adults swallowing them for therapeutic purposes.

The above case was originally treated by Dr. E. J. Glynn and Mr. N. L. Shepperd. I have only seen the child recently and I thank them for allowing me to publish the details.—I am, etc.,

Bexhill.

LESLIE SCOTT.

"What's What's Syndrome"

SIR,—On opening the *Journal* these days we often see case reports of, shall we say, "What's What's" syndrome associated with gout or "Istheresucha's" syndrome with the less psittacosis, etc. Might I appeal for a definition of the less widely known (e.g., Raynaud's) syndromes by writers referring to them? Too often correspondents either assume that their readers know what they are writing about, or perhaps attempt to impress the less informed. A very recent encyclopaedia is not always at hand to enlighten us, and in one of your recent issues two syndromes were referred to, neither of which is mentioned in a recently published textbook of medicine consisting of over 2,000 pages. Little extra space would be required for a brief statement by your correspondents of what constitutes the syndrome to which they refer. May I enlist their sympathy?—I am, etc.,

Cardiff.

LAMBERT ROGERS.

Cancer of Uterus

SIR,—The letter of Dr. Robert P. Towers (*Journal*, March 20, p. 704) and the paper by Dr. J. W. Magner and Professor W. Kearney (*Journal*, February 20, p. 434) on the relative incidence of carcinoma of the uterine body and cervix prompt us to submit the corresponding figures for East Kent, based on material examined histologically during the period January, 1951, to the present day.

One hundred and twenty primary uterine cancers were encountered. Eighty-one were of cervical origin (80 epidermoid carcinomas and 1 adenocarcinoma) and 39 were endometrial adenocarcinomas, 3 showing extensive epidermoid metaplasia. This 2:1 ratio of cervical to corporeal carcinoma occupies an intermediate position between those recorded in most textbooks and those given by your contributors, who found an equal incidence or a preponderance of endometrial tumours. The material was drawn from a mixed urban and rural community which includes the full range of socio-economic groups. Care has been taken to exclude from our totals cases of carcinoma (all cervical) who attended the radiotherapeutic centre from localities outside the specified area.

We feel that our findings are probably representative of the relative frequency of these two types of carcinoma throughout the country, but evidence from other areas is needed before a conclusion on this point can be reached.—We are, etc.,

Canterbury.

Smoking and Mouth Cancer

SIR,—In commenting on my article "Cancer of the Tongue, Mouth, and Pharynx: Sex Differences in Prognosis following Radiotherapy" (*Journal*, February 20, p. 430), Dr. Phyllis Wade, using lung cancer as an analogy, expresses the opinion (*Journal*, March 27, p. 761) that "prognostic differences which appear to be linked with sex or age could be due, wholly or in part, to differences in smoking habit and/or duration of smoking."

Had my observation been limited to this particular study I should have shared Dr. Wade's opinion and added the smoking factor to the other suggestions described as "three obvious lines of inquiry." It seemed to me, however, that, for the situation to be analogous with lung, one would expect to see not only the worse response to treatment already demonstrated in male patients, but also an increased incidence.

It was stated in the article that incidence rates and their changing pattern (based on a population of approximately 4½ million) are the subject of a separate survey in course of preparation. Measured over an interval of a decade by the calculation of a comparative morbidity index to evaluate the effect of changes in the age-constitution of the population, this survey will show a marked decrease in cancer of the tongue and mouth in men, a substantial increase in women (a trend concealed largely in mortality rates because of the better response to treatment), and an appreciable increase in cancer of the pharynx in both sexes.

Faced with these conflicting trends in incidence and behaviour, I felt loath at this stage to put forward smoking habits as a possible explanation of the difference in results between men and women. Nevertheless, although the picture seems rather complex to me at present, this is not to say that Dr. Wade's suggestion may not prove to be a useful line of investigation.—I am, etc.,

Manchester, 20.

MARION H. RUSSELL.

Recurrent Intussusception in Children

SIR,—The article by Mr. D. A. Macfarlane and Mr. L. P. Thomas on "Recurrent Intussusception in Children" (*Journal*, March 6, p. 559) prompts me to record the experience with this condition at the Royal Belfast Hospital for Sick Children.

While reviewing the results in 200 consecutive cases of acute intussusception admitted over a ten-year period (1943-52), I found that 12 of these young patients had had recurrences, one little girl having had three separate intussusceptions in as many weeks. In four other cases there were histories very suggestive of a previous attack, but not confirmed by operation. Nine of the 12 proven cases were in boys, and two-thirds of the patients were more than 1 year of age—in the entire series of 200 acute intussusceptions, three-quarters of the patients were aged 1 year or less. The interval between attacks varied from 5 days to 19 months, with an average of 6 months, and in only one case was a possible aetiological agent found at the second operation. Two of the patients had had a brother or sister who also had suffered from intussusception, and in half the cases recurrence took place at a different site. All 12 patients survived, although one boy had a burst abdomen—probably the skin stitches should be left in a little longer than usual to prevent a complete breakdown of the wound. Fraser¹ reported a case (not included here) from this hospital of a girl of 2½ years who had had an intussusception on four separate occasions, and Hipsley (quoted by Clubbe²) had a similar case. Wansbrough and Cram³ have also reported a case which recurred three times, and another which recurred four times, but gave no details apart from stating that the recurrences did not take place in the immediate post-operative period.

Your contributors point out that in most cases the aetiology of intussusception is unknown, and theories blaming weaning, etc., have gained credence more by repetition than by any scientific proof. The enlarged glands so often found in many ways resemble those of non-specific mesenteric adenitis of older children, and if they played any part in the aetiology their continued presence might explain the recurrences. Gross⁴ thinks that an enlarged ileo-caecal valve may be responsible and advises the removal of the ileo-caecal part of the bowel if there has been a recurrence, although he is against preventive operations in the treatment of first attacks of intussusception.—I am, etc.,

Belfast.

Burns and the Adrenal

SIR,—Dr. H. F. West's criticism (*Journal*, March 27, p. 763) that my paper on "Adrenocortical Function in Burned Patients" (*Journal*, March 6, p. 541) "does little to clarify the indications for cortisone therapy" requires an answer. The uses of cortisone may be divided into two main groups. First, there are uses based on the physiological correction of a known endocrine deficiency, such as in the treatment of Addison's disease, and, secondly, there are uses based on the pharmacological (may I say "non-specific"?) action of the drug in conditions like rheumatoid arthritis, in which there is no evidence of adrenocortical failure.

In the opening sentence of my article I stated: "This paper is concerned with the activity of the adrenal cortex of burned patients, and in particular with a search for evidence of adrenocortical failure arising during the illness"—in other words, with indications for "replacement" therapy. The pharmacological or non-specific use of the drug in burned patients was outside the scope of the paper. In my opinion only a carefully-controlled clinical trial, involving many patients, could answer whether cortisone is or is not a life-saving measure in some burned patients. This has not been answered in the enthusiastic reports, mainly from the U.S.A., involving the treatment of a few patients. My information is that the initial enthusiasm has waned as experience has grown. It should not be forgotten that cortisone therapy is not without potential danger. A large burn becomes an extensive open wound infected with various bacteria. The infection is difficult enough to control with modern antibiotics, and cortisone therapy might well increase the number of septicæmic complications and the fatality rate.

Both Dr. West and Dr. J. A. Strong (p. 763) make certain criticisms of the methods I used in determining adrenocortical activity. I agree that any indirect method, including those based on changes in the blood eosinophil count, is open to fallacies. So too are the urinary steroid estimations advocated by Dr. West. While such estimations have their use and place, they are even less reliable than the blood eosinophil count. For example, only a very small (about 1%) and apparently variable fraction of parenterally administered cortisone can be recovered from the urine. Only results based on a satisfactory, direct method of determining the changes in the corticoid level of the blood after burning will be free from these criticisms. Such an investigation using polarography is taking place elsewhere in Britain, the results of which will be interesting to compare with my indirect evidence based on the eosinophil count.

Dr. Strong states: "There must be few who regard subcutaneous or intramuscular adrenaline as an adequate adrenocortical stimulus." This is rather surprising, since there is abundant evidence that adrenaline can stimulate the production of A.C.T.H. by the anterior pituitary and thereby induce hyperactivity of the adrenal cortex.¹⁻³ Indeed, the eosinopenia occurring after subcutaneous adrenaline in some adrenalectomized mice can be correlated with the presence of accessory adrenals or with adrenal remnants⁴ and subcutaneous adrenaline is advocated as a test of completeness of adrenalectomy.⁵ Moreover, adrenaline does not have a direct eosinopenic effect on eosinophil leucocytes, since it fails to reduce the eosinophil count in totally adrenalectomized animals. We can safely conclude that eosinopenia following subcutaneous injection of adrenaline into animals with intact adrenals is due to stimulation of the adrenal cortex. The difference of real opinion is in interpreting how much of the eosinopenic activity is due to indirect stimulation of the adrenal cortex (via the pituitary) and how much is due to direct stimulation of the gland. While there is general agreement that adrenaline stimulates the production or release of A.C.T.H., some workers claim that the eosinopenic activity of adrenaline is not entirely due to the release of A.C.T.H. and that adrenaline may directly stimulate the adrenal cortex in hypophysectomized mice.^{6,7} Consequently the difficulty of the adrenaline test is in interpreting how much of the eosinopenia is due to direct stimulation and how much is due to indirect stimulation of the adrenal cortex. In this connexion, the dosage of adrenaline may play an important part. Large doses may directly stimulate the gland, while smaller doses fail to do so. Consequently the dose of 0.3 mg. of adrenaline—a small dose was eliminated the direct stimulatory effect of adrenaline and to increase the selectivity of the adrenaline as an indirect stimulator of the adrenal cortex.

The two patients giving abnormal results with adrenaline were considered worthy of report because repeated tests failed to produce satisfactory eosinopenia during a phase of mental abnormality, and because later the adrenaline became eosinopenic when the mental condition of the children was returning, or had returned, to normal. Would Dr. Strong and Dr. West not agree that the 12 patients in whom the A.C.T.H. tests gave normal results had more stimutable reserves of the adrenal cortex? Would they not agree that the post-burn phase of eosinopenia which occurs in all patients indicates adrenocortical hyperactivity? The interpretations of the abnormal results in two patients were, I had hoped, critically and cautiously dealt with: against adrenocortical failure (Cases 30 and 52). Inactivation of the injected A.C.T.H. may well have been the cause of the abnormal results obtained in Case 52, as there was no other evidence supporting adrenocortical failure.

May I criticize your annotation of my paper (p. 572)? I believe that the main conclusion should be, not "that there is a case for treating some burned patients with cortisone," but that 90% or more of burned patients do not require replacement therapy either with cortisone or A.C.T.H. Finally you state that "patients were found in whom intravenous adrenaline was ineffective" (my italics). This is incorrect: adrenaline was used subcutaneously or intramuscularly.—I am, etc.,

Birmingham, 15.

Fructose in Diabetes Mellitus

SIR,—In your annotation (*Journal*, February 27, p. 510) concerning the intravenous administration of fructose, you state that "fructose may prove to be a more useful sugar in conditions where glucose has a time-honoured place—for example, in the treatment of hypoglycaemia." It is the purpose of this letter to draw attention to another hexose sugar that merits study—namely, mannose.

Mannose is slowly absorbed from the gastro-intestinal tract, but if given intravenously there is every evidence that it is well utilized and capable of forming glycogen in the liver and muscles. As long ago as 1924 mannose was shown to be as effective as glucose, and much better than fructose, in preventing the symptoms of insulin hypoglycaemia in experimental animals.¹ Moreover, like fructose but not like glucose, mannose disappears rapidly from the blood stream in the absence of insulin.² It is as effective as either glucose or fructose in supporting the respiration of isolated brain tissue.³ Mannose is as good as glucose, and much better than fructose, in supporting the metabolic turnover of pentosenucleic acid⁴ and phospholipid⁵ in respiring brain slices. Mannose, like glucose and unlike fructose, can maintain the life of an animal after the removal of the liver⁶ and, again like glucose and unlike fructose, can restore to normal the changes in the electro-encephalogram observed during the progressive hypoglycaemia in hepatectomized animals.⁷

The evidence is that insulin is not necessary for the peripheral utilization of either fructose or mannose, but that mannose, possibly because of its greater affinity for the brain phosphorylating enzyme, hexokinase,⁸ is much more effective in maintaining cerebral functions. It is to be hoped that in any further trials conducted along the lines suggested in your annotation mannose, as well as fructose, will be investigated.—I am, etc.,

London, Canada.

Congenital Hydrocephalus and Vitamin-A Deficiency

SIR,—Having worked for some years on vitamin-A deficiency,¹ I may perhaps comment on your annotation (*Journal*, April 3, p. 809). Your annotator rightly and cautiously underlines the importance of vitamin-A deficiency in the production of hydrocephalus in all 16 rabbits used in the Cambridge experiment.² However, most of the recent experimental work in this field has been carried out on rats. The offspring exhibited in decreasing frequency congenital defects of the eyes, diaphragm, urogenital system, aortic arch, and heart; administration of vitamin A to the deficient mothers at progressively earlier times during pregnancy resulted in a progressive decrease in the rate of malformations.³ It was therefore surprising to learn⁴ that an excessive intake of vitamin A in rats from the second to the sixteenth day of pregnancy causes gross developmental abnormality of the skull with an extrusion of the brain to the external surface of the head as well as more sporadic congenital abnormalities. As the quantity of vitamin A, not only its absence, in the antenatal diet seems to have an important influence on congenital defects, would it not be instructive to repeat the Cambridge experiments with an overdose of vitamin A?—I am, etc.,

Undescended Testicles

SIR,—Dr. G. I. M. Swyer (*Journal*, April 3, p. 815) attacks Dr. N. S. Craig's letter (*Journal*, March 20, p. 706) as being reminiscent of a mediaeval schoolman because, in support of his opinion that hormone treatment of undescended testicles is futile, he follows the universal practice of scientists and quotes published work. What else is he to do? If Dr. Swyer follows up the references he has been given, he will find he is being referred not to opinion nor to authority, but to questions of verifiable fact, that is to say, of gross anatomy. The best way of stopping this method of treatment would be to get its enthusiasts (preferably accompanied by professors of anatomy) into the operating theatre, and there demonstrate to them the structure of the region they treat, and in particular the misconception on which their treatment depends. In my experience, however, this is impossible; and I would suggest that what is really reminiscent of mediaeval theologians is a refusal to examine the truth of statements which conflict with one's own opinions.

I see two or three cases every week which have been diagnosed as "undescended testicles." Of these some 80% are demonstrably normal, that is to say the testicles can, by those who know how to do it, be brought well into the scrotum. The less anatomical knowledge a practitioner has, the less skill in palpation, and the earlier he tackles these cases, the more "cryptorchids" he will find: there should also be a significant increase during spells of cold weather. Quite a number of these normal cases are sent along for operation because hormones have made no difference in their condition; when left alone the testicles take the normal adult position in their own good time. In my experience hormones are quite unreliable as a means of distinguishing the congenital deformities which need operation from the delayed descent which does not.

Originally hormones were written up as a cure for all varieties of cryptorchidism, and testicles were regularly reported as being brought out of the inguinal canal and the abdomen. In fact I have just received a commercial puff which advises that the testicle should not be brought out of the abdomen too rapidly, in order to give time for the processus vaginalis to close behind it in its flight. One early writer stated that so powerful was the action that he had known the testicle descend twenty minutes after the injection: in default of more exact information of what Dr. Swyer means by curing cases "there and then," I regard this as the record.

However, since I described the retractile testicle, and stated that hormone successes only occurred in this variety,¹ these claims are gradually being abandoned. Now hormones are used to distinguish between ectopic and retractile varieties, on the principle that if the treatment succeeds it is shown to have been unnecessary. I see a number of unilateral cases with one testicle well down in the scrotum which have had hormone treatment, apparently on the notion that in their case the natural substances have been confined to one side of the body. In two seen recently injections had gone on for three and four years respectively before hope and finance failed. As to the psychological aspect, worry about the absence of testes from the scrotum is unknown in the small children whose treatment is being advocated, whereas terror and distress are invariably caused by regularly recurring needle pricks. Worry about non-descent comes on late in development when nearly all cases are in need of surgery; it is curiously rare in any event.

Regarding the claim that in the congenital deformities the cord is lengthened by hormone treatment and facilitates operation, I have never found this effect myself, even after years of injections. I should be grateful for a reference to any exact work on this subject. I do know, however, of some interesting though alarming reports of the effect of hormones on the spermatogenic cells of the rats on whom the original work was founded.—I am, etc.,

London, W.1.

DENIS BROWNE.

The Sickle-cell Trait and Sickle-cell Anaemia

SIR.—It is unlikely that any one factor by itself will represent the complete answer to the question why a potentially lethal gene can survive at a high incidence. The particular purpose of this letter is to prevent workers in this field from neglecting three approaches:

(1) *The Anthropological Importance of the Sickling Gene.*—The fact that a gene has a selective value and that its frequency may be influenced by known external conditions such as malaria (Allison¹) does not deter from the fact that knowledge of its distribution will be of value in anthropology. One might as well deny the anthropological value of skin-colour determination on the basis of its being accepted that the pigmentation of a race depends on the climate where this race has been living. All genes exist for one reason or another, and those which we think to be neutral are merely genes of which we have not yet been able to recognize the part they play in evolution. The population of Africa changes rapidly, and tribal barriers may disappear within the next few years. It is hoped that collectors of sickling data will continue to take into account the anthropological classification of the people they investigate.

(2) *The Homozygous-Sickle-cell Anaemia, Heterozygous-Sickle-cell Trait Theory.*—While a very severe sickle-cell anaemia patient will be homozygous for the S gene and a perfectly healthy and normal sickler a heterozygote, there will be a variety of intermediate states. There are factors of which we know yet little (modifiers) which determine the actual quantity of the S haemoglobin in different individuals. Why, for instance, is the proportion of S haemoglobin <50% in S-heterozygotes with normal, and >50% in S-heterozygotes with C haemoglobin? There are other factors which determine that one sickle-cell anaemia patient suffers more from crises than another with the same haemoglobin level. Dr. Edington² has reported that in his experience a sickle-cell anaemia patient may cease having crisis attacks, and I have already commented³ why I thought that this finding might help in explaining that in some areas a discrepancy exists between the number of sickle-cell disease diagnoses and the calculated incidence of S-homozygotes. In the United States I was impressed by the number of known sickle-cell anaemia patients—adults of both sexes and parents of children who had a persistently lowered haemoglobin level of about 9–11 g.%, but who had otherwise no complaints. Such individuals—presumably homozygotes—are not discovered easily, and to search for them in Africa will require careful surveys. A past history (of crises) which would help in recognizing them is rarely available in Africa. Family studies are often quite impossible and the chemical proof of homozygosity by determining the percentage of S-haemoglobin has only recently come to hand. It is therefore likely that more such people exist in Africa and that they hitherto escaped attention. I believe, in retrospect, that I have seen such individuals in Uganda and for that matter in India. Perhaps some of the cases described by Foy⁴ belong to this category. On the other hand, Dr. Edington (*Journal*, April 10, p. 871) is not convinced that sickle-cell crises may not occur in heterozygous individuals. There certainly exists in the United States increasing evidence for yet another condition, a specific intermittent haematuria of sickle-cell trait carriers. No sickle-cell disease patient should be classified as a homozygote unless this has been borne out at least by chemical determination of the haemoglobin composition and if possible also by a family study.

(3) *The Role of Malaria in Maintaining a High Sickling Frequency.*—Edington² and for that matter Choremis and his colleagues⁵ have both claimed the reverse of Brain's⁶ and Allison's⁷ suggestion that there was evidence for Raper's⁸ tentative proposal that sickling protected against malaria (see also Mackey and Viverelli, *Journal*, January 30, p. 276). They stated that malaria seemed to precipitate sickle-cell crises. It is not necessary to assume that such influence of malaria on sickling conditions should necessarily be disadvantageous. Here again it will be important that one should clearly differentiate between sickle-cell anaemia by itself and the anaemia plus the deleterious crisis, the sickle-cell disease. It is striking that sickle-cell disease is found to be frequent where sickling exists in the absence of malaria or where malaria has recently been eradicated: in the U.S.A., in the Lake Kopais area of Greece, and in the last years in certain townships of Africa. Yet although I was shown many sick infants in the Nilgiri hills in India, where malaria incidence is high, I did not see one with sickle-cell crises. It may be said that areas where malaria has been exterminated are also places where medical services are above average and the diagnosis of sickle-cell crisis will be made more often because of better medical facilities. This can hardly explain why an experienced child specialist should be unable to find at any frequency patients with

sickle-cell crises at the most important hospital of Nigeria and yet be able to diagnose the condition in large numbers of people at the University Hospital of Jamaica.⁹ If malaria were to have a protective effect against, or a beneficial modifying effect on, sickle-cell anaemia and sickle-cell crisis, this would be another factor helping in sustaining the gene in malarious areas at a higher frequency than one might expect. Sickle-cell crisis where established has such a serious prognosis that the exploration of any possible beneficially modifying agent would be justified.

There will now be a number of investigations such as Dr. Edington's evaluating elsewhere Dr. Allison's findings in East Africa. I would like to plead that an open mind should be kept as to whether malaria could maintain sickle haemoglobin frequency not only by preferentially killing off the non-sickling homozygotes but also by diminishing the disadvantages of the gene in the sickling individuals.—I am, etc.,

London, E.C.1.

International Nomenclature for ABO Groups

SIR.—Dr. W. Smith (*Journal*, March 13, p. 643) will be interested to know that there is international agreement regarding the nomenclature of the sera used for ABO blood group testing. The World Health Organization set up two international standard sera for ABO blood grouping in 1950¹; these are called anti-A and anti-B, and many countries, including the United Kingdom, have similarly named national standards. All sera for ABO grouping issued by the Blood Group Reference Laboratory have been labelled in this way since 1946, and the same nomenclature was in general use in this country throughout the war. The "Minimum Requirements" of the National Institute of Health, Washington, D.C., U.S.A., which corresponds roughly to the Therapeutic Substances Regulations in this country, have used the nomenclature anti-A and anti-B at least since 1946.—I am, etc.,

The Longevity of Cambridge Sportsmen

SIR.—Sir Alan Rook in his admirable report (*Journal*, April 3, p. 773) has shown why his conclusions are tentative. It could also be argued that the athletic group on entering the university would reasonably be expected to live longer than the control group if it did not participate in strenuous sport. I do not suggest this was the case and obviously this aspect cannot be tested. The conclusions therefore must be tentative. I am, etc.,

New Barnet, Herts.

L. L. WYNN JONES.

Osler Memorial Tablet

SIR.—I read the letter from Dr. L. Carlyle Lyon in your columns in 1952¹ about the placing of an Osler Memorial tablet on his old home in Oxford. Visiting Oxford the other day, I looked in vain for a tablet or plaque on the exterior of No. 13, Norham Gardens, commemorative of the fact that the late Sir William Osler, whom it is no exaggeration to describe as "the world's best doctor," lived there during the whole of his tenure of the chair of medicine at the University till his death in December, 1919.

I beg to request the small amount of space required in your columns to bring this matter, for necessary action, to the notice of all who share my view—I feel they must be many.—I am, etc.,

Tilbury.

Obituary

W. H. S. NICKERSON, V.C., C.B., C.M.G.
M.B., D.P.H.

Major-General W. H. S. Nickerson, who was awarded the Victoria Cross during the South African War, died at his home at Kintyre, Argyllshire, on April 10 at the age of 79.

William Henry Snyder Nickerson was born at New Brunswick, Canada, on March 27, 1875, the son of the Reverend D. Nickerson, who was an Army chaplain. From Portsmouth Grammar School he went on to study medicine at Owens College, Manchester, and graduated M.B., Ch.B. from the Victoria University of Manchester in 1896. Two years later he entered the R.A.M.C. as a lieutenant, and served throughout the war in South Africa from 1899 to 1902, winning the Victoria Cross at Wakkerstroom on April 20, 1900. According to the citation, "Lieutenant Nickerson went, in the most gallant manner, under a heavy rifle and shell fire, to attend a wounded man, dressed his wounds, and remained with him till he had him conveyed to a place of safety."

When war broke out in Europe in 1914 Nickerson, who had by then attained his majority, served with the cavalry in the retreat from Antwerp, and saw further action in the first and second battles of Ypres, at Neuve Chapelle, and on the Somme. Later he served in Salonika. He was mentioned in dispatches six times, promoted to brevet colonel, appointed C.M.G. for his war services in 1916, and C.B. for service in the Black Sea theatre of the war in 1919, in which year he was also awarded the Greek Medal for Military Merit. His promotion was exceptionally rapid all through his Army career, and he was made a major-general at such a young age that when he had served in that rank for the statutory period he was permitted to continue in it for another four years. In 1927 he was appointed Director of Medical Services in India, in succession to the late Sir Walter H. Ogilvie. He was an honorary surgeon to the King from 1925 to 1933, the year he retired. During the last war Major-General Nickerson served variously as a medical officer in an Atlantic convoy, in the Port of London Authority's river emergency service, and in the Home Guard. He married Miss Nan Waller in 1919, and she survives him, together with the son and daughter of the marriage.

Mr. A. E. WYNNE, who died at his home at Margate, Kent, on February 7, was for many years anaesthetist at the Incorporated Dental Hospital of Ireland in Dublin. He was 88 years of age. Albert Edward Wynne was born at Birmingham on September 14, 1865, and had a distinguished career, both academically and on the sports field, at King Edward VI School before he went on to Trinity College, Dublin, to study medicine. He qualified L.A.H. in 1890, taking the Scottish triple qualification in the same year. In 1900 he was elected a Fellow of the Royal College of Surgeons in Ireland, and seven years later he proceeded to the degrees of M.A. and M.D. In Dublin he combined the work of a busy general practice with that of anaesthetist to the Dental Hospital, where he will be long remembered. He continued in practice until his 70th year, when he retired to live at Margate to be near his son, Mr. W. E. C. Wynne, a general surgeon at the Ramsgate and Margate General Hospitals. During the first world war he served as a captain in the R.A.M.C. and acted as assistant surgeon to Drumcondra Hospital. He is survived by his son, Mrs. Wynne having died in 1948.

Dr. CHARLES MELVILLE died on March 25 at the age of 57 after a long illness. Born at Falkirk, he studied medicine at Glasgow University and graduated M.B., Ch.B. in 1920, his studies being interrupted by a period of service in the Army during the first world war. In 1922 he entered general practice at Grangemouth, but managed to continue his studies and took the D.P.H. in 1925. Later he became assistant in the Ear, Nose, and Throat Department of Falkirk Royal Infirmary, and on the retirement of his chief, Dr. George B. Brand, took over full charge of the department. He carried on this work in addition to that of his general practice until the advent of the National Health Service, when he resigned from his practice to devote himself to consultant work. In 1951 the onset of a vascular lesion forced him to give up all active work.

Dr. G. M. FERGUSON writes: Dr. Melville was one of the most widely known and respected members of the profession in central Scotland. As a busy general practitioner for 26 years in Grangemouth, he gained the confidence and affection of his patients for his continuous devotion to their interests, and later as a consultant he merited and obtained the gratitude and trust of his colleagues. He took a leading and energetic part in the affairs of the B.M.A. during most of his career. His work for its charities and as a member of a number of its committees, and his services as chairman of the local panel committee, were recognized in 1948 by a presentation from his colleagues. In the same year he was elected vice-chairman of the executive council, a post which he held until his illness. He was honorary secretary of the Stirling Branch of the B.M.A. from 1927 to 1932 and president of the Branch in 1934–5. He also represented his constituency at eleven Representative Meetings from 1937 to 1948. Dr. Melville was also well known in the world of cricket, captaining both his university and county teams in his younger days and playing for Scotland against the Australians on one occasion. In addition he was an expert angler and deeply interested himself in his later years in the study of bird life. In spite of all these activities, his main interest was always centred in his work, and even during his last illness his greatest desire was to be allowed to continue that work. He had a strong sense of duty, and was a loyal colleague and a trusted friend, unsparing of his own time and health in the service of his patients. His loss will be widely mourned. He is survived by his wife and daughter, both medical graduates, and a son, to all of whom deep sympathy is extended.

Medico-Legal

VICARIOUS RESPONSIBILITY OF HOSPITAL AUTHORITIES

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

The vexed question of the vicarious responsibility of hospital authorities for the negligence of various members of the hospital staff was once more canvassed in the Court of Appeal in the case of *Roe and Woolley v. Minister of Health*,¹ although the appeal was dismissed on grounds which involved no decision upon it.

At the trial Mr. Justice McNair had decided that, if Dr. Graham had been negligent—though in fact the judge found he had not been—the hospital authority would not have been vicariously liable for his negligence. Dr. Graham's position was that he was visiting anaesthetist to the hospital, paid from a fund set aside for the purpose from the hospital funds, and under an obligation with another doctor to provide regular anaesthetic services. Mr. Justice McNair considered that his position was equivalent to that of "consulting physicians and surgeons," and based his decision that the hospital authority as employer was not responsible if Dr. Graham had been negligent on the judgments of Lord Greene in *Gold v. Essex C.C.*² and of

Lord Justice Somervell and Lord Justice Morris in *Cassidy v. Ministry of Health*.^{1,2} He impliedly rejected the judgment in *Cassidy's case* of Lord Justice Denning, which was based upon broader grounds than those of Lords Justices Somervell and Morris. Lord Justice Denning had decided that, since the hospital authority is under a duty of care towards the patient, it cannot escape liability by delegating the performance of the duty to a consultant employed under a "contract for services" any more than by delegating it to a house-surgeon employed under a "contract of service."

In his judgment in the Court of Appeal in *Roe and Woolley's case* Lord Justice Somervell decided that Mr. Justice McNair had been wrong in holding that Dr. Graham was in a position similar to a consultant. In his view the anaesthetists were in the same position as the house-surgeon in *Cassidy's case*. The Lord Justice did not deal with the matter on the wider ground on which Lord Justice Denning had based his judgment in *Cassidy's case*. Lord Justice Denning, consistently with his previous judgment in *Cassidy's case*, held that Mr. Justice McNair was wrong because the hospital authority was vicariously responsible for the negligence of the whole of its staff. Lord Justice Somervell added that the position of hospitals in this respect under the National Health Service Act might be different from that of voluntary or municipal hospitals and would have to be decided when it arose.

By the decision of this appeal the law in England is left where it was left by *Cassidy's case*, and it remains to be seen whether, if the hospital authority's vicarious responsibility for consultants were litigated to the House of Lords, the House would adopt the wider principle as exemplified in the judgments of Lord Justice Denning.

The law as applied in Scotland is the very reverse, and is still based on Lord President Clyde's judgment in *Reidford v. Magistrates of Aberdeen* in 1933, that—

"All the managers undertake to provide an efficient, heated, clean, wholesome sick-house, equipped with the necessary furniture and fittings for the reception of patients; to employ a competent staff; and to provide the necessary medicine and food. But they do not, as I understand any conceivable view of their functions, undertake to treat or to dose or to operate upon any of those who come into their institution."

This sturdy view is broadly the same as had been taken in *Hillyer's case*³ in England. Although attractive, it leads to the sort of logical difficulties expressed by Lord Goddard in *Gold's case*, where he said: "I cannot understand on what principle a hospital authority is to be exempt from liability if a nurse carelessly administers a dose of poison to a patient instead of medicine, and yet is liable if the cook mixes some deleterious substance in the patient's food."

Although in many fields the law of England and the law of Scotland are wholly different, negligence is not in theory one of those fields. It is evidently high time some gallant litigant on one side of the Border or the other appealed to the House of Lords to give that august tribunal the opportunity to resolve the conflict.

The Services

Major-General A. G. Harsant, C.B., O.B.E., late R.A.M.C., has relinquished his appointment as Director of Surgery and Consulting Surgeon to the Army.

Lieutenant-Colonel J. D. Galloway, R.C.A.M.C., has been appointed O.B.E. (Military Division) in recognition of gallant and distinguished services in Korea.

Colonel F. R. Langmaid, O.B.E., T.D., R.A.M.C., T.A., has been appointed Honorary Physician to the Queen in succession to Colonel F. R. Sandford, C.B.E., M.C., T.D., who has been transferred to the T.A.R.O.

Medical Notes in Parliament

Welfare Foods

Sir GUY LLOYD (Renfrew, East, Con.) asked the Minister of Food what were the proportions of welfare foods available through his department for children and expectant mothers that were being taken up. Major LLOYD GEORGE stated on April 12 that about 97% of those entitled to obtain milk or national dried milk under the welfare foods service did so. The quantities of the vitamin supplements taken up in 1953 expressed as a proportion of the full entitlement were as follows: orange juice 29.4%; cod-liver oil 23.8%; vitamin tablets 32.6%. The percentage of persons who obtained the vitamin supplements was higher than these figures suggested, because many did not take up their full entitlement.

Clean Food Rules

Lieut.-Col. M. LIPTON (Brixton, Lab.) asked the Minister of Food on April 14 what representations he had received from the National Caterers' Federation relating to the Food and Drugs (Amendment) Bill, and what reply he had sent. Dr. CHARLES HILL, the Parliamentary Secretary, said that the department received a letter and memorandum from the Federation on March 16 expressing certain views about the new legislation and suggesting further consultation with trade interests about the form of public food hygiene regulations. They attended a conference on April 5 and made a number of points, which would be carefully considered.

Iodized Salt

Mr. J. B. HYND (Sheffield, Attercliffe, Lab.) asked the Minister of Food whether he had considered, in connexion with the proposed legislation for the compulsory use of iodized salt, the number of people who were allergic to iodine, and whether he would give the House assurances on their behalf. Dr. CHARLES HILL, the Parliamentary Secretary, replied on April 14 that no decision had yet been taken to add iodine to salt. Before any such decision was taken full consideration would be given to the point raised.

Tuberculosis Among Kikuyu

Mr. SOMERVILLE HASTINGS (Barking, Lab.) asked the Secretary of State for the Colonies on April 14 what percentage of Kikuyu prisoners were suffering from tuberculosis, and what precautions were being taken to prevent the spread of this disease among the prisoners. Mr. H. L. HOPKINSON, the Minister of State, said that he would obtain the figure from Kenya. The following precautions were taken against the spread of the disease: regular inspection by medical officers of hygiene conditions in all prisons; medical examination of all convicts on admission to prison; special diets and medicine for all convicts in low physical condition; isolation of all tuberculosis suspects; and evacuation of all infected cases to tuberculosis wards in the prison hospital in Nairobi.

Diphtheria Inoculations in Scotland

Mr. JAMES STUART, Secretary of State for Scotland, supplied Mr. S. P. VIANI (Willesden, West, Lab.) with figures showing the estimated percentages of children under 15 years and under 5 years of age in each Scottish county who had been inoculated against diphtheria. Those under 15 ranged from 96% in Peebles to 45% in Orkney, and those under 5 from 99% in Midlothian to 34% in Orkney.

Cancer Experiments on Mice

Sir DAVID MAXWELL FYFE, Home Secretary, informed Mr. PETER FREEMAN (Newport, Lab.) on April 15 that since 1907, when records were first kept, to the end of 1952, a total of 1,367,820 experiments had been made on animals—almost all of them on mice—for cancer research. He gave the list of annual totals, which (apart from war years) varied

between 8,083 in 1924 to 95,991 in 1952. In the early years 1907-11 the numbers were between 40,000 and 49,000, then fell to 24,000 and continued falling until 1928, spurted to 43,000 and 50,000 in 1933 and 1934, fell again until 1947, and since 1948 have been 56,585, 75,343, 78,192, 91,410, and 95,991 respectively.

Dental Technicians

Mr. R. E. WINTERBOTTOM (Sheffield, Brightside, Lab.) drew attention on April 15 to unemployment among dental technicians, and the loss of highly skilled craftsmen to the Health Service, which he attributed to the cuts in the Service.

Miss PAT HORNSBY-SMITH, Parliamentary Secretary to the Ministry of Health, disputed this, and suggested that the cause was that there had been too many entrants. In 1950, owing to the immediate and high demand, 5,000,000 dentures were supplied under the Health Service. Even without the imposition of the charges for dental treatment the level of 5,000,000 could not possibly have been maintained. In 1953 the number of dentures supplied was 2,000,000, and she thought this figure would represent the average annual demand for some years, and she hoped that it would gradually get less as the effect of greater emphasis on conservation work became apparent.

Myxomatosis Outbreaks

Mr. G. R. H. NUGENT, Parliamentary Secretary, Ministry of Agriculture, informed Mr. A. HURD (Newbury, Con.) on April 15 that there were 17 established centres of myxomatosis infection among rabbits, five of which had been confirmed in the past month. The Minister would report from time to time on the spread of the disease into new areas, but weekly statements for which Mr. Hurd had asked did not seem justified at present. The advisory committee would continue to watch closely the extent and character of the outbreaks.

Coroners Bill.—The Coroners Bill was given a third reading in the House of Commons on April 9 and has been sent to the House of Lords.

Universities and Colleges

UNIVERSITY OF OXFORD

The following elections are announced: To the War Memorial Medical Scholarship at University College, I. G. McGill (Bablake School, Coventry); to a Nuffield Scholarship in Medicine at Pembroke College, D. C. E. Speller (Caterham School); to a Nuffield Medical Scholarship at Worcester College, W. R. A. Muntz (Oundle School); to a Nuffield Scholarship in Medicine at Somerville College, S. N. Clayton (St. Felix, Southwold); to an Exhibition in Medicine at St. Hugh's College, G. M. Roberts (North London Collegiate School).

UNIVERSITY OF LONDON

The following candidates have been approved at the examinations indicated:

ACADEMIC POSTGRADUATE DIPLOMA IN MEDICAL RADIOLOGY (DIAGNOSIS).—P. L. Brangwin, Edwina R. Goodall.

ACADEMIC POSTGRADUATE CERTIFICATE IN PUBLIC HEALTH.—*London School of Hygiene and Tropical Medicine*: G. A. Ademola, Doreen P. Allan, N. K. Bharucha, D. W. Boatman, S. C. Bose, H. H. S. Brown, J. Chatterjee, H. J. S. Coldham, C. P. Collins, L. P. Darmanin, C. B. Drew, Y. G. Farran, E. R. Gauld, G. S. Godiwalla, G. McL. Gorrie, Catriona M. Gourlay, A. Grut, K. L. Gupta, T. B. Harrison, M. A. Heasman, F. M. James, H. James, B. Lall, R. J. Lande, I. Laufer, W. S. Millar, S. L. Morrison, B. J. L. Moss, H.-H. Mueller, K. W. Newell, Joycelyn Quantrell, C. J. Radway, D. H. Shennan, Rachel E. W. Sillett, C. Slome, C. I. Somaya, R. J. K. Tallack, Pin Hui Teng, A. E. P. Twort, K. L. Vasa, R. B. Walker, F. A. Wickremasinghe, F. Zangen.

ACADEMIC POSTGRADUATE CERTIFICATE IN TROPICAL MEDICINE AND HYGIENE.—*London School of Hygiene and Tropical Medicine*: L. Noronha.

J. M. Ledingham, M.D., M.R.C.P., Lecturer in Medicine at the London Hospital Medical College, has been appointed to the University Readership in Medicine tenable at that College.

The following candidates have been approved at the examinations indicated:

M.D.—Part I: C. P. T. Alexander, J. A. S. Amos, P. B. Cook, P. W. Darby, Katharine M. Dormandy, J. H. Evans, J. T. Groves, C. P. Handforth, P. M. Higgins, Margaret A. Holroyde, E. T. Hughes, A. R. Kagan, C. S. Livingstone, Eunice Lockey, C. J. Lucas, R. P. Michael, G. R. J. Moodie, R. Moore, J. D. Pollit, F. C. Rose, A. L. Slater, C. K. M. Thacker.

M.S.—Part I: P. J. W. Monks.

Professor Charles Singer has been appointed to represent the University at the XIVth International Congress of History of Medicine, to be held at Rome and Salerno from September 13 to 20, 1954.

Professor J. M. Mackintosh has been re-nominated for appointment as a representative of the University on the governing body of the London School of Economics and Political Science.

The following have been appointed representatives of the University on the committees of management of the federated and associated institutes of the British Postgraduate Medical Federation, indicated in parentheses, for the three years ending December 31, 1956: Dr. C. F. Harris and Dame Lillian Penson (Institute of Basic Medical Sciences); Mr. W. P. Cleland (Institute of Cardiology); Professor W. E. Herbert (Institute of Dental Surgery); Sir Archibald Gray (Institute of Dermatology); Dr. E. Bonham Carter (Institute of Diseases of the Chest); Mr. V. E. Negus (Institute of Laryngology and Otolaryngology); Professor R. W. Russell (Institute of Neurology); Professor W. C. W. Nixon (Institute of Obstetrics and Gynaecology); Professor J. Z. Young, F.R.S. (Institute of Orthopaedics); Professor F. R. Winton (Institute of Psychiatry); Mr. D. F. Ellison Nash (Institute of Urology).

Professor J. E. Roberts and Professor J. Whillis will be the representatives of the Board of Pre-clinical Studies on the Board of Advanced Medical Studies for 1954.

The following have been recognized as teachers of the University in the subjects indicated in parentheses: *London Hospital Medical College*, Mr. Geoffrey Flavell (Surgery); *Charing Cross Hospital Medical School*, Dr. H. I. Winner (Pathology); Dr. J. B. E. Baker (Pharmacology); *University College*, Dr. M. de B. Daly (Physiology); *Guy's Hospital Medical School*, Dr. J. A. Nissim (Pharmacology).

Mr. J. B. Kinmonth has been appointed a representative of the Board of Advanced Medical Studies on the Special Advisory Board in Veterinary Medicine, in place of Sir James Paterson Ross, who has resigned.

The following have been recognized as teachers of the University in the subjects indicated in parentheses: *St. George's Hospital Medical School*, Dr. J. A. Dudgeon (Pathology); *Institute of Psychiatry*, Dr. A. D. Leigh, Dr. D. A. Pond, Dr. P. D. Scott, and Dr. F. K. Taylor (Psychiatry); *University College Hospital Medical School*, Dr. E. N. Rowlands (Medicine).

UNIVERSITY OF EDINBURGH

At a Graduation Ceremonial held on December 18, 1953, the following degrees and diplomas were conferred:

M.D.—R. C. Humphreys, J. D. Kerr, T. W. Lees, R. G. Mitchell, C. F. Rolland.

Ch.M.—A. I. S. Macpherson.

Ph.D.—*In the Faculty of Medicine*: W. St. C. Bauld, D. S. Chowdhary, M. Ishaq. *In the Faculty of Science*: A. B. Monro.

M.B., Ch.B.—A. McI. Anderson, B. R. Bayne, A. T. Burnet, G. Gilray, I. B. Grant, Christine F. Hannah, J. L. Leadbitter, W. D. W. Miller, Jadwiga M. Weyndling.

DIPLOMA IN MEDICAL RADIODIAGNOSIS.—G. M. Ashurst, A. A. Donaldson, H. Gardner, H. Levon, Margaret C. Macleod, A. M. Stewart.

DIPLOMA IN MEDICAL RADIOTHERAPY.—N. R. Mackay, J. McLelland, J. Newall, J. G. Pearson.

The following scholarships, etc., in the Faculty of Medicine were awarded: *Wilkie Surgical Research Scholarship*, H. A. F. Dudley. *Andrew Graham Ritchie Bursaries*, C. J. W. Huston and Rosemary McCredie. *Mackie Bursaries*, J. B. Rae and J. T. Wilson. *E. B. Jamieson Prizes in Anatomy*, Joan E. G. Cave. I. D. Heath, C. J. W. Huston, Joan L. Young. *Russell-Crichton Prize*, D. Dow.

¹Highly commended for thesis. ²Commended for thesis. ³In absentia.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At the annual meeting of the College held on December 3, 1953, Dr. L. S. P. Davidson was elected President, Dr. Ian G. W. Hill, C.B.E., T.D., was elected Vice-President, and the following were elected Members of Council: Dr. Edward R. C. Walker, Dr. W.

Lindsay Lamb, Dr. I. Simon Hall, Dr. R. M. Murray-Lyon, and Dr. Thomas Anderson. Dr. J. Halliday Croom was reappointed Secretary, and Dr. J. Alastair Bruce was reappointed Treasurer.

At a quarterly meeting of the College held on February 2, with the President, Professor L. S. P. Davidson, in the chair, the following were elected Members of the College: J. H. Bowie, B. Ghosh, M. E. Mahdi, S. S. Manchanda, J. C. Simson, C. W. Marsden, J. B. Mackay, K. P. N. Pai, K. Parameswaran, H. Klevansky, G. Larkins, S. N. Sengupta, W. B. Muston, A. Horden, M. K. El Shawarby, I. C. Brannen, N. Radhakrishnan, J. A. Clark, J. Hampson, C. R. R. Pillay, S. A. R. Ali, V. P. Datta, M. H. M. Gaber, P. N. Mathur, R. G. Willison.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At a meeting of the College held on December 16, 1953, with Professor Walter Mercer, President, in the chair, the following were admitted Fellows after having passed the requisite examinations: S. Ansari, G. O. Clark, A. K. Das, R. A. Daws, D. C. D'Netto, F. H. Gamali, A. Ghani, P. Goldstein, I. M. Grant, W. McI. S. Ironside, F. D. Johnston, R. N. Katariya, G. Kerridge, P. Kilburn, J. S. Lekias, I. Opekin, M. G. Pearson, M. Q. K. Raja, J. R. Salas, G. R. T. Serpell, R. P. Sharma, P. R. Shroff, A. M. Shukri, E. H. J. Smyth, M. J. Twohig, W. B. Young.

Vital Statistics

Some Vital Statistics of 1953

The estimated home population of England and Wales at December 31, 1953, was 44,166,000 (21,249,000 males, 22,917,000 females).¹ This is an increase of about 420,000 since the 1951 census. Projections of the population show that, on certain assumptions, the total population will increase to 45,378,000 in 1963, 46,175,000 in 1973, and 46,617,000 in 1983, declining to 46,382,000 in 1993. On the basis of the death rates for the year 1952 the expectation of life of a boy at birth is 67.06 years and of a girl 72.35. This compares with 48.53 and 52.38 respectively on the basis of the death rates for the years 1901-10.

Deaths from accidental poisoning rose, reaching 659 in the first three quarters of 1953 compared with 586 during the corresponding nine months of 1952, while deaths from accidental burns dropped from 593 to 522. The number of suicides increased in the same period from 3,299 to 3,541.

In the December quarter the death rate per 1,000 population in Greater London was 9.8. This compared with 10.1 in New York and Copenhagen, 9.0 in Stockholm, 8.7 in Oslo, and 8.2 in Rome. A comparison of death rates of children under 1 year of age in September quarter, 1953, shows that the England and Wales rate of 22 per 1,000 related live births compared with Netherlands 19, Australia 25, U.S.A. 26, Scotland 28, France 33, and Italy 64.

Venereal Diseases

In England and Wales during the quarter ending September 30, 1953, 1,446 new cases of syphilis were reported as attending the clinics. Of these, 256 were classified as primary, secondary, or latent in first year of infection. 23 cases of congenital syphilis in children aged under 1 year were reported, and 172 cases in people over that age. New cases of gonorrhoea numbered 5,588, of chancroid 84, and of non-gonococcal urethritis (males only) 3,682.

Northern Ireland in 1952

Live births numbered 28,760 in Northern Ireland in 1952, giving a rate of 20.9 per 1,000 population. This was 0.2 above that for 1951 but 0.8 below the average rate for 1947-51. The infant mortality rate was 39 per 1,000 live births, the lowest so far recorded in Northern Ireland. The total number of deaths registered was 14,812, giving a rate of 10.8 per 1,000 population. This was 2.0 below the rate for 1951, and 1.1 below the average rate for 1947-51. The

¹ Registrar-General's Quarterly Return No. 420. H.M.S.O., 2s.

death rate from tuberculosis continued to fall, being 0.3 per 1,000 population as compared with the average rate of 0.39 for 1947-51.

England and Wales in First Quarter

The incidence of infectious diseases was generally below the average of the first quarter, the only exceptions being dysentery and enteric fever. The number of notifications of dysentery has steadily increased throughout the quarter from 322 in the first week to 1,642 in the thirteenth. The high level of enteric fever was due to the recent outbreak of paratyphoid fever in South Wales: 170 of the 244 cases of enteric fever were notified in Wales. The fall in the number of notifications of diphtheria was quite small, and it seems that an irreducible hard core of infection is being reached.

A comparison of the number of notifications for the last five first quarters is given below:

Disease	1950	1951	1952	1953	1954
Scarlet fever	24,802	12,088	18,013	20,550	15,868
Whooping-cough	23,619	66,865	35,042	34,207	28,985
Diphtheria	955	572	456	264	246
Measles	54,568	311,709	64,596	350,836	23,340
Acute pneumonia	13,720	26,536	12,960	20,005	10,507
Meningococcal infections	536	662	562	595	515
Acute poliomyelitis	512	339	288	345	332
Dysentery	3,938	13,995	6,936	4,449	10,808
Enteric fever	154	149	126	123	244

Infectious Diseases

The largest fluctuations in the trends of the notifications of infectious diseases in England and Wales during the week ending April 3 were increases of 327 for dysentery, from 1,315 to 1,642, and 263 for measles, from 2,067 to 2,330, and a decrease of 132 for acute pneumonia, from 661 to 529.

The largest increases in the notifications of measles were 91 in Cumberland, from 58 to 149, and 90 in Lancashire, from 339 to 429, and the largest decrease was 56 in Staffordshire, from 264 to 208. 1,474 cases of scarlet fever, 18 fewer than in the preceding week, were notified, and only small fluctuations were reported in the local trends. The number of notifications of whooping-cough were 2,546, being 7 fewer than in the preceding week, and the only large variation in the returns was an increase of 59 in Yorkshire West Riding, from 143 to 202. 22 cases of diphtheria were notified, being 8 more than in the preceding week. The chief features of the returns for diphtheria were a rise in Lancashire from 3 to 6 and in Durham from 0 to 3.

The number of notifications of paratyphoid fever declined from 20 to 11 and in Wales from 17 to 7. The chief centre of infection was Glamorganshire 5 (Cardiff C.B. 4).

21 cases of acute poliomyelitis were notified. These were 1 fewer for paralytic and 2 fewer for non-paralytic than in the preceding week. The largest returns were Warwickshire 4 (Birmingham C.B. 3), Somersetshire 3, and Nottinghamshire 3 (Beeston and Stapleford U.D. 2).

The notifications of dysentery were the largest since this disease was made notifiable in 1919, except for the week ending March 17, 1951, when 1,672 cases were notified, 30 more than in the week reviewed here. The largest returns were London 266 (Islington 84, Lewisham 36, Chelsea 29, Hackney 19, Hampstead 12, Shoreditch 10), Lancashire 226 (Salford C.B. 57, Bolton C.B. 30, Manchester C.B. 20, Eccles M.B. 20, Preston C.B. 13, Liverpool C.B. 10, Worsley U.D. 10), Yorkshire West Riding 198 (Brighouse M.B. 47, Bradford C.B. 26, Leeds C.B. 26, Hebden Royal U.D. 22, Dewsbury C.B. 21, Sheffield C.B. 19, Keighley M.B. 13), Leicester 121 (Leicester C.B. 115), Middlesex 107 (Hornsey M.B. 28, Southall M.B. 18, Willesden M.B. 18, Ealing M.B. 10), Carmarthenshire 86 (Carmarthen M.B. 81), Berkshire 78 (Maidenhead M.B. 69), Essex 64 (West Ham C.B. 16, Walthamstow M.B. 12), Norfolk 52 (Norwich C.B. 51), Surrey 47 (Epsom and Ewell M.B. 37), Kent 45 (Margate M.B. 28), Warwickshire 45 (Birmingham C.B. 35), Oxfordshire 41 (Oxford C.B. 36), Devonshire 40 (Exeter C.B. 34).

Staffordshire 37 (Cannock U.D. 20), Cheshire 30 (Ellesmere Port U.D. 29), Sussex 23 (Hove M.B. 13), and Gloucestershire 20 (Bristol C.B. 12).

In Scotland dysentery reached a new high level with 438 notifications. The largest returns were 235 in Glasgow, 89 in Lanark county, 42 in Edinburgh, and 35 in Dundee.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1945-53 are shown thus -----, the figures for 1954 thus -----. Except for the curves showing notifications in 1954, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending April 3 (No. 13) and corresponding week 1953.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1954					1953				
	Eng. & Wales	Lon.	Scot.	N. Ire.	Eire	Eng. & Wales	Lon.	Scot.	N. Ire.	Eire

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Medical News

Holiday Exchanges Abroad.—The International Medical Visitors' Bureau of the British Medical Association is able to assist doctors in Britain, through the medical associations of the countries on the Continent, to find medical families on the Continent interested in arranging holiday exchanges for their children, *au pair* visits for older children, or occasionally exchange of houses. Last year more than 50 families (Continental and United Kingdom) are known to have made satisfactory exchange arrangements. Notices about exchange hospitality wanted by Continental doctors are published from time to time under "Notes and News" in the *Supplement*. Anyone interested in this scheme should write, giving full details, such as children's ages, when and where they would like to go, what facilities are offered in this country, etc., to Brigadier H. A. Sandiford, Medical Director, International Medical Visitors' Bureau, B.M.A. House, Tavistock Square, London, W.C.1.

Residential Unit for Psychotic and Maladjusted Children.—In every area there are some children who are so mentally disturbed that they cannot attend any recognized school, or benefit by treatment in child guidance clinics or hospital psychiatric departments. To meet their need the North-west Metropolitan Regional Hospital Board has established a small residential unit in a large country house, "High Wick," near St. Albans. The unit aims to provide a stable, friendly environment and the necessary psychotherapy for about 20 psychotic and maladjusted children aged between 3 and 10 years. It will be staffed by a matron, a teacher, and house mothers, each of whom will endeavour to establish and maintain a continuous relationship with the individual children. The Mid-Herts Group Management Committee, which is responsible for the unit, regards it as experimental in nature, and its development will be guided by experience of its working. The unit opened officially on April 23.

Royal College of Surgeons of England.—On April 18 the council met for the last time in the old Council Room of the College which has been used for these meetings for over 100 years. The next meeting will be in the new room in the rebuilt College. The honorary Fellowship was conferred on Dr. G. Gavin Miller, of Montreal, and the following were admitted to the Fellowship without examination as medical practitioners of at least 20 years' standing: Mr. J. W. H. Grice (Tunbridge Wells), Mr. D. M. E. Thomas (Sully, Glamorgan), Professor G. Hadfield (London), Professor J. Trueta (Oxford), and Mrs. D. R. Campbell (Coventry). Others admitted to the Fellowship were Mr. W. A. Jackman (Bristol) and Mr. R. R. Simpson (Hull). Dr. W. D. Paton, reader in pharmacology and therapeutics at University College Hospital Medical School, London, was admitted as the first professor of pharmacology at the College.

British Cardiac Society.—The thirty-third annual general meeting of the British Cardiac Society was held at Downing College, Cambridge, on April 9 under the chairmanship of Dr. Leslie Cole. Both the morning and afternoon sessions were devoted to short communications, and included papers on the pathological lesion in endomyocardial fibrosis, baroreceptor responses in acute rhythm change, the diagnosis of mitral incompetence by cardiac catheterization, a review of 30 cases of isolated pulmonary stenosis, valvotomy for both acquired and congenital aortic stenosis, and the action of hexamethonium bromide on the pulmonary circulation in mitral stenosis. A dinner was held in college.

Conference on Industrial Atmospheric Pollution.—The British Occupational Hygiene Society held a conference on April 6 at the London School of Hygiene and Tropical Medicine to discuss problems of atmospheric contamination in industry. In his opening address, Professor E. J. King,

the president, thanked Dr. Thomas Bedford, on behalf of members, for his work in founding the Society and for leading it through its first year of life. He also welcomed visitors from overseas. The papers presented at the conference were "The Investigation and Control of Atmospheric Contaminants in Factories," by Drs. M. W. Goldblatt and J. C. Gage, of the Industrial Hygiene Laboratories, I.C.I., Ltd.; "The Measurement of Dust Exposure," by Dr. B. M. Wright, of the Medical Research Council's Pneumoconiosis Research Unit; and "Permissible Levels of Exposure to Ionizing Radiations and Radioactive Materials," by Dr. W. G. Marley, of the Atomic Energy Research Establishment, Harwell. The conference was attended by 150 members and visitors. Copies of the proceedings will be available from the Hon. Secretary, Mr. Peter C. G. Isaac, Public Health Engineering Laboratory, King's College, Newcastle-upon-Tyne.

Jacksonian Prize.—The 1953 prize was awarded by the council of the Royal College of Surgeons to Mr. J. H. Peacock, lecturer in surgery at Bristol, for his essay on "Pathology and Surgery of Peripheral Vascular Occlusion." The subject for the 1955 Jacksonian prize essay will be "Diaphragmatic Hernia."

Metropolitan Regional Board's Clinical Prizes. Last year we announced that the South-west Regional Hospital Board was offering up to nine £100 research prizes during 1953 (*Journal*, January 31, 1953, p. 283). A similar competition is being held this year. The winners in last year's competition were:—*Consultants and S.H.M.O.s*: Dr. M. Hamilton, Dr. A. M. Read, and Dr. D. A. J. Williamson; *Senior Registrars and Registrars*: Mr. G. Bennett, Dr. G. S. Crockett, and Dr. C. Donovan; *House Officers*: Mr. A. O. Wilson and Mr. M. Wynyard.

Sir Russell Brain, P.R.C.P., has been elected an honorary Fellow of the American College of Physicians.

Irish Honorary Degrees.—On April 8 the honorary degree of LL.D. of the National University of Ireland was conferred on Dr. E. P. Carey, president of the Graduates Club of the N.U.I. in London for six years, and on Dr. P. P. Lynch, a member of the Dental Council and the Medical Research Council of New Zealand.

Professor G. I. Strachan, professor of obstetrics and gynaecology in the Welsh National School of Medicine, is to receive the honorary degree of LL.D., Glasgow University, at a ceremony on June 16.

COMING EVENTS

Renal Association.—The annual general meeting will be held at the Ciba Foundation, 41, Portland Place, London, W.1, on April 28 at 4.30 p.m., not on May 28 as stated in our issue of April 17, p. 943.

Hunterian Society.—The annual general meeting will be held at the Talbot Restaurant, London Wall, E.C.2, on April 26 at about 8.30 p.m. It will be preceded by the fourth dinner meeting at 7 for 7.30 p.m. An address will be given by Mr. W. R. Le Fanu, librarian of the Royal College of Surgeons, on "The Hunter-Baillie Manuscripts." Further information from Mr. R. S. Murley, 95, Harley Street, London, W.1.

Contraceptive Technique.—A lecture and demonstration will be given by Dr. Marie Stopes, Ph.D., at the Mothers' Clinic, 108, Whitfield Street, London, W., on May 6 at 2.30 p.m. Tickets must be obtained in advance.

Christian Medical Fellowship.—A week-end house party will be held at the Belsfield Hotel, Windermere, from May 7 to 10, and a week-end conference at the Linden Hall Hydro, Bournemouth, from May 21 to 24. Details are obtainable from the secretary of the Fellowship, 39, Bedford Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Monday, April 26

ASSOCIATION OF PSYCHIATRISTS: SOUTH-WEST METROPOLITAN REGION.—At B.M.A. House, 5.30 p.m., general meeting.
● HUNTERIAN SOCIETY.—At Talbot Restaurant, 64, London Wall, E.C.2, 7 for 7.30 p.m., annual general (dinner) meeting. Mr. W. R. Le Fanu: Hunter-Baillie MSS. in the Library of the Royal College of Surgeons.
ROYAL EYE HOSPITAL.—5.15 p.m., Dr. T. H. Whittington: The Hypermetropic Patient. Astigmatism. Bifocals.

Tuesday, April 27

ROYAL STATISTICAL SOCIETY: STUDY CIRCLE ON MEDICAL STATISTICS.—At Westminster Medical School, 6 p.m., Discussion of the Report of the Working Party set up to examine the Assessment of the Need for Clinical Services.
SOCIETY FOR ENDOCRINOLOGY.—At Royal Society of Medicine, 5.15 p.m., special lecture by Dr. G. Pincus: Pathways of Steroid Synthesis in the Animal Organism.
WEST END HOSPITAL FOR NERVOUS DISEASES.—5.30 p.m., neurological demonstration by Dr. T. Rowland Hill.

Wednesday, April 28

BIRMINGHAM MEDICAL INSTITUTE: SECTION OF PSYCHIATRY.—At Queen Elizabeth Hospital, Birmingham, 8 p.m., clinical meeting.
INSTITUTE OF DENTAL SURGERY.—5.30 p.m., Dr. R. W. G. Wyckoff: Significance of the Electron Microscope in Biology and Medicine.
RENAL ASSOCIATION.—At Ciba Foundation, 4.30 p.m., annual general meeting. Mr. L. H. Griffiths: Renal Arteriography; Dr. R. M. Gaunt: Studies on the Experimental "Eclampsia-like" Syndrome.
ROYAL EYE HOSPITAL.—5.30 p.m., Mr. L. H. Savin: Ophthalmic Neurology (4).
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Dr. T. A. H. Munro: lecture-demonstration in psychiatry.

Thursday, April 29

BRITISH INSTITUTE OF RADIOLOGY.—8 p.m., 33rd Sir Ivan Thompson Memorial Lecture by Professor J. K. Robertson: An Experiment in Medical Education.
INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., Professor F. C. Ormerod: Some Aspects of Sinusitis.
● INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Hammersmith Hospital, 2 p.m., Professor A. Duncan: Histamine and Histamine in Pregnancy.
INSTITUTE OF PSYCHIATRY.—5.30 p.m., Dr. Gregory Pincus (Massachusetts): Steroids in Aging.
LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Medical Society of London, 8.30 p.m., debate: That Quackery Plays a Useful Part in Medicine To-day. Proposed by Dr. M. Marcus and Dr. S. H. Chazen; opposed by Dr. D. Preiskel and Mr. I. Preiskel.
LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5 p.m., special university lecture in hygiene and public health by Dr. E. L. French (Melbourne): Epidemiological Aspects of Murray Valley Encephalitis.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor I. P. Todd: Role of Elective Surgery in the Management of Diverticulitis of the Colon.
ROYAL EYE HOSPITAL.—5.15 p.m., Dr. T. H. Whittington: Non-paralytic Squint—The Aim of Modern Methods of Treatment.
ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Mr. W. M. Dennison: Advances in Surgery of Infancy and Childhood.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., neurology demonstration by Dr. J. H. Paterson.

Friday, April 30

BRITISH INSTITUTE OF RADIOLOGY.—5 p.m., meeting of medical members.
FACULTY OF RADIOLOGISTS.—At Royal College of Surgeons of England, 4 p.m., Radiotherapy Section meeting. Professor D. W. Smithers: Rotation Therapy.
INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—3.30 p.m., clinical meeting for general practitioners. Mr. W. D. Dooy: Indications for Tonsillectomy.
MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.—7.30 p.m., general meeting. Presidential Address: Personal Reflections regarding the Trichomonas Vaginalis.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Professor A. G. R. Lowdon: Surgical Management of Intestinal Obstruction; 4 p.m., Dr. J. E. Caughey (New Zealand): Hypopituitarism.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor J. C. Moir: Obstetric/Gynaecological Conference.
● SOCIETY OF CHEMICAL INDUSTRY: FINE CHEMICALS GROUP.—At National Institute for Medical Research, 6.15 p.m., Dr. R. K. Callow: Medical Research and Fine Chemicals.

Saturday, May 1

ASSOCIATION OF CLINICAL BIOCHEMISTS: SOUTHERN REGION.—At Radcliffe Infirmary, Oxford, 2 p.m., meeting. Scientific papers.
● INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Queen Charlotte's Hospital, 11 a.m., Mr. J. Hamilton: Breech Presentation.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Ball.—On April 9, 1954, at the Central Middlesex Hospital, London, N.W., to Francesca, wife of Dr. Keith Ball, a daughter—Phyllida Jane.
Chalmers.—On April 16, 1954, at St. David's Hospital, Cardiff, to Doreen, wife of Dr. T. M. Chalmers, a son.
Gibson.—On April 11, 1954, at The Shiel, Elgin Road, Weybridge, to Graeme (formerly Galbraith) wife of Dr. Eric Gibson, a son.
Helsby.—On April 12, 1954, at Liverpool Maternity Hospital, to Joyce, wife of Raymond Helsby, F.R.C.S., a daughter.
McCarthy.—On April 6, 1954, at Stamford, Lincoln, to Agnes (formerly Baker), M.B., B.S., D.A., wife of Cedric McCarthy, a son—James Whyte.
Richardson.—On March 5, 1954, at the Phyllis Memorial Home, Melton, Woodbridge, Suffolk, to Pamela, wife of Dr. J. Derek Richardson, a daughter—Jennifer Anne.
West.—On April 15, 1954, at the Plummer Hospital, Saulte-Ste.-Marie, Ontario, Canada, to Kathleen (formerly Stanhope), wife of Michael H. West, M.D., M.R.C.P., of Thessalon, Ontario, a daughter.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Bags Under the Eyes

Q.—Is there any treatment—surgical or medical—for "bags" under the eyes?

A.—If the puffiness which occurs in the lower lids with advancing age is due to atony of the muscles of the lower lid allowing the peri-orbital fat to project forwards, fatigue increases the bagginess and this accounts for the variation in degree which is constantly noted.

The treatment is surgical, and consists in removing the herniated fat and tightening up the eyelid by a lateral pull. Very rarely should eyelid skin be removed from the lash edge. The operation is attended by good results, but should be carried out only by a competent plastic surgeon.

The Reticuloses

Q.—What diseases are included in the "reticuloses"? What criteria are required for diseases to be included in this group?

A.—Reticulosis is one of those generic terms like neuritis or gastritis which can have a definite connotation but is more often used to mean anything or nothing.

The term was introduced by Letterer¹ in 1924 to describe the histopathology in the organs of a child aged 6 months who died following an acute illness characterized by pyrexia, purpura, aural discharge, and generalized lymph node enlargement with hepato-splenomegaly; there was found to be a widespread proliferation of primitive histiocytes or reticulum cells in the lymph nodes, liver, spleen, bone marrow, and skin. The case is the first clearly described account of the condition known as Letterer-Siwe disease.

Subsequent to this case report, a number of other cases showing generalized proliferations of histiocytes were described, and classifications relating these cases to the leukoses, storage disorders such as Gaucher's disease, and the lymphosarcomata were propounded. Pullinger,² in a detailed study of the histology of Hodgkin's disease, suggested that a group of diseases of the reticular tissue exists in which differentiation is possible into one or several of the possible cell progeny, and following this Ross³ and Robb-Smith⁴ put forward detailed classifications based on anatomico-histological divisions which included both definite disease entities such as Hodgkin's disease, the leukaemias, and storage disorders, as well as reactive change of lymphoreticular tissue; there have been numerous modifications of these classifications such as those of Symmers⁵ and Israels.⁶ On the Continent there has of recent years been a tendency, as shown by van der Meer and Zeldenrust⁷ or Cazal,⁸ to restrict the term reticulosis to those conditions in which there is a proliferation of histiocytes or their precursors rather than to use it in the broad sense of English writers. In America the term reticulosis is little used, as they have adopted an all-embracing term "lymphoma" (Custer and Bernhard)⁹ which includes the progressive hyperplasias and the sarcomata, whereas in England and on the Continent there is a clear distinction made between these two types of tissue reaction, although in certain instances the progressive hyperplasia may alter so as to become sarcomatous.

If we follow English usage of the term "reticulosis" we can define it as a generic histological term to describe all the hyperplasias of the reticular tissue. These can be divided into two large groups, the reactive or reversible

hyperplasias or the progressive or irreversible hyperplasias; usually the term "reticulosis" is restricted to the latter group. The reactive or reversible hyperplasias of reticular tissue include a large range of infective disorders characterized by hyperplastic or granulomatous proliferations of reticular tissue, such as typhoid fever, tuberculosis, perhaps sarcoidosis, histoplasmosis, malaria, leishmaniasis, and many more; it also includes the reactive conditions in which there is no known aetiological cause, such as sinus catarrh, reactive hyperplasia, and perhaps the storage disorders, because, although these are not usually reversible, they may be on occasions and there is some knowledge of the proximate biochemical lesion. The progressive hyperplasias include the leukoses (lymphoid, myeloid, and monocytic, whether aleukaemic or leukaemic), di Guglielmo's disease and myelomatosis, lymphoid follicular reticulosis (follicular lymphoblastoma), lymphoreticular medullary reticulosis (the majority of cases of Hodgkin's paraneoplasia (Jackson and Parker¹¹) and benign Hodgkin's disease (Harrison¹²), Hodgkin's disease (lymphadenoma verum), mycosis fungoides, myelocytosis (osteosclerotic myelopathy), histiocytic medullary reticulosis, and reticulum-celled medullary reticulosis (Letterer-Siwe syndrome, eosinophil granuloma, Hand-Schüller-Christian syndrome, reticuloendothelial granuloma, histiocytosis X (Lichtenstein¹³)).

It should be realized that the term "reticulosis" is a generic morphological term and not a clinical term, unless qualified by its specific histological characters. To say that a patient has "a touch of reticulosis" is probably less informative than to say that a patient has enlarged lymph nodes, though, as Arnold of Villanova pointed out a long time ago in respect of another term, it might sound more impressive.

Deodorants in General Practice

Q.—I would be grateful for your suggestion for a good deodorant which can be used by our district nurses in private houses when doing very offensive dressings.

A.—No deodorant is known which gives satisfactory results under the conditions stated. The problem presents two phases for consideration: (1) Is it possible to deal quickly with a relatively large volume of foul gas suddenly released into the air of the bedroom when dressings are removed? (2) Is there a method for dealing with the slow trickle of foul gas which is continuously escaping from the affected tissues?

There is much to be said theoretically for spraying the room with solutions of substances which react chemically with the offensive gas and thus change it to an odourless compound. In practice there are difficulties: the deodorizing solution must be non-toxic to man and animals, and it must not damage the furnishings by staining, bleaching, corrosion, etc. It has been claimed that certain chlorophyll derivatives act as deodorants in this way, but the claim has been vigorously disputed.

The cleansing and deodorizing of offensive wounds and skin surfaces can be achieved by the local application of active carbon (charcoal), but only those preparations should be used which are guaranteed by the manufacturers to be

potent adsorbents. There may also be a place for an inexpensive air-filtering apparatus consisting of a box fitted with a fan which sucks the air through a deodorizing screen containing active carbon. The method is most effective against gases which have a high molecular weight—such as the mercaptans—and *per contra* least effective when the molecular weight of the gas is low, for example, with sulphuretted hydrogen and ammonia.

A charcoal blanket has been devised for use in cases where there is intractable foul discharge—for example, in inoperable cancer of the uterus or rectum. The principle consists in screening the patient from the neck to the feet with material which contains particles of active carbon. This has been shown to be effective under controlled experimental conditions and in clinical practice. Nevertheless it fails if the nurse or the patient omit to carry out the simple instructions; and of course it ceases to act as a filter when it is removed with the other bedclothes preparatory to dressing the wound.

Patients with offensive discharges from colostomies can also be treated with active carbon in small doses by mouth, say half a teaspoonful four times daily. The powdered carbon is made more manageable if it is moistened with water to make a paste. The same method can be used for other patients who pass offensive stools. It must be remembered, however, that prolonged oral medication with active carbon may possibly interfere with nutrition by adsorption of enzymes and other essential substances in the alimentary canal.

Luminous Paint

Q.—How much radiation is given off by luminous paint? Have any examples been reported of radiation damage to users (as opposed to manufacturers) of articles coated with luminous paint?

A.—Radioactive luminescent compound usually contains radium, though occasionally a mixture of radium and mesothorium is employed. The amount of radium used per gramme of compound is of the order of 70 μC for instrument dials (for example, for aircraft), of 38 μC for watches, and of 12 μC for alarm clocks. As will be appreciated, only minute quantities of compound are used for luminizing watches and clocks. No case has been reported of radiation damage to users of luminized objects.

3-D in a Medical Journal.—The editorial manager of *Medicine Illustrated* has written to point out that last November's issue of that journal included a supplement with stereoscopic illustrations. This controverts the claim for priority made by the editor of *Anaesthesia* (see *British Medical Journal*, April 10, p. 886).

"Any Questions?" Book.—The second book of selected "Any Questions?" is available, price 7s. 6d. (postage 6d.). Copies may be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: *Atiology, Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 4499. TELEGRAMS: *Britmedads, Westcent, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 4499. TELEGRAMS: *Medisecra, Westcent, London*.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY MAY 1 1954

A MILESTONE IN MEDICAL HISTORY*

THE CENTENARY OF THE METROPOLITAN COUNTIES BRANCH

BY

J. ARTHUR MOODY, M.B., B.Ch., B.A.O.

Twenty years previous to the foundation of this Branch the Provincial Medical and Surgical Association had just been formed, and the medical profession had undergone in that time great and striking changes in its social and educational aspects and in its general tone, the well-informed practitioner tending to displace the apothecary, and the level in the standard of treatment in all fields already becoming more expert. The year 1853 was a milestone in the history of our Association (then known as the Provincial Medical and Surgical Association), not only for the newly founded Metropolitan Counties Branch. The Association's journal—till then known as the *Provincial Medical and Surgical Journal*—had up to this date been edited in Worcester and published in London, and by a decision of the Annual Meeting at Oxford in 1852 it was in future to be edited as well as published weekly in London with its better literary and scientific facilities. Furthermore, it was to have a new editor.

One cannot read the *Journal* of the period (1853–6)—then named the *Association Medical Journal*—without sensing in most of the controversies of the time a considerable gulf between the London doctors and those in the provinces. Membership of the Provincial Medical and Surgical Association did not involve attachment to any particular local unit of the Association; indeed, membership was on a rather scattered geographical basis, and it was later found necessary to establish some kind of local unit. This local unit, one of the first steps in our organization, appears to have been the Branch. The Metropolitan Counties Branch, then, started its career on November 26, 1852, as a District Branch (as it was called) of the Provincial Medical and Surgical Association, consisting of members of that Association resident in Middlesex and "such parts of Essex, Kent, Surrey, and the adjoining counties as are not included in any existing Branch."

Notable Original Members

Who were some of the original members? The *Journal* of December 8, 1852, gives an account of the first meeting of the Metropolitan Counties Branch, with a list of some of the members present. Many of them became famous, and I trust that my somewhat modest research into the paths they took may be of interest.

Sir John Forbes

In the chair was Dr. Forbes, later to become Sir John Forbes. He was a schoolfellow and lifelong friend of

* The Presidential Address delivered at the Annual Meeting of the Metropolitan Counties Branch of the British Medical Association on June 9, 1953.

Sir James Clark, Physician to Queen Victoria, and was himself appointed to the Queen's Household in 1840. After obtaining a diploma in surgery at Edinburgh he entered the Navy in 1807 as assistant surgeon, and on discharge in 1816 he returned to Edinburgh, graduating M.D. in 1817. Not only was he a popular and very successful physician, first at Penzance and later in Chichester, where he appears to have succeeded men who, like himself, later moved to London, but in his early days he was the author of papers on meteorological and geological subjects. In 1827, while at Chichester, he was mainly instrumental in founding the Infirmary, which was the first general hospital established in the county.

Forbes appears to have combined very successful practice at Chichester with much literary activity. For instance, he translated and published Laennec's work on the stethoscope, which went to a fifth edition. His chief credit here, however, is that he was in advance of most of the physicians of the day, who appear to have treated Laennec's great discovery with contempt and ridicule. Although Forbes was certain that the stethoscope would be acknowledged to be one of the greatest discoveries in medicine he does express some doubt whether it would come into universal use. He followed up this translation with another (1824) on the same subject—Auenbrugger's remarkable work on percussion—and he added to the translation an account of his own with the title "Original Cases Illustrating the Use of the Stethoscope and Percussion in the Diagnosis of Diseases of the Chest."

He next undertook with John Conolly—his professional rival in Chichester—the *Cyclopaedia of Practical Medicine*. The most eminent physicians of the day contributed to it; the same applies to a periodical known as the *British and Foreign Medical Review*, a quarterly journal, in which he was also associated with Dr. Conolly. This quarterly review was a great event, not only in Forbes's life, but also in medical literature. It soon became the leading medical journal in the country—its reputation extended not only all over Europe but also to America, where it was reprinted. Chiefly with the object of improving the *Review*, Forbes moved to London in 1840—a move which must have involved him in considerable pecuniary loss, for he could never expect at the age of 53 (even though through the influence of his friend Sir James Clark he was appointed to the Queen's Household) to pick up a London practice equal to that which he enjoyed at Chichester. After 12 years the circulation of the *Review* began to fall off and he had to terminate the

publication, which, although it had been self-supporting for eight years, had cost him £500 in the undertaking. An article on homoeopathy in which he appeared to be too fair to the homoeopaths gave considerable offence to the profession, and may have had something to do with its discontinuance. The *Review* was amalgamated with a rival which enjoyed an even larger circulation—Johnson's *Medico-Chirurgical Review*—under a new title, the *British and Foreign Medico-Chirurgical Review*, and continued on similar lines until 1877.

Forbes became F.R.C.P. and Hon.D.C.L. Oxford, and in 1853 was knighted. He was a member of various learned and scientific societies, both in Europe and in America. He gave some attention to the question of mesmerism, and wrote an amusing account of his detection of certain impostors in this particular field. Towards the end he devoted himself, in London, chiefly to benevolent and literary work, and to travel on the Continent, publishing accounts of his visits to Germany and Switzerland. He died in 1861 at Whitchurch, near Reading, in the house of his only son, and through all his life was loved and honoured. Few men of the nineteenth century have done more to promote the cause of sound medical literature than this Founder-President of our Branch: the Branch was most fortunate in starting its career under a President of such distinction and versatility—literary and medical.

John Rose Cormack

Probably the next personality of interest present at the first meeting was Dr. John Rose Cormack. A Scot, like Forbes, and a son of the manse, he resembled Forbes in his literary ability. His great distinction, so far as our Association is concerned, is of course that he became editor of the *Journal* in 1853. With his M.D. Edinburgh in 1837 he received the gold medal for his thesis on the presence of air in the organs of circulation. After studying in Paris he started practice in Edinburgh, was appointed Physician to the Royal Infirmary and the Fever Hospital, and greatly enhanced his early reputation by a paper on the relapsing fever epidemic in 1843. He resigned his appointment at the Royal Infirmary on being refused permission to give clinical lectures, and in 1847 removed to London. By this time he had had much experience in medical journalism, for in 1841 he had established the *Edinburgh Monthly Journal of Medical Science*, known and referred to as *Cormack's Journal*, and later the *Edinburgh Medical Journal*. Incidentally, he had been President of the Edinburgh Royal Medical Society in the year of its centenary festival.

On arriving in London Cormack settled in practice at Putney, and soon started another monthly periodical—the *London Journal of Medicine*. As with Forbes's periodicals, so with Cormack's—the names of most of the physicians and surgeons of distinction at that time in London appear on the list of contributors. That journal ceased to appear when the *Association Medical Journal* began. He remained editor of the latter until 1855, and a perusal of the leading articles of the period manifests a high standard of literary style and expression. Ill-health compelled him to settle in Orleans in 1866, and in 1869 he removed to Paris, graduated M.D. Paris, and became Physician to the British Embassy. Cormack's fame and his knighthood in 1872 (also Legion of Honour in 1871) were the reward for his devoted services to the distressed foreigners and to the sick and wounded during the siege of Paris. An unselfish, public-spirited man, he died poor in 1882, and his family had to be helped by subscription among his former colleagues. He seems to have been a man of great industry and fine character, highly respected by the British colony in Paris. He was the first editor of the Association's *Journal* to have a name and reputation outside its ranks. He had been appointed

physician to the Hertford British Hospital in Paris, established by Sir Richard Wallace, who incidentally provided the medical education for Cormack's only surviving son. His publications, apart from his editorial work, included a collection of clinical studies on cholera, diphtheria, paralysis, and a translation of four volumes of Trousseau's *Clinical Lectures*. (Trousseau was the first to aspirate the pleural cavity, and actually invented an aspirator.)

Daniel Hack Tuke

The third notable figure who deserves mention is Daniel Hack Tuke (1827-95). He came from a family of Quaker philanthropists—his grandfather and his great-grandfather were closely associated with the designing of the York Retreat for the Insane, and he himself became famous as a mental specialist. Before contemplating the study of medicine he appears to have entered the service of the York Retreat, and not only to have studied the literature of insanity but in his spare time to have made some informal study of the patients. At Bart's, as a student, he distinguished himself by gaining several prizes, and in 1853 obtained the M.D. Heidelberg. His career was sadly interrupted for 15 years by pulmonary tuberculosis, which necessitated his retirement as physician to the York Retreat and Infirmary: but in 1875, when his health permitted his re-entry into practice, he settled in London as a consulting mental specialist, becoming a governor of Bethlem Royal Hospital, and a lecturer and examiner in mental disease at Charing Cross Hospital. He was one of the founders of the After Care Association (an association which takes charge of the poorer class of convalescents from insanity). He wrote and published extensively on mental illness, and his *Manual of Psychological Medicine* kept its place for many years as a standard treatise. In 1880 he, like Forbes and Cormack, also became an editor—joint editor of the *Journal of Mental Science*. He was President of the Medico-Psychological Association in 1881, and Glasgow University conferred on him its LL.D. in 1883. He appears to have been encyclopaedic in his knowledge of lunacy and prolific in his writing, and to him and his family must go a great deal of credit for the humanizing of the treatment of the mental patient in asylums.

John Conolly (1794-1866)

John Conolly graduated at Edinburgh in 1821, and devoted himself from the start to the study of insanity. He began practice in Chichester, where Dr. (afterwards Sir John) Forbes was already in practice, and the young men at once formed a strong and lasting friendship. They were, however, rivals, and together they concluded that the "district" did not afford sufficient employment for both, and in a year's time Conolly moved to Stratford-on-Avon. He remained there about five years, but does not appear to have been very successful so far as the general practice of his profession was concerned. Like Forbes and Cormack, he was much attracted by literary work, and edited (with Dr. James Copland) the *London Medical Repository*—a large part of their endeavour being to call attention to the numerous medical books then appearing in France and Germany. While at Stratford Conolly took a prominent part in public affairs, and was twice mayor of the town. He interested himself in every matter for the public good and was enthusiastic for sanitation and public health.

In 1827 Conolly moved to London, and in the following year was appointed Professor of the Practice of Medicine at University College, London. While he held that chair he published his work on *Indications of Insanity*, but failed in his endeavour to introduce at London University systematic clinical instruction into the curriculum. In London he was the friend of influential men like Lord Brougham and Lord John Russell, but in spite of these friendships he seems to have failed in London as a physician: nor does he appear to have filled the professorial chair with any great ability.

In 1830 he left London and returned to Warwick, there resuming his post of inspecting physician to the asylums in

Warwickshire. He continued to write a good deal, and assisted his old friend Forbes in editing *British and Foreign Medical Review* and the *Cyclopaedia of Practical Medicine*. While living at Warwick Conolly maintained his interest in the neighbouring town of Stratford-on-Avon, and successfully led the inhabitants of the town against a proposal to remove the body of Shakespeare from its resting-place. Not only was he one of the pioneers—if we may refer to them as such—of the Metropolitan Counties Branch, but earlier (about 1830) he was most closely associated with Hastings and Forbes in the foundation of a medical society—the Provincial Medical and Surgical Association—afterwards to become the British Medical Association.

Conolly returned to London in 1839, and was appointed resident physician to the Middlesex Asylum at Hanwell, then the largest institution of its kind in England. He devoted himself there to the principles enunciated by the Tukes, emancipating the asylums from the role of prison houses, and freeing the lunatics literally from their strait-jackets and chains. Within the 12 years during which he was supreme at Hanwell a revolution was effected throughout the country in the management of the insane. His sincerity and enthusiasm overcame every difficulty, and by dint of great devotion and eloquence he was able to convert not only our profession but also the public to a complete reorientation of attitude towards the insane, and a consequent revolution in their treatment. In all this he generously acknowledged his obligations to the Tuke family, and the methods of which in this country they were the pioneers at the York Retreat. He maintained positively, in his own words, "There is no asylum in the world in which mechanical restraint may not be abolished, not only with safety, but with incalculable advantage." From this flowed a further great advantage—the proper study of insanity; for the study of insanity as a disease began when asylums ceased to be prisons. Unfortunately, some of Conolly's literary labour was devoted too much to destructive criticism of the older methods of asylum management, rather than to constructive minute investigation or patient research, and, being of Irish descent (his father mentioned by Dean Swift), his writings are tainted with some sentimentalism and on occasion an overindulgence in rhetoric, which detracts from their scientific value. About 1852 he resigned his post at the asylum, but ran a private asylum in the village of Hanwell, and although, as I have already indicated, his early years do not shine with success, he appears now to have had a large consulting practice in mental disease.

Conolly's best and most eloquent works belong to the later period of his life, when he wrote extensively on the treatment of the insane. Oxford University awarded him the Hon.D.C.L. in 1852, and on the occasion of his resignation from Hanwell a great public testimonial and his portrait were presented to him, the presentation being made with imposing ceremony by Lord Shaftesbury, Chairman of the Lunacy Commission. He died in 1866 at Hanwell, after a series of what would appear, in the light of modern knowledge, to be cerebral vascular attacks.

Francis Sibson

Francis Sibson (1814-76) (whose name appears here as Chairman of Council in 1865-6 and 1867-8) is worthy of note for his varied career. Like many of his contemporaries, he took his diploma (1831) at the Royal College of Surgeons, Edinburgh, as a first step. Before turning to a more serious and thorough study of medicine, Sibson was apprenticed to a surgeon—and served in the cholera wards around Edinburgh and Leith, then settled in general practice at Cockermouth, but soon left to continue his studies at Guy's, where he had the distinction of being a friend and pupil of Hodgkin. He had the further distinction of being the first physician appointed to St. Mary's Hospital, which was opened in 1851, and one of the first lecturers at its Medical School. He published papers on the flexible stethoscope and on the "mechanism of respiration" and articles on

ether, chloroform, and narcotic poisons. These publications were all made before he came to London, and in fact while he was in Nottingham, as resident surgeon and apothecary to the General Hospital; and when he came to London about 1850 he obtained the M.D. London, becoming F.R.C.P. in 1853; he was made an F.R.S. in 1849. At the Royal College of Physicians he was Goulstonian, Croonian, and Lumleian lecturer and curator of the Museum. He was a member of the Senate of London University, and it may interest the ladies to know that he opposed the admission of women to degrees of the University.

Sibson's remarkable versatility was also exemplified in his demonstrations of visceral anatomy—a course which he arranged at his own house in Brook Street, and which commanded a remarkable attendance. He also published an atlas of anatomy, illustrated with coloured plates—a laborious and useful work of reference, illustrating specially the relative positions and movements of the internal organs. He wrote extensively, and was a man of great industry. All his works of permanent importance are published in four volumes—the *Collected Works of Francis Sibson*, including several contributed to *A System of Medicine*, by Sir John Russell Reynolds. He was particularly expert in publishing his own observations. He died suddenly at Geneva. During his lifetime he appears to have enjoyed a considerable practice as a physician, in addition to his innumerable adventures as anatomist and author.

Ogier Ward

Thomas Ogier Ward (1803-79) is worthy of our attention as the first Secretary of the Metropolitan Counties Branch—a position which a perusal of the *Journal* shows he filled with much industry and all the initiative, intuition, and tact necessary on any new venture. I am grateful for the collaboration and help of his grandson—also Ogier Ward—whom many of you undoubtedly know as consulting surgeon to St. Peter's Hospital, who has been kind enough to supply at my request a few facts regarding his grandfather. They demonstrate not only his unique ability as our first Secretary, but his originality and, as with Francis Sibson, his expertness in observation. While practising in his early days at Wolverhampton, during the great cholera epidemic of 1834, he achieved a greater measure of success in treatment by putting into practice his observation that the collapsed patient was much helped by hot baths. Another of his observations was made while holding the post of physician to the Birmingham Dispensary—this time in cardiology. He showed that the "bruit de diable" (now known as the "venous hum") was produced in the veins and not in the arteries.

As with his contemporaries, he seems to have moved about, practising in Kensington at the time of his secretaryship, and ending up, like his friend and colleague Sir John Rose Cormack, in France. Indeed, while Cormack was tending the British colony during the siege of Paris, Ogier Ward was experiencing the discomfort entailed by the billeting of German troops while living at Caen and St. Germain.

It may be of interest that the conception of the Metropolitan Counties Branch first arose at the Annual Meeting at Oxford, as a result of a conversation between Dr. Cormack and Dr. Ogier Ward.

Formation of the Branch

The actual proposal to form the Branch was, strangely enough, made by Dr. Charles Cowan, of Reading, who expressed the hope that places within convenient railway distance of London, such as Reading, would be embraced in the Metropolitan Branch, and that it was to be representative enough to exclude any cleavage as between "provincial" and "metropolitan." It appears to have been one of the first Branches formed throughout the country. Membership of a Branch was automatic upon the payment of 2s. 6d., in addition, of course, to the £1 ls. membership to

the parent Association. A rather amusing and potentially serious interlude arose very early upon the question of this automatic membership. It was sought to exclude a member, and the method adopted was to add to the clause relating to the admission of members the words "provided the majority of members present at a general meeting concur in their admission." This particular gentleman had paid over his 2s. 6d. to one of the officials of the publishing department, but next day found himself without membership, owing to the rather precipitous alteration of the by-law, and minus 2s. 6d. He was none other than Mr. Wakley, the editor of the *Journal's* great rival, the *Lancet*, and the lead in excluding him appears to have been openly taken by none other than the *Association Medical Journal's* editor, Dr. Cormack, who committed himself so far as to say that "as Mr. Wakley was so highly unacceptable to the majority of the members his presence among them would destroy the Branch from the numerous resignations it would occasion." A number of collateral issues and problems were connected with this episode, and did literally stir the profession and its conscience. There was a practice, very prevalent at the time, of the publication of biographies of medical notabilities and other aspirants seeking public notice during their lifetime, often with portraits. This system of biographies of the living (sometimes indeed autobiographies) had almost become a kind of moral pestilence in the profession, and amounted frequently to open advertising, as in the case of one gentleman who had ordered 15,000 copies of his biography to be distributed throughout the country, and in that of another who permitted his butler, when his patients were leaving the house, to offer each of them a book, saying, "Have you seen my master's biography?" Or the traffic in biographies could go the other way, leading almost to victimization and ruin, by the publishing of abusive biographies in medical periodicals. The unpopularity of Wakley was bound up with this, for the *Lancet* of 1853 was accused on more than one occasion of murdering its victim, even if it did subsequently bury him with honours. Possibly the first great meeting of doctors to be held in this country took place at the Hanover Rooms, London, organized by this Branch in 1853—the issue being biographical advertising. The meeting, however, was not ostensibly called for this purpose. It was called—as indeed similar meetings were called throughout the three kingdoms and all well attended—to protest against the dismissal of a surgeon, a Mr. John Gay, from the Royal Free Hospital. Mr. Gay seems to have had no responsibility for or initiative in the biographical sketch which was the cause of his dismissal, and which would appear to have been offensive to the management committee chiefly because of the statement that the hospital would be unknown were it not for the repute of Mr. Gay. Wakley, whose son was also on the staff of the Royal Free Hospital, was suspected of having had some hand in the initiation of Gay's dismissal. The case was not a good one for the purpose of making an example of doctors by doctors, but it provided wide opportunity for the ventilation of the whole subject of biographical advertising, which was profoundly disturbing the profession. The proceedings were remarkable not only for the immense attendance at the London meeting of 1,200 doctors, and similar attendances throughout the country, but also for the fine discrimination manifest in debating the two big issues—the palpably wrong dismissal on this occasion by a lay management committee, and, secondly, the growing evil of biographical advertising.

Representation in Parliament

One of the questions which exercised the Branch in its first year was the representation of the profession in Parliament. The comparatively imminent measures of medical reform and public health, already much in the minds of leaders in the profession and others, provided the chief stimulus for the obviously altruistic desire for medical representation in Parliament; indeed, a special Franchise Committee was appointed, and the rather roundabout pro-

cedure was advocated of first securing Parliamentary representation of the University of London, when presumably it was anticipated that the medical element amongst the graduates would be strong enough to secure the election of a medical member to Parliament. The University of Edinburgh at that particular time, and possibly for some time afterwards, would appear to have had a preponderating number of medical graduates, and might reasonably have been expected to compete with London for the honour of actual representation.

In these days of almost penal taxation it may be of interest to note that the problem of what they called "the income tax" absorbed sufficient attention in 1852 for the Association to appoint a special Income Tax Committee, and that the second meeting of this Branch was called for the purpose of petitioning both Houses of Parliament and of appointing a deputation to the Chancellor of the Exchequer, protesting against the iniquities of taxation. The overriding preoccupation of the meeting seems to have been that taxation of income (as against property), which, as you may know, fell into abeyance for a short time, would be reimposed, and the fear was expressed by Dr. Cormack that "the income tax" might even become permanent. To us, with our considerable sophistication in matters of taxation, the pleas put forward by our predecessors 100 years ago demonstrate a refreshing innocence, and may even be regarded as amusing; for instance:

"The Humble Petition . . . sheweth—

"That your petitioners have, for the most part, no other income than that derived from their professional exertions.

"That their income so derived is uncertain and precarious, necessarily ceasing under illness, in advanced life, and at death.

"That considering their position in society, the exercise of their profession requires them to maintain unusually expensive establishments, involving considerable direct taxation.

"That your petitioners are, for the most part, married men with families, for whose education and present and future support they have to provide by these uncertain and precarious incomes, and under the contingencies of illness, advanced age, and death.

"That your petitioners represent, moreover, that their lives are shorter, they are more liable to accidents and disease, frequently communicated by their patients; and that the decline of their professional incomes is earlier than in any other profession.

"That for the above reasons and others that might be adduced, the capitalized value of the precarious income of a medical man is not only below that of an income derived from a permanent annuity, but is also even considerably below the value of a received life annuity, which itself is scarcely half the value of a permanent annuity.

"That for the above reasons and others that might be added your petitioners feel it a great grievance, and cannot but consider it most unjust that their professional incomes, thus precarious, should be taxed at the same rate as incomes derived from realized property.

"And your petitioners, therefore, humbly pray that it may please your Honourable House so to deal with the income-tax, if it be indispensable to retain it, that its pressure on medical men and others whose incomes are temporary and uncertain, may be equitably adjusted in proportion to their real value.

"And your petitioners will ever pray, etc."

Seed of Medical Reform

The year 1852 is also marked by the germination of the seed of medical reform. The seed had been sown many years before and the subject had been discussed for a long time in a rather desultory manner by the doctors, amongst others; but it was only at the Annual Meeting at Oxford in 1852 that a decision was taken that a draft Bill on medical reform which had been prepared by the Central Council should be referred to Parliament. A strong deputation, headed by Sir Charles Hastings and the President and other leading members of the Branch and about 60 M.P.s, waited on Lord Palmerston to present the draft Bill, whose provisions, as you well know, were uniformity of qualification,

equal right to practise throughout the United Kingdom, and the adoption of the representative principle in the formation of the councils and other governing bodies.

As might be expected, one of the greatest difficulties throughout the long controversy on medical reform had been the clash of interests, the interests now of this College of Physicians and Surgeons, now of that. Viewed in retrospect, this was not without its humorous side. When, for instance, there arose the high probability that there would be registered as surgeons persons who were only licentiates of the Society of Apothecaries, one well-known critic expressed his conviction that the examination at Apothecaries' Hall was more conducive to public safety than that of the R.C.S., and that the examination of the College was no test of fitness for the discharge of any duty connected with the profession: that the object of the College of Surgeons appeared to be to form two distinct classes—the one a superior grade, the consulting surgeon, the other an inferior grade, to make and find work for the superior. It is of much interest at the present moment to recall the proposition made about this time for the establishment of "The Royal College of General Practitioners." There is in the minutes of the R.C.S. a record of negotiations between the R.C.S. and the R.C.P., the Society of Apothecaries, and a body known at the time as the National Association of General Practitioners; and an account of a meeting at the R.C.P., with a resolution that a Charter of Incorporation should be granted to the surgeon apothecaries of this country under the title of the Royal College of General Practitioners of England. It is also of interest that the medical Bill drafted in 1852 which substantially became the epoch-making Act of 1858 was drafted by a barrister, Mr. George Hastings, M.P., the son of the founder of the Association and Secretary of the Medical Reform Committee.

One of the anomalies of the time was that even if a doctor had the highest university honours he had not the right to practise in London, but must also obtain a licence from the College of Physicians, and this particular licence did not qualify him to practise out of London.

The highly commendable aims for the better education of the doctors, and their increase in status and usefulness, was probably the chief stimulus in seeking medical reform. Another stimulus was undoubtedly the considerable competition of quacks, of whom in 1851 there were estimated to be 21,400 in the country. As a forerunner of osteopathy, with its original and only pathology in the spine, came also from America the system known at the time by the rather significant name of "Coffinism." In this system the pathology of all disease is in the stomach, and consists of a "canker or vitiated secretion" that forms in the stomach or bowels to a greater or less extent, and interferes, presumably, with the function of the stomach. The adherents of the "Coffinite" school did appear to exhibit some versatility in their choice of what they considered necessary to remove this "vitiated secretion." At one inquest we read of the death of a woman suffering from hernia, a treatment consisting of jalap, cayenne pepper, and gin, a drachm glassful every morning—the verdict, "Death from natural causes." At another inquest a man of 27 suffering from cholera, so common in Britain at the time as to require the establishment of special cholera hospitals, was found at the post-mortem examination to have present in his stomach the same ingredients, plus ginger, plus lobelia. Lobelia seems to have figured very largely in the therapy. Dr. Letheby, lecturer on chemistry at the London, at this particular inquest stated that he had known 22 deaths from lobelia (whilst in America the cases were very much more numerous). The coroner in this case observed in the summing-up that he had on two occasions sent this particular quack for trial for manslaughter at the Old Bailey, but that the judges took a view of the cases different from that entertained by the juries. The juries, we can be pretty sure, did not themselves always entertain the correct view. The Coffinites were also referred to as "botanical physicians" or "Thompsonians," one Thompson being the first plausible

exponent of the system. Thompsonian quacks maintained several journals in America and one in London, although the actual cult seems to have been more widespread in the provinces than in London. The textbook was entitled *The Practice of Medicine on Thompsonian Principles*, by J. W. Comfort, M.D. The terms "Coffin" and "Comfort" in the same context are noteworthy and even cynical! The textbook had reached its fourth edition by 1853, and was a portly tome of 582 octavo pages.

Homoeopathy, which appeared to start as a reaction simply against over-drugging, was classified by orthodox physicians at the time as quackery, and our Association did draw up regulations for keeping homoeopaths out of the Association and for expelling them if they were found to profess or practise homoeopathy.

Other aspects were troubling the doctors and guiding their thoughts in the direction of medical reform. There was, for instance, no protection against any man calling himself M.D., M.B., or surgeon; and the registration of pharmaceutical chemists had given them a status and recognition, especially in the towns and villages of the provinces, which the doctor did not possess, and which had every appearance of supplanting him. Then there was also the facility with which the advertisements of quacks and their nostrums were published in the newspapers and in religious periodicals, especially of the provinces and in the Colonies.

The profession therefore had every reason at the time for seeking the highest possible representation in Parliament, with a view to ultimately securing the largest measure of medical reform.

Another of the formidable problems of 1852–3 concerned the Vaccination Act, making vaccination compulsory about that time. The controversy is interesting, as demonstrating the first efforts to crystallize medical opinion on a question of social policy. The effort was late, it is true, for the Act appears to have been rushed through Parliament in the first instance, without reference to or collaboration with the profession. The doctors at the time appeared to speak with different voices, and presumably when an amendment to the Act was suggested they did get together in a really representative way. It is of interest, also, that for the first time the suggestion was made that the opinion of counsel should be sought on how far the Government, by putting vaccination in the hands of the Registrar-General, had made itself responsible for all the expenses which might be incurred.

The Gratuitous Advice Committee

The question of gratuitous advice and the abuses alleged in hospital and dispensary practice appear to have assumed such high proportions that in 1853 the Branch actually called a further special committee into being, the Gratuitous Advice Committee. The abuses alleged would appear to have existed only in the metropolis, hence the special move in this Branch, but the impact of these abuses would appear to have affected not merely the pockets of the doctors but also their ethics—so much so that we find this particular committee working with the Ethical Committee of the Association in the collection and digesting of facts and opinions of various contributors. In the machinery for collecting these we also see the first suggestion of a questionnaire.

While recognizing the motives of kindness and charity, and the definite moral obligation of a generous profession to give unpaid advice to the poor and the necessitous, the allegation was made that special dispensaries or clinics sometimes sprang into existence, not to meet the exigencies of the poor, but to bring before the public notice some struggling member of the profession, to make himself known. There was the further charge that, although these gentlemen gave their advice gratis, some of them had entered into collaboration with the chemists, receiving a percentage on every prescription; and it was even reported that an F.R.C.P. who was the proprietor of a chemist's shop

constantly attended there to audit his accounts. Something had to be done about it, and the terms of the special committee were those of inquiry in the first instance. Ten questions were sent out to the whole profession, questions which admitted of an answer more than a simple "yes" or "no." In comparison with the charge of apathy which seems to afflict us in this modern age, it would appear that, even then, 2,000 such inquiries drew only 250 replies.

Medical News Items in 1853

Those were the chief problems and controversies of the times, which I have purposely not followed historically to their solution. Many of them, indeed, are much too protracted and involved to be dealt with in the time at my disposal, but it may be of interest to mention a few of the subjects treated in the articles and correspondence at the time and debated at meetings. In 1853 there was a report of a court-martial on a medical officer acquitted of the charge of "conduct disgraceful to the character of an officer and a gentleman," in having subjected himself to the indignity of being publicly kicked; all he appeared to have done was to decline to fight a duel.

On April 7, 1853, Dr. John Snow administered chloroform to Queen Victoria in labour, and this event gave rise to much discussion and many letters in the pages of the *Journal*.

On June 7, 1853, the Irish Medical Association was formed at Dublin upon the model of our own Association. Interesting articles of the time appear on medical ethics, arrears in subscriptions, lunacy acts, advertising, apathy, cholera, and a suggestion for "the establishment in London and other medical schools of a Medical Students' Association."

The year 1853 also saw the foundation of the Medical Benevolent College at Epsom. There are articles illustrating the poor conditions and salaries of medical men doing Poor Law work and of medical officers in the Army and Navy, also on sanitary legislation and preventive medicine.

Conclusion

This review of our founders and their problems has been necessarily sketchy. You may have been impressed, as I have, with the versatility of many in that generation. Certainly their accomplishment in languages and in the literary field reached a perfection which most of us must envy. Compared with them, our present set-up and our outlook is rigid. They seem to have been at all times flexible, not only in thought but in method and in action. We must marvel for instance at the facility with which some of them changed the location of their practices and appeared to take up new roots with great success and with no inhibition as to the future. Above all, certainly on the great question of medical reform and everything that went with it—the increased stature of the doctor, protection of the public, and so on—these pioneers played their necessarily formidable part, as did the parent association. On the question of medical reform they were nearly 40 years ahead of contemporary thought, for the Act of 1858 only granted half of what was in the profession's mind 20 years before, and which did not become law until 1886, and it is probably no exaggeration to say that they blazed a trail through a forest of contention and prejudice, even of the medical corporations at the time, one of which was even accused of selling midwifery licences, and encouraging the creation of a vast number of Members and Fellows for pecuniary gain.

On medical reform the ideal and the approach of our medical forebears transcended the narrow and self-centred outlook of the licensing bodies, and indeed of some universities. As an Association it should give us heart to recall their courage and their altruism, so that, when necessary, we can remind modern public bodies, whether educational or administrative, of the greatness of our heritage.

AN OUTBREAK OF TRICHINOSIS IN LIVERPOOL IN 1953

BY

ANDREW B. SEMPLE, V.R.D., M.D., D.P.H.

AND

C. A. ST. HILL, M.B., Ch.B.
Consultant Pathologist to Royal Southern Hospital, Liverpool; Lecturer in Clinical Pathology, University of Liverpool

[WITH SPECIAL PLATE]

An outbreak of trichinosis occurred in the Liverpool area in late October and early November, 1953. In the past, localized epidemics of this disease have occurred in various parts of the country, and these have been reviewed by Young (1947). Sheldon (1941) and Jolly (1941) reported the epidemiological features of an outbreak in Wolverhampton, and Evans and Lennox (1953) a somewhat similar occurrence in the Borough of Barry. The main reason for giving an account of this outbreak is that it presented an admirable opportunity of studying the epidemiology and clinical features of trichinosis. The parasitological and pathological findings will be reported in greater detail in the *Annals of Tropical Medicine and Parasitology*.

The first of the 82 cases traced came to our notice when Dr. Robert Kemp telephoned on Friday, November 6, to say that he had just seen a case on a domiciliary visit which he suspected was trichinosis. This patient was admitted to hospital and the diagnosis was later confirmed by muscle biopsy. However, as the clinical findings were so suggestive of trichinosis, inquiries were made immediately in the same and other hospitals, and three further suspicious cases came to light.

It was felt that these cases might be part of a more widespread outbreak, so a letter was sent from the medical officer of health to all general practitioners and consultants describing features of the cases already seen and requesting that he be informed of any further suspected cases. There was a prompt and most helpful response, and cases continued to be reported until the third week in November. All patients were visited by a doctor from the Health Department, and the clinical data presented below were collected in this way. Epidemiological investigations were carried out by two sanitary inspectors, and health visitors undertook the follow-up visits on all the cases.

Epidemiology

The first case occurred on October 25 and the last one on November 18, and the dates of onset of the cases are shown in Fig. A. Those cases in which the diagnosis was confirmed by muscle biopsy are specially

marked; it will be seen that they include the first and last cases. The outbreak rapidly rose to a peak during the first week of November, but died away more slowly, 24 days separating the date of onset of symptoms in the first and last cases.

FIG. A.—Date of onset of the cases.

Patients were traced from all parts of the city and surrounding districts on the north bank of the River Mersey, but the majority lived in the northern part of this area. There was no evidence that different dates of onset were related to the area in which the patient lived.

Source of Infection

(1) *Sausages*. The earliest inquiry suggested that sausages of a certain local firm were most likely to be the cause of infection as the early cases gave a history of eating these sausages, and many of the patients had eaten them raw. Further confirmation came when one of the patients was found to be working in the sausage factory concerned, and reported that she habitually nibbled at raw sausage-meat whilst at work. The diagnosis in her case was established by muscle biopsy. Later, another worker in this factory was found to have developed trichinosis at the same time, and he also gave a history of tasting raw sausage meat whilst at work. As more and more patients were questioned, the connexion between this firm's sausages and infection became more firmly established, as 12 of the patients were employees of the firm—seven butchers, three grocery personnel, and two workers in the sausage factory. Of 82 cases (Table I) 67 gave a history of eating these sausages (34

TABLE I.—Eating Habits in 82 Cases of Trichinosis	
	No. of Cases
Infected sausage eaten (raw in 34 cases; cooked in 33 cases)	67
Persons handling infected sausage but not eating any, or any pork product except bacon	5
Persons who ate cooked sliced ham from firm handling infected sausage meat	5
Persons eating pork from different sources (no sausage and no product at all from firm handling infected sausages)	2
Story unreliable through lack of data	3

raw and 33 cooked). In 10 further cases there was a less definite connexion, as these persons had either handled infected sausage or eaten cold sliced ham bought from a shop known to have dealt with infected sausages. It was impossible to obtain accurate information in three of the cases.

(2) *Pork*. There were two persons, however, both reliable witnesses, who were emphatic that they had not handled or eaten any material from the firm involved, and the diagnosis in both cases was undoubted, on clinical grounds, though it was not possible to carry out muscle biopsy. These two cases suggest that at least two or more infected carcasses must have been involved. One of these patients was a widow of 63 living with her two daughters; she bought a joint of pork on October 31 from her butcher, cooked and ate it hot with her daughters on Sunday, November 1. The pork was then placed in the meat safe and she finished off the joint cold on Wednesday, November 4; in doing so, she ate the meat close to the bone.

She then gave her dog the bone; this animal was violently sick the following day. The patient developed a typical clinical attack, with swollen eyes, headache on the 12th, and was found to have an eosinophilia. In addition, the dog developed swollen eyes and conjunctivitis on the 14th. A biopsy on the dog was refused, but there seems little doubt that this animal had also developed trichinosis. The other patient in whom no connexion was traced also gave a history of eating pork at the same time as the case just described, and it was found that both butchers, who were widely separated in the city, received one half-carass of pork from the abattoir on October 24. No record mark is kept of the individual animal carcass delivered, and it has been impossible to trace whether both came from the same pig. There is a need for some form of record which would permit the tracing of such a finding to a particular animal and piggery. In both cases epidemiological investigation pin-pointed the particular carcass involved, but it was impossible to follow up our findings any further.

The investigation was then concentrated to see whether there was any possible connexion between the infected pigs delivered to the sausage factory and those delivered to the two butchers on October 24, as it was felt that the obvious disadvantage of suggesting two different infected sources would be greatly minimized if it could be shown that the pigs came from the same piggery. Once again the lack of adequate marking of individual pig carcasses made it impossible to check on this point. It is, however, of interest that the abattoir supplied both sausage factory and butchers, and that at that time a large consignment of pigs which was going to a bacon factory was diverted for ration meat but was found to be too fatty and, in consequence, most was used for sausage-making. It is, however, possible that one or two carcasses went to butchers for rations and that these, together with the carcasses which went to the sausage factory involved, came from the same infected source.

Methods of Infection

Anderson and Arnstein (1953) state that heating to a temperature of 58° C. for a few minutes kills the *Trichinella* larvae in pork, and that freezing to a temperature of —18° C. for at least 24 hours is required to kill them.

It is easy to understand how infection occurred in the 34 patients eating raw sausage. In a further 33 cases there was a history of eating cooked sausage (Table I), although this group also contained many who handled raw sausages and cooked them. Many of these persons were emphatic that their sausages were not grossly undercooked, and this suggests that what is regarded as ordinary cooking may not destroy all larvae. This is not surprising when it is recalled that the centre of a sausage is often relatively undercooked. The two cases traced to pork roasted at home also suggest that larvae deep in the joint may not be destroyed, and that thorough cooking may be required to render pork completely safe.

The experience of the five persons giving a definite story of handling but not eating any infected sausage, or any other product connected with the outbreak, is most interesting. Infection in these cases probably resulted from either infected sausage-meat on the hands being conveyed accidentally to the mouth indirectly, or by a knife used first to cut sausages and later to prepare a cold dish without adequate cleansing. The former probably occurred in the butchers infected and the latter in the kitchen when the housewives became infected. In all these cases the individual readily agreed that one of either suggestions could have occurred. Infected knives also probably resulted in the five cases traced to cold cooked sliced ham bought from a shop also selling infected sausages.

Characteristics of the Outbreak

Age and Sex Incidence.—Out of 82 cases, 20 were males and 62 females. The full age and sex incidence is given in Table II. The higher incidence in the females than the males is made the more impressive when it is realized that

TABLE II.—Age and Sex Incidence

Ages	Men	Women
0-14 years ..	1	4
15-24 " ..	0	5
25-34 " ..	8 (2 butchers + 1 sausage worker)	12 (1 sausage worker)
35-44 " ..	4 (2 butchers + 1 grocer)	20 (1 grocer)
45 years and over	7 (3 butchers + 1 grocer)	21
Total ..	20	62

10 of the men were employees of the firm involved (butchers, grocery assistants, or worker in the sausage factory), but only two of the women worked for the sausage company implicated. Forty-one of the cases occurred in women over 34, and of the 21 cases in women over 44, 11 were habitual raw-sausage eaters or nibblers. That these women, most of whom have eaten raw sausages for years, should develop trichinosis so late in life suggests that either overt infection is uncommon in Liverpool or that the immunity from any previous infections is inadequate to suppress completely the clinical symptoms on further exposure.

Occupation.—It was noted time and again that the only person affected in the household was the housewife who did the cooking. Further evidence that those handling raw food were in a more vulnerable position came from the finding that 10 male workers in the firm were clinically affected. In most instances the association could be easily explained by the eating or tasting habits of the individual involved. Occasionally there was an emphatic denial of these habits, and the inadvertent finger in mouth or infected knives probably explained these.

Incidence of Raw-Sausage Tasters in General Population (Adult Females)

Sheldon (1941) showed that the eating of raw sausage-meat was a fairly common habit in Wolverhampton. During the present outbreak health visitors, on every routine visit made in the course of their work, were asked to inquire into the habits of the housewife in the family. The following results were obtained:

Housewives interviewed ..	3,412
No. of housewives eating or tasting raw sausage ..	497
No. of housewives not eating or tasting raw sausage ..	2,915
No reply ..	320

From the 3,092 replies received 497 (16.1%) of the housewives were found to be habitual raw-sausage eaters or tasters.

Incubation Period

In only very few cases was it possible to obtain accurate information on the incubation period. This was mainly because most persons usually ate the same kind of meals from week to week, obtaining their supplies from the same source. In two cases there were two phases of the illness. The first case was that of a man who developed an acute attack of diarrhoea and vomiting on October 25. He was very ill, had blood in his stools, from which, however, no pathogenic organisms were isolated, and was admitted to the isolation hospital. He was discharged from hospital on November 4, but developed sudden swelling of the eyes, headache, and pyrexia on November 7, and was readmitted. Larvae were found in a muscle biopsy on November 21. If it is assumed that the acute gastro-enteritis symptoms developed within one to two days of eating the infected meal, this gives an incubation period measured to the initial general symptoms of 14-15 days. This patient's wife was also affected, but her first symptoms were general, developing on November 8. The second case had an interval of 13 days between diarrhoea and eye-swelling. In three other patients there were intervals of 10, 12, and 15 days between the last meal of sausages or pork products and symptoms.

Symptomatology

In former outbreaks of trichinosis in this country the symptomatology has been described mainly of the more serious cases which had been admitted to hospital. An attempt has been made in this outbreak to obtain full clinical details from all types of patients affected, including many of the milder cases treated at home; 22 were admitted to hospital and 60 remained at home. Most of the patients seen were treated by their general practitioner, but a few, who had not attended a doctor for their symptoms, were discovered by health visitors; these persons were advised to consult their general practitioners.

It is of importance in such an investigation to ensure that no case was included which was not suffering from trichinosis. The only certain method of establishing the diagnosis is the demonstration of larvae by muscle biopsy; this was obtained in 16 cases, and included three patients with milder disease treated at home. In most of those patients in whom a muscle biopsy was not carried out the diagnosis was easy to make clinically, as they presented a clear history, together with typical physical signs, and showed a marked eosinophilia. In the absence of eosinostances, but it was found that four patients in whom larvae were found on muscle biopsy had normal eosinophil counts on the 11th-17th day of disease. All cases doubtful on clinical grounds were excluded.

The incidence of the symptoms presented by 82 patients is given in Table III, and it will be seen from this list that these varied considerably from case to case. The classic

TABLE III.—Incidence of Symptoms in 82 Cases

picture of an illness of infection or a gastro-intestinal upset, followed 10-14 days later by general symptoms, was seen in only two cases. In spite of this, many of our patients presented a somewhat similar history, and the following is a detailed description of the commonest signs and symptoms.

Signs and Symptoms Commonly Seen in Patients During the Outbreak

Onset.—In most cases this was sudden, the usual story being that of a patient noticing marked swelling of the eyelids on waking one morning. This swelling was the only finding constant in every patient, and varied from puffiness just below the lower eyelids to gross oedema of the eyelids spreading on to the face, sufficient almost to obscure the eyes. It was usual for the oedema to increase for two to three days and then to disappear more gradually. The oedema became more noticeable after the patient had been lying in bed for some hours. Patients almost invariably have had some pyrexia at the time of the swelling of the eyes, and the temperature most commonly was in the range 100-103° F. (37.8-39.4° C). Some pyrexia often persisted for two to three weeks, and usually the temperature gradually subsided over this period.

Headache.—This was present in 72 patients (87.8%), was mainly frontal, and was located by many as being behind the eyes. It usually began after the swelling of the eyes had been present for about 24 hours; in a few persons, however, headache did not develop till a few days later. Headache was a distressing symptom; many patients described it as severe and likened it to a feeling as if the

($\times 10$.) FIG. 3.—Longitudinal section of stem of new prosthesis illustrating depth of crazing. Fragments of polymethyl methacrylate 1-2 mm. in thickness adhering to metal rod. ($\times 15$.)

FIG. 4.—Metal rod seen through head of prosthesis, showing crazing. ($\times 10$.) FIG. 5.—Surface of metal rod showing corrosion pits. Prosthesis of which this rod was a part was in body for 18 months. ($\times 11$.) FIG. 6.—Case 1. (March 30, 1953.) Rarefaction of inferior cervical margin with enlargement of track resulting in shift of fulcrum laterally.

FIG. 7.—Case 1. (May 4, 1953.) Fracture of stem of prosthesis and of bone inferiorly. FIG. 8.—Case 2. (July 21, 1952.) Excessive varus insertion of prosthesis. Note short metal reinforcing rod. FIG. 9.—Case 2. (October 30, 1952.) Widening of track.

J. T. SCALES AND J. M. ZAREK: BIOMECHANICAL PROBLEMS OF THE ORIGINAL JUDET PROSTHESIS

FIG. 10.—Case 2. (December 1, 1952.) Following insertion of second prosthesis with extended head. Length of neck further reduced.

FIG. 11.—Case 2. (February 16, 1953.) Shows fracture of stem at theoretical position.

FIG. 12.—Case 3. (September 26, 1952.) Five weeks after insertion of prosthesis. Appearance of avascular necrosis of superior medial portion of neck. No widening of track.

FIG. 13.—Case 3. (May 21, 1953.) 29 weeks later. Great trochanter not united. Absorption of femoral neck and widening of track with shift of fulcrum to region of fracture of stem.

FIG. 14.—Case 4. (July 30, 1951.) Prosthesis does not penetrate lateral cortex.

FIG. 15.—Case 4. (November 17, 1952.) 68 weeks post-operative. Widening of track. Superimposed outline shows skirt must have impinged upon superior margin of neck of femur. Fracture of skirt has probably occurred, giving rise to pain and limitation of movement.

FIG. 16.—Case 4. (March 25, 1953.) 18 weeks later. Further widening of track with fracture of inferior part of neck of femur. There is reorientation of trabeculae in relation to distal end of stem.

FIG. 17.—Judet prosthesis after 21 months in the body, showing crazing of unworn area of the surface of the head. ($\times 100$.)

front of the head was about to burst. Photophobia usually accompanied this violent headache and lasted often for four to five days.

Muscular Pains.—These nearly always first occurred two to four days after the swelling of the eyes, and varied considerably from case to case, but the intensity of muscular pain did not seem to depend upon the severity of the case. Patients found it unusually difficult to describe the type of pain which they experienced; the most commonly used descriptions were those of a "stiffness type of pain" or of a "heavy dull pain," and many patients reported that their pains increased on movement, especially on moving a muscle after rest, although when the muscle was further exercised the pain became less apparent and often disappeared. In this way patients themselves noticed that their muscular pains were similar to those felt in muscles following unusual exercise, such as the pains experienced by any athlete at the beginning of a new season of sport. Muscular pains have not been the predominating symptom of most patients, although they were very acute in a minority. In most persons the severe headache usually developed before the muscular pains, and was more troublesome.

Insomnia.—At the start of their illness 46 patients (56.1%) suffered from marked insomnia. This finding was commented upon by patients and relatives who, having noticed that the patient was very lethargic and found concentration difficult, were surprised at the difficulty in sleeping. This insomnia has been a characteristic of so many patients that it has suggested a useful additional diagnostic sign, for, in most persons, the insomnia could not be explained satisfactorily by the symptoms, and represented an obvious feature of its own.

At the end of the first week of illness, the swelling of the eyes had largely disappeared and the picture in most cases was that of a persisting pyrexia, with some muscle pains and marked lethargy and weakness, and this condition usually then slowly improved until after two to three weeks the patient was free from symptoms although still feeling very weak.

Splinter Haemorrhages.—Splinter haemorrhages under the finger-nails as described by Sheldon (1941) were seen in eight cases (9.8%).

In all instances these haemorrhages developed late in the disease (second and third weeks) and therefore were of no value in early diagnosis. Characteristically, the haemorrhages occurred under the tips of the nails (see Fig. B), and in all but one patient they occurred under all the finger-nails.

Eosinophilia.—Apart from four persons, in all of whom larvae were demonstrated by muscle biopsy, an eosinophilia was present in all cases, varying from 550 to 12,000 eosinophils per c.mm.

Other Signs and Symptoms.—Constipation was reported in 29 cases (35.4%), and was a much commoner finding than diarrhoea (7 cases, 8.5%). Vomiting occurred in 24 patients (29.5%), and was usually of short duration, being most commonly reported on the first and second days of the illness. Lethargy was a very obvious feature of 26 cases (31.7%), although a much larger number reported that they felt tired and washed out. Neck stiffness was reported in 26 persons (31.7%), and included in roughly equal proportions a stiffness when moving the head antero-posteriorly and from side to side.

Complications in Central Nervous System

In five patients (6.1%) obvious abnormal central nervous system signs developed. In four these began at the end of

the first week of illness and in the other at the end of the second week. One patient developed signs of cerebellar involvement and later a monoplegia; another quickly lapsed into coma, adopting a meningeal position and cry. A further case developed a wrist-drop. Two additional patients lapsed into a semicomatose state and remained critically ill for one to two weeks—one of these also developed a monoplegia. In the five cases with C.N.S. involvement lumbar puncture showed no abnormality.

Nine cases showed minor psychic disturbances, with either delusions or an obvious personality change; these findings resulted in one family considering seeking psychiatric advice, while three patients confessed that they thought they must be going mad. The personality changes mainly took the form of the patient behaving in an unusual manner. One sang constantly; another climbed out of bed and calmly urinated on the floor. Hallucinations and visual disturbances were not reported.

Disturbances of balance mainly associated with dizziness occurred in 23 cases (28.0%). This was not a troublesome symptom and usually cleared up within a few days.

Cardiac Complications (Including Details of a Fatal Case)

In the whole series there was one fatal case (see below). Another patient died from a pulmonary embolism during the third week of the disease.

Report of Fatal Case.—A man aged 45 began his attack on November 3 with sudden swelling of the eyes; frontal headache developed a day later. The initial part of his illness lasted one week, at the end of which he began to suffer from cramp-like pains in the back of his neck. At this stage his family had become extremely worried on account of his unusual behaviour. On November 17 he noticed that his right hand felt very heavy and that he was unable to lift it up.

He was admitted to hospital on November 20, and on examination was found to have a right wrist-drop, but, with the exception of a doubtful positive Babinski sign, no additional abnormalities were found in his central nervous system. Lumbar puncture findings were normal. He had a low-grade pyrexia, and on November 21 a blood count showed an eosinophilia of 3,800 cells per c.mm. He was treated with cortisone, 100 mg. daily, beginning on November 21. By the 23rd an obvious improvement in the condition of his right hand was noticeable as well as in his general condition. Next day he felt further improved, had breakfast, but, on sitting up, suddenly collapsed and died within a few moments.

At necropsy, no abnormality was found on naked-eye examination in any organ except the heart, which showed moderate left ventricular hypertrophy. Patchy atheroma was present in the coronary arteries, but complete occlusion was not found.

Histological examination of the heart showed a widespread focal destruction of the muscle fibres with an acute inflammatory reaction, the cells consisting of polymorphonuclear leucocytes with a high proportion of eosinophils (Plate, Figs. 1 and 2). The foci varied in size, some consisting of small clusters of inflammatory cells, others being about 1 mm. in diameter. The foci seemed to be of different ages, the youngest being at the stage of cellular infiltration, the oldest showing the changes of early organization. No parasites were found in any of these foci, nor were masses of foreign material seen which might have been the remnants of partially absorbed parasites.

Sections of the voluntary muscle of a limb showed a much more marked eosinophilic and polymorphonuclear leucocytic infiltration, but no focal areas of necrosis were found such as occurred in the cardiac muscle. In contrast, the cells were widely scattered between the individual muscle fibres and separated them. Larvae were found in fusiform gaps between muscle fibres which contained an inflammatory reaction at both ends. No cysts had formed. Neither parasites nor tissue reactions were found in sections in any other organ, including the brain.

The absence of any abnormal macroscopic signs at necropsy to account for this patient's sudden death suggested that he might have died from a sudden failure of the heart similar to that seen occasionally in diphtheria, and the subsequent microscopical findings supported this theory. Consequently a very careful watch was kept for any other patients developing signs late in their illness suggestive of a possible heart failure.

Three cases of sudden unexplained breathlessness beginning at the end of the third week of illness were traced.

All these patients had an obvious breathlessness and one had oedema of the legs, but there was no venous congestion in any of them and all had a regular rhythm of the heart. All did, however, show some tachycardia of 110-120 a minute. Unfortunately, further detailed examinations, including E.C.G. tests, were not carried out.

When the findings of these cases are considered in conjunction with the microscopical findings in the heart muscle of the fatal case, it seems suggestive that unexpected cardiac failure may occur in trichinosis as a late complication, especially towards the end of the third week of the disease. Certainly any unexplained fainting or breathlessness at this stage of the illness, particularly if associated with tachycardia or a low blood pressure, should be taken seriously and the patient nursed in the recumbent position.

It is interesting to consider the possible causation of the myocarditis in the fatal case, which occurred two to three weeks after the first larvae had migrated from the bowel. As no larvae were found in the heart muscle it is unlikely to be a direct reaction to their continued presence. It is usually believed that the larvae encyst mainly in the muscles with a high metabolic rate, such as the oesophageal muscle, diaphragm, and the intercostal muscles. The fate of other larvae in the rest of the body—and there must be a very large number of them—is unknown. By analogy with experimental animal infections with trichinellae, destruction of the larvae in muscles of low metabolic rate would occur from the second week onwards. This raises the possibility that the myocarditis occurred at the time of larvae destruction in the heart muscle and may have been due to the products of destruction.

Sequelae

Fifty-two of the cases were followed up by health visitors four to six weeks after their illness. Only 15 of these patients reported that they felt fully recovered. The majority complained of tiredness and lack of energy, and 24 had not returned to work. Nine of the group had some transient breathlessness which lasted a few days, developing in every case from the third to fifth week. Further visits were paid to all patients still showing some symptoms, and at the time of writing this report 16 were still being visited. The general picture is of an exhausting debilitating disease from which recovery is very slow.

Laboratory Investigations

The methods used in examining the muscle are described in detail, since it is only by this means that the diagnosis can be established with certainty in a suspected clinical infection. A piece of muscle about 2 c.cm. in size was removed under local or general anaesthesia from the deltoid or the outer aspect of the thigh, or wherever local symptoms suggested, with due regard to cosmetic results. A small flat disk about 5 mm. in diameter, with the muscle fibres running along the surface, was pressed between two glass slides until it was about 2 cm. in diameter, and examined unstained under the low power of the microscope. Coiled larvae were usually seen clearly, but the smaller earlier stages, which have less well-defined morphological features and which lie along the axis of the muscle fibres, were seen only with difficulty. In a heavily infected case a larva was usually found in a few minutes, but in others half an hour or an hour was spent before one was found. As will be seen from Table IV in seven cases no larvae were found by direct examination, though they were found in a digest.

Digestion of the muscles was done in all cases. A weighed quantity about 2-5 g. was cut into small fragments and incubated overnight in 250 ml. of 1% acid pepsin, then centrifuged and a little formol saline added to the deposit. The fixed deposit was examined in a "perspex" cell 4 cm. by 3 cm. by 3 mm. on a inverted microscope. Since the larvae are much heavier than the debris, they can be

seen clearly as refractile objects with definite morphological characteristics lying on the bottom of the cell against the vague background of the debris (Plate, Figs. 3, 4, 5, and 6).

Summary

An outbreak of trichinosis is described which occurred in Liverpool in the late autumn of 1953 and involved 82 persons.

Infection was traced to sausages in most cases. In two instances pork roasted at home was responsible. Although epidemiological investigation traced the infection to a particular carcass of pork, it was impossible to trace this finding back to a piggery, as no records existed to enable this to be done. There is an obvious need for such records to be kept by the Ministry of Food.

Women were affected more often than men (60 to 22). Analysis of the eating habits of 3,412 housewives in Liverpool showed that 16.1% habitually ate raw sausage.

The symptomatology of 82 cases is considered in detail. Oedema of eyelids, headache, muscular pains, pyrexia, photophobia, and insomnia were the most commonly reported signs and symptoms.

A fatal case is recorded, together with the post-mortem findings. The complication of myocarditis developing in the second and third weeks of disease is considered, and it is emphasized that any suggestion of cardiac involvement should be treated seriously and the patient nursed in a recumbent position, as there is a possibility of sudden death.

Larvae were isolated from the muscles of 16 patients.

Thanks are due to the many general practitioners and consultants, hospital staff, and our public health colleagues in neighbouring districts who, by their whole-hearted co-operation, made this epidemiological and clinical study possible.

We are indebted to Professor B. G. Maegraith, Dean of the Liverpool School of Tropical Medicine, for his assistance with the photographs and to Mr. J. Brady for taking them.

 (University of London), London

[WITH SPECIAL PLATE]

In the treatment of pathological conditions of the hip-joint much surgical ingenuity has been exercised in the development of various types of arthroplasty. Recently the Judet technique seemed to offer a considerable prospect of success, and indeed the preliminary results published by J. and R. Judet (1950) were encouraging. The results achieved in this country, however, have been less satisfactory than those claimed by the Judets in 1952. In their later report they state that "fracture of the stem of the prosthesis has not occurred in 500 operations since the stem of the prosthesis has been reinforced with a steel core. Undue wear of the surface of the head has occurred in three cases, and we are seeking its cause."

In view of the number of breakages and instances of wear of prostheses manufactured in this country, however, it was decided to investigate the reasons for these mechanical failures. The work has been made possible only by the generous co-operation of a number of orthopaedic surgeons. Our investigations suggest that both the design of the prosthesis and the combination of materials used in this country are unsatisfactory.

It seems that delayed failures of the operation are commonly attributable to one or more of the following: (1) failure of the materials; (2) malposition of the prosthesis; (3) interference with the local blood supply to the bone.

Before giving examples of causes of failure it is important to consider the mechanics of the hip-joint, the materials used in the prosthesis, the design, the method of manufacture, and the blood supply of the neck of the femur.

Mechanics of the Hip-joint

In a person standing erect with both feet together the weight of the head, arms, and trunk is distributed equally between both hip-joints. For example, assuming the total weight of the patient to be 70 kg., and the weight of each lower limb 15 kg., there will be 20 kg. carried by each femoral head, with the body weight acting vertically downwards in a sagittal plane. If now the patient stands on one leg, keeping the pelvis horizontal, the hip-joint becomes the fulcrum of a lever (Fig. A). The weight of the body carried by the supporting hip-joint becomes 40 kg. for head, arms, and trunk, plus 15 kg. for the non-weight-bearing limb. Because the femoral head represents a fulcrum of a lever, the total moment about this point which has to

be resisted by the contraction of the glutei, tensor fasciae latae, etc., can be calculated as follows from Fig. A:

Assuming that the distance OW from the symphysis pubis to the centre of the area of contact of the femoral head with the acetabulum is 10 cm., then the moment due to the weight of the head, upper limbs, and trunk is $40 \text{ kg.} \times 10 \text{ cm.} = 400 \text{ kg.cm.}$ The moment due to the non-weight-bearing limb is $15 \text{ kg.} \times 20 \text{ cm.} = 300 \text{ kg.cm.}$ The total moment is therefore 700 kg.cm.

Assuming that the resultant force due to muscle pull acts on the great trochanter at a distance OQ of 5 cm. from the centre of the femoral head and at an angle of 45 degrees, then, from the consideration of moments, $Q = 140 \text{ kg.}$, and the vertical reactive force (R_1) is equivalent to $140 + 40 + 15 \text{ kg.} = 195 \text{ kg.}$

From a consideration of statics the total reactive force carried by the head is equal to 240 kg. (R) and acts at 36 degrees to the vertical. Therefore the angle between the axis of the prosthesis in the bull's-eye position and the direction of the force transmitted by this joint is 12 degrees. As in the process of obtaining this result a certain number of assumptions

had to be made, the results will vary from patient to patient, but they give an indication of the magnitude and direction of the acting forces under static conditions.

When the patient is walking, accelerating and retarding forces come into operation and, according to their magnitude, may produce a load on the joint which will exceed the static value. At times the line of body weight may move further from the hip-joint, and this will also increase the load carried by the joint. Under shock load conditions, as when a patient accidentally steps off a kerb, the instantaneous loading value will be even greater. Considerable work on the mechanics of the hip-joint has been done by Ros y Codorniu (1949), by Osborne and Fahrni (1950), and by Endler (1953b).

Materials, Design, and Method of Manufacture

Materials.—The development of organic synthetic materials has resulted in a range of materials which appear suitable for use in contact with body tissues. Any material to be used inside a joint must fulfil certain requirements (Scales, 1951). It should be chemically inert, physically unaffected by tissue fluids, incapable of provoking an inflammatory or foreign-body response in the tissues, non-carcinogenic, incapable of producing a state of allergy or hypersensitivity, capable of standing up to the mechanical strains imposed upon it, and capable of being fabricated simply into the form required. Because polymethyl methacrylate satisfies most

FIG. A.—Patient standing on one leg, assuming pelvis horizontal. $W = 40 \text{ kg.}$ $L =$ pendant limb $= 15 \text{ kg.}$ $O =$ fulcrum of joint. $O'A =$ axis of femur. $O'B =$ direction of resultant force transmitted through joint. $O'C =$ axis of neck of femur and prosthesis when inserted in bull's-eye position.

of these requirements, the Judets, in 1946, used it for their reconstructive procedure. In this country the material used is unplasticized polymethyl methacrylate produced by Imperial Chemical Industries, Ltd., under the trade name "perspex." The mechanical properties of thermoplastics are a function of temperature, and it may be taken that the following values for perspex apply at 37° C.: maximum tensile stress, 490 kg./cm.²; modulus of elasticity, 2.625×10^4 kg./cm.²; Vickers pyramid hardness, 15-18. The linear coefficient of thermal expansion at 37° C. is 9.7×10^{-5} per °C.*

Design.—The standard Judet acrylic prosthesis used in this country up to the time of writing is a "mushroom-like" structure. Various stem lengths and head diameters are available. The head is approximately two-thirds of a sphere and is recessed to take the shaped basal part of the head and adjacent neck of the femur. The grooves on the stem and the squared taper are devices to prevent rotation, and vary according to the manufacturer. The stem is reinforced with a metal rod which is totally enclosed by the resin.

Method of Manufacture.—The shape of the prosthesis having been turned from the solid block, a hole of slightly less diameter than the metal rod is drilled up the stem into the head. The method of insertion of the rod depends on the ideas of the manufacturer. The hole is filled with a solvent or cement in order to soften the surrounding acrylic locally, thus allowing a metal rod to be forced into the cavity—a type of "shrinking" fit being obtained. A perspex plug is next inserted to fill the remainder of the hole, and the tapered end of the stem is subsequently fashioned. The coefficient of expansion of polymethyl methacrylate is eight times that of steel, and consequently the bond between the acrylic and the metal rod is subject to disturbance when the temperature of the prosthesis is raised either during sterilization by heat or, to a less extent, when it is placed in the body after formalin sterilization. For greatest reinforcement of a structure there must be, of course, adequate bonding between the two materials used, and a sufficient anchorage. We have found that in a number of cases the reinforcing rod had such a loose fit that it rattled. One manufacturer drilled a hole through the metal rod; the acrylic cement filled this hole and thus prevented the rod from rattling.

Biomechanical Analysis of the Design.—The design of the prosthesis should be such that: (1) it is strong enough to transmit the forces due to body weight and the action of the gluteal muscles to the shaft of the femur, without danger of mechanical failure; (2) it can distribute the load on the femur as uniformly as possible without endangering the blood supply and without producing local crushing of the bone; (3) the dimensions of the head will give greatest loading area with least limitation of movement of the femur.

Theoretical Considerations

Fig. B shows a prosthesis with a stem correctly penetrating the cortex; it rests on an area represented by the point B₁, where the bone may be either cancellous or cortical or both. The resultant action of the weight of the body and the action of muscles is represented by force P acting medially to B. This force can be resolved into two components, P₁ and P₂. Thus the prosthesis is subjected to bending and shearing due to P₁ and direct stress in the direction of the stem due to P₂. Torsional stresses should be negligible. Owing to the penetration of the cortex the direct stresses due to the component P₂ are taken up by the annular part of the prosthesis under the skirt. The stem will thus be subject only to bending and shearing stresses due to P₁ as indicated diagrammatically by I and II in Fig. B.

As the angle i increases, the component in bending P₁ also increases, since $P_1 = P \sin \alpha$, the angle α being directly

proportional to angle i . The moment about B thus increases, since it is a product of P₁ × AB.

Should AB increase because of the movement of the point of support laterally, as occurs with absorption of the cancellous of the inferior cervical cortex, then there will be a further increase in the value of the moment about B₁ (Fig. C). This distance AB is necessarily large when a prosthesis with an extended head is used. As the value of the bending moment increases, so the value of R₁ must also increase. There are thus three situations which may arise: (1) a state of equilibrium of the structure is reached; (2) the flexural strength of the stem of the prosthesis is exceeded and failure occurs; and (3) fracture of the bone takes place. When the stem does not penetrate but abuts against the lateral cortex, or where there is incomplete penetration of the cortex by the taper of the stem and the annular part of the prosthesis is not in contact with the transected neck, then direct stress will be additionally introduced in the stem. Should the stem not be long enough to reach the cortex, the direct stress will again be taken up by the annular surface, but the prosthesis will undoubtedly be in a less stable equilibrium.

When comparing the loading of the neck of a normal femur with that in which a Judet prosthesis has been inserted, it is clear that the distribution of load through the prosthesis is far from favourable. As seen in Figs. B and C, the reactive force R₁, which may be either local at B₁, or distributed along a greater or lesser extent of the lower surface of the stem, may be excessive; nor does its direction of action correspond with the normal anatomical "lines of force" in the region of the calcar femorale.

As the ratio of the modulus of elasticity of stainless steel to that of polymethyl methacrylate is as high as 86:1, full advantage of the metal insertion can be achieved only if adequate anchorage of the reinforcing rod is provided and the bonding stress between the two materials is high enough to ensure that no movement between the plastic and the metal insert takes place during straining. If the bond is poor or the insert is actually loose, then failure of the plastic part of the stem will take place under a very low load.

Experimental Findings

Preliminary tests on the prosthesis under static load were carried out. A prosthesis of the Judet type but without a metal reinforcement, fitted into a femur, failed under a vertically applied load of 470 kg., giving a failing stress in bending in the stem of 490 kg./cm.² This result agreed with the one obtained by Endler (1953a).

In order to test prostheses reinforced with steel, a metal reproduction of the femur was made

FIG. B.—Prosthesis in bull's-eye position. I = Bending moment diagram. II = Shearing force diagram.

FIG. C.—Shift of fulcrum B, due to absorption.

for the plastic part of the stem of a number of tested prostheses were in the range of 420-560 kg./cm.²

If the prosthesis is correctly fitted the forces involved during normal movement of a patient produce much lower stresses in the stem, but nevertheless cause failure. It was evident that other factors such as fatigue of the materials and stress corrosion must be responsible. Examination of a number of prostheses which had failed in the body confirmed this belief. The results of a typical metallurgical investigation are given below.

The metal pin under investigation was part of a prosthesis which failed in service after insertion. It was supposed to be made from austenitic stainless steel of the 18% chromium and 8% nickel variety, but when reference was made to the makers no indication of the exact type or condition of the steel could be obtained. Examination of the surface of the pin showed that it was badly polished, having the appearance of a "filed" type of finish. The fractured surface (Plate, Fig. 1) of the rod consisted of two parts: first, a fairly smooth area marked with a series of concentric rings, the centre of which was a point on the periphery of the pin; and, secondly, an area with a fine-grained "crystalline" type of fracture. These findings are typical of a fatigue failure.

In order to examine the micro-structure of the rod, a longitudinal section was polished and examined in the unetched condition. The following observations were made: no sign of cracking was noticed either immediately adjacent to the fracture, or anywhere on the specimen; and the steel did not contain any non-metallic inclusions, or any other signs of defects.

Subsequently the specimen was etched in Murakami's reagent to examine for carbides, and the following observations were made: the structure now showed a number of black particles and pits; these particles appeared to be parallel to the direction of the working of the pin; no other structure was visible.

It was considered that free carbides were present in the material. Finally, the specimen was repolished and etched in aqua regia and the following observations were made: (a) The general structure was typical of an 18/8 austenitic stainless steel. (b) The structure again showed the presence of particles elongated by working, which were assumed to be carbides; another constituent, the nature of which was not established, was probably free chromiferous ferrite. (c) There was no plastic deformation of the surface of the grains over the fractured surface, or any signs of defects.

The hardness of the steel was of the order of 230 Brinell, which is equivalent to a tensile strength of 7,560 kg./cm.² and represents a nominal figure for this type of steel. In conclusion it may be said of the fracture that: (a) It is a fatigue fracture. (b) It may have been due to either too low a fatigue limit of the material used or a lowering of the fatigue limit by structural or corrosive effects. (c) The material, although an 18/8 stainless steel, shows in its microstructure the presence of a certain amount of included material. These inclusions, unusual in this type of steel, may consist of free ferrite or free carbide, and could act as stress raisers and thus seriously reduce the fatigue strength of the steel. (d) The presence of these constituents in the structure would seriously reduce the corrosive resistance of the steel, and only a slight corrosion of the pin would be sufficient to reduce the fatigue strength even further. No evidence of corrosion was found in the specimens, but it should be noted that corrosion effects are rarely seen in stainless steels when failure occurs by corrosion fatigue.

Polymethyl methacrylate, according to the makers' tests, loses 50% of its strength when subjected to a constant load well below its breaking strength for about 1,000 hours at 20° C. (Hoff, 1952). Its ultimate static strength also depends on the straining rate (Maxwell and Harrington, 1952). Fluid absorption, which according to the makers may reach 2%, will also have some effect on its mechanical properties.

When a material is subject to cyclic stressing well below the value of the static failing stress, a progressive deterioration of its strength takes place and may finally result in failure. For the investigation of the behaviour of metals suitable methods of testing have been developed, resulting in reliable information.

It is realized that the characteristics of metals and plastics differ widely. As there are no suitable methods of fatigue testing for plastic materials, we have adopted the well-established method used in the investigation of metals, which, we believe, should give an approximately correct result.

Specimens of perspex made from rods as supplied by the makers were fatigued in flexure with full reversal of stresses at 2,000 cycles a minute. Curve A in Fig. D shows that the stress fatigue limit is in the range of 110 kg./cm.²

As it is a customary procedure to sterilize the prosthesis by boiling, a series of tests were performed as for Curve A, but, before testing, the specimens were boiled for 30 minutes and then plunged into cold water. It is evident from

FIG. D.—Fatigue test results on polymethyl methacrylate. Curve A = material as supplied by the makers. Curve B = test specimen, boiled and cooled before testing.

Curve B (Fig. D) that this procedure has reduced the fatigue limit to approximately 70 kg./cm.². The same degree of reduction in strength was observed when, after boiling, the specimen was allowed to cool very slowly.

From these tests the following comments can be made: (1) The fatigue strength of polymethyl methacrylate when subjected to rapidly fluctuating stresses is from 15% to 25% of its ultimate strength. In both tests the results indicate a high degree of scatter which may, in part, be attributed to poor heat conductivity of the material and high hysteresis losses. (2) The decrease of strength of the material after boiling may be due to water absorption or to an alteration in the structure of the polymer. (3) In application to the human body the frequency of 30 cycles per minute may be accepted as around normal and therefore a certain percentage of strain recovery is possible.

Fig. E shows results of fatigue tests in flexure on prostheses with a 6.3 mm. stainless-steel reinforcing rod. In

FIG. E.—Fatigue tests in flexure on prosthesis with a 6.3-mm. diameter metal reinforcing rod.

two cases the plastic and the rod failed simultaneously. In all others the plastic part of the stem failed and slipped off the metal rod. The tests suggest that the value of the moment of resistance of 41 kg./cm. may be accepted as a fairly safe limit. From simple calculations, assuming the force transmitted by the joint to be 240 kg. and the angle of insertion i to be 56 degrees, it is found that in the human body the above moment of resistance will be exceeded only if the point of application A of

*Values as given by Imperial Chemical Industries.

load P (Fig. B) is further than 8.2 mm. from the point of support B. This figure was obtained using the experimentally determined safe value for stress in the plastic part of a stem with a 6.3 mm. reinforcing rod. Again, simple calculations indicate that if an 8.0 mm. steel rod were used the critical value for the distance AB would be about 18 mm.

This critical condition could be satisfied with much greater ease if the 0.67 sphere of the Judet head could be replaced by a hemisphere. All these calculations are based on experimental results obtained under laboratory conditions with a frequency of 2,000 cycles a minute. It is realized, however, that the carrying capacity of the Judet stem may be greater under actual working conditions, because the less frequent straining may allow strain recovery. Nevertheless it seems that the distance AB should not exceed 2 cm.

The average failing strength of the prostheses in which both the steel reinforcing rod and the acrylic failed was appreciably higher than that in which the acrylic alone failed. The two different types of failure of the stem may be explained in terms of anchorage and bonding stress between the acrylic and the metal rod. The better the bond the higher is the fatigue failing strength of the prosthesis. Sterilization by boiling disturbs the bond, and therefore other methods not involving a rise in temperature should be used. Qualitative analysis of bonding stresses in a great number of prostheses, by means of the photo-elastic method, indicated that the bonding stress between the acrylic and the metal rod of an initially good prosthesis was reduced considerably in the process of boiling. Immediately after boiling, residual thermal stresses were present in the head of the prosthesis, causing high stress concentration at the point of junction of the stem and the head. These decreased slowly, disappearing in about two hours.

A prosthesis in a state of stress will be more vulnerable to impact, which may cause failures during insertion.

The grooves in the stem vary in length, depth, shape, and surface finish. When a structure is subjected to cyclic stresses it is of the utmost importance that a perfect polished-surface finish should be obtained, as a rough finish is a source of stress raisers (Plate, Fig. 2).

Examination of new prostheses which failed in fatigue under laboratory conditions revealed a brown deposit on the inner wall of the acrylic stem and the surface of the reinforcing rod. A chemical analysis indicated that this was iron oxide, and the quantity formed was directly related to the magnitude of the stress in the metal rod, the deposit being greatest at the point of maximum bending moment.

It is known that materials which in an unstressed condition show no signs of corrosion may behave differently when in a stressed condition. In engineering practice the term "corrosion fatigue" is used to describe the simultaneous action of corrosion and fatigue. It has also been found that corrosion which takes place in a material before subjection to cyclic stress has a far less damaging effect than a slight corrosion taking place simultaneously with the applied stresses. It is thus of great importance to investigate the behaviour of materials under the action of body fluids and the chemical constituents of the resins and solvents, both in the stressed and in the unstressed condition.

In an effort to overcome the shortcomings of the Judet prosthesis, some surgeons have resorted to the use of stainless steel or vitallium prostheses. It is only in recent years that materials have been used in orthopaedics in situations where they will be subjected to constant fatigue stresses in contact with tissue fluids. Most metal appliances have been used for temporary fixation of fractures and have rarely been exposed to prolonged fatigue stresses once union of the fracture has occurred. A metal prosthesis may initially have a better load-carrying capacity, but the problem of stress corrosion remains.

Polymethyl methacrylate is also subject to crazing (Russell, 1948; Sauer and Hsiao, 1953) which is defined as

fine mechanical cracking over the surface of the material, penetrating to a depth which depends on the intensity of the cause. It may be brought about by the simple or compound action of such factors as mechanical stressing, solvents, and high energy radiation. Only the first two factors, however, are significant. It has been found that only tensile stresses produce crazing, the direction of cracks taking place at right angles to the direction of action of the tensile stress. The intensity depends on the magnitude, rate, and duration of the stress applied, the dimensions of the specimen, and its heat treatment. Solvent crazing patterns are irregular, in contrast to the well-orientated ones produced by tensile stresses, although the physical effects are the same. Stresses due to the forced fitting of the metal rod in the presence of solvent cause crazing of the inner wall of the stem; it has been found that the penetration of crazing was considerable even before stressing the prosthesis externally (Plate, Figs. 3 and 4). It is evident that serious defects exist in the prosthesis even before it is put into use.

Blood Supply

The blood supply to the head and upper neck of the femur is derived from three main sources: the nutrient artery, the retinacular vessels, and the trochanteric fossa anastomosis.

The proportion of flow from each of these sources is variable from patient to patient. The retinacular vessels are arranged in three main groups (Tucker, 1949) postero-superior; postero-inferior; anterior—which pass up beneath the synovial membrane reflection and penetrate the base of the head and upper neck through a number of foramina to anastomose with branches of vessels from the nutrient artery and trochanteric fossa. We have found that the vessels supplying the cortex of the femur originate mainly from the medullary network (J. T. Scales, unpublished observations). Any reaming of the neck to take the skirt may cause considerable damage to the retinacular vessels. The insertion of the stem of the prosthesis must further interfere with the vascularity of the bone. Revascularization is made more difficult by occlusion of parts of the neck by the skirt. It is vital that the cortex should be interfered with as little as possible and that prostheses with occlusive cuffs should not be used.

Analysis of Clinical Material: Prostheses

Thirty prostheses removed because of structural failure have been examined. In most cases the clinical notes and radiographs have been made available to us.

Of the 30 prostheses sent to us 21 were removed because of fracture of the stem. In 17 cases the site of the failure was within 2 cm. of the base of the head. This was found to coincide with the most probable position of the point of support B₁ (Fig. B)—that is, the position of the greatest bending moment. Here also the surface of the stem is interrupted by the beginning of the milled grooves. The stems of six were broken near the distal end of the rod, in the region of C. Two stems had fractured in both regions.

Coarse crazing of the surface due to the milling operation was present in all stems examined. In many cases deductions made about the position of the fulcrum B₁ and the distally situated point of reaction C on radiographs were confirmed by worn areas on the acrylic stem in the corresponding positions.

Leakage of tissue fluid around the stem plug was seen in a number of cases. This is a serious matter when the reinforcing rod is not inert.

Of the 30 broken prostheses studied the metal rod had failed in 15. In 12 cases the site of the fracture was about the mid-point of the rod, coinciding with the position of failure of the acrylic part of the stem. In three instances in which the metal rod had been drilled at its distal end failure occurred in the cross-section of the rod. In six cases the rod was intact, although the stem had fractured,

and the site of failure in these cases was either immediately adjacent to the base of the head or at the distal end of the metal rod. The rods examined were from prostheses produced by five different manufacturers. Their diameters, together with the number of failures in each category, are given in the Table. Nitric acid (S.G. 1.200) was applied to

Diameter of Metal Rods, With Number of Failures in Each Size

Diameter of Metal Rod (mm.)	No. of Rods	No. Broken
4.5-	1	1
5.0-	1	1
5.5-	19	11
6.0-	3	1
6.5-	3	1
7.0-	0	0
7.5-8.0	3	0

28 rods and a positive reaction was obtained in 11 cases, indicating that these rods were not stainless steel. Of the 17 that were negative to nitric acid, eight were magnetic and were therefore most probably not of the austenitic variety of steel. (Austenitic steel can become slightly magnetic during working, but usually loses this property in a short time.) Corrosion pits were visible in nine of the rods (Plate, Fig. 5), all giving a reaction to nitric acid. One manufacturer used rods of a copper-zinc-nickel alloy, which had been chromium-plated and had the appearance of stainless steel. The surface finish of most of the rods was poor. A mirror finish should be obtained, as small scratches and grooves are apt to be centres of corrosion.

In a few instances, when the acrylic stem was cut and the metal rod withdrawn, a quantity of liquid was found which smelt strongly of burnt sugar. After a few minutes the inner surface of the stem turned yellow. This phenomenon was unexplained. A number of rods were surrounded by a white powder which fluoresced under ultra-violet light. In a number of instances the surface of the polymethyl methacrylate and the metal rod were not every-

FIG. F.—Voids at metal/acrylic interface. Note also leakage around plug and crack in acrylic at pointed end of metal rod. (x3.)

where in contact (Fig. F), so there was a very poor bond between the metal and plastic. Wear of the weight-bearing area of the acrylic head was plainly visible in 12 of the 30 prostheses. The Vickers diamond test (1 kg. load at 20° C.) gave hardness numbers between 22 and 26, with one at 18, on 23 prostheses, the worn areas giving slightly higher values.

Examination of 21 heads by ultra-violet light revealed crazing of the surface (Plate, Fig. 17)—never in the worn part, but always in the surrounding area. In the nine heads showing no apparent wear, crazing could not be demonstrated, suggesting that crazing precedes wear.

It is possible that wear of the head is a cause of pain and limitation of movement in those patients in whom the prosthesis appears to be mechanically satisfactory.

The movement of any synovial joint has two components—sliding and rotation. The conditions for efficient lubrication are critical, being related to the nature of the two surfaces in contact, their relative velocities during move-

ment, and their area of contact (MacConaill, 1950). Even if a cartilaginous acetabular roof is present initially, it is unlikely that the dimensions of any implant made in eight sizes of head and having a surface which is not congruous with the acetabulum will fulfil the critical requirements. The surface hardness of a foreign body used as a component of a joint must be such that it will not wear when in contact with bone. If local wear of the prostheses takes place, then in certain positions during movement an excess loading/unit area will result.

Our radiographic studies suggest that the load-carrying capacity of a joint is determined early in life. It is possible that one of the causes of osteoarthritis is an increase in load per unit area which the head of the femur has to carry when the weight of the patient increases in middle and later life. It is suggested that the acetabulum therefore should be reamed so as to accommodate an artificial head of abnormally large diameter, so that the load should be distributed over a greater area.

It has not been possible to correlate wear of the prosthesis with sclerosis of the roof of the acetabulum or with irregularity of its radiographic outline. It was found, however, that wear occurred when the depth of the acetabulum exceeded two-thirds of the diameter of the prosthesis, or, in other words, when the head was relatively small. Thus the femoral head selected should be as nearly congruous with the acetabular cavity as possible.

Examples of Mechanical Failure of Prostheses in Patients

In view of the many interdependent mechanical features, it is not possible to assign a simple reason for failure on radiographic evidence. It is clear from Figs. B and C, however, that where the angle of insertion i is large and where the fulcrum B₁ occurs some distance down the stem, the prosthesis is subject to a large bending moment. Both these factors may be assessed qualitatively on the radiograph. As the direction and point of application of the forces acting through the hip-joint cannot be estimated accurately, it is not possible to predict quantitatively the values of the transverse force P₁ and the direct force P₂, and the bending moment (P₁ × AB). A standardized radiographic technique could be developed which would enable these values to be measured. The method would include the use of the scanogram technique.

Two main methods have been used in the examination of the available radiographs. (1) The dimensions of the radiograph shadow of the metal rod, and the metal rod of the Judet prosthesis which was removed from the patient, have been measured. From these measurements the magnification was determined for each x-ray film. In this manner a reproduction of the outline of the prosthesis was made from transparent cellulose acetate film. (2) The angle of insertion of the prosthesis is defined as the acute angle included between the line of the stem and the axis of the femoral shaft with the limb in the neutral position. This angle may be called the stem-shaft angle. It is, of course, realized that there are a few degrees difference in anteversion from patient to patient.

It has been found that when it was possible to measure the angle of insertion, and either the stem or the skirt, or both, were broken, the angle of insertion always exceeded 40 degrees. In the radiographs of nine patients in which the prosthesis was apparently satisfactory the angle of insertion was in the region of 40 degrees or less.

Case 1

This case illustrates the effect of too great an angle of insertion.

The patient, a married woman aged 65, developed osteoarthritis of the left hip after a fall four years previously. On November 12, 1952, a Judet prosthesis, 43/80, was inserted, the neck being reamed to take the skirt of the prosthesis. On January 13, 1953, she was discharged, the movements being as

follows: flexion with extended knee, 90°; flexion, 90°; extension, 10°; abduction, 15°; adduction, 10°; external rotation, 10°; internal rotation, 10°.

When seen as an out-patient on March 13 she was not complaining of any pain and could walk one mile. Fig. 6 (Special Plate) is a radiograph taken at four and a half months and shows the angle of insertion to be approximately 60 degrees. Thus from Fig. 6, since $P_1 = P \sin \alpha$, the value of the transverse component is large. Also the distance AB exceeds the theoretical value of 8.2 mm.

On April 13 the patient felt a sudden snap in the left hip with pain down the leg. Radiographs showed fracture of the prosthesis (Plate, Fig. 7).

The skirt would, of necessity, be broken, because the neck of the femur is displaced upwards. Other factors such as crazing of the acrylic and the use of unsuitable metal were found to have contributed to the failure.

Case 2

This case shows the combined effect of a large angle of insertion, too short a metal reinforcing rod, and the use of an extended neck.

The patient, a man aged 59, had a five-years history of osteoarthritis of the right hip. A Judet arthroplasty was performed in May, 1952. A large cystic space was found in the postero-inferior aspect of the neck, and consequently the stem was inserted as high as possible (Plate, Fig. 8). A radiograph taken in October, 1952, showed a fracture of the acrylic part of the stem of the prosthesis near the distal end of the metal rod (Fig. 9). From the radiographs it will be seen that the stem pierced the lateral cortex, and that the fulcrum was slightly medial to the position of the break. Note that here again the angle of insertion is large and the distance AB is greatly in excess of the theoretical value. The fracture was due to the discontinuity of structure of the stem at a point near the fulcrum.

At operation in November, 1952, it was found that there had been a fracture of the inferior aspect of the femoral neck. It is probable that fracture of the bone, under high bending moment, occurred first, resulting in a shift of the fulcrum laterally. The primary cause of fracture may have been interference with the blood supply at the time of operation. The prosthesis was not available for examination.

The neck was further cut back and reamed and a second prosthesis with an extended head was inserted; Fig. 10 shows that the skirt is impinging on the lower portion of the neck. The distance AB has been further increased. Ten weeks later this prosthesis broke (Fig. 11). The design of the second prosthesis and the unsuitable metal used for reinforcement were contributory factors in its failure. The metal rod, diameter 6.1 mm., was of non-austenitic steel. There was no bonding between the metal rod and the acrylic. The radius at the junction of the skirt with the base of the head was insufficient and there was crazing of the head and stem. There was a visible leak around the acrylic plug.

Case 3

This case illustrates excessive bone absorption and fracture of the stem of the prosthesis through a weak part.

A married woman aged 79, suffering from osteoarthritis, had a right Judet arthroplasty performed in August, 1952. The angle of insertion was approximately 43 degrees (Fig. 12). Progress was satisfactory with no pain until April, 1953, when she complained of severe pain in the hip with some crepitus on movement. A radiograph shows that the stem of the prosthesis had fractured at the cross-section where the metal rod had been drilled, and that there had been considerable widening of the track, the angle of insertion having now increased to 55 degrees (Fig. 13). No fracture of the neck of the femur was visible, but there had been considerable bone absorption of the neck, and the base of the head no longer appeared to be in contact with the bone. The stem was apparently firmly held at its distal end, but with gradual bone absorption the fulcrum was shifted laterally, and this resulted in a high bending moment in the region of the fracture site. This bone absorption was probably caused by interference with the blood supply to the proximal part of the neck. Wear of the head of the prosthesis could not be demonstrated. The surface hardness was 23.2. There was no crazing of the surface of the head or skirt, although crazing was present along the stem. The metal rod was of a non-austenitic steel and was positive to the nitric acid test. Corrosion pits were found in the region of the fracture. No leakage of the stem plug could be demonstrated. The reasons for failure were both anatomical and structural.

Case 4

This case illustrates the detection of a failure by means of a transparent outline model.

The patient, a man aged 71, suffering from bilateral osteoarthritis, had a Judet arthroplasty performed on the left side in July, 1951 (Fig. 14). In November he was free from pain and walking well. Movements were as follows: flexion, 45°; extension, 0°; abduction, 20°; adduction, 20°; external rotation, 20°; internal rotation, 20°.

From January to October, 1952, attacks of pain were relieved by diathermy and other physical treatment, but in November the left hip became much worse. A radiograph revealed widening of the track with downward displacement of the prosthesis (Fig. 15). In December, 1952, movements were: flexion, 70°; extension, -20°; abduction, 20°; adduction, 20°; external rotation, 30°; internal rotation, 0°. There was squeaking of the joint on movement.

His condition deteriorated until March, 1953, when little movement was present (Fig. 16). The hip was re-explored and the skirt of the prosthesis was found to be broken. The larger fragments of the skirt were not found. There was considerable wear of the head and eburnation of the stem just below the base of the head.

On examination the prosthesis was found to have a surface hardness in the worn area of the head of 24.7 and in the unworn area of 23.3. There was considerable crazing of the surface of the unworn part of the head although none was visible on the worn area. There was also crazing of the stem and skirt. The nitric acid test on the metal rod was positive, and it was found to be a chromium-plated copper-nickel-zinc alloy rod.

As the stem of the prosthesis did not penetrate the cortex, it was able to rotate downwards about a point situated near the distal end of the stem, the cancellous bone not offering enough resistance to the reactive force at the fulcrum. A transparent model of the outline of the prosthesis when superimposed on the radiograph taken in November, 1952, suggested that failure of the skirt had already occurred.

Intramedullary new bone formation in the neck of the femur has not been seen in any of the radiographs that have been examined. The normal head of the femur is a structure designed to carry considerable load and to distribute it to the neck and shaft by means of the trabeculae, each one being subjected to a small portion of the stress. Insertion of any prosthesis must destroy the three-dimensional structure and result in the overloading of too few trabeculae. The Judet prosthesis is particularly apt to produce this effect, because of the relatively small surface area of the stem and base of the head. The survival of their blood supply. As part of the blood supply comes through the great trochanter, it would seem advisable not to remove it at operation.

It has not been possible to correlate failure of the prosthesis with the sex, weight, or post-operative activity of the patient. The time between insertion and removal of the prosthesis has varied between two and twenty months.

Discussion

Various defects in the British manufactured prostheses could have been avoided if a detailed specification had been available. There is no doubt that the design and method of manufacture of all implants should be very carefully considered, so as to avoid the great number of mechanically unsound features with which the original design of the Judet prosthesis as made in this country is overloaded. It is interesting to note that an improved design has recently been developed by Judet *et al.* (1954) in an endeavour to solve some of the problems. They have, for example, abandoned the skirt of the prosthesis. The head has been set at an angle of 60 degrees to the shaft in order to retain more of the head and neck and so distribute the load to a greater area of bone and reduce the distance AB (Fig. B).

There are a number of problems associated with the properties of synthetic materials and metals, especially when they are combined to form a structure which is subjected to the simultaneous action of stress and tissue fluids at body temperature.

Not the least important point is the individual operative technique. This, however, is beyond the scope of this paper, and those primarily concerned with the use of this prosthesis will be able to draw their own conclusions from the observations we have made.

Summary

The mechanics of the hip-joint have been examined, with special reference to the Judet prosthesis. The materials used in the manufacture of the prosthesis and its ultimate strength have been investigated under laboratory conditions. Thirty prostheses which were removed from patients either because of pain and/or mechanical failure were examined in conjunction with the clinical records of the patients concerned.

The disadvantages of the present design can be summarized as follows: (1) The stem is not strong enough. Flexural strength is diminished by fatigue; the acrylic is weakened by crazing and the metal by stress corrosion. Unless the prosthesis is placed in the most favourable position its load-carrying capacity will be exceeded. (2) The skirt is weak and vulnerable, and interferes with revascularization. (3) The head has not sufficient surface hardness. The distribution of the forces acting upon the prosthesis has been examined. It is clear that both the angle of insertion i and the distance AB (Fig. B) must be as small as possible. (4) The local blood supply should be interfered with as little as possible. The great trochanter should not be divided, for both mechanical and anatomical reasons.

The reasons for the large number of worn prostheses require further investigation. In the light of our present knowledge, the use of any prosthesis must be regarded as an experimental procedure. The need for a standardized method of radiological follow-up of cases has been apparent in this work, as well as for a method of recording the clinical results of treatment.

While there are many reasons for failure over which no one can have control, the development of standards governing the materials to be used in the manufacture of prostheses could by now have been devised.

Since writing this paper a further 20 prostheses that have had to be removed from patients have been examined. The information gained has further substantiated the conclusions drawn from our previous work.

We wish to express our thanks to Professor S. J. Davies, Faculty of Engineering, King's College, University of London, for his enthusiastic support in carrying out this work; Professor D. H. Hey and Mr. L. Singlehurst-Ward, King's College, University of London, for their help on metallurgical and chemical problems; and to Mr. G. D. Winter, technical assistant, Plastics Research Unit, for his unfailing willingness in working long hours while engaged with us on the Judet problem. We are indebted to Messrs. Down Bros. Ltd., Lusterlite Ltd., the London Splint Co. Ltd., and the Medical Supply Association Ltd. for supplying samples of material and Judet prostheses.

The following very kindly responded to our appeal for notes, x-ray films, and prostheses, and thus made the work possible: G. Arden, E. H. Bannister, J. Bastow, J. Briggs, H. J. Burrows, St. J. D. Buxton, P. Cromack, F. W. T. Davies, E. O. Davis, M. B. Devas, E. A. Devenish, G. R. Fisk, A. Fletcher, A. T. Frupp, J. Garden, W. Gissane, L. C. Gonet, C. Gray, W. Herschell, S. L. Higgs, K. F. Hulbert, J. P. Jackson, A. W. L. Kessel, T. King (Australia), W. B. Law, P. S. London, K. Lucas, D. V. Marshall, M. L. Mason, J. S. Maxwell, K. I. Nissen, G. Platt, E. Shephard, N. A. Stephens, D. Trevor, W. Waugh, W. A. Watt-Maney, K. G. Westcombe, V. H. Wheble, B. L. Whitaker, P. Wiles.

HEPARIN AND ETHYL BISCOUMACETATE IN PREVENTION OF EXPERIMENTAL VENOUS THROMBOSIS

BY

PAMELA JEWELL, M.B., B.S.

Lecturer in Bacteriology

THOMAS PILKINGTON, M.D., M.R.C.P.

Medical First Assistant

AND

BRIAN ROBINSON, M.B., M.R.C.P.

Late Resident Clinical Pathologist

St. George's Hospital Medical School

[WITH SPECIAL PLATE]

In recent years anticoagulant drugs have been increasingly used for the treatment of thrombo-embolic disease. There are two groups of these drugs—those which lengthen the clotting-time (heparin group), and those which lengthen the so-called prothrombin time (coumarin derivatives): of the latter group ethyl biscoumacetate ("tromexan") is a typical example.

Many clinicians believe that heparin is more efficient in preventing thrombosis, and choose ethyl biscoumacetate only because it can be given by mouth. We have, however, found no clinical or experimental evidence for this belief; the only experiment reported in the literature which compares the ability of heparin with that of dicoumarol in preventing thrombosis following damage to the vein wall was one performed in rabbits, and led to the conclusion that neither drug was effective (Moses, 1945). This lack of support for clinical impressions prompted us to study the relative actions of heparin and ethyl biscoumacetate in preventing thrombosis following experimentally induced phlebitis in rabbits. The drugs were given in a manner as closely comparable as possible to the methods of administration used in clinical practice.

Methods

Buck rabbits weighing from 1.8 to 3 kg. were used; they were fed on a mixture of bran and oats, with fresh greens and an unrestricted amount of water.

Administration of anticoagulants was controlled by frequent examinations of venous blood taken from a marginal ear vein reserved for this purpose. In the case of heparin, clotting-times were estimated by Wright's capillary

tube method, which is simpler than the Lee and White method, and was found by us to give equally satisfactory results. Normal clotting-times varied from 5 to 12 minutes. Ethyl biscoumacetate administration was controlled by prothrombin times estimated by Quick's one-stage method, using human brain thromboplastin. Owing to the rapidity with which rabbit's blood will clot, consistent prothrombin times could not be obtained unless the following technique was adopted: all the glassware was treated with silicone and cooled before use, a solution of potassium oxalate was used as anticoagulant in the syringe, and the estimations were made within half an hour of taking the blood. With this method the normal prothrombin time varied between 11 and 16 seconds in rabbits, compared with 15-16 seconds in man.

A total of 95 rabbits was used: of these, 31 were treated with ethyl biscoumacetate and 34 with heparin, while 30 were used as controls. A satisfactory anticoagulant effect was first established and then the vein wall was damaged by chemical irritation. In both control and treated animals 0.1 ml. of monoethanolamine oleate ("ethamolin") was injected into one of the marginal ear veins in the direction of the blood flow and held in a 4-cm. length of vein for five minutes, by digital pressure above and below. The irritant effect of this procedure was confirmed by the fact that microscopical examination showed inflammation in and around the vein wall even when there was no thrombosis. Following the injection of monoethanolamine oleate the anticoagulant drugs were continued for a further five days. The rabbits were then lightly anaesthetized with sodium thiopentone, and phlebograms of the ear veins were made, using 1 ml. of 50% diodone. The animals were immediately killed and the ears were preserved for histological examination.

Experimental Heparin

Throughout, the heparin was used in a concentration of 5,000 units per ml.; the doses per kilogram were two to three times those used in man. Monoethanolamine was injected 24 hours after treatment had started.

FIG. A.—Rabbit No. 95. Clotting-times following an intravenous injection of 800 units of heparin: six-hourly administration. The dotted line indicates the upper limit of the normal clotting-time, the arrows indicate times of injections.

FIG. B.—Rabbit No. 81. Clotting-times following an intramuscular injection of 1,200 units of heparin: six-hourly administration.

mals did not return to normal until just before the next injection was due (Fig. B).

An attempt was then made in 13 rabbits to prevent the clotting-times from ever falling to normal. Intramuscular injections of 500 to 1,000 units were given every four hours. In most instances prolonged clotting times were well maintained (Fig. C), but of the 50 estimations made before injections were due 12 showed a fall to normal.

The only form of bleeding which occurred in any rabbit receiving heparin was into the site of the injection, which in the last group was occasionally sufficient to produce a temporary but obvious anaemia.

FIG. C.—Rabbit No. 103. Clotting-times following an intramuscular injection of 800 units of heparin: four-hourly administration.

This dose varied from 20 to 80 mg. a day, and was two to three times the dose used in man. In most cases the prothrombin time reached a steady level in three to four days and the injection of the sclerosing agent was then given.

Rigid control of the effect of ethyl biscoumacetate was difficult, resulting in a wide range of prothrombin times, and according to these it was found that the animals could conveniently be divided into three groups. The prothrombin times for one rabbit in each group are shown in Fig. D.

FIG. D.—Prothrombin times in three rabbits during an eight-day period on ethyl biscoumacetate. The arrow indicates injection of sclerosing agent.

Seven animals had prothrombin times which rose above 75 seconds, in 12 they rose to between 35 and 75 seconds, and in 12 to between 19 and 35 seconds. The last two groups had times comparable to those maintained with safety in man. With ethyl biscoumacetate there was no example of spontaneous external or internal bleeding, although in the presence of the more prolonged prothrombin times it was sometimes difficult to arrest the bleeding at the site of venepuncture.

Results

The phlebograms showed one of three findings: (a) complete patency, (b) a filling defect representing a partial

block, or (c) complete occlusion (Figs. E, F, and G). Similarly the microscopical examination of the vein made on 5-8 transverse sections of the traumatized area showed (a) absence of thrombus, (b) small mural thrombus, (c) large mural thrombus, and (d) blockage by thrombus (Plate, Figs. 1 and 2).

Control Group.—In 28 of the 30 control animals extensive thrombosis occurred, and there was radiological evidence of this in 26 of the 27 veins examined.

Heparin-treated Group.—The effects of heparin are summarized in Table I. As many as 25 of 34 veins of

FIG. E.—Phlebogram of an ear showing apparently normal veins in a rabbit which received ethyl biscoumacetate. The marker indicates the point of injection of the sclerosing agent.

FIG. F.—Phlebogram of an ear showing partial blockage in a rabbit which had received heparin.

FIG. G.—Phlebogram of an ear vein showing complete blockage in a rabbit which had received heparin.

heparin-treated animals showed extensive thrombosis, six showed mural thrombosis, and only three veins were quite normal: in fact, there was no significant difference between these results and those of the control group. When the results with the three different modes of heparin administration were examined it was found that they were all equally unsuccessful (Table II). Even when the prolonged clotting-times were almost continuously maintained the results were not significantly better.

Intramuscular 4-hourly	13	2	2	4	5

Group Treated with Ethyl Biscoumacetate.—The results with this drug are summarized in Table III. Of the 31 animals which had received ethyl biscoumacetate, only four showed extensive thrombosis. It is interesting to note, although not statistically significant, that the four animals in which ethyl biscoumacetate failed came into the group with the least-prolonged prothrombin times. Even in this group, however, there was significantly less thrombosis than in the control animals ($P < 0.01$).

Control	30	1	1	8	20

$P < 0.01$

Discussion

Our experiments indicate that heparin fails to prevent the occurrence of thrombosis in veins damaged by chemical irritation. Even when achieving almost continuous prolongation of clotting-time, with heparin given intramuscularly every four hours, no significant inhibition of thrombosis was obtained. This failure might be explained in part by the fact that we used discontinuous administration, either intravenously or intramuscularly, as suggested by Swedish workers (Crafoord, 1939; Jorpes, 1950), and in no rabbit could we be sure that the clotting-time was always above normal. Our results would seem to support those obtained in the original experiments with heparin, in which good effects were achieved only when the drug was given by continuous transfusion (Murray *et al.*, 1937).

On the other hand, ethyl biscoumacetate was found to be highly successful in preventing thrombosis. Similarly successful results were obtained with ethyl biscoumacetate using the arteries of dogs (Reinis, 1950), and also with dicoumarol (Dale and Jaques, 1942; Richards and Cortell, 1942; Thill *et al.*, 1943). The doses of ethyl biscoumacetate used by us were only slightly (two to three times) greater than those used in man, and they produced a comparable prolongation of prothrombin time, which differs from the findings of Wright *et al.* (1953), who found it necessary to give much larger doses of ethyl biscoumacetate (more than 20 times the human dose) to achieve comparable effects.

While experimental results in rabbits cannot be applied directly to man, we feel that the unexpected differences found between the two drugs makes it desirable that their comparative value in the prevention of thrombosis in man should be critically assessed.

Summary

A comparison was made between the actions of heparin and ethyl biscoumacetate in preventing thrombosis in chemically induced thrombophlebitis in rabbits. Ethyl biscoumacetate was strikingly successful when given in doses comparable to those used in man, whereas under the same conditions heparin did not significantly reduce the incidence of thrombosis.

We are extremely grateful to Professor T. Crawford for his guidance and for performing all the histological examinations, to Dr. S. D. Elek and Dr. J. N. M. Chalmers for their help and encouragement, and to Dr. Fraser Roberts for the statistical analysis. We are indebted to Evans Medical Supplies Ltd. for the supplies of heparin, and to Geigy Ltd. for supplies of tromexan. We wish to thank the Board of Governors of St. George's Hospital for a grant from their Endowment Fund towards the expenses of the investigation.

An Ehrlich-von Behring Centenary postage stamp was issued in March by the West German Government. It is a 10-pfennig stamp with the heads of Ehrlich and von Behring facing right on a mid-green background, the names of the two scientists and the dates "14 und 15 März 1854." The stamp has now been included in the Ehrlich exhibition arranged by the Wellcome Historical Medical Museum at 183, Euston Road, London, N.W.1.

THE NUMBER OF MELANOCYTES IN HUMAN EPIDERMIS

BY

G. SZABÓ, M.Sc.

Department of Zoology, University College, University of London

[WITH SPECIAL PLATE]

Melanomas of skin (cf. Raven, 1950; Pack *et al.*, 1953; Clark and MacDonald, 1953; Wright *et al.*, 1953) have a characteristic regional frequency distribution. Melanomas are more frequent per unit area on the face, neck, feet, and external genitalia than on other regions of the body. It is now almost universally believed that, in cellular origin, melanomas of skin arise from pigmentary dendritic cells, "melanocytes."

There are alternative (but not mutually) exclusive reasons why the frequency of melanomas should vary from one part of the body to another: (a) the individual melanocytes have different degrees of susceptibility to malignant change, or are more exposed in certain areas to stimuli predisposing them towards this transformation; or (b) the likelihood of a melanocyte's undergoing malignant transformation is fairly constant throughout the body, and the observed differences of frequency are mainly due to differences of population density. Wright *et al.* (1953) have already suggested that there may be a greater concentration of "melanoblasts or precursors" in the skin of lower limbs, head, and neck than of upper limbs. Their opinion was based on observations of the duration of sun-tanning and not on statistical cellular counts.

The present investigation therefore represents a first attempt to estimate the frequency distribution of melanocytes in different regions of the human body. It was founded upon the use of Bloch's "dopa reaction" in conjunction with the "skin-splitting" technique of Billingham and Medawar (1951), which causes the epidermis to separate cleanly from the corium by enzymatic fission. By using these methods, counts of melanocytes were carried out by the methods described in full by Billingham and Medawar (1953). These authors have already shown that there are about twice as many melanocytes per mm.² in guinea-pig's ear skin than in trunk skin, but both showed great variation between individuals. There was no correlation between melanocyte concentration and differences of colour.

This report contains only a first series of estimations, relating chiefly to the melanocytes of the skin of the thigh and arms.

Material and Methods

Human skin was obtained in the course of plastic surgical operations through the kindness of Mr. Rainsford Mowlem, at the Middlesex Hospital. The skin samples, removed as Thiersch (thin "split thickness") grafts, were incubated in buffered commercial trypsin solution to bring about the disengagement of the epidermis. The epidermis was thereupon stuck to a cover-glass, inner (dermal) side uppermost, with paraffin and rubber stopcock lubricant, fixed in 1-2% formal-saline overnight or sometimes longer (two to four days), and then incubated at 38° C., until the melanocytes, alanine adjusted by phosphate buffer to pH 7.4. After a second fixation in 4% formal-saline, followed by dehydration and cleaning, the pure epidermal sheets were permanently mounted in Canada balsam for inspection from the inner

side (Plate, Figs. 1-4). On a number of occasions very thin Thiersch grafts were impregnated with the dopa reagent without splitting: in these specimens the dermis was thin enough to be transparent. Paracarmine was sometimes used as a counterstain, to make the epidermal pattern more easily visible.

These methods are unsuitable for counting melanocytes in hair follicles.

Observations

The numerical results are set out in the accompanying Table, with information on the sex and age of the subject, the position and extent of the area counted (usually in 10

randomly chosen samples), and the mean number of melanocytes per mm.² of the epidermis in plane projection ± the standard error of the mean. The following preliminary conclusions can be drawn from the numerical and histological analyses.

(1) There are great differences between the numbers of melanocytes in corresponding areas of different human beings.

(2) There are also well-defined differences between the numbers of melanocytes in different areas of the same individual. The higher population densities were found on the ear (Fig. 1), cheek (Figs. 3 and 4), forehead and neck areas; the lower densities on the upper arm, forearm, and thigh (Fig. 2).

(3) Within any one sample of skin, melanocytes are principally concentrated in the epidermal ridges or "hills"—that is, in those areas which appear in orthodox transverse sections as inwardly directed projections of the epidermis

into the corium. Between the ridges—that is, in the areas underlain by the dermal papillae—their concentration is lower.

(4) Melanocytes vary greatly in shape. They may be fully dendritic cells, with branches projecting in many directions, or they may be almost fibroblast-like, with only two terminal processes. Although the shapes of melanocytes may be largely influenced by mechanical factors, such as the pattern and mode of packing of neighbouring Malpighian cells, there appears also to be a clear-cut dimorphism, particularly in the skin of the cheek and forehead (Fig. 4): large melanocytes with abundant cytoplasm lie among the more numerous smaller melanocytes with relatively little cytoplasm.

Comment

The results of this numerical investigation are in favour of the second of the alternative explanations proposed above to account for differences in the frequencies of melanomas between the face and neck on the one hand, and the trunk and thigh on the other—that is, the differences of frequency may be due to differences in the population densities of melanocytes. As no melanocyte counts are yet available from the foot, it is impossible to say whether a similar interpretation may not account for the high frequency of melanomas in this region; it is relevant, however, that melanocytes are very much more abundant in the sole of the guinea-pig's foot than in the skin of the ears and trunk (Billingham and Medawar, 1948, 1950).

The population densities of melanocytes in different regions of the body are, of course, correlated with differences in the thickness and mitotic activity of the epidermis as a whole. Both may be at least partly under the influence of environmental factors—for example, differences in the degree of exposure to mechanical irritation and radiation—but cell counts on infants would be necessary to determine what proportion of the difference was due merely to environmental factors. It is already known that some differences of epidermal thickness—for example, between trunk and sole-of-foot skin—are of developmental origin.

A dimorphism of melanocytes was also found by Grand *et al.* (1935) among the melanocytes of melanomas of mice and of human origin, cultured *in vitro*.

Summary

In human epidermis the population density of melanocytes (pigmentary dendritic cells) is of the order of 1,000 per mm.² in the skin of the thigh and arms, but may be twice to four times as great in the skin of the face and forehead. There is nevertheless a wide range of variation between the corresponding areas on different individuals. It is suggested that regional differences in the frequency of occurrence of melanomas may be primarily due to differences in the population density of melanocytes.

I am grateful to Mr. Rainsford Mowlem, whose co-operation, interest, and help have made the collection of specimens possible; to Professor P. B. Medawar for suggesting this line of investigation and for correcting the manuscript; and to Mr. R. E. Billingham for his many helpful suggestions. Thanks are also due to Mr. W. Brackenbury for taking the photomicrographs.

CONGENITAL SYPHILIS DIAGNOSED BY BONE CHANGES

BY

K. L. MARKS, M.Ch.Orth., F.R.C.S.Ed.

Assistant Orthopaedic Surgeon, Chester Royal Infirmary

[WITH SPECIAL PLATE]

With the improvement in medical care of the syphilitic woman at the time of marriage and during pregnancy, congenital syphilis is becoming a comparative rarity. Many working outside special centres have never had the opportunity of examining an infant who is suffering from the disease. The following is a case history of a patient presenting in the classical manner.

Case Report

A full-term male child born on December 13, 1952, was brought to the casualty department on February 25, 1953, with the history that after an outing in his perambulator the preceding afternoon he had refused to move the left upper limb. When his mother attempted to move the arm the child screamed with pain. He was referred to the fracture clinic as a possible case of pulled elbow or as a doubtful case of greenstick fracture of the left upper humerus.

Clinical examination showed a normal healthy-looking baby of 10 weeks. Movements of all the limbs except the left upper limb were normal. That limb was held by the side, and any attempt at movement was resented. There was tenderness on palpation over the metaphysis at both the proximal and the distal end of the left humerus. A doubtful greenstick fracture of the upper humeral shaft without displacement was demonstrated radiologically. The arm was placed in a collar-and-cuff sling and an appointment was made for the child to be seen in a week's time.

The next day the mother returned to the clinic stating that not only did the child resent movement of the arm but he now refused to move the left lower limb.

Further clinical examination confirmed the loss of function of both the left upper and lower limbs. There were no visible physical signs other than the "paralysis," but the metaphyseal regions of all four limbs were found to be tender on palpation. Radiographic examination demonstrated well-marked osteochondritis and chondro-epiphysitis in the long bones of all four limbs. Figs. 1 and 2 (Special Plate) show the right upper limb and the left lower limb. The temporary zone of calcification in the distal metaphysis in the radius and ulna, and particularly the femur, is thickened and shows as a white line. The submetaphyseal zone is decalcified and is shown best in the radius and ulna. The width of this zone indicates roughly the length of intra-uterine infection. The irregularity of the decalcification is best shown at the proximal end of the tibia (Fig. 3). Further radiographs one month later demonstrated increasing irregularity of decalcification and commencing periostitis. The Wassermann reaction was +++; Kahn reaction +; and quantitative Kahn 240 units.

Only after positive serological findings did the mother concede the positive family history. Both parents had received treatment at a special centre from October 2, 1946, until September 13, 1947, when both defaulted. There was an older child born on May 27, 1948, who was serologically and clinically normal.

Discussion

Jones and Lovett (1933) state that osteochondritis is the most common manifestation of congenital syphilis in infants. As in this patient, it is symmetrical and may give rise to the classical pseudo-paralysis. Gumpesberger (1951), in an investigation of x-ray changes in 571 infants and young children of treated and untreated syphilitic mothers, noted

that of 57 serologically positive cases with congenital syphilis 34 showed syphilitic bone changes.

In the above case the diagnosis was made from the positive radiographs. These in turn led to confirmatory serological tests. Had the child not presented with pseudo-paralysis in both the left upper and lower limbs the diagnosis might well have been missed.

TABETIC CHARCOT'S SPINE

REPORT OF EIGHT CASES

BY

DOUGLAS J. CAMPBELL, F.R.C.P.Ed.

AND

J. OLIVER DOYLE, M.D., M.R.C.P.J.

From the Department of Venereology, Royal Hospital, Sheffield

In 1868 Charcot first described tabetic arthropathy of the spine. The condition is believed to be the rarest arthropathy occurring in tabes dorsalis and is a relatively uncommon disorder. Charcot's spine is diagnosed largely on circumstantial evidence (stigmata, history, Wassermann reaction) rather than on local recognition. It may be discovered quite accidentally during the course of a barium-meal examination.

The following eight cases seen during the past two years in the Department of Venereology, Sheffield Area, are thought to be interesting enough to merit publication.

Case Reports

Case 1.—A labourer aged 50 was admitted on November 14, 1950, to the medical ward, City General Hospital, with severe abdominal pain, and a twelve-months history of delay in micturition. He had clinical signs of tabes—Argyll Robertson pupils, absent knee- and ankle-jerks, positive Romberg's sign—and "lightning" pains in the limbs and chest. Barium meal and fasting test meal were normal. He had been treated for syphilis 15 years previously, but defaulted. The blood Wassermann reaction and Kahn tests were negative. On November 24 he complained of pain in the lumbar area. X-ray report on lumbar spine: "Lesion involves second and third lumbar vertebrae chiefly; there is considerable destruction of bone, with the separation of the fragments and new bone formation. Mainly a destructive lesion with little if any sclerosis. There is fairly marked scoliosis." Examination of the cerebrospinal fluid showed: clear fluid; Wassermann reaction positive 1:2; white cells, 10 per c.mm.; protein, 120 mg. per 100 ml.; globulin, very slight increase; Lange, 0000000000. Despite treatment with penicillin, arsenic, and bismuth, in August, 1952, the patient complained of tenderness of the right foot, and the radiologist reported the appearances as those of well-developed Charcot's disease.

Case 2.—A millwright aged 53 attended the special treatment centre, Sheffield Royal Infirmary, on March 1, 1948, complaining of "shooting" pains in his legs of three years' duration. He had clinical signs of tabes dorsalis—Argyll Robertson pupils, knee- and ankle-jerks absent. The blood Wassermann reaction was positive 1:160, Kahn + + + +. Penicillin, tryparsamide, and bismuth gave little relief of symptoms. On February 21, 1952, he complained of pain in the lumbar region. Examination revealed marked scoliosis. Lumbar puncture was attempted, but was not

successful. X-ray report on spine: "In the lumbar spine there is gross destruction and deformation of the second and third lumbar vertebrae with some bone sclerosis. In the absence of injury this could well be accepted as an example of Charcot's spine." Clinically there was no limitation of spinal movements.

Case 3.—A retired man aged 68 attended Sheffield Royal Infirmary on March 10, 1952, complaining of severe shooting pain in his legs on and off for the past 20 years. He had been treated for syphilis in 1929. Examination revealed typical signs of tabes—bilateral ptosis, Argyll Robertson pupils, knee- and ankle-jerks absent, Romberg's sign strongly positive. Blood Wassermann reaction was negative, Kahn reaction negative. Cerebrospinal fluid: clear; Wassermann reaction, negative; cells, 0 per c.mm.; protein, 40 mg. per 100 ml.; globulin, no increase; Lange, 0000110000.

Procaine penicillin G in oil, followed by arsenic and bismuth, were given, but he continued to get severe shooting pains in the legs. On April 13, 1953, the x-ray report on the spine read: "There is a slight forward displacement of the fourth lumbar vertebra on the fifth, and the appearances are consistent with a moderate degree of neuropathic spine."

Case 4.—A housewife aged 55 had had asthma since early childhood. Routine Wassermann reaction and Kahn test were positive in March, 1952. She was referred to the special treatment centre on March 27, where she complained of "shooting" pains in her legs and back of nine months' duration. There were clinical signs of tabes dorsalis—Argyll Robertson pupils, knee- and ankle-jerks sluggish, Romberg's sign positive. Cerebrospinal fluid: clear; pressure normal; white cells, 46 per c.mm.; protein, 50 mg. per 100 ml.; Lange, 3221000000; Wassermann reaction not reported on. She continued to get low back pain, also pain in the rectum, especially at night, and over buttocks. X-ray report on spine: "There is an increase in lumbar lordosis with scoliosis, subluxation of the fourth lumbar vertebra and loss of disk space between it and the third. There is new bone formation in the tissue to the left of the third and fourth vertebrae and sclerosis of the bodies of the third, fourth, and fifth lumbar vertebrae. The appearances are those of a neuropathic spine."

Case 5.—A labourer aged 40 attended the special treatment centre of Doncaster Royal Infirmary on May 4, 1952, complaining of swelling of the left testicle for two days.

He denied extra-marital intercourse. He had been treated for syphilis at another hospital from July, 1944, to June, 1946, when his blood Wassermann reaction was found positive after his first wife's infidelity, and then defaulted from surveillance. Examination showed a gumma of the left testicle and typical signs of tabes dorsalis—pupils dilated and fixed, knee- and ankle-jerks absent, Romberg's sign positive. Blood Wassermann reaction and

Case 5. Radiograph of spine.

Kahn test were doubtful. His mother had been treated for venereal disease and his four brothers and three sisters had died in early childhood. One brother had no nose and one sister had only one arm. The patient had a well-marked

kyphoscoliosis and swelling of the right knee-joint. X-ray report on spine on May 7: "A well-marked scoliotyphosis of the dorsal spine with reverse curve in the lumbar region. In the latter region the lower three lumbar vertebrae show a marked deformity due to bone destruction and proliferation. The intervening disks are disorganized and there is a marked hyperostosis of the articular processes. The appearances are consistent with neuropathic bone disease" (see illustration). An x-ray film of the right knee showed a neuropathic joint. In August, 1945, whilst attending another hospital, an x-ray examination showed extensive scoliosis and osteoarthritis of the spine. The patient had no symptoms referable to the spine or right knee-joint. In view of the family history he would appear to be suffering from hereditary Charcot's spine. He later developed a perforating ulcer on the ball of the right foot.

Case 6.—A labourer aged 59 attended the orthopaedic department of Doncaster Royal Infirmary on October 4, 1952, with a spontaneous fracture of the left femur. A Smith-Petersen pin was inserted, and during serial x-ray control arthritic changes were noticed in the lumbar spine. The changes are consistent with Charcot's spine, although not absolutely typical. The blood Wassermann reaction was positive 1:80; Kahn + + +. He had clinical evidence of tabes dorsalis and slight scoliosis with the convexity to the left, but there were no symptoms referable to the spine. Cerebrospinal fluid examination showed: clear fluid; pressure normal; cells, no increase; globulin, negative; Lange colloidal gold curve, 0011100000; Wassermann reaction not reported on. In 1918 he had had 12 injections of arsenic for syphilis.

Case 7.—A miner aged 57 had classical signs of tabes dorsalis—pupils fixed, knee- and ankle-jerks absent, Romberg's sign positive. The blood Wassermann reaction was positive 1:20; Kahn + + +. Had been treated at the special treatment centre of Doncaster Royal Infirmary from November 4, 1949, to July 14, 1950, with penicillin, arsenic, and bismuth; then defaulted. In May, 1953, he developed a swelling of the ankles and reattended. Examination showed pitting oedema of the ankles; nothing gross in the cardiovascular system; urine normal; scoliosis with the convexity to the left; tenderness on pressure over the third lumbar vertebra. X-ray report on spine: "The lumbar spine shows a marked scoliosis convexity to the left with flattening of the disk and tipping on the concavity of the spinal curve. There is a good deal of sclerosis of the vertebral bodies and the upper cartilage plate of the fifth lumbar vertebra is collapsed. The appearances are consistent with neuropathic disease." The patient had had an injury to the spine in a coal-mine on October 20, 1947. An X-ray film taken next day was reported on as follows: "Lumbar scoliosis, congenital abnormality of sacrum or last lumbar vertebra. Marked osteoarthritis of spine. No recent bony injury. Developmental abnormality at lumbosacral junction."

Case 8.—A miner aged 55 was referred to the special treatment centre of Doncaster Royal Infirmary in April, 1951, as a case of tabes dorsalis. There were classical signs of tabes, including Argyll Robertson pupils, knee- and ankle-jerks absent, Romberg's sign positive. He complained of severe "shooting" pains in his legs and trunk. The blood Wassermann reaction was positive; Kahn + +. Cerebrospinal fluid: clear; pressure normal; cells, no increase; protein, 15 mg. per 100 ml.; Lange, 1122100000. Penicillin, arsenic, and bismuth produced no improvement in shooting pains. Later he complained of severe pain in the right hypochondrium somewhat suggestive of gastric ulcer pain. Barium-meal examination revealed no ulcer in either the stomach or the duodenum. However, during screening marked arthritic changes were noticed in the lower lumbar spine, somewhat suggestive of neuropathic disease. Further x-ray films of the spine revealed very extensive changes in the lower lumbar spine with bone destruction and new bone formation, the appearances being those of Charcot's spine. Clinically there was no deformity of the spine or any limitation of spinal movement.

Discussion

According to Herndon (1927), one of the most characteristic features of Charcot's spine is the disproportion between the severity of the process disclosed by the x-ray film and the slight discomfort and disability complained of by the patient. Usually, clinical evidence of tabes is present. One of the earliest and most constant signs is deformity which is due to bone destruction and subsequent compression of the vertebral body with posterior or lateral displacement. This process is usually limited to one or two vertebrae, and is most often found in the lower dorsal and lumbar spine. The resulting deformity is usually a kyphus with more or less lateral curvature and rotation. There is usually no tenderness and no muscle spasm.

Considerable discomfort is often caused by pressure of the collapsing spine or that of hypertrophic bone formation upon the spinal nerves. These root pains are usually gradual and insidious in onset and of moderate severity. Occasionally, however, they attain considerable intensity, somewhat simulating gastric crises or peptic ulcer pain. The mobility of the spine is little involved unless in cases of excessive destruction.

The existence of hereditary Charcot's spine has long been doubted, but it is now an acknowledged fact. Various observers consider many cases of apparent Pott's disease associated with other joint involvement in young children as luetic.

It is claimed that radiologically the alternation between sclerosis and rarefaction, bone absorption and bone apposition, is the most striking feature in Charcot's spine. In some cases the destructive, in others the proliferative, changes prevail. Often both are seen concomitantly.

The treatment of Charcot's spine consists in general antiluetic therapy and local measures for support and immobilization of the spine.

Summary

Tabetic Charcot's spine probably occurs much more commonly than most textbooks lead us to believe. Severe persistent shooting pains, especially of a girdle distribution, should indicate an x-ray examination of the spine in order to rule out Charcot's disease. Brief case histories of eight tabetics with Charcot's spine are presented.

In Case 7 trauma would appear to have been a predisposing factor in the aetiology of the Charcot's spine.

We are indebted to Drs. M. M. Beveridge and A. I. Morrison, of the Department of Venereology, for assistance in the preparation of this paper.

Because reports were being received that some nurses and doctors working both in hospital and in public health services were suffering from dermatitis after giving injections of streptomycin and penicillin, an inquiry was instituted into the best way of preventing it. As a result, recommendations for an improved injection technique for giving antibiotics were approved by the Standing Medical Advisory Committee of the Central Health Services Council and announced to hospitals and local health authorities (see *British Medical Journal*, 1953, 2, 40). The Ministry of Health has now made a ten-minute 16-mm. film to illustrate the technique. The film is for use in teaching student and postgraduate nurses, and is also suitable for showing to doctors, pharmacists, and medical students. Copies of the film may be hired (5s. for the first day, 1s. for subsequent days) from the Central Film Library, Government Building, Bromyard Avenue, Acton, London, W.3. The film was written and directed by Margaret Thomson and made by Basic Films.

VITAMIN K₁ IN ANTICOAGULANT THERAPY

BY

M. TOOHEY, M.D., M.R.C.P.

Physician, New End Hospital, London, N.W.3

Vitamin K₁ has proved to be a most potent antidote to anticoagulant drugs with a prothrombogenic action, and is clearly the antidote of choice in controlling the dangers of anticoagulant therapy. The use of large doses of vitamin K₁ in patients on anticoagulant therapy, with the consequential restoration of the blood prothrombin to normal or near normal levels, only, however, replaces the danger, or possible danger, of haemorrhage by that of a possible further thrombotic or embolic episode. In addition, large doses of vitamin K₁ are very likely to make the patient refractory to further anticoagulant therapy. Valuable time may therefore be lost in assessing the correct dose of the anticoagulant drug required to restore and maintain an adequate reduction in the blood prothrombin level. Therefore, whenever it is intended to continue anticoagulant therapy it is essential to use vitamin K₁ with the utmost discretion and to prescribe, so far as is possible, the minimum effective dose.

Assessment of Minimum Effective Dosage

To assess the minimum effective dose of vitamin K₁ required to antagonize the action of anticoagulant drugs is not easy. In addition to the actual level of the blood prothrombin (which is, of course, in itself very important) and the presence or otherwise of haemorrhage, several other factors must be considered, including the type of anticoagulant used and the general condition of the patient. Long-acting cumulative anticoagulants such as dicoumarol, phenylpropyl-hydroxycoumarin ("marcoumar"), and cyclo-cumarol ("cumopyran") require larger doses of vitamin K₁ than the short-acting anticoagulants, such as phenylindandione ("dindevan") or ethyl biscoumatate ("tromexan").

The stage of anticoagulant therapy reached must also be taken into account; sometimes in the first few days of anticoagulant therapy, owing to the unavoidable difficulty of assessing the correct dose of the anticoagulant, the blood prothrombin may be reduced to too low a level. In most cases merely withholding further doses of the anticoagulant within a therapeutic and safe range. Where, however, the blood prothrombin is so severely reduced that haemorrhage is likely it is wise to give vitamin K₁, but small doses will in most cases be effective. This is because, unless the dose of the anticoagulant has been grossly miscalculated, there is no large accumulation of the anticoagulant in the body which would require large doses of vitamin K₁ to counteract its effect.

The general condition of the patient is also of prime importance in assessing the minimum effective dose of vitamin K₁ required to antagonize the action of anticoagulant drugs. For example, the presence of heart failure, shock, or deficient renal or liver function will mean that large doses of vitamin K₁ are needed if it is to be effective. The only failure met with in vitamin K₁ therapy has been in desperately ill patients who subsequently died within a short period.

It has been shown previously (Toohey, 1952) that 500 mg. of vitamin K₁, given orally, is entirely effective in antagonizing and controlling haemorrhage due to massive doses of such anticoagulants as dicoumarol, phenylindandione, and ethyl biscoumatate. Such massive doses of anticoagulants as were used in these experiments would not, however, normally be given in clinical practice; nor, therefore, are

such large doses of vitamin K₁ needed. In the series of experiments under review in this paper doses of vitamin K₁ varying from 5 to 50 mg. were given orally on approximately 96 different occasions to 70 patients on anticoagulant therapy, and as a result it was found that these smaller doses of vitamin K₁ were always effective in counteracting the action of the anticoagulant drugs except in two instances (see later).

Classification of Cases

Most of the uses of vitamin K₁ in anticoagulant therapy may be considered in connexion with the following three groups of cases. Group 1: Cases of frank haemorrhage or of a severe lowering of the blood prothrombin to a dangerous level in which it is not intended to continue with anticoagulant therapy. Group 2: Cases of frank haemorrhage in which it is intended to continue with anticoagulant therapy. Group 3: Cases of severe lowering of the blood prothrombin to a dangerous level, with or without minimal haemorrhagic manifestations, in which it is intended to continue with anticoagulant therapy.

Group 1.—In this group little difficulty should arise. As anticoagulant therapy is not being continued, fairly large doses of vitamin K₁ can be given. If the anticoagulant in use is one of the short-acting variety (phenylindandione, ethyl biscoumatate), then 20–25 mg. of vitamin K₁ will be sufficient. If, however, long-acting anticoagulants (dicoumarol, phenylpropyl-hydroxycoumarin, cyclocumarol) are in use, the initial dose of vitamin K₁ should be 25 to 50 mg., according to the degree of haemorrhage. This dose may in a few cases have to be repeated. Doses of vitamin K₁ in the region of 25 to 50 mg. will in nearly all cases result in the blood prothrombin level returning to normal or near normal. In addition, the patient may become refractory to further anticoagulant therapy for some days. As, however, it is not intended to continue with anticoagulant therapy this factor can be ignored.

Group 2.—It is in this group of patients that most anxiety will arise. Here it is essential to give a dose of vitamin K₁ sufficient to restore the blood prothrombin quickly to a safe level. At the same time the prothrombin must be kept within a safe therapeutic range, otherwise a further thrombo-embolic episode may occur. Also, as mentioned above, too large a dose of vitamin K₁ may render the patient refractory to further anticoagulant therapy for a few days. If the patient is receiving the short-acting anticoagulants, 15 mg. of vitamin K₁ should in most cases be enough. Larger doses than 15 mg. should be given only in exceptional cases. If, however, the patient is receiving the long-acting anticoagulants, 15 to 25 mg. of vitamin K₁ should be given, depending on the urgency of the case. The lower the blood prothrombin level, the more severe the haemorrhage, and, most important, the more seriously ill the patient, the larger the dose of vitamin K₁ required. It is in this group of patients with a severe reduction in the blood prothrombin accompanied by frank haemorrhage that most difficulty will arise in estimating the correct dose of vitamin K₁. Frequent blood prothrombin estimations are essential to assess the response to treatment and to decide whether further doses of vitamin K₁ are necessary.

Group 3.—In this group, in which there is a severe reduction in the blood prothrombin, but no or only minimal haemorrhagic manifestations, the urgency and anxiety are not as great as with patients in Group 2. For nearly all patients receiving the short-acting anticoagulants 5 to 10 mg. of vitamin K₁ will be sufficient. Patients receiving the long-acting anticoagulants will need slightly larger doses of vitamin K₁, but it is rarely necessary to give more than 15 mg., at least as an initial dose.

For all patients it is best to assess the response to vitamin K₁ therapy by means of prothrombin estimations taken about eight hours after the initial dose. In patients in Group 3, however, in whom there is no evidence of bleeding, it is usually sufficient to do the first prothrombin estimation after vitamin K₁ therapy the following day if this is

more convenient. In Group 2 patients, however, especially those receiving the long-acting anticoagulants, prothrombin estimations should be routinely made eight (or even six) hours after the initial dose of vitamin K₁. If an appreciable rise in the blood prothrombin level has not occurred a larger dose of vitamin K₁ should then be given.

Results of Vitamin K₁ Therapy

Given in the doses quoted above, in only 2 out of 70 patients did vitamin K₁ fail to have an effect. Both patients were seriously ill, suffering from myocardial infarction accompanied by shock and heart failure, and both died several days after admission to hospital. It was realized that each was desperately ill, and smaller doses than usual of the anticoagulant drugs were given. Nevertheless, the blood prothrombin fell to a dangerously low level, with microscopical haematuria in one case. Repeated doses of 20 to 25 mg. of vitamin K₁ had only a slight effect in raising the blood prothrombin. At necropsy there was no sign of haemorrhage in either case.

Desperately ill patients with signs of shock and heart failure therefore need initial doses of 25 mg. of vitamin K₁, even when there is little or no haemorrhage, in order to counteract the effect of anticoagulants, especially the long-acting ones. If there is no response to this initial dose—that is, if there is no rise in the blood prothrombin after six to eight hours—then 50 mg. of vitamin K₁ should be given. If a patient fails to respond to vitamin K₁ therapy it is an ominous prognostic sign, and it will be found that most such patients die.

In conclusion it should be stressed that vitamin K₁ is a most powerful drug, and unless the dose is carefully controlled its use will give rise to added difficulties in anticoagulant therapy. Vitamin K₁ should therefore be used only if haemorrhage has occurred as a result of anticoagulant therapy or if the reduction in the blood prothrombin is so great that haemorrhage is very likely to develop. In most patients, except those who are extremely ill, merely withholding further anticoagulant therapy will be enough to raise the blood prothrombin to a safe level without the need to use vitamin K₁. This is especially true when the short-acting anticoagulants are used. With the long-acting cumulative anticoagulants vitamin K₁ therapy will, however, be more often required.

Conclusions and Summary

In 68 patients out of 70 on anticoagulant therapy, vitamin K₁, in oral doses of 5 to 50 mg., was entirely effective in counteracting the action of the anticoagulant and restoring the blood prothrombin to a safe level. In two of these patients in whom slight haemorrhage (haematuria) had occurred the bleeding soon ceased. In only 2 of the 70 patients did vitamin K₁ fail to have effect. Both these patients were extremely ill and died from heart failure and shock following myocardial infarction.

Vitamin K₁ should be used only if haemorrhage has actually occurred or if the blood prothrombin is so low that haemorrhage is very likely to develop. Uncontrolled vitamin K₁ therapy may rescue the patient from the danger or possible danger of haemorrhage, only to render him liable to the risk of further thrombo-embolic phenomena.

In all cases in which it is intended to continue with anticoagulant therapy the minimum dose of vitamin K₁, which will be effective in restoring the blood prothrombin to a safe therapeutic range must be aimed at. In assessing this minimum effective dose of vitamin K₁, the general condition of the patient and the type of anticoagulant used are most important, in addition to the actual blood prothrombin level.

Patients receiving the short-acting anticoagulants require only small doses of vitamin K₁ to restore the blood prothrombin to a safe therapeutic level. In nearly all cases 5 to 15 mg. will be sufficient, and it is rarely necessary to exceed 15 mg.

Patients receiving the long-acting anticoagulants require larger doses of vitamin K₁ if the desired effect is to be achieved, but 10 to 25 mg. will usually be enough. The larger doses of vitamin K₁ should be given if haemorrhage has actually occurred or if the patient is desperately ill, especially if there are signs of shock and heart failure.

In cases of frank haemorrhage in which it is not intended to continue with anticoagulant therapy 25 to 50 mg. of vitamin K₁ should be given. The larger dose should be administered to patients who had been given the long-acting anticoagulants and also to the more seriously ill patients.

Response to vitamin K₁ therapy should be assessed by estimation of the blood prothrombin six to eight hours after the initial dose of vitamin K₁. If an appreciable rise in the prothrombin level has not occurred a larger dose of vitamin K₁ must be given.

I wish to thank Roche Products Ltd. for the generous supplies of the vitamin K₁ used in this work.

Medical Memorandum

Orthograde and Retrograde Intussusception

Although it is stated that 80% of cases of intussusception occur in patients under 2 years of age, this was not my experience in North Szechwan, China. A number of cases were seen in adults of all ages and some in older children, but none in infants or young children. Although sometimes there was obvious cause such as a pedunculated tumour of the ileum or inflammatory swelling of a mobile caecum, often none was found. The following two cases were different from usual in that both also had retrograde intussusceptions. Although such a condition is not unknown, it seems uncommon enough to merit reporting.

CASE 1

A man aged 24 was seen in the out-patient department on October 31, 1949, complaining of abdominal pain for a little more than a month. He was admitted with a diagnosis of intussusception. Amoeboma was thought to be a possible cause, and therefore general treatment and a course of emetine injections were prescribed. This seemed justified by improvement in symptoms and resolution of the palpable mass, but one week later acute symptoms recurred with an enlarging mass in the right upper abdomen.

Laparotomy was performed under general anaesthesia. There was an intussusception of the terminal 3 in. (7.5 cm.) of ileum into the caecum and ascending colon, almost to the hepatic flexure. In addition there was a reverse intussusception of about 3 in. of the right half of the transverse colon, thus leaving a small length of normal colon at the hepatic flexure. Both intussuscepta were reduced with comparative ease; a lump about the size of a walnut could then be felt in the caecum. An end-to-side ileo-transverse colostomy was then performed. Three weeks later, under spinal anaesthesia, right hemicolectomy was performed, from which the patient made a good recovery.

On macroscopic examination of the specimen the wall of the caecum was found to be much thickened; there was no ulceration or definite tumour. Unfortunately, microscopic examination was not possible.

CASE 2

A boy aged 11 was admitted on November 3, 1951, with a diagnosis of intussusception and acute intestinal obstruction for about one day. During the previous six weeks he had been seen at intervals in the out-patient department complaining of abdominal pain and a lump. Apart from slight distension and poor nutrition, no definite physical signs had been noted. Ascariasis had been treated successfully, and the possibility of tuberculous peritonitis (which is common in the district) had been considered.

On admission he was seriously ill and dehydrated; the abdomen was distended and there was a large firm mass on the left side: this seemed to be a large firm mass in the left hypochondrium, with a smaller one rather lower and a small gap between. The apex of the intussusception could be felt about 1 in. (2.5 cm.) within the anal canal.

After saline infusion, laparotomy was performed under general anaesthesia (ether with an Oxford vaporizer). Considerable difficulty was experienced in determining the true condition namely, an intussusception starting in the terminal ileum and traversing the whole colon to the anus; and also a secondary reverse intussusception of the primary intussusception (all three layers) starting about the middle of the descending colon and extending back to the middle of the transverse colon, thus making the big mass palpable before operation. The apex of the intussusception could be reached only with the help of an assistant pressing digitally per anum, but even then reduction could not be effected. With considerable difficulty the secondary intussusception was first reduced by combined movements: digital dilatation of the secondary intussusceptions, pressure on the secondary apex, and gentle traction. When this was eventually reduced the primary intussusception was reduced with great ease. The gut was carefully examined, but, apart from deep congestion, oedema, and plastic exudate, there was no obvious pathological condition to account for the intussusception, nor was there serious question of viability. The whole colon from caecum to rectum was exceedingly mobile with long mesenteries. The colon was replaced in the approximate anatomical position and the abdomen closed.

The patient made an uninterrupted recovery; two and a half months later he was well and obviously gaining weight.

COMMENT

Aetiology.—The cause in Case 1 was thought to be inflammatory thickening of the caecum, but in several such cases I have wondered whether the caecal thickening was primary or secondary to the intussusception. Histological examination has not been possible. In Case 2 it was obviously a chronic condition with partial resolution over a period of several weeks, possibly initiated by ascariasis; the exceptionally mobile colon can be regarded as a facilitating factor. Disordered peristaltic movements seem the only explanation of the retrograde intussusceptions, though not a complete one.

Treatment.—The remittent course of both these cases raises the question whether intussusception ever undergoes complete reduction spontaneously. At operation one often finds that reduction is comparatively easy except for the remissions? If so, then earlier exploration is called for. In Case 2 the diagnosis was missed and operation delayed till it was almost too late, because insufficient importance was attached to the boy's description and no lump was felt when he attended the out-patient department. It is not usual to do anything to prevent recurrence unless there is an obvious removable cause. Such has been my practice, except with a suspicious lesion in the caecum. This course was successfully followed in Case 1. In Case 2 nothing was done beyond replacing the colon anatomically, in the hope that the exudate would form some anchoring adhesions. The condition at operation precluded anything further, and the subsequent course seemed entirely satisfactory.

Reviews

KIELLAND'S FORCEPS

Kielland's Forceps. By E. Parry Jones, M.B., B.S., M.R.C.O.G. (Pp. 212; illustrated. 35s.) London: Butterworth and Co. 1952.

The Kielland forceps has climbed slowly to favour. Introduced in 1910 for the delivery of the foetal head arrested in the high transverse position, it at first received scant attention. Soon, however, it was championed by Döderlein and other leading obstetricians, and by the late 1920's it was firmly established in many European clinics. It was in Vienna that I was introduced to this instrument, and in the 25 years since that time I have used it with satisfaction, if not with burning zeal, for transverse arrest of the head.

In present-day practice neither the Kielland nor any other obstetric forceps is used to deliver the head from the brim of the pelvis; Caesarean section is now the method of choice. But for the head arrested in the low transverse position the Kielland forceps undoubtedly has a place, and is an important alternative to manual rotation followed by "ordinary" forceps delivery. In this country the principles behind the Kielland forceps have never been very adequately explained. Some workers have used the instrument like any other for "normal" forceps deliveries; others have restricted it to use in special circumstances. Some enthusiasts have insisted on the original "Kielland method" of application—a method which in unsuitable cases or in unskilled hands may easily lead to a rupture of the lower segment of the uterus. Others—rightly in many instances—have introduced the blades by more conventional methods, but in applying traction have failed to observe other rules on which the advantage and safety of the instrument depend.

An altogether admirable monograph has now come to hand. In a well-documented and reasoned discussion Dr. Parry Jones discusses the history, the theory, the indications, the technique, the dangers of, and the results obtained with the Kielland forceps. Many of his views and arguments apply to forceps in general, but more are strictly applicable to the Kielland instrument. If he overstates his case—which in my opinion he occasionally does—this is an excusable fault in a publication intended to "convert" a new body of obstetricians.

There is little to criticize and much to praise. Dr. Parry Jones has the gift of explaining difficult technical points tersely and clearly. The treatment of deep transverse arrest of the head is fully considered, and a distinction is rightly drawn between this condition and that of deep transverse position of the head. The virtue of the Kielland forceps as an axis-traction instrument, to which Heidler many years ago directed attention, is again expounded. There is an optimistic reference to the correcting of asynclitism by the forceps (pages 72 and 111). I doubt if this is justified: if the position of the head can be so easily altered as is implied, it would seem that "accommodation," moulding, and other changes normally associated with labour have not yet had time to take place. The danger of compression of the foetal skull is emphasized, and the warning given that the forceps handles should not be gripped but that traction should be applied only by means of the index and middle fingers applied over the shoulders of the forceps. The possibility of maternal injury such as the occurrence of vesico-vaginal fistulae is admitted, but it is pointed out that in some of these cases the damage may be caused by the conditions which necessitated the use of the forceps. The claim is made, though I doubt its substance, that there is less chance of causing injury to the foetus, and especially facial injury, if the Kielland forceps is used. More important in my opinion is the care and understanding with which the chosen instrument is used; and here it is pertinent to quote Dr. Parry Jones's own words (p. 55):

"Whenever the obstetrician finds that a reasonable amount of traction exerted in the right direction does not produce descent

of the foetal head, he should re-examine to confirm the position of the presenting part. If he is then certain that the foetal head is flexed and is lying correctly, he should conclude that he is faced with a dangerous degree of disproportion and should desist from further attempts at vaginal delivery. The only condition other than disproportion which may be causing difficulty is a constriction ring, and if this has not been relaxed by general anaesthesia and anti-spasmodics it is best to resort to Caesarean section."

Later (p. 73), referring to a head which remains high in the pelvis, he states:

"... the greatest care is necessary to exclude disproportion ... the operation should be undertaken tentatively with plans already made to proceed immediately to Caesarean section if the delivery proves more difficult than anticipated. A carefully made tentative pull is without danger to the foetus or to the maternal birth canal. It does not fall within the class of 'failed forceps' cases as ordinarily understood, and might well become an established, although rare, hospital procedure."

This book is convenient in size, and by virtue of the style of writing and the many clear headings is easily read. Numerous diagrams clearly illustrate the arguments presented in the text. Printing errors seem entirely obviated, though there is a mis-spelling of Moloy's name on page 53. There are two appendices: one contains tables dealing with the results of the forceps operation in the Liverpool Maternity Hospital; the other is a translation of the original publication by Kielland entitled "The Application of Forceps to the Unrotated Head; a Description of a New Type of Forceps and a New Method of Insertion."

I regard this as an important publication and strongly commend it to every doctor who gives serious attention to operative obstetrics. While it is particularly concerned with the Kielland instrument, it contains much factual information and wise counsel concerning the use of forceps in general.

J. CHASSAR MOIR.

OBSTETRIC FORCEPS

The Obstetrical Forceps. By L. V. Dill, M.D., F.A.C.S. (Pp. 156; 91 figures. 37s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications Ltd. 1953.

This monograph is one of the American Lecture Series and is delightfully printed, illustrated, and bound. Its text, too, is attractive in its clarity and simplicity. The author sets out to cover the history of the development of obstetric forceps as well as the indications, mechanics, and technical details governing the use of various instruments. This is a large subject and it is obvious that in a small book of this kind many of its aspects can be covered only in barest outline. The author has simplified his task, however, by assuming that his readers already have some practical experience, and he aims to give them most help by generally picking out for mention only those forceps which are well known internationally and which are in current use. In this he shows commendable freedom from prejudice. He describes the basic principles governing the use of forceps in relation to the Anderson or Simpson type of instrument, and this is perhaps the best section of the monograph; it is detailed and contains several useful hints. The Tarnier, Kielland, Barton, and Piper forceps each receive a small chapter to themselves, and the description of their particular features and the circumstances under which they may be applied with advantage is generally adequate.

"Forceps should be compared to golf clubs, not to tennis rackets; that is, optimum utility is obtained by a set, not by familiarity with a single favourite." This is the underlying theme of the monograph, but it is open to question and it would be an ideal subject for debate. Practice makes perfect; proficiency in the use of more than one instrument calls for a very large practice and daily opportunities for carrying out forceps delivery in varying circumstances during several years, so that many experts with wide experience are content with one pattern of forceps, and few use more than two. Dr. Dill's arguments may or may not persuade them to change their outlook in this respect. The

book will prove of most value to the specialist and potential specialist, although according to the dust-cover it is also intended for students, house-surgeons, and general practitioners. These last, however, have relatively so few opportunities to practise the forceps operation that most of them cannot expect to become familiar with more than one instrument. A putter is what they require, and if the situation calls for a driver, mashie, or niblick, then surely expert assistance and sometimes another method of delivery are needed.

T. N. A. JEFFCOATE.

SURGICAL TECHNIQUE

Surgical Technique and Principles of Operative Surgery. By A. V. Partipilo, M.D., F.A.C.S. Fifth edition, revised. Foreword by Alton Ochsner, M.D., F.A.C.S. Original illustrations by W. C. Shepard and Hooker Goodwin. (Pp. 704; 548 figures containing 998 illustrations. 110s.) London: Henry Kimpton. 1953.

In this volume Professor Partipilo presents the fifth edition of a textbook of surgical technique as practised in the hospitals of Chicago, but the scope is limited, except for a postscript on the thyroid, to the abdomen and the thorax. Although there are ten other contributors, Professor Partipilo himself dominates the scene, and one cannot but be impressed by the experience and mature judgment which his articles present. Equally impressive is the thoroughness with which every subject is developed, whether it be the tying of a knot, the opening and closing of the abdomen, or the most complex detail of different methods of gastrectomy. Every item is well described and superbly illustrated, so that the details can be grasped at once without any possibility of error.

The standard of all the articles is high, but two appear outstanding—that on the gall-bladder and bile ducts by Oberhelman, and that on duodenal obstruction by Professor Partipilo. The first is not only a most finished article on technique but describes in full detail the variations which may occur, the unusual difficulties which these may present, and the means by which these may be overcome. The second is a most original and interesting contribution to a subject whose importance every abdominal surgeon will appreciate. The whole volume is well produced and the illustrations are superb, combining high artistic skill with obvious appreciation of the surgical problems. It is a worthy tribute to a great surgical school and one for which every surgeon may well be grateful.

HENRY SOUTTAR.

SYNOPSIS OF ANAESTHESIA

A Synopsis of Anaesthesia. By J. Alfred Lee, M.R.C.S., L.R.C.P., M.M.S.A., D.A., F.F.A.R.C.S. Third edition. (Pp. 488. 72 illustrations. 21s.) Bristol: John Wright and Sons Ltd. 1953.

We have much pleasure in welcoming the third edition of Dr. Lee's admirable synopsis. The book has already obtained the reputation of being a compendium of accurate information on all the varied aspects of anaesthesia and analgesia, and the present volume brings this knowledge up to date. The tremendous advances in this subject are indicated by the fact that the third edition has nearly twice the number of pages as the original volume, and it is difficult to see how the author will be able to cope with future progress without considerable omissions. It is quite difficult to pick on a subject connected with anaesthesia, however remotely, which is not found in the excellent index. We note, however, that Dr. Lee does not discuss hypothermia, hibernation, or "lytic cocktails," doubtless waiting to see whether these innovations prove their worth.

This type of book does not give much scope for literary style, since brevity must be the overriding consideration, but in spite of this limitation it is quite readable. The lay-out is good, full use being made of different forms of type in the numerous tables and classifications. Most of the illustrations are printed on glossy paper, which improves their clarity.

There is little doubt that this book gives the reader with a basic knowledge of anaesthesia the best value obtainable at the present time.

C. LANGTON HEWER.

CHEMICAL MYSTICISM

The Doors of Perception. By Aldous Huxley. (Pp. 63. 6s.) London: Chatto and Windus. 1954.

Mescaline, used in American Indian religious ceremonies, has fascinated psychiatrists for many years now. This drug can produce schizophrenic-like symptoms in many normal persons, and its near chemical relationship to substances in the body, like tyrosine and adrenaline, has been known for some time. Each new generation of psychiatrists feels this should at least provide a clue to the causation and treatment of certain types of schizophrenia; but so far nothing has come of this hope.

Now Aldous Huxley covers the same ground with a brilliant mind and pen. He compares experiences he had under mescaline with those that have been previously reported in the vast literature of mysticism. He learned how intolerable ordinary living can seem to those to whom even an ordinary chair or a flower becomes so all-absorbing and full of inner meaning, and who cannot switch back to everyday thinking and feeling again. Refuge may finally be sought in suicide, as in the case of van Gogh. Huxley suggests that what has to be done for the insane is to help them to "remain undistracted—undistracted by the memory of past sins, by imagined pleasures, by the bitter taste of wrongs and humiliations, by all the fears, hates, cravings. . . ."

Psychiatrists have to face this problem in treatment every day of their working lives. How is it to be done? After personally experiencing a chemically induced schizophrenia for only a few hours, Huxley returns to some of his earlier "Brave New World" ideas for an answer. Other philosophers, too, might try out the same drug instead of waiting for an attack of the toothache to put their treatment concepts to the test. Huxley argues that if such abnormal experiences can be induced chemically it may sometimes only be possible to use other drugs to relieve them. He discusses some of those now available, and why used despite their attendant dangers. Unfortunately only a full posterior leucotomy can as yet produce the result he demands in the quotation given above. He also suggests that mescaline might from time to time be used to give certain people "self transcendence" who are too much tied to day-to-day living to learn other methods of acquiring more euphoriant drugs.

This book should be very interesting reading to doctors and especially to psychiatrists. It will make us even more uneasy at our present failure to relieve so much of the mental suffering of our patients, so vividly brought to life by this book. It may put in better perspective our sometimes too detached philosophic viewpoints on such problems. One can only hope it will persuade general medicine to take a greater interest in the physiological aspects of psychiatry, for if drugs so near to adrenaline can create mental disorder others should almost certainly be found to antagonize them. With half the hospital beds in the country filled with psychiatric patients, the Medical Research Council should at least consider spending more than it does out of its annual budget of £1,500,000 on psychiatric research, apart from its purely psychological aspects.

WILLIAM SARGANT.

Methuen's Monographs are extremely handy guides to recent work in fields which touch medicine at many points. They are well documented and slip easily into the pocket. *Sex-Determination of the Nucleic Acids* by J. N. Davidson (second edition, 10s. 6d.); and *Tissue Culture* by E. N. Willmer (second edition, 9s. 6d.) bring the reader thoroughly up to date in these subjects.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MAY 1 1954

TRICHINOSIS

Infection with *Trichinella spiralis* occurs focally at a low endemic level throughout Great Britain, as shown by Young,¹ but it is only rarely recognized clinically. A recent outbreak of trichinosis in Liverpool, described in the *Journal* this week by Professor Semple and Drs. Davies, Kershaw, and St. Hill, illustrates clearly the characteristic features of the clinical pattern and the epidemiology. The classical course of the infection is a sharp gastro-intestinal upset, with diarrhoea and vomiting beginning one or two days after the infecting meal and followed about ten days later by general symptoms. The initial alimentary symptoms were rarely present in the Liverpool outbreak and elsewhere have occurred in under 10% of cases. As a rule the first signs appear some ten to sixteen days after infection, and they almost always consist in swelling of the eyelids and often of the face, accompanied by remittent fever of 100°–103° F. (37.8°–39.4° C.) or higher. Distressing headache, sometimes associated with photophobia, is common. These preliminary symptoms are rapidly followed by aching stiffness of the muscles, which, when it is detected in the neck, may suggest meningitis. Insomnia is commonly present, even at the same time as lethargy and apathy. Splinter haemorrhages under the finger-nails occur in about 10% of cases and are a valuable diagnostic sign when present. The eyes sometimes show episcleral haemorrhages and a waxy-yellow, swollen appearance of the conjunctiva. Involvement of the central nervous system is common, usually in the form of dizziness or disturbance of balance but occasionally as psychic disturbances or a monoplegia or hemiplegia. A dry cough is often present. Symptoms start to subside about a month after infection, when the adult worms in the intestine begin to die. Myocarditis and derangement of the central nervous system are apt to appear about the fifth week after infection, and in severe cases death may occur. Convalescence is often protracted and normal health may not be restored for some months.

Diagnosis of the first cases in an outbreak is usually established by accident. During routine examination the patient's blood count is investigated and an

eosinophilia of 25 to 50% is found. It is this which directs attention to the possibility of trichinosis. Eosinophilia appears about fourteen days after infection, soon after the first appearance of symptoms, and reaches a maximum about the twentieth day. The urine is usually normal, but albumin or blood may occasionally be present for a few hours. The cerebrospinal fluid is always normal. Conclusive proof of *T. spiralis* infection is provided by finding larvae in a small piece of muscle removed from a limb by biopsy. This should be strongly compressed between glass plates and examined directly under the microscope. The larvae resulting from recent infection lie along the axis of the muscle fibres, and they are more difficult to recognize than when coiled or encysted. Heavy infections are rapidly identified by this examination and moderate infections after careful searching. In light infections when direct examination is negative the biopsy specimen should be incubated overnight in an acid-pepsin mixture and the centrifuged deposit examined for larvae. A presumptive diagnosis may also be made by complement deviation, which usually becomes positive during or soon after the third week. This test is not absolutely reliable.

The symptoms and signs of trichinosis can be very diverse, and it may have to be distinguished from typhoid, influenza, acute rheumatic fever, nephritis, exanthematous fevers, and other conditions. Cases which do not show facial oedema but begin with disorders of the central nervous system are not likely to be recognized unless an outbreak of the disease is known to exist at the time. The presence of a marked eosinophilia will help in clarifying the diagnosis and should direct suspicion towards the cause. The gastro-intestinal upset immediately after infection will probably be regarded as food-poisoning or a dysenteric attack. The diagnosis is usually not established until general symptoms appear some ten days later.

In Liverpool and in the outbreak in Wolverhampton described by Sheldon² the incidence of infection was found to be considerably higher among women than men, though this is not always so. A higher incidence among women results from their habit of eating raw sausage meat. In Sheldon's series 80% were women, and he found that raw sausage meat was eaten by some members of about half the working-class households investigated. In Liverpool, where 75% of the patients were women, 16% of over 3,000 housewives admitted to this habit. Among male cases occupation was an important factor, half of them being concerned with the preparation or sale of pork products. Some of these patients were prob-

² *Lancet*, 1941, 1, 203.

³ *J. Amer. med. Ass.*, 1954, 154, 653.

⁴ *Ann. trop. Med. Parasit.*, 1950, 44, 357.

ably infected accidentally by handling infected pork or by contaminating their food from the knives used in cutting infected pork. Sausages are the principal source of human trichinosis, and only occasional cases are infected from inadequately cooked pork joints.

Personal protection against trichinosis consists in adequately cooking all pork and pork products before consumption. It is a legal obligation on pig farmers that all food should be thoroughly cooked before being given to pigs. Pork which is processed for eating without cooking can be made safe by adequate heating or by rapid freezing to -35°C . for a few minutes or at slightly higher temperatures for a longer time. Recently experiments have been made in controlling trichinosis by irradiating pork with x or γ rays. Gould, Gomberg, and Bethell³ have reported the effect of γ radiation from cobalt⁶⁰ or from waste fission material in old nuclear fuel rods on infected pork joints of large size. A suitable exposure was found to prevent subsequent maturation of the larvae without affecting the quality of the meat.

One disquieting feature is mentioned in the report on the Liverpool outbreak. It proved impossible to trace back the infected pig beyond the abattoir. Some form of record is required which will permit the tracing of pigs from birth to the consumer so that in the event of an outbreak of trichinosis the infection may be traced to the particular piggery responsible. Griffiths⁴ noted the same difficulty in his investigation of the increased incidence of cysticercus bovis in cattle. While it would be difficult to provide a record of the movement of cattle through many hands over some years, it should be comparatively simple to record the movements of pigs, which change owners infrequently and are slaughtered when only a few months old. This matter deserves the serious attention of the Ministers of Health and Agriculture.

THE SMALL-LIST PRACTITIONER

While endorsing in its entirety the Working Party's scheme for redistributing the central pool of money for the payment of general practitioners consequent upon the Danckwerts award, the Special Conference of Local Medical Committees meeting in June, 1952, wisely put in a caveat for those doctors who might be found in the light of experience to be unfairly penalized by the scheme after it came into effect. The Special Conference passed the following resolution:

"That if, when the new scheme of distribution has been endorsed by both parties, it is found in the light of experience that certain groups of practitioners who under the terms of reference of the Working Party might have expected to have benefited have, in fact, not done

so, it be left to the Working Party provisionally to allocate an appropriate proportion of the final settlement monies for the purpose of remedying any obvious defects in the distribution scheme, such allocation to be subject to confirmation by the next Conference before it becomes a permanent feature of the scheme."

In the discussions which followed the acceptance of the Working Party's report it became clear that some G.P.s with small lists might be adversely affected by the new method of distribution. But the size of the problem and who would suffer most could not be told precisely until the new scheme was in operation. In accordance, therefore, with the Conference rider quoted above, and at the request of the Ministry and the General Medical Services Committee of the B.M.A., the Working Party was recalled to look at the problem in the light of available evidence since the scheme began on April 1 last year. It has now finished its task, and its report and recommendations are printed in full in this week's *Supplement* (p. 206) as Appendix F of the Supplementary Report of the G.M.S. Committee to the forthcoming Annual Conference of Local Medical Committees which meets on June 3.

The Working Party has examined the remuneration from Health Service sources of those doctors with lists of under 1,200 patients, and of these it has concerned itself with doctors in single-handed practice only. It found that two groups, amounting to some 500 to 600 practitioners in all, could be said to have been placed at a disadvantage by the new arrangements—the first group, a small number who had lost income because of the replacement of their fixed annual payments by the new initial practice allowance; and the second, and larger, group, the elderly doctors. The Working Party's proposals are, therefore, designed to assist both these groups. There are two main recommendations. First, that there should be a basic payment of £250 per annum for single-handed doctors with National Health Service lists of not less than 300 and not more than 1,200 patients. Secondly, and in addition to this basic payment and to the normal capitation fee, there should be a loading of 10s. on each capitation fee for every patient on the list between 300 and 500. But no loadings under the usual arrangements will be paid for patients on the list above 500. Thus a doctor with a list of 300 will get normal capitation fees amounting to £255 plus the basic payment of £250, making a total of £505—an increase on his present remuneration of £250. The doctor with a list of 400 patients will get, in addition to normal capitation fees of £340, the £250 basic payment plus £50 from the special loading on 100 capitation fees—a total of £640, and an increase of £300 on the present. The doctor with 500 patients will

be remunerated on the basis of £425 from normal capitation fees, plus £250 basic payment, plus £100 from the 10s. loading on 200 capitation fees. His total payment will come to £775 and his increase will be £350. Lists from 600 upwards to 1,200 will attract the basic payment of £250 plus the £100-worth of loading from the capitation fees for the 200 patients on the list between 200 and 500: but, since the normal loadings are not to be paid, the increase over the present scale will be a diminishing amount until parity is reached with a list of 1,200 patients. The comparative figures are clearly set out in an explanatory table attached to the report. All payments are to be retrospective to April 1, 1953.

There are certain conditions attached to the proposals. Young doctors previously in receipt of a fixed annual payment will not receive the new payment for more than five years and they must be genuinely trying to build up their practices. Their lists must normally be increasing, and payments will be withdrawn if their lists fall substantially and continually. Elderly doctors must have been in single-handed practice in the same area for at least ten years and must be over 60 years of age to qualify for the new payment. It will be stopped if their lists drop to, and remain below, 300. Eligibility for payment will be reviewed at the age of 70, but will not necessarily cease.

The General Medical Services Committee has already accepted the Working Party's proposals and is recommending them to the Annual Conference. A welcome feature is that there is not that smack of charity about them which in the eyes of many tainted the hardship payments, which they will gradually replace. The new payments are to be made solely in relation to the size of the doctor's Health Service list and without regard to his income from other sources. Furthermore, the cost, which it is estimated will be about £120,000 per annum, will come from money already allocated for the purpose. In any scheme which gives priorities in the distribution of a fixed sum of money—and such a distribution scheme was inherent in the Danckwerts award—it is inevitable that some groups must gain greater advantage. Within the existing distribution scheme these new proposals seem likely to commend themselves to the Conference and to the small-list doctors as a well-thought-out plan to interpret the Conference's wishes fairly.

HAEMOGLOBIN C

In 1949 Pauling *et al.*¹ discovered that sickle-cell haemoglobin (haemoglobin S)² differs from normal adult haemoglobin (haemoglobin A)² in electrophoretic

mobility—that is, in speed of movement in an electric field—and this opened the way for rapid advancement in our understanding of the hereditary haemolytic anaemias. In the same year Neel³ and Beet⁴ put forward the modern interpretation of the genetics of sickle-cell disease: people who are heterozygous for the sickle-cell gene have the sickle-cell trait, which is not in itself a significant cause of morbidity, while those who are homozygous for the gene suffer from sickle-cell anaemia. On this hypothesis both parents of every patient with sickle-cell anaemia should have the sickle-cell trait. In most cases this is true,⁵ but undoubted exceptions to the general rule have come to light. It has been found^{6,7} that people who inherit the sickle-cell gene from one parent and the thalassaemia gene from the other parent develop a haemolytic disease very similar to sickle-cell anaemia. Then Kaplan *et al.*⁸ described a patient with a mild form of sickle-cell anaemia in which the haemoglobin, investigated by Itano and Neel,⁹ consisted partly of the sickle-cell type and partly of a new type, which was designated haemoglobin C. The haemolytic anaemia was termed sickle-cell-haemoglobin-C disease. Haemoglobin C is characterized by its electrophoretic mobility, which is distinct from that of both haemoglobin A and haemoglobin S; in other properties haemoglobin C closely resembles haemoglobin A. The presence of haemoglobin C is determined by a single gene, evidently an allele of the gene controlling normal adult haemoglobin synthesis, and inherited independently of haemoglobin S, which is determined by another allele of the same gene. In sickle-cell-haemoglobin-C disease the sickle-cell gene is inherited from one parent and the haemoglobin-C gene from the other parent.

Until 1953 the electrophoretic analyses had all been carried out in the Tiselius apparatus. The introduction of a simple, rapid, and inexpensive filter-paper electrophoretic technique¹⁰⁻¹² has made the study of abnormal haemoglobins possible in many haematological laboratories. Kaplan *et al.*⁸ had reported that people with the haemoglobin-C trait (that is, the heterozygous condition) have a few target cells (so called because they look like targets) in the circulating blood but exhibit no other detectable haematological abnormalities. This has been amply confirmed in two recent communications,^{13,14} in which investigations of many American Negroes with the haemoglobin-C trait are reported. Each of these papers describes, in addition, a case of haemoglobin-C disease, the patient being homozygous for the haemoglobin-C gene. This disease is characterized by the presence in the peripheral blood film of numerous target cells, anisocytosis, poikilocytosis, and slightly increased polychromasia. A haemolytic tendency is revealed by the somewhat elevated reticulocyte counts

and serum bilirubin. That the haemolysis is due to a corpuscular defect is indicated by the short survival time of the erythrocytes of haemoglobin-C disease when transfused into normal recipients.¹³ The haemolysis in both cases was mild, however, and in spite of minor haemolytic crises, with joint swelling, the patient of Ranney *et al.*¹⁴ had survived to 35 years of age, had four uneventful pregnancies, and produced four healthy children. This observation is important genetically, since it establishes that the haemoglobin-C gene (unlike the thalassaemia and sickle-cell genes) is not sub-lethal when homozygous, and has little, if any, adverse effect on reproduction. If haemoglobin-C genes are being eliminated in the Negro population of the United States, this must be mainly due to the failure of patients with sickle-cell-haemoglobin-C disease to reproduce. But the haemolytic manifestations in these cases, of which Ranney *et al.* have seen twelve, are relatively mild. Hence the elimination of haemoglobin-C genes as a result of disease seems to be much slower than the elimination of sickle-cell and thalassaemia genes.

The incidence of the sickle-cell trait in United States Negroes is about 9%,⁵ and that of the haemoglobin-C trait is about 1.8%.¹² The expected frequency of sickle-cell-haemoglobin-C disease is 1 in 2,273, and the expected frequency of haemoglobin-C disease is 1 in 11,365 American Negroes. Spaet *et al.* and Ranney *et al.* are to be congratulated on finding their cases against such odds.

Another inherited abnormal haemoglobin type, haemoglobin D, has been identified,¹⁵ and more recently yet another, haemoglobin E, was reported to the American Chemical Society.¹⁶ In five years this field of investigation has grown to occupy a respected place in human genetics and clinical pathology. Many problems remain unsolved, among them why the haemoglobin-C mutation seems to be practically confined to people of African extraction.¹² There is every indication, now that techniques of haemoglobin analysis are generally available, that progress in this field will continue to be rapid.

MELANOCYTES AND MELANOMAS

Melanocytes (otherwise pigmentary dendritic cells) are the cells in skin epithelium which are responsible for cutaneous pigmentation. It was at one time believed that ordinary Malpighian cells were capable of making pigment, particularly after actinic stimulation, but it is now known with certainty that Malpighian cells are only a passive repository of pigment granules synthesized in the melanocytes near by.

The melanocytes of white human skin reveal themselves in transverse section as "clear cells"^{1 2}—a term which applies to their appearance but not to their visibility, for they are not easy to see. Indeed, some textbooks of histology disregard clear cells and melanocytes altogether. Until now the omission has perhaps been excusable, for it is only in the last few years that suitable methods have been devised for showing them up.

The only satisfactory way of inspecting melanocytes is from the under side of a whole-mount of the epidermis after it has been split away from the corium by some method which preserves both the structure and the vitality of the cells. Such a method has been used for several years by Billingham and Medawar,^{2 3} and Mr. G. Szabó, as he describes in a paper published at p. 1016 of the *Journal* this week, has now extended its use to the study of human skin. His photographs of "split" skin preparations impregnated with the "dopa" reagent illustrate the structure, ubiquity, and abundance of epidermal melanocytes. Each melanocyte is a branched cell lying in the basal layer of the epidermis and surrounded by a little cluster of Malpighian cells, upon which its branches end. Mr. Szabó finds that melanocytes vary in number from one person to another and from one part to another of an individual. There are about 1,000 per mm.² in thigh skin (roughly one to every 10-15 Malpighian cells) and anything from 2,000-4,000 per mm.² in the skin of the face and forehead.

These facts should be taken into account in any theory which attempts to account for the different frequencies of melanomas in different parts of the body. There are several by no means incompatible reasons why their frequency should vary from place to place. One is that melanocytes show regional variation in their innate susceptibility to cancerous transformation; a second that melanocytes of different areas are unequally exposed to stimuli (such as irritation or actinic influences) which promote malignant change. A third possibility is that the frequency of melanomas is an expression of the regional population densities of melanocytes. Mr. Szabó's census shows that this third interpretation is anatomically well founded—which is by no means to say that the others are untrue. At all events, no future theory to account for the spatial distribution of melanomas can neglect these differences of melanocyte population density, and much more work is needed of the type that Mr. Szabó has begun.

PRIMIDONE IN EPILEPSY

A new anticonvulsant, primidone, known by the trade name "mysoline," was introduced for clinical trial by I.C.I. in 1949 after extensive experimental trials on animals. This substance is closely linked in chemical structure to phenobarbitone, the only difference being the substitution in the former of an -H₂ radical for -O at one carbon atom of a pyrimidine ring. It has already proved an effective clinical agent. The first report of its use by Hanley and Stewart,¹ on 40 patients in an epileptic colony, suggested that it was effective for grand mal and petit mal and also had a beneficial effect on some of the temperamental difficulties shown by epileptics. Butter² also gave an encouraging report of its use in a colony. Whitty,³ using it in neurological

⁹ Briggs, J. N., and Tucker, J., *Lancet*, 1954, 1, 19.

out-patient practice, found it benefited both grand mal and to a lesser extent petit mal, and remarked especially that it seemed to reduce both the seizures and the personality difficulties of some patients in the psychomotor group. He found it effective as a symptomatic remedy also in seizures due to cerebral trauma and neoplasm. This was confirmed by Nathan,⁴ who also noted that the drug was usually effective within a few days of starting if it was going to be of benefit and that its initial therapeutic effect sometimes became less after a few weeks. Three recent papers from Australia⁵⁻⁷ confirm these initial findings. However, Greenstein and Sapirstein⁸ found it ineffective in psychomotor attacks and sometimes aggravating in petit mal, though this conclusion was reached on only two cases, and is contradicted by the experience of Briggs and Tucker⁹ in 22 cases of clinical petit mal. All these authors claimed that attacks were controlled or much improved in 50-80% of cases, and as all used the drug in patients whose disease was unsatisfactorily controlled by other anticonvulsants their results are the more impressive. All report an absence of any severe toxic effects and seem agreed that drowsiness, ataxia, and occasional vomiting are observed early in treatment but are usually transient. Confusional states with adverse personality changes were noted by Whitty, but these also were usually short-lived.

In general it seems clear that primidone constitutes a valuable addition to the medical treatment of epilepsy. It is most convincingly effective in grand mal, and present evidence suggests it may prove more beneficial than most drugs used for the psychomotor group: certainly extensive trial is important here. There is no convincing evidence that it aggravates petit mal: indeed, the weight of opinion is that it may improve this condition also. Dosage is important, because toxic effects are more likely with an initial high dosage. It is probably best to start with half a 250-mg. tablet two or three times a day, and gradually increase this to 3 or 4 tablets a day if necessary. If other drugs are already being used, the dosage of barbiturates should be reduced as that of primidone is increased, since the combination of these two is sometimes extremely soporific. The hydantoins may prove a useful adjuvant to primidone in controlling attacks, though it is best also to reduce their dosage slightly when adding the primidone. Amphetamine can be used here to reduce drowsiness, just as with other anticonvulsants. From the results so far reported, and especially the lack of toxicity, there is a strong case for using this drug as the initial treatment for grand mal and psychomotor epilepsy, combining it with a hydantoin if necessary. In petit mal also, if the "-diones" have proved ineffective, it should be given a trial.

TWENTY-FIVE YEARS OF OPIUM CONTROL

The Permanent Central Opium Board has now been established for 25 years. It began its work in the heyday of the League of Nations and survived the vicissitudes of war into the period of United Nations. The Board, which has its headquarters at Geneva, con-

sists of eight members representing as many countries; its newly elected chairman is Sir Harry Greenfield, the United Kingdom representative. The latest report of the Board¹ describes what has been achieved during the last quarter of a century. When the first statistics were compiled the consumption of opium for non-medical purposes was permissible in eighteen countries and territories of Asia, and in most of these the sale to addicts was a monopoly of the State. By 1953 the consumption for opium smoking and other non-medical purposes had ceased to be legal in eleven of these countries, and the most important of the others are now taking steps to bring such consumption gradually to an end with a view to total prohibition by 1959. The total production of raw opium used licitly for non-medical purposes in 1952 was 166 tons as against 1,585 tons a quarter of a century ago. The world production of morphine at the time the Opium Board was constituted amounted to 55 tons a year, and it was considered at that time that an annual average of 15 tons of the drug found its way into illicit traffic. The production of morphine has steadily increased over the last twenty years, reaching 75 tons in 1952, but 90% of it is used for the manufacture of other drugs, mainly for codeine and ethylmorphine, which are little liable to cause addiction. The production of cocaine in 1952 was only 38% of what it had been in 1929, yet no shortage has been experienced in the licit market. The production of diacetylmorphine (heroin), the drug most favoured by addicts, has fallen even more strikingly. In 1952 the world production was only 3.3% of what it had been in 1929.

Nevertheless, a considerable illegal traffic in drugs of addiction still exists. The clandestine production of Indian hemp, which is the basis of hashish or marihuana, continues to present a serious problem. A large quantity of diacetylmorphine also still finds its way into the wrong hands. So long as this drug is extensively used in medicine there is always a danger of supplies being diverted into the illicit market. The amount medicinally consumed per million inhabitants has fallen markedly over the last six years in Finland, Italy, Sweden, and New Zealand. In the United Kingdom there have been fluctuations, but the amount in 1952 (1.79 kg. per million inhabitants) was the smallest since 1947. Forty-two countries, including Soviet Russia, are listed as no longer using the drug at all, and three others have declared that they are now using up their stocks, and when this is completed the use of the drug will be stopped. Italy is admonished by the Board for having reacted to the discovery of illicit manufacture of diacetylmorphine by suspending only for fifteen days the licence of the firm on whose premises this had been going on since 1948. This, it is pointed out, can only have the effect of encouraging transgressors and might again lead to the creation of centres of illicit traffic. Complaint is also made that Persian statistics are contradictory, and that reporting from certain Asiatic and South American countries is not as regular as it should be.

CLINICAL PATHOLOGY IN GENERAL PRACTICE TROPICAL DISEASES IN BRITAIN

BY

A. W. WOODRUFF, M.D., Ph.D., F.R.C.P., D.T.M.&H.

Wellcome Professor of Clinical Tropical Medicine, University of London, at the London School of Hygiene and Tropical Medicine; Physician, Hospital for Tropical Diseases, University College Hospital, London

The problems most commonly confronting the practitioner dealing with patients who have returned from the Tropics are those concerning the investigation of fevers and alimentary upsets. The possible causes of the illness, and therefore the way in which the investigation is conducted, depend to a considerable extent on the time which has elapsed since leaving the Tropics. Thus air travel enables patients to be first seen at the onset of tropical infections with short incubation periods such as primary malaria, sandfly fever, dengue, yellow fever, rickettsial fevers, and bacillary dysentery. Among those falling ill after arrival in this country by sea, malarial relapses, dysentery, enteric fevers, and kala-azar have been most commonly found. Diseases in which the incubation period is long are, however, as likely to occur among those travelling by air as they are in those travelling by sea. Air travel merely adds to the list of diseases it is possible to encounter by reducing the time elapsing between leaving the Tropics and arriving in this country.

Malaria

Malaria is the commonest cause of fever in those who have visited endemic areas less than 18 months before the onset of their symptoms. Awareness of the possibility of the infection is the first step towards its diagnosis, and light might be thrown on many diagnostic problems besides that presented by malaria if an inquiry into the patient's recent movements were made in all cases in which such information is not already known to the practitioner. The two commonest forms of malaria are malignant tertian, caused by *Plasmodium falciparum*, and benign tertian, caused by *P. vivax*. It is important to keep the former in mind, especially with patients who have very recently visited tropical Africa, as unless this infection is promptly diagnosed and treated grave illness with cerebral complications and possibly a fatal outcome may result. Infections with *P. vivax* are more commonly encountered among patients who have lived in the Middle or Far East, and latterly have constituted a special problem in soldiers returning from Korea. In these the possibility of malaria is commonly overlooked, as there may be no history of a primary attack in the endemic region, this having been adequately suppressed by the routine administration of antimalarial drugs. Such patients may have chronic ill-health until the infection is adequately treated. It is important to stress that if *P. falciparum* infections are similarly overlooked the result is usually much more serious.

The Search for Malarial Parasites

In cases in which malaria is suspected, the most important investigation is examination of one or more blood films, and these should invariably be made before treatment is started. Whether they are thought to show or to fail to show parasites they should be retained for possible further examination, as mistakes may be made by platelets or artifacts being confused with parasites. To prepare a blood film is one of the simplest medical procedures, yet it is amazing how seldom it is done well. Microscope slides must first be rendered grease-free, and for this a good method is by washing with "monkey brand" or similar

soap, soaking in alcohol, and flaming. A spreader is made by breaking off the corners of a slide after scratching with a diamond. The lobe of an ear or the tip of a finger is then cleaned with spirit or ether. The lobe of the ear is to be preferred to a finger, as it is not only less sensitive to pain than the finger but is also less exposed to infection. Ether is perhaps best for cleaning the skin, as its use reduces the possibility of grease interfering with the spreading of the film. Hypodermic needles are unsuitable for puncturing the skin, for the drop of blood obtained is often too small to make a satisfactory film. A special skin-puncturing needle or, if none is available, a large-sized venepuncturing needle is more satisfactory. A sharp jab causes less discomfort to the patient than a wound made slowly and hesitantly.

Thick and thin preparations should be made, the former by using a pin to smear the drop of blood on the slide over a circular area of approximately $\frac{1}{4}$ in. (12 mm.) in diameter, the latter by spreading the drop with the spreader already prepared. The drop is placed at one end of the slide and allowed to run across the width of the spreader, which is held at an angle of 45 degrees and pushed along the length of the slide. Thick preparations must be allowed to dry thoroughly for 20-30 minutes. Their contained blood is then laked in an aqueous solution of 2% formalin and 1% glacial acetic acid. They are washed in distilled water and stained with dilute Giemsa stain, one drop being added to 1 ml. of distilled water and allowed to remain on the slide for 20-30 minutes before being poured off, and the slide allowed to dry without heating or blotting.

If large numbers of slides are to be stained, Field's method is conveniently rapid and labour-saving. For this a solvent is made by dissolving 10 g. of anhydrous disodium hydrogen phosphate and 12.5 g. of anhydrous potassium dihydrogen phosphate in 1 litre of distilled water. Solution A is prepared by dissolving 0.8 g. of powdered methylene blue and 0.5 g. of azure I in 500 ml. of the solvent. Solution B is prepared by dissolving 1 g. of yellow eosin in 500 ml. of solvent and filtering. Films are stained by immersing in solution A for one to three seconds, rinsing for five seconds in tap-water or in solvent, immersing for one to three seconds in solution B, and washing for three seconds in tap-water. They are then allowed to dry. In using this method films are not fixed and care is therefore necessary in handling them lest they become detached from the slide.

Thin films are most conveniently and satisfactorily stained with Leishman's stain. The slide is covered with undiluted stain, the number of drops required being noted, and after 10 seconds three times this volume of distilled water of pH 7.2 is added. This pH is obtained by adding lithium carbonate to the water till an aliquot gives a yellow reaction with bromthymol blue. The slide is stained with the diluted stain for 30 minutes and then flushed with the distilled water of pH 7.2 and allowed to dry. This method has the advantage of showing up well the Schüffner dots in cells infected with *P. vivax*.

A description of the various malarial parasites is outside the scope of this article, and for that the reader is referred to the standard works on tropical medicine and parasitology. It should, however, be mentioned that, unless parasites are being searched for frequently, errors, even by trained pathologists, are not uncommon. Perhaps the commonest is to regard an artifact as a parasite; less commonly, parasites when scanty are overlooked.

It is often questioned whether antimalarial treatment should be begun before a definitive diagnosis has been

made. There can be no doubt that falciparum malaria in non-immune subjects, if not promptly treated, may give rise to severe and even fatal illness. Thus when it is considered that possible delay in treatment would be dangerous and the blood cannot be examined promptly, it is best to start treatment, though blood films should be made for later examination and confirmation of the diagnosis. To give treatment without awaiting the report on, or making a personal examination of, a blood film may be a method of managing cases in emergency, but it is not a method of diagnosis. If the temperature comes down following treatment in such cases, it is unwise to deduce that malaria was the cause of the fever unless confirmation of the diagnosis is ultimately obtained from examination of blood films. Therapeutic diagnoses of this kind are associated with innumerable pitfalls, and such slipshod methods are harmful alike to the patient and to the profession.

Investigation of Non-malarial Fevers

Non-malarial causes of fever in persons recently returned from the Tropics include bacterial diseases such as bacillary dysentery, typhoid and paratyphoid fevers, brucellosis, tuberculosis, urinary infections, and tonsillitis; protozoal infections such as kala-azar (visceral leishmaniasis), trypanosomiasis, amoebic dysentery, and amoebic liver abscess; and virus infections including the common cold and its upper respiratory complications, especially maxillary sinus infection, influenza, and rarely sandfly and dengue fevers. Typhus and psittacosis are occasionally encountered. These may be confused with malaria, and patients with them have at various times been sent to the Hospital for Tropical Diseases in London diagnosed as cases of malaria. In some such cases slides have been recovered in which artifacts or platelets have been shown to have been wrongly mistaken for parasites. In others no slides had been examined before admission to hospital, but it is remarkable that even so not uncommonly the diagnosis of malaria had been regarded as so incontrovertible that the malaria was said to be of a type insensitive to the drug used. In the Tropics, where the disease is commoner and laboratories may be lacking, or overburdened with work, such errors are more often made. They are responsible for many of the false notions regarding the efficacy of anti-malarial drugs which from time to time become widely held.

The investigation of patients presenting with symptoms suggesting dysentery is discussed below. Tests which may help to differentiate malaria and urinary and respiratory infections from the other causes of fever mentioned include the white blood cell count. This should be carried out as a routine; it is usually low in enteric fevers, brucellosis, kala-azar, and sandfly and dengue fevers, and a differential count shows a reduction in the proportion of polymorphonuclear cells. The urine and the deposit obtained from it after centrifuging should be examined microscopically for pus cells and cultured if any are found. In males mid-stream specimens of urine collected after cleansing the glands may be used for the purpose, in females a catheter specimen is essential. A radiograph of the chest should be taken in all cases in which the cause of the fever is not apparent, even if there are no symptoms or signs referable to the chest.

In cases in which the diagnosis does not become clear as a result of these investigations enteric fever, brucellosis, and typhus must be considered, and blood should be collected for culture, for enteric and brucella agglutination tests, and for the Weil-Felix reaction. For the cultural investigations 5 ml. of blood is added to 100 ml. of broth containing 0.5% sodium taurocholate, and a second 5-ml. sample is added to 100 ml. of plain broth. In taking the blood it is advisable to use a dry sterilized syringe; boiling should be relied upon only in emergencies. It is commonly said that for positive cultural results in enteric fever blood must be taken within the first few days of the attack. This, however, is not strictly true; the chances of obtaining a

positive culture at that time are greater than they are later, but positive results may be obtained at any stage in the illness and it is never sound practice to omit this investigation. It is important to inoculate the broth with the blood as soon as it is withdrawn from the vein and to transfer the specimen to an incubator with the minimum of delay. Where brucellosis is suspected the fact should be clearly stated, as cultures should then be incubated in air containing 10% carbon dioxide, for in primary culture *Brucella abortus* will often grow only under increased CO₂ tension. *Br. melitensis* and *Br. suis* will, however, grow satisfactorily in atmospheric air.

Blood for the Widal and brucella agglutination tests and for the Weil-Felix reaction should be collected in a dry sterile syringe and allowed to clot in a dry sterile tube or screw-capped bottle. If the journey to the laboratory is one occupying more than an hour or two, the serum should be pipetted off the blood clot and sent in a sterile screw-topped container or in a sealed glass ampoule.

Kala-azar should be suspected especially in those chronically or intermittently febrile and who have hepatosplenomegaly without marked prostration. Isolation of the causal parasite, *Leishmania donovani*, is the only satisfactory way of making a diagnosis, and it should first be searched for in blood films. In these, however, parasites are invariably scanty; they are more numerous in films of sternal marrow. In making the films it is important for the microscope slides to be absolutely dry, otherwise the parasites will be damaged and may not be recognizable. If examination of blood and marrow films gives negative results, blood should be cultured on N.N.N. (Nicolle, Nory, and MacNeal), Adler's, or Lourie's medium. On these media blood is sown in single drops, and great care must be taken to exclude secondary bacterial infection. The culture is kept at 28° C. and growth is to be expected within three weeks. Material in which *L. donovani* can be found may also be obtained by splenic puncture, but this procedure is best carried out only in hospital and by those trained in the technique. The formol-gel and antimony, or Chopra, tests are useful guides to the diagnosis of kala-azar. These tests are positive when serum globulins are increased, but as this occurs in several other diseases they are not specific. The formol-gel test is carried out by adding a drop of commercial formalin to 1 ml. of the patient's serum, which in positive cases becomes opaque and sets into a gel in 10-30 minutes. In the Chopra test a few drops of a 4% solution of any pentavalent antimony compound are added to a 10% solution of the patient's serum in distilled water. In positive cases the mixture becomes opaque in a few minutes.

Alimentary Disorders

In patients recently returned from the Tropics and presenting with symptoms referable to the alimentary system the most common causes are amoebic dysentery, amoebic hepatitis, amoebic abscess of the liver, and a functional or nervous upset. Less common causes include bacillary dysentery, schistosomiasis, ulcerative colitis, and neoplasms of the bowel wall.

Dysentery

Examination of the stools macroscopically and microscopically will do more to elucidate the diagnosis than any other tests. Thus in bacillary dysentery blood, mucus, or a purulent cellular exudate will be found; in amoebic dysentery exudate is less abundant, the specimen more faeculent, and *Entamoeba histolytica* or its cysts are present. In functional or nervous alimentary upsets the stool may be fluid, semi-formed, or formed—it is not uncommon for several small formed stools to be passed daily. Intestinal spasm may cause the stools to be ribbon-shaped. In such cases there is often an excessive amount of mucus, and sometimes this is passed as casts of the intestinal wall or in long strings.

There is often disagreement on the number of stools which should be examined before a diagnosis of amoebic dysentery

is excluded. Wenyon and O'Connor have said, "If *E. histolytica* are giving trouble, the probability is that amoebae or their cysts will be found at once." Their experience is similar to that of most others practising tropical medicine. Much depends on the skill and experience of the person examining the specimens; if he is fully conversant with the appearance of the parasite and is practised in stool examination, a series of six specimens is usually regarded as sufficient. It should be stressed that, unless a person is examining such specimens frequently, he is liable to commit errors in identification of parasites and objects resembling them, and in view of this it is highly desirable that these investigations should be carried out at a centre established for the purpose. Some advocate that stools should be collected after saline purgation, but the consensus is that purgation does not increase the chances of finding amoebae or cysts; there is also the possibility that salines may destroy amoebae by their osmotic effect.

Cultural methods of isolating amoebae are not recommended for routine use, as it is not uncommon for cultures to be negative even when stools are known to contain the amoebae. Various concentration techniques increase the chances of finding cysts in a specimen, but these methods are not suitable for the isolation of vegetative amoebae, as the latter are destroyed by the solution of zinc sulphate or other salt used in the process. Some state that the chances of finding amoebae or cysts are increased by giving the patient one or two doses of emetine by injection. But no reliable evidence of the effectiveness of this so-called provocative emetine has ever been put forward. It seems probable that such popularity as the method obtained was based on confusion with the use of provocative arsenic in syphilis. Each specimen should be collected in a dry bedpan at room temperature, as parasites may be damaged by undue warmth or by water which sometimes remains in bedpans after they have been washed. When collecting faeces for examination it is important to warn the patient not to micturate into the container into which the faeces are being passed.

Vegetative forms of *E. histolytica* become immobile and disintegrate within a few hours; thus any examination for them must be carried out as quickly as possible. Nevertheless, undue emphasis is sometimes placed on this point. There is certainly no truth in the oft-stated belief that if a specimen cannot be examined immediately it should be kept warm to preserve motility of the amoebae. The reverse is in fact true, for if they are kept cool they remain alive much longer than if kept warm. When chilled, amoebic trophozoites lose their motility, but this rapidly returns when they are again brought up to body temperature. Amoebic cysts remain identifiable for several days in faeces kept in a closed container at room temperature.

In the diagnosis of amoebic dysentery the complement-fixation test is as yet completely unreliable; the same can also be said of barium enemata and other radiological procedures. Sigmoidoscopy is occasionally helpful, but it is remarkable how seldom it affords positive evidence of the disease in cases in which the diagnosis has not already been proved by stool examination. It is, of course, of great value in distinguishing ulcerative colitis or neoplasms of the bowel from dysentery, and negative sigmoidoscopic findings also assist in excluding organic disease. An increasing number of observers are becoming sceptical of small pits in the bowel mucosa as evidence of previous amoebic infection. These received much publicity towards the end of the second world war and were supposed to be the scars of amoebic ulcers. Such ulcers, however, unless of great size, normally heal and their scars completely disappear. In this respect they are similar to abrasions and ulcers of other mucous surfaces and parts of the body. It is probable that many of the depressions to which attention was drawn were the mouths of mucous glands normally present in the rectum and colon.

Thus, in dysentery, the most valuable diagnostic procedure remains the examination of a series of specimens of faeces

and particularly of any blood or mucus adherent to or intermingled with such specimens. The specimens are best collected without purgation or the use of provocative emetine.

Amoebic Hepatitis and Liver Abscess

Amoebic hepatitis is usually an accompaniment of an acute attack of amoebic dysentery; its presence is indicated by pain and tenderness in and enlargement of the liver, by leucocytosis, and sometimes by pain in the right shoulder. Acute hepatitis of this kind usually settles down satisfactorily with adequate anti-amoebic treatment and is seldom difficult to diagnose. An amoebic abscess of the liver may, however, cause a more complicated diagnostic problem. Months or years may elapse between the time of the original infection and that at which the first symptoms develop. In some patients there may be no antecedent history of amoebic dysentery, the bowel infection having been subclinical or mild and regarded as transient enteritis only. In the diagnosis of amoebic liver abscess the investigations of greatest value are screening of the liver and diaphragmatic areas, the white blood cell and differential counts, and aspiration of the abscess contents. Stool examination usually gives negative results, for by the time the abscess has developed the original alimentary infection has in most cases been adequately treated or resolved spontaneously. In such cases radiological screen examination usually shows elevation and paradoxical movement of the right diaphragm on respiration. There may also be collapse or patchy consolidation of the base of the right lung. A moderate leucocytosis is usual with some increase of the polymorphonuclear cells, though this is by no means invariable and cases occur in which the white blood cell and differential counts depart but little from normal.

If the clinical picture and/or radiological appearances suggest that a collection of pus is present in the right lobe of the liver, a diagnostic aspiration should be carried out. Aspiration of the left lobe of the liver should not be attempted, as it cannot be reached other than by open operation without incurring risk of damaging vital structures. The right lobe is best aspirated with a large-bore needle introduced in the right mid-axillary line in the ninth or tenth intercostal space or in the right scapular line in the eleventh intercostal space. Any pus obtained should be examined microscopically and cultured. Amoebae are only rarely obtained in such pus, as they live in the abscess wall. Unless there has been secondary infection the pus is sterile on culture. In cases in which it is not infected it is of the same colour as the liver and is commonly likened to anchovy sauce. When infected it has a greenish or yellowish tint.

Schistosomiasis

When schistosomiasis is suspected examination of both urine and faeces is important. Ova of *Schistosoma mansoni* are most commonly found in the faeces or in material removed by biopsy of the rectal wall. Ova of *S. haematobium* are more numerous in the urine though they may be found in the faeces or in rectal mucosa. It is in the last few drops of urine expressed during micturition that the eggs of *S. haematobium* are most numerous. If examination of such a specimen reveals no eggs a 24-hour collection of urine should be allowed to sediment, three-quarters of the collection is then siphoned off and the remainder centrifuged and examined microscopically. In schistosomiasis the differential white blood cell count often shows an eosinophilia. At the Hospital for Tropical Diseases, London, a complement-fixation test for schistosomiasis can be done and this gives reliable results.

Conclusion

The diagnosis in most tropical diseases can be reached by carrying out simple laboratory procedures often involving the use of little more than the microscope, but the interpretation of results and the recognition of the various parasites and or the structures and artifacts which may simulate them call for considerable training and experience. The late effects of errors in interpretation and consequent

mismanagement are not uncommonly encountered at the various tropical centres in Great Britain, and such mismanagement may lead to chronic ill-health and in some cases even to the death of the patient. It is therefore in the patients' interest that whenever possible they should be investigated in a centre for tropical diseases. Apart from various military establishments there are three of these in Great Britain—namely, the Hospital for Tropical Diseases, 4, St. Pancras Way, London, N.W.1.; the School of Tropical Medicine, Pembroke Place, Liverpool; and the Tropical Diseases Unit, Eastern General Hospital, Edinburgh.

Refresher Course Book.—The first collection of articles in the Refresher Course for General Practitioners (fully revised) are available as a book containing 55 chapters, price 25s. Copies can be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

MEDICAL ART

[FROM A SPECIAL CORRESPONDENT]

Gaiety once again is the keynote of the exhibition¹ of work by members of the Medical Art Society. Nearly all the paintings evade the criticism of much contemporary art that it cannot be lived with; indeed, any of these would lend distinction to the kind of rooms that most of us are condemned to inhabit. But if the gay spontaneity of this work betokens the amateur, the technique often suggests a more practised hand. Mr. Elliott Blake's impressionist oil painting of autumn leaves in a Sussex lane (No. 23) catches the eye immediately as a fine piece of painting, though the composition is somewhat precisely balanced. Another plastic surgeon, Sir Harold Gillies, also enchants the eye with a landscape of winter, "Beech Trees in Snow" (No. 20). Dr. A. B. Hewlett, as usual, contributes one of the outstanding paintings of the show, "The Upper Reaches" (No. 42), a beautiful evocation in his highly distinctive style of a typical corner of the English countryside. "The Edge of the Downs" (No. 64), by Dr. G. M. Archer, is also a most successful landscape; though more conventional in technique, it glows with unusual warmth of feeling. Other pictures in this room that should not be missed include the two negroid heads by Dr. W. Hartston (Nos. 2 and 6), "Summer Mist" (No. 26) by Dr. E. P. Scott, and "The Reef" (No. 54) by Dr. A. G. Duncan.

Few of these week-end painters—or of any amateur painters in this country—owe much of their technique to any of the artistic movements that succeeded the Impressionists. However, Mr. R. T. Payne shows some fanciful abstractions, attached to rather than illustrating texts from Genesis; Mr. W. M. Van Essen has evidently had an encounter (No. 111), not altogether fruitless, with Picasso; and Mr. Geoffrey Parker's "Bruges" (No. 89), misprinted in the catalogue, suggests some affinity with the German expressionist movement of the 'twenties. Dr. H. Hales's *jeu d'esprit* in wire (No. 80) belongs more to the realm of doodling than of art, but it is an amusing contrivance all the same. On the opposite wall near by is a particularly colourful and decorative painting by Lady Whitby, "Dahlias" (No. 98). Here we are back with the Impressionists again, and it is an easy step to Dr. Joy Patrick's striking portrait of "Cecilia" (No. 107).

Among the water-colours Dr. A. E. O'Donnell shows an excellent snow scene that yet communicates a feeling of

¹At Walker's Galleries, Bond Street, London, W.1, until May 8. Open 10 a.m. to 5 p.m., Saturdays 10 a.m. to 1 p.m.

warmth derived from the pleasure of painting it. Mr. Holmes Sellors catches the passer's eye with some gay scenes (Nos. 183 and 184), and Dr. Reginald Morshead has recorded Sussex's "Chanctonbury" (No. 171) in a refreshingly cool study. In this same room is a beautiful piece of sculpture by Dr. Geoffrey Konstam, a head of a baby (No. 141). This exquisite work deserves long contemplation.

The president of the society, Sir Philip Manson-Bahr, himself contributes several paintings, in No. 9 giving an agreeable portrait of his horse, and in No. 150 bringing to Sussex an eye that seems to have been averted only momentarily from tropic climes. He and the members of the society deserve our thanks as well as our congratulations for putting on this exhibition of such enchanting talent.

THE CHANGING AND THE UNCHANGING FACE OF MEDICINE

FIRST SYDNEY BODY LECTURE BY
Sir FRANCIS WALSH, F.R.S.

The first lecture under the Sydney Body Trust was delivered at Southend-on-Sea Hospital, Rochford, on April 14 by Sir Francis Walshe. This Trust has recently been instituted under a benefaction by Mr. Sydney Body, M.P.S., to provide for a lecture to be given every year designed to promote sympathetic understanding between the medical profession and the public; also a gold medal to be awarded, not necessarily annually, to a medical man or woman for outstanding merit in some field of research or achievement.

Sir FRANCIS WALSH addressed a large and distinguished audience on "The Changing and Unchanging Face of Medicine." Medicine, he said, was the oldest learned profession in the world, and each successive generation of doctors stood on the shoulders of its predecessors. During the forty years of his own professional life medicine had undergone vast changes, but equally there were aspects of it which had not and would not change.

When he started medicine there was no scientific chemotherapy as they now saw it. Patients suffering from pernicious anaemia survived for about four years, and nothing could check the ruthless course of their malady. Surgery of the lung, the heart, and the brain had developed during his lifetime. The triumphs of asepsis, anaesthesia, and post-operative care had transformed the surgical operation. Preventive medicine had advanced out of all knowledge. The men of his generation in medicine had been privileged to live in an era of more rapid advance than anything the previous history of medicine had seen.

At the same time he looked back occasionally on the doctor of 40 years ago, and realized how often he had possessed that clinical judgment without which none of the modern techniques could be used to full advantage. These modern resources were two-edged weapons, and it was easy for zeal to outrun discretion.

The Impact of the Health Service

Since the introduction of the National Health Service, Sir Francis Walshe continued, many people seemed to have developed an attitude of helplessness concerning their own and their children's health. In former days if a child fell down and grazed his shin his mother bathed it and put on a plaster, but to-day he was sent to join the queue at the surgery. "After all, why do what the doctor is paid to do? We pay for welfare; why should we not have it?"

Doctors were only human beings: they had their private lives, their foibles, too; they sometimes made mistakes. It was not unknown for them to make errors of judgment

when the diagnostic situation was difficult or they were tired or working under pressure. There was too general an assumption that when misfortune occurred someone was to blame. But if such an assumption grew it might well entail a shrinkage on the part of the doctor from taking any bold action at all. He might recall those lines of A. H. Clough:

Thou shalt not kill; but need'st not strive
Officiously to keep alive.

"Safety First" was often a miserable motto, but it might be encouraged by the growing practice on the part of patients to have recourse to law.

He sometimes wondered whether judicial pronouncements in cases of alleged negligence or misdoing on the part of the doctor might not be a little more restrained if litigants could proceed against counsel when they failed in their actions, or even against a judge for negligence should his decision be reversed on appeal. But no profession had a keener sense of self-preservation than the law. The lawyers had seen to it that nothing could happen to them.

Corruption by the State

The unchanging face of medicine was its obligation of prudence which the ancients spoke of as practical wisdom and placed in the category of moral virtues. The doctor must be informed in his actions by a wise regard for the individual patient, which did not necessarily mean doing what the patient asked of the doctor. The Hippocratic oath told the doctor in general terms what he might or might not do. Throughout recorded history kings, prelates, and judges had on occasion been responsible for the most monstrous inhumanity to man, but until our own age the profession of medicine had never stained its record in this respect. As a body of men they had endeavoured sincerely to serve the human race. But in Continental concentration camps in the last war they had been made aware of the attempted corruption of the profession by the State, and the abandonment by some members of it of all that the Hippocratic oath involved.

The doctor must refuse to betray his principles at the bidding of any State. He must have the courage and the practical wisdom to use his powers only for proper ends and decline to use them for base ones. It was so easy to believe that what could be done might be done. If we believed that there was a divinity that shaped our ends, it was not for us to rough-hew them how we would. In the world of medicine the moral issue abided. However brilliant in scientific achievement the future of medicine might be, he trusted that the activity of doctors would always be inspired by the moral virtue of practical wisdom, whose name was truth.

Presentation to Dr. William Evans

After a vote of thanks had been accorded to Sir Francis Walshe on the proposition of Dr. T. Rowland Hill, Mr. SYDNEY BODY presented to Dr. William Evans the first gold medal of the Sydney Body Trust for his work in cardiology, and spoke of the high esteem in which he was held in Southend and its neighbourhood, and the reputation he had achieved in the field of medicine. Dr. WILLIAM EVANS, in acknowledging the honour, paid a tribute to all those who had helped him, including his colleagues at the hospital and his patients.

A factory for producing D.D.T. will shortly be established in North Ceylon to ensure adequate supplies for the country's antimalarial campaign. Unicef will provide essential equipment costing 250,000 dollars, while the Government of Ceylon will bear capital costs equivalent to 415,000 dollars and annual operating costs of 450,000 dollars. It is estimated that an annual production of 700 tons of D.D.T. will be sufficient for the island's needs.

Preparations and Appliances

A MICROSCOPE LAMP FOR USE IN THE FIELD

Mr. J. SMILES and Dr. J. A. McFADZEAN, of the National Institute for Medical Research, London, N.W.7, write: At present there is no satisfactory source of illumination available for microscopy in the field. Six-volt electric lamps may be run from an accumulator, but accumulators are often unreliable, particularly in the tropics, and require

to be charged at intervals. Dr. W. E. Ormerod suggested the use of a Tilley lamp. The photograph shows a paraffin pressure lamp made by the Tilley Lamp Co., Ltd. (model No. AL.21), which has been adapted at the National Institute for Medical Research for use as a field microscope lamp in West Africa. The lamp is mounted on a base in conjunction with a small optical bench which carries a collector lens with a diaphragm, and a filter-holder. There is a metal baffle in front of the lamp, with an opening 2 in. (5 cm.) in diameter, which prevents stray light and heat reaching the observer. The lamp is easily detached from the unit and may thus be used for general purposes. The unit has been tested for transmitted light, dark-ground illumination, and phase-contrast, and is satisfactory for all three systems. We wish to express our thanks to Mr. A. S. Maslen, who constructed the unit.

JACK FOR SUSPENDING THE BOYLE-DAVIS GAG

Mr. W. BRYCE MCKELVIE, consultant E.N.T. surgeon, Booth Hall Hospital, Manchester, writes: The jack for suspending the Boyle-Davis gag in dissection tonsillectomy here illustrated is simple to make and does not include screws or springs liable to rust, or rubber. It is constructed of stainless steel by Allen & Hanburys Ltd. A prototype has been in use for over five years.

Correspondence

Changes in Skin Response in Asthma

SIR,—The place of clinical allergy in medical teaching and practice has long been bedevilled by controversy regarding the methods of investigation and the validity of the results obtained. On the whole, there has been much "false pleading" on the part of the critics, since they have attributed to the allergist much greater confidence in the prognostic significance and validity of skin-test results than he has himself claimed. The immunological validity of these results, on the other hand, can be demonstrated by methods of refined precision, provided that all efforts are made to minimize sources of error in testing. In his article (*Journal*, February 13, p. 370) and in his later spirited reply (*Journal*, April 3, p. 818) to Dr. R. S. Bruce Pearson's pertinent criticism of his technique (*Journal*, March 13, p. 642), Dr. A. G. Ogilvie has arrived at conclusions regarding skin-test results, in the course of which he has employed methods which reduce the reliability of testing. It is as well to point out that there has been concern in recent years over the variability of biochemical and other laboratory investigations as between different laboratories handling the same specimens. The reactions to skin-testing are made manifest by tissue and vascular responses, and careful technique is made all the more necessary.

For precise detailed study, prick testing is a most suitable method, although the incidence of positive reactions may be lower than with intradermal testing. If, however, intradermal testing is employed the ideal method is one in which negative or nearly negative reactions are produced at control tests. Wide experience has shown that the smallest dose consistent with accuracy which can be injected into the superficial dermal tissues is 0.01–0.02 ml. If the injection is given into the deeper layers of the skin reactions can be markedly altered. The dose of 0.1 ml. employed by Dr. Ogilvie's assistants is far in excess of this, and, in spite of his protest to the contrary, this volume injected into the superficial layers of the skin can be both painful and irritant. He describes the disappearance within 10 minutes of the bleb raised by the injection of 0.1 ml. of fluid, and this too is far shorter than the time regularly observed for the disappearance of a similar volume of saline in tests of the absorptive capacity of the skin (Aldrich-McLure test). Even though this volume is too large for test purposes, positive reactions are undoubtedly obtained, but the size of the control reactions vitiates its value for follow-up studies of the variability of skin-test reactions. Even when prick testing is used for threshold testing variability of reactions can be seen. For example, the prick test can elicit reactions with grass pollen extracts containing from 5–10 units per ml., and multiple tests carried out simultaneously can show discernible differences, due either to local skin factors or to imperceptible differences in the prick itself. It would be surprising if differences in intensity of reactions did not appear at tests carried out at different times. This problem has already been considered previously, although Dr. Ogilvie was unable to find any pertinent references, for Vaughan in his *Practice of Allergy*¹ lists variation in intensity of reactions to skin testing in the index, and he gives a tabulated record of scratch-test results to 49 different allergens in the same subject over a period of 12 years. He suggested that tests should be repeated from time to time, since there may be variations in intensity due to technique or to changes in the subject's sensitization. It would seem then that, whilst there is agreement with regard to the variability and prognostic value of skin-test results, studies, however worthy, which purport to illustrate this should employ the most precise techniques, and should respect the sources of error in testing.—I am, etc.,

J. PEPYS.

London, W.2.

Drinking Sea-water

SIR,—The crossing of the Atlantic by Dr. Alain Bombard on a rubber raft, and his subsequent claims regarding survival methods, have caused much discussion. In particular, his views on drinking sea-water have been widely disseminated, and his heterodox opinions have caused some alarm among those who have responsibilities in advising on survival policy. Dr. Bombard will soon return to this country to give a second series of public lectures, in which no doubt he will reaffirm his belief that sea-water should be drunk by castaways. There has as yet been no public denial of Bombard's claims, and this might suggest that his theories have been accepted. Nothing could be further from the truth, and it seems appropriate to say again that the bulk of experimental evidence has shown that sea-water drinking must do castaways more harm than good.

Criticism of Bombard's physiological notions is often misunderstood as criticism of his achievement. His courage and determination have never been in doubt, and the difficulties he has overcome in his attempts to "prove that man can exist for a long period of time at sea are indeed formidable. However, it is not upon psychological issues alone that survival at sea depends. In addition to many other factors, the concentrating power of the kidney, which has a known physiological limit, plays no small part in regulating the conservation of body water. Bombard's advice to drink sea-water is not backed by any acceptable evidence which would show that our present concepts of renal function are inaccurate, and Bombard's own evidence is unsatisfactory and contradictory.

Bombard is wrong when he supposes that traditional advice is based upon the fact that sea-water could not be drunk. The advice given against sea-water drinking depends upon the fact that it *should* not be drunk. The fact is that at the present moment the experimental evidence shows quite clearly that it is possible to drink sea-water but never to advantage. Those who are cast away at sea who do not drink sea-water and wait for the rain that saved Bombard will be more certain to survive than those who do drink sea-water, provided they are equally courageous.—I am, etc.,

T. C. MACDONALD,
Director of Hygiene and Research,
Air Ministry.

London, W.C.2.

Action of Chlorpromazine and Promethazine

SIR,—At a discussion on chlorpromazine and promethazine at the Royal Society of Medicine on April 2 Professor J. H. Burn (*Journal*, April 17, p. 931) noticed that little interest was taken in the temperature falls produced by these two drugs. While it is true that a fall of temperature occurs under ordinary methods of anaesthesia, this is not so pronounced as that resulting from chlorpromazine. A drug which produces a marked fall of temperature and presumably reduction in metabolism is surely interesting.

The doses of chlorpromazine and promethazine used in my cases have not exceeded 50 mg. of each drug, but large doses of pethidine (200 mg. and over) or morphine have been given to a number of cases to demonstrate potentiation. The analgesia of both these drugs has been undoubtedly enhanced, but curiously enough the respiratory depressant effects have been reversed. For want of a better term, paradoxical potentiation is suggested. The "nalorphine"-like effect of chlorpromazine has restarted respiratory arrest due to pethidine and morphine in every case. The effect of promethazine, however, is unreliable. For instance, respiration was abolished by 200 mg. of pethidine in a fit female with bilateral hallux valgus, artificial respiration being carried out with closed circuit air and basal oxygen. The insertion of towel clips was resented but the respiratory rate was still nil. After 35 mg. of promethazine the skin incision was tolerated, but respiration did not restart. Three minutes after 35 mg. chlorpromazine was given, respiration restarted. The bilateral operation proceeded uneventfully with a respiratory rate of 11 per minute,

and no supplementary anaesthesia was given. In this series (so far) the potentiating effect of chlorpromazine on pethidine or morphine is greater than with promethazine. The effect of chlorpromazine and promethazine on thiopentone is dependent on the amount of pethidine in the mixture.

After 35 mg. each of chlorpromazine and promethazine have been given, respiratory tracings show that little reduction of amplitude occurs after 350 mg. of thiopentone given slowly. In another tracing in which 70 mg. of pethidine was added to the chlorpromazine and promethazine, respiratory arrest occurs with 200 mg. of thiopentone.—I am, etc.,

Edware, Middx.

DAVID RECKLESS.

SIR,—During the past six months I have been able to observe the separate and combined effects of chlorpromazine, promethazine, and pethidine as suggested by Professor J. H. Burn (*Journal*, April 17, p. 931).

When either chlorpromazine or promethazine is given separately by the oral or intramuscular route there is a similarity of the central effect which is characterized by a state of indifference and detachment rather than a true hypnosis and analgesia. However, the action of chlorpromazine is clearly more pronounced in depth and duration, extending fully over 24 hours compared with a maximum of 12 hours with promethazine. The central effect of pethidine on the other hand is predominantly analgesic and sedative. When combined with either chlorpromazine or promethazine each provides a quality that the other lacks, supplementing each other in a most satisfactory manner.

Neither pethidine nor promethazine, separately or combined, have been able to confer protection against haemorrhagic or traumatic shock in the manner obtained when chlorpromazine is added. Neither does either bring about that marked facial pallor and emptiness of capillaries that is characteristic of chlorpromazine and which French workers contend is explained by its strong central sympatholytic action.

There is certainly need for careful evaluation of the precise action of these three drugs. However, I hope that no one will take Professor Burn's suggestion too literally and give a patient 200 mg. of chlorpromazine either intramuscularly or intravenously. A state of permanent "hibernation" might well follow and make Drs. F. S. Preston and H. Y. Wishart's difficulties following a dose of 25 mg. seem quite trivial (*Journal*, March 13, p. 645).—I am, etc.,

London, S.E.11.

D. A. B. HOPKIN.

Prostatic Obstruction Due to Ephedrine

SIR,—At last I have seen in print a description of the annoying side-effects produced by ephedrine in elderly male asthmatics, and it has puzzled me for years that this problem has never been fully discussed, or that I have seen no reference to it.

Dr. H. J. Wright, in "Points from Letters" (*Journal*, April 10, p. 878) draws attention to the difficulty of micturition experienced by this group of patients. He attributes the symptoms, which have amounted to acute retention of urine in a number of my own cases, to an effect of ephedrine on the prostate gland. Surely the action is either on bladder sphincter tone or on bladder muscle, or both, increasing the former and decreasing the latter. I have based my conclusions on personal observations. Twenty years ago I used to take ephedrine because of hay-fever and noticed a remarkable diminution of the force and volume of the urinary stream. More recently I have seen the same symptoms on taking the amphetamine group of drugs, and it has made me wonder if the benefit claimed in nocturnal enuresis is produced by this "local" action on the bladder rather than by the decrease in depth of sleep, which is put forward as the explanation.

Those people who are predominantly sympathetico-tonic would be particularly affected, the vago-tonics much less so, hence the discrepancies in results reported in the enuretics,

and the qualms I feel when I go to bed having left an old man with ephedrine to take for his nocturnal wheezing for the first time.—I am, etc.,

Llminster.

HUGH CARTWRIGHT.

SIR,—In answer to Dr. H. J. Wright (*Journal*, April 10, p. 878) I would refer him to Hale-White's *Materia Medica*,¹ which mentions the fact that urinary retention may occur with ephedrine medication, particularly in children. I have myself on occasions seen acute retention in adults as a result of heavy ephedrine medication.

I have, on several occasions, seen elderly males admitted in a state of left hypertensive failure associated with bronchospasm who have, as an incidental finding, a retention of urine due, probably, to ephedrine therapy which has been given before admission for the bronchospasm.—I am, etc.,

Liverpool, 6.

"New Cure for Gastric Ulcer"

SIR,—Some time ago you wrote to me about rumours of a new vitamin allegedly discovered by me. These rumours have now culminated in the statement in the lay press that I have announced the discovery of a new dietary factor which cures gastric ulcer in humans in 10 to 30 days. I have not made such an announcement. And I should like to disclaim any responsibility for it and the accompanying sensationalism.

For a number of years I have studied the dietary development and prevention of gizzard ulcers in chicks, a subject which may or may not be related to the human ulcer problem. At present certain dietary materials (not "new vitamins") that counteract gizzard ulcers in chicks are being tested for their value as dietary constituents in the treatment of gastric ulcer in man. An American gastro-enterologist is studying the problem, and several Danish physicians have begun clinical trials too.

Since, to my knowledge, no clinical reports have appeared in the medical literature, newspaper articles about "the cure for ulcer," and, concomitantly, direct or indirect advertising of preparations purported to cure the disease, are, to say the least, premature.—I am, etc.,

Copenhagen.

HENRIK DAM.

Dangers of E.C.T. in Elderly Psychotics

SIR,—Whilst agreeing with Dr. G. I. Tewlik (*Journal*, April 10, p. 876) in his criticism of the statement by Drs. Vera Norris and Felix Post (*Journal*, March 20, p. 675) that "fainting turns, transitory pareses, or speech disturbances . . . even in the absence of neurological signs or patchy intellectual defects, was regarded as indicative of cerebral arteriosclerosis," I cannot agree that the concept of arteriosclerotic dementia is based on shaky pathological and clinical criteria. Certain clinical pictures correlate too well with the necropsy findings of atherosclerosis in cerebral vessels coupled with areas of cerebral infarction on microscopic examination, or even gross cerebral haemorrhage or cyst formation,¹ deposits of iron in the extrapyramidal system and senile plaques in the cortex. Many old patients suffering from cerebral arteriosclerosis are labelled senile dementia.²

Clinically, cerebral arteriosclerosis should be diagnosed by emotional lability, patchy amnesia, confusion, relatively well-preserved personality, and retention of insight, with some evidence of generalized arteriosclerosis, or focal signs in the C.N.S. I do not think one should be so enthusiastic about giving E.C.T. in such cases, because the increased metabolic demands resulting may precipitate a prolonged amnesia; I have known such patients die from left ventricular failure due to coronary ischaemia, even when treatment has been modified by succinylcholine chloride.—I am, etc.,

Willesby, Yorks.

Relief for Entropion Sufferers

SIR,—For about three years I have suffered from entropion with the resultant constant irritation by the hairs of my lower lid on the cornea. A first-class oculist on two occasions removed skin below my lower eyelid. Neither operation proved successful and indeed each time he informed me that they might not be.

About eight weeks ago a lay friend, who observed me constantly drawing down the lower lid, suggested that if I wore an eyeglass frame inside my glasses it might be helpful. For some reason I was unable to keep the frame in situ. I asked an optician to fit a "ledge" along the lower right eyeglass which by its weight would fit snugly on to my cheek and so keep the lower lid everted. The ledge is $\frac{1}{4}$ in. (16 mm.) at its widest part, tapering to about $\frac{1}{8}$ in. (6.4 mm.) at its narrowest, and $\frac{1}{4}$ in. (3.2 mm.) thick. It lies slightly more than at right angles to the rim of my glasses. It is slightly serrated on its edge and has perforations along its middle to prevent condensation on the eyeglass.

This idea may have been used before, but neither my oculist nor other doctors to whom I have shown it have ever seen it. I have now perfect comfort and am free from all irritation. I will be glad to know if such a treatment for relief from entropion has been previously tried.—I am, etc.,

Dublin.

CECIL W. C. ROBINSON.

Pregnancy Following Haematosalpinx

SIR,—In the medical memoranda (*Journal*, October 10, 1953, p. 814) Dr. J. G. Dumoulin reported a case of pregnancy following haematosalpinx, and he commented on his failure to find a similar case reported in the literature.

On November 6, 1944, a girl of 16 was admitted to hospital with a history of lower abdominal pain and dysuria. She had never menstruated. She had a mid-line tumour arising out of the pelvis and was diagnosed as a case of congenital retention of the menses. At operation dense tissue replacing the lower part of the vagina was incised and a haematocolpos was reached at a depth of $1\frac{1}{4}$ in. (3.7 cm.). About 18 ounces (0.5 kg.) of an odourless, more or less tarry fluid was evacuated. The cervix was patulous and admitted a No. 7/8 Clifford and Walls dilator. A bimanual examination showed a uniformly enlarged uterus, and a tubal swelling on the left side. The enlarged uterus was a haematometra which was draining slowly. A new introitus was fashioned by undercutting the lower end of the vaginal skin and suturing it to the edges of the original incision. The abdomen was then opened with the intention of dealing with a suspected haematosalpinx by salpingectomy. There was a little dark free

fluid in the pelvis. The right tube appeared to be normal. On the left side was a haematosalpinx which seemed to be getting smaller when it was exposed and handled. An attempt was made to reduce the size of the haematosalpinx still further by milking it gently towards both ends. Although there was no further reduction in size, the decision to remove the tube was revoked and the abdomen was closed. After a follow-up examination on December 15, 1944, I never saw the patient again. Mr. O. Vaughan Jones, of Bangor, has very kindly traced this patient for me and has written to tell me that she has had normal deliveries of full-term live infants in 1949, 1951, and 1953.

Dr. Dumoulin mentions the fact that most textbooks only briefly describe haematosalpinx from congenital vaginal atresia. Many British textbooks are either silent or equivocal on procedure. W. Shaw¹ recommends salpingectomy. Conservation of the tube is suggested by Eden and Lockyer.² American textbooks are much the same. In successive editions of Curtis (now Curtis and Huffman³) there has appeared a drawing of a specimen of haematocolpos, haematometra, and bilateral haematosalpinx—"removed from a girl of fourteen." Te Linde,⁴ however, states clearly that "one should be restrained from doing salpingectomy. . . ." Well-known Continental authors like Martius⁵ and Guggisberg⁶ advise salpingectomy. In their classical paper "Congenital Retention of the Menses," Christie Brown and Alan Brews⁷ collected and analysed 50 cases in 21 years in the largest teaching hospital in London. Of the 50 cases, only 7 had a haematosalpinx. In the 7 case notes of haematosalpinx, Christie Brown and Alan Brews record that 3 were unilateral and 4 were bilateral (there was another case of a ruptured tube that might have been another unilateral haematosalpinx). This illustrates the rarity of the condition and possibly explains the dearth and conflict of advice on what should be done.

In these days when the possibility of infection should not influence the operator one can at least make a plea for conservation of the tube in cases of haematosalpinx from congenital atresia of the vagina.—I am, etc.,

Carmarthen.

Domiciliary Obstetrics

SIR,—In his account of obstetric practice in the Gloucester area, Dr. Ivor Cookson (*Journal*, April 10, p. 841) has rightly pointed out several dangerous types of patient who cannot safely be confined at home. But I think that he has made some unjustifiable assumptions from the data which he has examined, and has painted altogether too idyllic a picture of the ease with which domiciliary midwifery can be practised. Dr. Cookson says: "It does not need postgraduate experience to select for hospital, women who have had many previous deliveries and those with a history of an abnormal third stage. . . . Interest in obstetrics and adequate instruction as a student are the only essential qualifications for the family doctor who wishes to practise obstetrics in an area where consultant support is available." He has, I think, forgotten how much or how little knowledge a student possesses after his final examination. Such a student is uncertain about his findings on abdominal examination, and more so about those on vaginal examination. He will quickly forget much that he has learnt unless he is practising it daily. In theory, he can easily book a patient for hospital confinement if she has a history of post-partum haemorrhage, provided he recalls that this is an indication for delivery in hospital and remembers to ask her if she has such a history: he can send her to have her breech delivery in hospital, provided he has diagnosed breech presentation correctly. Every student should know that a vaginal examination must not be performed on a patient with antepartum haemorrhage

in her own home, yet the number of such patients arriving at hospital who have been examined vaginally is still appallingly high.

To someone like Dr. Cookson, who has postgraduate experience of obstetrics and is continuing to practise it, such counsels of safety are readily appreciated. He knows the danger of neglecting these precautions because he has seen the accidents which follow; but the doctor who has not seen them, but has merely been told that they occur, will appreciate them less readily, and will much sooner forget them. I doubt if such a doctor will, for long, resist his patient's insistent demands to have her twins delivered at home. We all have a strong tendency to hope that everything will be all right. Even in his personal cases, Dr. Cookson states that "it was decided with some reluctance to deliver one breech and two sets of twins at home." The inexperienced doctor might easily decide to do so too, but would not be able to deal with intrapartum haemorrhage from premature separation of the first placenta by rapid extraction of the second twin, as Dr. Cookson did. He says also of his difficult cases: "All these could, of course, have been transferred to hospital." Why, therefore, was this not done if it is so simple and advisable? The statement that pelvic contraction "is rare and likely to become rarer" may be true of some areas of the country. It is certainly not so of others. In the industrial areas of the North of England and in Scotland, pelvic contraction is still common and a most serious danger, especially in multiparae, in whom it is most likely to be overlooked.

His article states of forceps extraction: "Domiciliary forceps delivery is inevitable in a small proportion of cases, but the risks are not great." Now, the simplest rule which the adequately instructed student should know is that forceps should never be applied until the cervix is fully dilated; yet in an industrial area of the north where consultant support is easily obtained the commonest cause of failed forceps is incomplete dilatation of the cervix (Gadd, *Journal*, March 27, p. 735). Surely there can be no other reasonable explanation for this than that the doctor without practical experience has failed to recognize the degree of dilatation of the cervix. The fact that forceps are still being applied under such circumstances and that grandes multiparae and patients with a history of post-partum haemorrhage are still commonly confined at home seems to indicate to me that something more than simple teaching is required to convince most doctors of the dangers of such practices. Dr. Cookson admits that it will take an average doctor ten years to accumulate records of 150 cases. He will require better experience than this to make him convinced of what he is feeling on abdominal and vaginal examination, and to give him the skill to interpret his findings correctly.

Not only is it necessary for the practitioner in the country districts to have experience in obstetrics, but also for his colleague in the less remote areas to have it too in order that he can recognize when consultant help is required. It will not matter how much consultant support is available if such support is not asked for.—I am, etc.,

Sheffield, 3

C. J. DEWHURST.

SIR,—Dr. Ivor Cookson is to be congratulated on his revised version of his Sir Charles Hastings Clinical Prize Essay (*Journal*, April 10, p. 841). It well deserved your careful and important leading article (p. 861). The essay succeeds in demonstrating the excellent results which can be obtained in domiciliary obstetrics by a general-practitioner obstetrician who has some training and obviously exceptional enthusiasm. There will be much agreement with his conclusions on the selection of cases for hospitalization, but there remains a strong case for having all primigravidae under the care of a hospital, if only for the earlier detection of pre-eclampsia and a more energetic management of this complication in its earliest phases. The hospital would be much concerned with weight increase and with the labile blood pressures and take action on these findings. It is true that we now see fewer cases of "contracted pelvis," but we are still meeting disproportion in small women and dystocia arising from perversions of pelvic shape. Further, though few primigravidae in respect of their pelves rate a "trial of labour," all are very much on a trial of the uterus and a trial of the soft tissues. Tables VI and X, dealing with delayed labour and perineal damage respectively, demonstrate this clearly.

It seems likely that the demand for confinement in a hospital will not diminish while the present differential maternal mortality as between hospital series and domiciliary series persists. In this area (Stirlingshire and Clackmannan) between the years 1947 and 1951 inclusive there were 10,570 institutional confinements with 5 maternal deaths and 12,195 domiciliary confinements with 20 maternal deaths. This gives maternal death rates of 0.46 per 1,000 and 1.64 per 1,000 respectively. Professor Baird¹ showed a very similar disparity between the two forms of service for Aberdeenshire and Aberdeen City for 1946-50. At a meeting of the Edinburgh Obstetric Society during this session it was stated by an official that the domiciliary maternal death rate for Scotland at the present time was four times higher than for the institutions.

Baird in the same article declared that maternal mortality in well-equipped hospitals could possibly fall to about 0.25 per 1,000. I believe that the domiciliary maternal death rate can also be reduced, but the general-practitioner obstetrician carries three severe handicaps. First, very few practitioners carry a "giving" set and a suitable fluid with which to combat haemorrhage and shock. A great deal of experience as well as matched blood and an armamentarium are required to deal satisfactorily with the haemorrhagic emergencies which are now the chief cause of death. Secondly, few general practitioners are alert to note the onset of pre-eclampsia early enough and to act vigorously at once. For this, teaching is probably at fault. We should be taught that pre-eclampsia (meaning oedema, hypertension, and albuminuria) is an end-state of which in most cases there has been adequate warning, and that complete pre-eclampsia practically never can be cured and not often ameliorated until the pregnancy is terminated. Thirdly, the presence or intercurrent onset of anaemia in pregnancy is not sufficiently regarded. Especially the onset of anaemia after infections—for example, after pyelitis—too often escapes notice and greatly intensifies the effects of haemorrhage, shock, and toxæmia. The simplest haemoglobinometry would suffice, since great accuracy is unnecessary. I am, etc.,

Stirling.

D. S. GREGG.

REFERENCE

¹ *Brit. Bull. (Edinb.)*, 1952, 10, 51.

SIR,—I was most interested in Dr. I. Cookson's article on domiciliary obstetrics (*Journal*, April 10, p. 841), but would like to inquire on one or two points which seemed not quite clear.

It is stated that most general practitioners will be able to apply forceps, yet admitted that this is not taught in the curriculum; where has this art been learnt? A little later the inexperienced practitioner is advised to call a consultant with little or no hesitation; the busy consultant, however understanding, is surely not likely to encourage this practice. Suturing the perineum, it is stated, should be taught to students. I considered myself fortunate to perform one such operation during my midwifery training. Thus I and my contemporaries can hardly be considered competent to suture perineums on our own.

Would Dr. Cookson agree with me that the best way of overcoming these difficulties could be to serve six months as obstetric house-surgeon prior to starting a career in general practice?—I am, etc.,

Disby, Linco.

P. WINTERSHILL.

Nocturnal Enuresis and Frequency

SIR,—With regard to nocturnal enuresis, apart from the usual effort along the lines of altering the drinking habits, or the use of phenobarbitone, ephedrine, nicotinic acid, or amphetamine sulphate, I have during the past six years made considerable trial with posterior lobe pituitary snuff ("dispidin"). The patients take a pinch of the snuff at night, and thus get the benefit of renal inhibition during the next five to seven hours. On the whole small children have not done so well with the snuff, but in older children or in cases in the second and third decades I have found it very useful.

My best case is a man of 36 who, since using the snuff, has been able to cut down his "accidents" from about every night to one or two a month. He has got married on the strength of this, and has been using it successfully for three to four years, but if he stops using the snuff he relapses.

I have also used the snuff to relieve nocturnal frequency in elderly patients where other measures fail and where their rest is seriously disturbed by having to micturate at frequent intervals. I have found it most effective in these cases, and have several very grateful elderly men who, by using the snuff, cut down the nightly disturbances from five to two times to one or two. I have never seen any written reference to the use of this snuff for such cases before, but so far, from my own experience, I have encountered no unpleasant effects from its use.—I am, etc.,

Clitheroe.

R. E. A. S. HANSEN.

Retention of Urine

SIR,—Mr. J. A. Lloyd Davies (*Journal*, April 3, p. 796) has drawn attention to the increased risk in operating on prostatic cases when they are in a state of bladder distension with overflow or acute added to chronic urinary retention, and has shown the high proportion of cases which come to hospital in the more dangerous conditions.

In the Victoria Infirmary, Glasgow, and Hairmyres Hospital, Lanarkshire, 770 patients have had operations for prostatic obstruction in the last five years: 412 cases (53.6%) have been admitted in acute retention. In many cases it is not possible to say whether there was chronic retention before the acute attack. Ninety-six cases (12.4%) had bladder distension with overflow, and 262 cases (34%) had chronic retention and difficult micturition. In the last group both clinical features were usually present; in some, one or the other predominated. These figures show a close relationship to the corresponding ones given by Mr. Lloyd Davies—53.6, 12.4, 34; 52, 13, and 35%.

Mr. Lloyd Davies points out that many patients fail to seek advice about apparently mild symptoms. He attributes this failure to ignorance of the great advances in the surgical treatment of prostatic obstruction. I believe that another factor is equally important. Many patients, and some of their doctors, believe that a consultation with a surgeon is equivalent to making arrangements to have an operation. They have known men who have had mild bladder symptoms for very many years and never suffered anything more than minor inconvenience. The significance of mild bladder symptoms in an old man can only be assessed by the intelligent interpretation of the history, rectal examination, intravenous urography with post-micturition film, and the bacteriological examination of the urine. We cannot expect to have patients referred for the investigation of mild urinary symptoms until patients and their doctors realize that an operation will be advised only when there is good reason to believe that the symptoms will increase in severity and become a danger to life.—I am, etc.,

Strangulated Hernia

SIR,—In answer to Mr. V. J. Downie's letter (*Journal*, April 10, p. 877), 28 infants in our series were treated by emergency operation and 17 were treated successfully by sedation and gentle taxis.

With regard to the second question: two infants only had an elective operation within a few months of the successful reduction of the incarcerated hernia by conservative means. Recurrent incarceration was found in one infant only, this a few hours after conservative treatment had been successful. In view of the fact that recurrence is unusual, elective herniotomy is not essential, but in practice the repair of an infantile hernia is such a safe operation in good hands that we feel that it should certainly be performed as soon as the patient's condition allows—usually a matter of a few days.—We are, etc.,

Single Incision for Bilateral Orchidectomy

SIR,—I was dismayed to learn from his letter (*Journal*, April 17, p. 934) that Sir Heneage Ogilvie advocates a scrotal approach to the testis, and I hope that young surgeons, particularly when dealing with such conditions as spermatocele, hydrocele, etc., will not be tempted to revert to this technique. Of course, one feels that Sir Heneage speaks with his tongue in his cheek, for how else could one account for the remark: "Nature pushed the testicles into the scrotum: why pull them out, trim or enucleate them, and then push them back again?" (the italics are my own).

Twenty-five years ago I learned from bitter experience that the position and the corrugated surface of the scrotum hampered efficient pre-operative cleansing and the maintenance of post-operative asepsis. In a large series of cases I recorded far fewer complications and a shorter period of hospitalization after inguinal than after scrotal incisions. As regards the risk of haematoma, it must be remembered that in the inguinal approach oozing is only likely to occur from the coverings of the testis. When the scrotum is incised, however, there is the added fear—in spite of drainage—that blood may infiltrate quite extensively between its layers. I would never agree that oozing following the scrotal approach was "harmless." Personally, I limit direct exposure to cases in which there is either a fluctuating abscess or a sinus connecting the organ with the skin surface.

Finally, if a good cosmetic result were the only matter of importance, how could one improve upon a neatly sutured inguinal incision situated entirely within the pubic hair field?—I am, etc.,

Swansea.

C. J. CELLAN-JONES.

The False Positive Jelly Test

SIR,—I have now collected 33 children out of a group of 550 who have a positive tuberculosis jelly test. All of them have a negative Mantoux reaction and show no radiological evidence of tuberculosis in the lungs. All of them exhibit clinical signs and symptoms of a catarrhal state of the upper respiratory tract and are prone to develop febrile catarrh. This condition is thought to be due to a hitherto undetected virus.¹ These same children are most frequent victims of acute inflammatory disease in tonsils, adenoids, and middle ear clefts.

In the opinion of the writer, the correlation of a positive tuberculosis jelly test with a stereotyped clinical syndrome and a predictable natural history are not fortuitous. This acceptance of the "false positive" is obstructing a new avenue of investigation. Perhaps others have noted and searched for the significance of these positive jelly tests in the absence of classical tuberculosis and would be able to enlighten the writer?—I am, etc.,

Cortisone and Carcinogenesis

SIR,—In relation to your leading article on "The Pituitary and Carcinogenesis" (*Journal*, February 6, p. 321), may I report the following case?

Twelve years ago a woman, then aged 45 years, was operated on for carcinoma of the breast and a radical mastectomy was performed. About the same time she began to suffer from recurrent attacks of bronchial asthma and from the onset was under my continuous observation at the allergy clinic of the Hadassa Municipal Hospital, Tel Aviv. She was one of the severest cases in my practice and visited the clinic frequently. Eighteen months ago she began taking cortisone tablets (generously supplied by her relatives in the U.S.A.), and became so used to them that hardly a few days passed without her taking tablets (cortisonism). In all she had about 15 g. of cortisone. In May, 1953, radiological examination showed no evidence of pulmonary pathology. In September, 1953, an ulcer appeared in the operation scar, which on biopsy proved to be metastatic

carcinoma. Radiological examination at that time showed pleural effusion with disseminated infiltration of both lung bases. The patient died in March, 1954, but unfortunately a necropsy could not be performed.

I wish to report this case for the sake of record only, and do not draw any conclusions. Have similar cases been observed?—I am, etc.,

Tel Aviv, Israel.

Distension Pressure in Rebreathing Bags

SIR,—The physical characteristics of the anti-static rebreathing bags which are in current use on anaesthetic machines are of some concern to anaesthetists. That there is some danger in their resistance to distension we have for some time been aware, but to what extent this would influence the pressure in the system in the event of an expiratory valve sticking or being accidentally left screwed down has not been the subject of precise examination.

Similar tests were made with a red rubber rebreathing bag and an anti-static bag as follows. A rubber bung bear-

ing two glass tubes was wired into the neck of the bag. The tubes were brought out through another rubber bung in the neck of a large aspirating bottle. The aspirating bottle was inverted and filled with water and a bicycle pump and valve attached to one tube and a mercury manometer to the other. When the bag was inflated it floated upwards and had room to expand freely, displacing its volume of water through the tap (now uppermost) at the bottom of the aspirating bottle. The graph shows the results. The pressures recorded before the bags were full are mainly hydrostatic.

Dangerous pressures may therefore easily and rapidly develop in the system when anti-static bags are in use.—I am, etc.,

J. G. ROBSON.

Change of Sex

SIR,—Everyone will agree with your correspondent, Dr. A. P. Cawadias (*Journal*, April 10, p. 876), regarding intersexuals and hermaphrodites, on which he is an acknowledged expert, but for him to class transvestists as a form of intersexuals surely shows a grave confusion of thought. No one so far has managed to discover an endocrine basis for homosexuality,¹ and how much less is such a basis to be found in the considerably less abnormal transvestist. He does not tell us to what writers he is referring when he says that "we find definite endocrine, genital, and other physical stigmata pointing to a definite intersexuality." Over the past twenty years I have seen as many transvestists as anybody in England, and a large number of these were seen in conjunction with Mr. L. R. Broster, but we have never noticed these "physical stigmata."

Transvestism is a psychical disease related, to some extent, to homosexuality—some homosexuals are transvestists, but not all transvestists are homosexual.² If this is the case—and to anyone who has had a chance of studying the psychosexual constitution of these people it obviously is so—then the abnormal minds should be treated in order to conform them with the normal body and not *vice versa*. For it must be accepted that it is impossible to change a person's sex. It is true that we can castrate a man, inject oestrogens and so on to enlarge the breasts, but this is not a transformation, it is a mutilation. Why is this mutilation contemplated? So that the patient can pose as a woman—which he is not—and wear female clothes.

There is nothing in the law of England which states that a man must not wear feminine clothes, but the police arrest anyone so doing for "insulting behaviour likely to lead to a breach of the peace." The right course, therefore, is to modify the conduct of the police so that they adopt a more tolerant attitude. This, surely, is more desirable than that men should be maimed and mutilated into travesties of the opposite sex, and to my mind it is derogatory that medical men should be asked to cut off or put on sexuality like a jobbing plumber lays on gas or water.—I am, etc.,

London, W.1.

"Edwardian" Adolescents

SIR,—The stimulating leading article on adolescence (*Journal*, March 27, p. 748) omits, I think, one factor of great importance. This is the driving need felt by a large proportion of adolescents, particularly male adolescents, for emotional adherence to a group with a ritual. It is this drive which has so often proved both the danger and the strength of insurgent political bodies. In Garibaldi's days it led British youth to Italy, and later it formed the core of the blackshirt movement in Great Britain. Surely it is an inadequate description of a dominant quality of adolescents to concentrate wholly upon training and give no place to the consideration of the need for emotional expression.

In primitive communities the need of adolescents for training, for ritual, and for identification with their future life as adults is recognized as an integral part of the life of the community, and in the national outlook of a civilized society this need is forgotten. A need, however, denied legitimate expression and honourable integration with society finds its own ways to satisfaction, and we are now seeing a very curious form of this satisfaction in the odd appearance of small groups of youth in the self-invented uniforms of a travesty of male Edwardian masculine attire. These groups, armed sometimes with razors, show the force of adolescent need for ritual by the invention of a queer, creeping, circular "dance" which seems to be part of their characteristic. In a big city it seems natural that all variants of behaviour should appear, but the fact that these "Edwardian" creepers are now appearing in small country towns some distance from the city should surely convince us that it is time to take this phenomenon soberly and to direct some attention to it.

Are these youths wage earners, and can they pay the cost of their equipment? An odd phenomenon is therefore before us: do the parents of the boys meet the expense of their "Edwardian" clothes, and, if so, what sort of parents are these? Can the general practitioner help us here? Have any of the readers of this *Journal* families under their care whose sons have been drawn into or who lead these groups? Could they tell us something of these families? Will not the sociologists help us in study of this emotional chicken-pox of the community? Cannot we do better for our lads than this?—I am, etc.,

London, W.11.

Depression Treated by E.C.T.

SIR,—I read with interest the letter of Dr. S. Karagulla (*Journal*, March 13, p. 646) and well remember the flutter in the doves of the protagonists of E.C.T. produced by her article in the *Journal of Mental Science* four years ago. In the evaluation of treatment of depressive states by E.C.T. it is necessary, as she says, to have an adequate control group, and her series from 1930 to the time of introduction of E.C.T. provides that control group.

In 1941 I described the recovery, etc., rate in a series of 212 consecutive cases at the Latchmore Hospital, Ham Common, for mentally affected officers in the 1914-18 war, all of whom I saw from beginning to end of their hospital career, excepting a few remaining after October, 1919.² The rates were: recovered 60.4%, relieved 17.5%, not improved 19.8%, died 2.3%. These 212 were of course of different types, including schizophrenics and paralytics, who lowered the recovery rate. The material was usually good, most cases were young, many were exhaustion cases, and a good recovery rate was to be expected. Although occurring so long ago, they may be considered, like Dr. Karagulla's earlier cases, as a control group. In the annual report of the Board of Control for 1952 the number of direct admissions is given as 66,773, of whom 16,552 were discharged as recovered, about 25%; and 29,052 were, however, discharged as relieved, about 45%; combined rate of discharge 70%. In 1921, the recovery rate was 32.5%, and had been much the same for many years previously. In 1946 the relieved rate practically equalled that of the recovered, combined 62%, as compared with 48% just before the Mental Treatment Act of 1930.

I must say I was surprised at the low recovery rate of 1952, and can only presume there must have been a greater proportion of senile admissions. The high relieved rate, I believe, is due to the large number of voluntary admissions. I think it is generally conceded that many more comparatively mild cases are now sent to mental hospitals, although these milder cases do not necessarily have a better prognosis as regards recovery.

My impression is that the value of E.C.T. has been overrated, with the possible exceptions of involution cases, and I agree with Dr. Karagulla that a critical review of physical methods of treatment is necessary. Indeed, Mr. Harvey Jackson, in an article on leucotomy, suggests that electro-convulsive therapy has been responsible for much atrophic change, possibly arising out of repeated diffuse petechial haemorrhages.³—I am, etc.,

Hastings.

Dangers of Induced Hypotension

SIR,—It is a relief to read Dr. Harry F. Griffiths's letter (*Journal*, March 20, p. 706) giving support of the technique of induced hypotension. During the past three years I have personally employed this method using hexamethonium bromide in 250 patients, for the operations of radical mastectomy, block dissection of glands of neck, major plastic repairs, prostatectomy, vaginal hysterectomy, and colporrhaphy. No serious complications have arisen, and I have met with no catastrophes, nor delayed ill effects which might be attributed to the anaesthesia. I have been much impressed by the excellent operating conditions, by the reduction in operating time, and by the satisfactory post-operative condition of the patients.

Is it not possible that the deaths reported with induced hypotension might have been largely due to unsatisfactory anaesthetic technique associated with the induced hypotension, rather than the hypotension itself? The following case illustrates how readily induced hypotension might have been incorrectly blamed for a post-operative hemiplegia.

In December last the patient, a woman aged 63, with a B.P. of 220/120, had a wide excision of malignant melanoma of cheek, and a graft. The anaesthetic was given by a registrar and induced hypotension was not used. On the third day this patient developed a sudden hemiplegia. She came to the theatre again last week, having partially recovered from the hemiplegia, for a block dissection of malignant glands of neck. The B.P. was 215/120 and I hesitated as to the advisability of using induced hypotension, but decided in favour, and employed my usual technique. The total dose of hexamethonium bromide used was 20 mg. Conditions were satisfactory, the systolic pressure remaining between 80 and 60 throughout the operation lasting 1½ hours. The patient was returned to the ward with a systolic B.P. of 60, and the foot of the bed slightly raised. One hour later the B.P. was 95 and it gradually returned to the previous level over three days. It is now ten days since operation and there has been an uneventful recovery.—I am, etc.,

Manchester, 3.

FLORENCE FAULKNER.

Medical Needs in the Gold Coast

SIR,—The Council of the Gold Coast Branch of the British Medical Association has read with interest the recent correspondence on the medical needs in the Gold Coast. It is suggested that members of the Association wishing to come to the Gold Coast should communicate with the secretary of the local Branch, as conditions in the Gold Coast are changing daily. I would do my best to supply any information about local conditions that may be required.—I am, etc.,

P.O. Box 297, Accra.

M. J. COLBOURNE,
Secretary, Gold Coast Branch.

Clergy and Doctors

SIR,—No one who has been in general practice can fail to realize that there are many problems that affect both doctors and clergy. Have we not all had patients whose complaints start from worry over some moral problem—perhaps one which they would rather disclose to us than to a clergyman? And do not the clergy constantly hear details of illness? There is surely overwhelming need for co-operation between us.

I would, however, suggest to the Rev. Tony Clemens (*Journal*, April 24, p. 983) that whilst co-operation must take place in the hurly-burly of parish and practice, it should not begin there. There are many difficulties to be faced—not merely those of preserving confidence—and I would suggest that the best way to begin would be by quiet thought and discussion in a small group of clergy and doctors, where difficulties could be foreseen and personal idiosyncrasies ironed out.—I am, etc.,

East Hothly.

F. GRAY.

London Medical Orchestra

SIR,—Congratulations to those who are responsible for the formation of the new London Medical Orchestra. Their inaugural concert on Saturday, April 3, showed a wonderful degree of precision, confidence, and musicianship under an evidently first-rate conductor. Not even a hint of the untidiness so noticeable in the writing of prescriptions. Without derogating the strings, I was particularly impressed with the quality of the wind playing, as it is on the whole harder to come by amateur wind players than strings. It is invigorating to meet with busy practitioners able and willing to devote leisure to so admirable a pastime—a real recreation for themselves and for us, their appreciative colleagues. I hope they enjoyed it as much as I did. I am glad to hear that they mean to aid medical charities. These will get more of my money than before. Good luck to these blenders of cures and keys.—I am, etc.,

London, W.12.

R. PATRICK ROSS.

Obituary

COLIN D. LINDSAY, M.D.

We record with regret the death on April 19 at his home at Plymouth at the age of 82 of Dr. Colin D. Lindsay, a Past President of the British Medical Association.

Colin Dunrod Lindsey (he changed his name to Lindsay in 1926) was born on May 22, 1872, his father being Assistant Commissary General to the Indian Army. From Plymouth College he went on to study medicine at St. Mary's Hospital, qualifying M.R.C.S., L.R.C.P. in 1894. He took the London M.B. in 1898, and proceeded to the M.D. six years later. After

qualification he held the appointment of junior demonstrator in anatomy at St. Mary's Hospital Medical School, and later became house-surgeon at Horton Infirmary (now Horton General Hospital) at Banbury in Oxfordshire. He then returned to Plymouth and settled in general practice. Always keenly interested in diseases of the lungs, he was appointed assistant physician to the then South Devon and East Cornwall Hospital in 1913, becoming senior physician

in 1926, and succeeding the late Dr. A. B. Saltau as principal senior physician in 1930. When he retired in 1937 the title of emeritus physician was conferred upon him. He was also for many years consulting physician to the Royal Eye Infirmary, Plymouth, and to Tavistock Hospital. Dr. Lindsay always strongly supported the proposal that the three voluntary hospitals in Plymouth—the South Devon and East Cornwall, the Royal Albert Hospital in Devonport, and the Central Hospital—should be amalgamated, but it was not until 1934 that the complicated negotiations were completed and the Royal assent given to the amalgamation.

During his long life Dr. Lindsay took a leading part in medical affairs in Plymouth, and was chairman of the Plymouth Division of the B.M.A. from 1929 to 1931 and president of the South-western Branch in 1933-4. He was also a past president of the Plymouth Medical Society. When the Annual Meeting of the British Medical Association was held at Plymouth in 1938 the nomination by the local executive committee of Dr. Lindsay as a suitable candidate for the Presidency of the Association was received with unanimous approval. His address was on the always topical subject of the relationship between the profession and the public, and his remarks are as apposite now as they were sixteen years ago, for they crystallized the opinions of a man of great practical wisdom and common sense who had been in practice for forty years both as a general family doctor and as a consultant physician. Under his guidance and by his example the Plymouth Meeting was a particularly happy and successful one.

Dr. Lindsay married the youngest daughter of Colonel Henry C. Creak, of the Bengal Cavalry: she survives him, together with one son, Mr. Donald Lindsay, who became headmaster of Malvern College last year, and one daughter.

Dr. STEPHEN M. DAVIDSON writes: Rarely can it be said that a man had no enemies, but with Colin Lindsay one can go further and say that everyone who came in contact with him admired and respected him. To his patients he was not only their trusted physician, he was their friend. To his colleagues his advice was sound and marked by considered restraint, and also by his ability to respect the viewpoint of the younger generation. Colin Lindsay was a man with great moral courage, high principles, and a strict ethical code, and these virtues were warmed and made lovable by his grand sense of humour, which endeared him to young and old alike. He was one of the last consultants who engaged in general practice—a factor which enhanced his value to the general practitioner and the patient, and enabled both to benefit from his humanity and far-sightedness. His forte lay in diseases of the chest, and for many years he was the leading figure in the work and organization of the old tuberculosis dispensary in Plymouth and was the first in the district to collapse a lung. Those who were fortunate enough to work with him have lost a colleague whose like will never be seen again; whose honesty was forthright; whose courtesy was old-fashioned and charming; and whose wisdom was profound and liberally leavened with humour.

H. T. EVANS, D.M., M.R.C.P.

Many former students of the Welsh National School of Medicine will have learnt with deep regret of the death of Dr. H. T. Evans, consulting physician to the Cardiff Royal Infirmary, on April 7 at the age of 80.

Herbert Thomas Evans was born on December 4, 1873, near Corwen, Merionethshire, the youngest of the three sons of the Reverend David Evans, who later became vicar of Dolanog, Montgomeryshire. He received his early education at Bancroft's School, London, and at Christ College, Brecon, and then entered Jesus College, Oxford, with an exhibition in mathematics. His first profession was that of schoolmaster, and he held posts at Christ College, Finchley, and then at Talmont, in Scotland. He then decided to become a doctor and studied medicine at St. George's Hospital Medical School, obtaining the B.M., B.Ch. degrees of Oxford as well as the M.B., B.S. degrees of London University in 1912. His first medical appointment was that of house-surgeon at the Radcliffe Infirmary, Oxford, and shortly afterwards, in 1914, he was appointed assistant physician to the King Edward VII Memorial Hospital, now known as the Cardiff Royal Infirmary. In the same year he obtained the M.R.C.P., and in 1915 proceeded to the D.M. In the first world war he served in the R.A.M.C.; first in France and later at Milton Hill Hospital. His services were recognized by the award of the King Albert Medal by the King of the Belgians.

Dr. Evans, despite his small stature, was a keen athlete: he created a record for hurdling at his school which remained unbroken for several years. From an early age he derived great pleasure from exercising his skill as a fisherman, and he also spent much time walking and cycling, pastimes which gave him ample opportunity to indulge in his fondness for nature studies. He often visited the Continent, and for many years went to Switzerland regularly for winter sports.

During his early years as an assistant physician to the Cardiff Royal Infirmary Dr. Evans also held an appointment as demonstrator in the department of anatomy, where his patience, tact, and kindness to students in their early years, and his sympathetic approach to their problems, endeared him to all. As a physician he devoted himself with skill and understanding to the care and interest of his patients, and he rarely missed an attendance at hospital in the days when such services were rendered voluntarily. Although of a shy and retiring disposition, he was always ready to help those who sought guidance or advice. His professional ability, integrity of character, and honesty of purpose gained for him the admiration and respect of his colleagues, students, and nurses. When the British Medical Association held its Annual Meeting at Cardiff in 1928 he served as a vice-president of the Section of Diseases of Children. He retired from the Cardiff Royal Infirmary in 1939, but he remained in private practice and was able to continue to walk long distances and to cycle until the onset of his fatal illness some six months before his death. Dr. Evans was married, and the sympathy of his colleagues is extended to his widow in her great loss.—L. H. H.

THOMAS CARNWATH, D.S.O., D.Sc., M.B., D.P.H.

Mr. S. T. IRWIN writes: I first met Tom Carnwath, whose obituary was printed in the *Journal* of April 17 (p. 937), when he entered the old Queen's College, Belfast, in October, 1896. He was then a conspicuously handsome young man, tall and straight, with jet-black wavy hair, a small moustache, and expressive features. From the first he took a prominent part in all student activities, especially the Students' Union, which was opened in January, 1897. He was a keen but not very successful athlete. His outstanding ability allowed him to spread his interests while still leaving him supreme in the examination-room. His personal charm made him popular in all student gatherings, then almost entirely male, but made him perhaps even more admired at evening mixed parties.

He was not an entrance scholar, but the following year, when he transferred from arts to medicine, he was awarded a first-year scholarship in literary subjects. By then he had established himself as one of the first men of his year, and scholarships followed year by year. He interrupted his medical course to read science, with chemistry as his main subject, in which he graduated with first-class honours. Automatically he therefore became senior scholar in chemistry in the session 1900-1, and the following year was elected to the Dunville studentship, the most valuable prize then in the gift of the College. Returning to medicine, he served as resident pupil in the old Royal Hospital in Frederick Street, and graduated with first-class honours in the Royal University in 1903.

After qualification he did not, I think, seek a hospital resident post, but became demonstrator of anatomy under Symington. At the same time he joined a brilliant coterie of young men who surrounded J. Lorrain Smith in the pathological laboratory. These were Tom (afterwards Sir Thomas) Houston, R. J. (afterwards Sir Robert) Johnstone, and John C. Rankin (still happily with us). This was at a time when bacteriology was in its infancy but was beginning to attract many of the ablest of the younger men. They worked far into the night, and I believe it was a great

occasion when John Rankin first demonstrated the *Spirochaeta pallida*. It was here that Carnwath made up his mind to devote himself to public health, and, by the influence of Lorrain Smith, obtained the 185th Exhibition, which took him to Hamburg and Berlin, where he worked in the years 1905-6.

After retirement in 1940 he came back to live in Northern Ireland and devoted his attention to his old school, which by this time had become Queen's University of Belfast. He received the coveted honorary degree of D.Sc., and represented Convocation on the Senate and on many of its committees, especially the Board of Curators, where he showed his wide knowledge and sound judgment in the making of appointments to the teaching staff. At first these were purely university posts, but later they extended to the joint appointments scheme of the university and the hospitals authority, a method of dealing with clinical teachers still peculiar to Northern Ireland.

Dr. W. V. TOTHILL died at his home at Capetown on March 25 at the age of 67. Though he had more than his fair share of illness and operations during the past two and a half years, he never complained and his courage was an example to all who knew him. Walter Vincent Tothill was born on April 15, 1886, and qualified L.M.S.S.A. from the London Hospital in 1913. After qualification he just had time to take a post as ship surgeon to Australia and act as a locum in a few practices before war broke out in 1914, and for the next four years he served with the R.A.M.C., first in West and then in East Africa. After the war he became the first British medical officer in Tanganyika, a position he was reluctantly forced to relinquish after an attack of blackwater fever. When he had completed the tropical diseases course in London and recovered his health, he returned to the Tropics, against medical advice, and spent fifteen happy and useful years in Trinidad, doing postgraduate work in Austria and Russia when on long leave. Again ill-health made a change of climate advisable, and to the sorrow of his patients—black and white, poor and rich—he left the West Indies and bought a practice in Western Australia. Before he could begin his new work he was involved in a car accident which resulted in a maimed left hand, among other injuries, and meant that it was useless to keep a practice where surgery brought in half the income. Eighteen months later he accepted the position of medical officer to the British Phosphates Commissioners on Nauru Island, in the Central Pacific, where he thoroughly enjoyed the work. But the entry of Japan into the last war enforced the evacuation of most of the Europeans and the Chinese labourers to Australia. On arrival in Australia he was asked to accompany the Chinese to Central Australia, and he worked there for two years under the greatest difficulties and in the utmost discomfort. When able to leave he went to New Zealand, where he put in eight years of useful medical and social work, until ill-health obliged him finally to retire from practice. His book, *Doctor's Office*, was written while convalescent after the car accident, and another, in an equally amusing vein, was written during his last illness and is being prepared for publication. He is survived by his widow, who, as Bridget Ristori, was formerly matron of the Colonial Hospital, San Fernando, Trinidad.

The death occurred at Aberdare on March 23 of Dr. M. LL. JONES in his 86th year. Martin Llewelyn Jones was born on August 28, 1868, the eldest son of the late D. W. Jones, J.P., of Aberdare, and was educated first at a private school and later at Perry's School, Cardiff. Receiving his medical training at St. Bartholomew's Hospital, he qualified M.R.C.S., L.R.C.P. in 1890 at the early age of 21. Three years later, after passing the Fellowship examination of the Royal

College of Surgeons of England, he found himself in the somewhat unusual position of having to wait until the prescribed age of 25 before being admitted a Fellow. Not many months before his death he received congratulations from the President and Council of the College on having completed 60 years as a Fellow. After qualification he held several resident appointments at St. Bartholomew's Hospital. He was always particularly proud of having been house-surgeon to Sir Tom Smith, who was Surgeon to Queen Victoria. Llewelyn Jones's qualities and qualifications might well have taken him to a high place in the wider world, but his home town and its surrounding hills and its people had a strong pull for him, and, returning to Aberdare to practise in 1894, he led a full and active life until his enforced retirement due to blindness in 1944. Taking the first steps in co-operation with the Powell Duffryn Company and the miners, he was one of the founder surgeons of the Aberdare General Hospital, a project which in the early years of the hospital and throughout his active life was very near to his heart. His experience was great, and, though recognizing keenly his responsibilities, he was a fearless and skilful operator: there are still many older patients who remember with gratitude his skill and kindness. He was medical officer to the Post Office for many years and a medical referee under the Workmen's Compensation Acts. He had a wide and expert knowledge of literature, for he was an avid reader with a remarkably retentive memory. Owing to a busy practice his recreations were of necessity curtailed, but he loved to fish and was an expert shot. He was confined to his house for the last four years of his life, but older townspeople still remember vividly his tall, straight figure, fine bearing, and grave but courteous manner, for he was a man of most distinguished appearance, the personification of what a doctor should look like in the eyes of the layman. He married Ethel, second daughter of Mr. and Mrs. Brunel White, of Carmarthen, in 1906, and she survives him together with two sons, the elder an ophthalmic surgeon at Salisbury, the other a solicitor and town clerk of Durham.

Dr. H. P. JAMESON died very suddenly from coronary thrombosis at his home at St. Albans on March 31. He was 50 years of age. Harold Parnell Jameson was born at Edgbaston, Birmingham, on February 29, 1904, and was educated privately and at Birmingham University, where he had an outstanding career as a medical student. He graduated M.B., Ch.B., with first-class honours, in 1925 at the age of 21, and proceeded to the M.D. three years later. In 1930 he took the M.R.C.P. After graduation he held appointments at the General Hospital and at the Children's Hospital, Birmingham, and later at the London Hospital. He then held a resident post at The Hospital for Sick Children, Great Ormond Street, for about two years. In 1929 he settled in practice at St. Albans, attracted there chiefly because there were children's beds at St. Albans City Hospital (then known as Osterhills), of which he had full clinical charge for ten years. As a medical officer in the Territorial Army attached to the Honourable Artillery Company, Dr. Jameson was mobilized a few days before the outbreak of war in 1939. He had a distinguished Army career as a medical specialist and served in India, Iran, and Ceylon. He attained the rank of lieutenant-colonel and was officer in charge of a medical division of Indian and British hospitals and consultant to a wide area. After the war he returned to his practice at St. Albans for a period before taking up the appointment of consultant on the medical staff of the St. Albans City and Hitchin group of hospitals. Although his early interest in the welfare of children never waned, his new work brought him more into contact with elderly people, and the state in which he found many of them greatly depressed him and he devoted much time to their care. He was a foundation member of the Medical Society for the Care of the Elderly, of which he was secretary for the past year. He also took an active interest in the voluntary nursing service of the British Red Cross Society as lecturer and examiner, and was medical

officer to a Hertfordshire detachment. For five years he was deputy coroner for the St. Albans and Barnet areas. He was chairman of the Mid Herts Division of the British Medical Association from 1948 to 1952. His contributions to the medical literature included articles published in the *Archives of Disease in Childhood* and other journals. An enthusiastic sportsman, Dr. Jameson was a keen and expert horseman, and he supported the Aldenham Harriers and the Hertfordshire Hunts for over 20 years. He was medical officer to point-to-point races at Friars Wash, having himself raced before the war. Rock-climbing and mountaineering, too, held a fascination for him, and only a few days before his death he had been rock-climbing with one of his sons. He was also a keen tennis player. In 1932 he married Joan Isabel Colthurst, and she survives him, together with the daughter and two sons of the marriage.

A. P. R. writes: Dr. Jameson's sudden and untimely death was a considerable shock and distress to his many friends in Hertfordshire, a county which he both loved and served well. Equally it has been a very considerable distress to his colleagues. He was essentially a quiet man, loving deeply his family and his gentle and peaceable pursuits. It is indeed a grief to his friends that a man who so tenderly cared for the plight of the old and sick should so early be taken from us. The problem of the old is one of the major issues we have to face in general practice to-day. Many of us are aware of it now: Jameson saw it earlier. In particular, I would remember, in common with many, his true kindness to younger colleagues, and the good will and unfailing hospitality he and Mrs. Jameson showed them. Even in this material age I am quite confident that there are many people, young and not so young, who will remember him with real affection.

By the death of Dr. H. G. CARLISLE on April 7, at the age of 76, Merseyside has lost a much-respected medical practitioner. Only two weeks before his death he was elected a life member of the Liverpool Medical Institution. Henry George Carlisle was born at Liverpool on November 12, 1877, but spent his early life in Edinburgh, where in due course he entered the university as a medical student. He graduated M.B., Ch.B. in 1899 and proceeded to the M.D., with honours, five years later. After graduation he held the appointment of assistant demonstrator in anatomy and physiology in Edinburgh University and later became house-surgeon at Chester General Infirmary. When he returned to Liverpool at the turn of the century it was with the intention of specializing in orthopaedic surgery, but the death of his father left him with the responsibility of supporting his brothers and sisters, so he entered an old-established general practice at Heswall. He still maintained a strong interest in orthopaedic work, however, and assisted the late Sir Robert Jones at his Liverpool clinic and in founding the Heswall branch of the Royal Liverpool Children's Hospital. During the first world war Dr. Carlisle served as a captain in the R.A.M.C. In 1916 he and the late Professor H. D. Dakin, F.R.S., who died two years ago, presented a report to the Medical Research Committee (now the Medical Research Council) on the use of sodium hypochlorite prepared by the electrolysis of sea-water for disinfectant and antiseptic purposes on shipboard, especially in hospital ships. During the last war Dr. Carlisle carried on the general practice alone while his five partners were away in the Services. A member of the British Medical Association for over forty years, he was chairman of the Birkenhead and Wirral Division in 1943-4. He is survived by a widow, one son, who is also a doctor, and three daughters.

K. W. M. writes: Dr. H. G. Carlisle, who died on April 7 after a few hours' acute illness, was in practice in the Wirral for some fifty years in association with partners in Neston and Parkgate. So eminently was he a doctor at heart throughout all these years that it is impossible to imagine him in any other profession. To say that he easily won the

confidence of his patients is to say only half the truth; he was their friend, and there can have been few of them who did not give him their affection in return. Outside his general practice he was on the staff of the Heswall Hospital for Children from the time it was founded by Sir Robert Jones, whose close friend he became. For about forty years he was the local medical officer of this hospital, visiting regularly and on call day and night; it is not therefore surprising that his knowledge of the orthopaedic treatment of children in all its detail was notable. After the first world war he had charge of many crippled pensioners, and from this experience he contributed an article on war fractures to the *Manual of Orthopaedics* edited by Sir Robert Jones. He was an expert fisherman and some of the salmon he landed were the season's records, but the chief recreation which helped him to live a life which always had the air of enthusiasm was his garden. His wife and he designed and made a famous rock garden, and there persuaded many rare plants to grow which were the envy and despair of other gardeners. In his work, and above all in his home, he spent a life that seemed to his friends always as happy as it was full.

The sudden death of Dr. CHARLES BEWICK on April 10 at the age of 48 came as a great shock to his many friends, colleagues, and patients. He had been in general practice in Durham since the end of the war, and had only recently built himself a house and moved to an expanding suburb at Framwellgate Moor. Born on December 21, 1905, William Charles Dickerr Bewick was educated at the University of Durham. Originally a science graduate—he took the B.Sc. with honours in physiology—he spent two years in America and then returned home to take his medical degrees at Newcastle-upon-Tyne in 1931. Before the war he was in practice for eight years at Welshpool, in Montgomeryshire. Like that of many others, his career was seriously interrupted by war service. He joined the R.A.F. in 1941 and spent three years in the Middle East. Of a shy, retiring nature, he did not seek the limelight, but he lived up to the best traditions of a family doctor. His one absorbing interest was medicine, and it always puzzled his friends how he found time in the midst of a very busy life for all the reading that he did. His early training in physiology and biology equipped him to grasp the complexities of modern scientific medicine.

J. R. McD. writes: The death of Dr. Charles Bewick has brought to a close in the prime of life a career that was an ornament to our profession. A student all his days, he was most conscientious and patient in his work, keeping careful records and following up those avenues where his interests lay. His chief recreations were mountaineering and painting. He had some of his works accepted at local exhibitions. As a man he exuded vigour and energy. Often he would spend a day climbing hills in the Lake District; the journey of over a hundred miles there and back seemed nothing to him. One cannot write of Charles without mentioning Helen, his wife and perfect helpmeet: for her and their children, one son and two daughters, the deepest sympathy is felt in their tragic loss.

Dr. H. E. THORN writes: The death of Dr. H. LINCOLN HATCH, whose obituary was printed in the *Journal* of February 13 (p. 400), is a great loss to general practice. I first met him when I came to Harrow thirty-five years ago. He was well established in Pinner and showed good fellowship to a newcomer. I found at once that he was one of the most active members of the local Division of the British Medical Association and well liked by all his colleagues. He maintained the old-established family adviser attitude as a practitioner and was duly appreciated by all his patients. He also did a good deal of refraction work. His views on current problems discussed at B.M.A. meetings were always well expressed and, although extremely moderate, tenaciously held. He was a man who lived for his patients, and his memory should be an example to the younger generation in medicine.

Medico-Legal

FOSTER CHILDREN

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

It was recently contended in an action before Mr. Justice Lloyd-Jacob in the Chancery Division that children at a boarding school for backward children were "foster children" within the meaning of s. 206 of the Public Health Act, 1936.¹ That section provides that a person who undertakes for reward the nursing and maintenance of a child under the age of 9 apart from his parents or having no parents should give notice of the fact to the welfare authority, and such children are called foster children.

The judge held that children away at boarding school were not properly to be regarded as "apart from their parents." The words involved an intention by the parents to part with the child, together with an intention to deny the child parental guidance and control or inability to provide it.

Most fee-paying pupils at boarding school had homes and parents, and went home for the holidays and could be visited at the school or removed from it by their parents. No distinction could be drawn between pupils whose fees were paid by their parents and pupils whose fees were paid by the local authority: in paying the fees the local authority did so as *alter ego* of the parents, and parental guidance and control could be regarded as susceptible of delegation to the local authority. None of these children could therefore be properly regarded as being "apart from their parents," and they were therefore not foster children within the meaning of the Act of 1936.

DEATH AFTER ANTICOAGULANT THERAPY

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

In May, 1953, Dr. J. L. Macaulay, a ship surgeon aged 66, had a cerebral thrombosis while on a voyage to the United States; it resulted in complete hemiplegia and affected his speech. He was flown home and ultimately went to live with his son in Kensington. He received no special treatment until he was seen in December, 1953, by Dr. T. C. Porter, who decided on anticoagulant treatment as a prophylactic measure.

Dr. Porter advised Dr. Macaulay to go to hospital, but he refused to do so. "Marcoumar," which Dr. Porter had found successful in a previous case, was the drug used, there being no contraindications. Treatment was started on December 18 with a dose of one tablet per day by mouth, and was not controlled by regular prothrombin estimations, which could be done only in hospital. It was carried on until January 22, 1954, when Dr. Porter was told that on the previous day Dr. Macaulay had had bleeding per rectum, and he treated him. The next day, after acute haemorrhage and vomiting, Dr. Macaulay was admitted to St. Stephen's Hospital, Chelsea. On admission he was unconscious, pulseless, exsanguinated, and suffering from shock. He died a quarter of an hour later after a massive haematemesis.

At the inquest before Dr. H. Neville Stafford at the Hammersmith Coroner's Court Dr. Margaret Briggs, medical adviser to Roche Products Ltd., gave evidence that marcoumar, although well known on the Continent, had been used in the United Kingdom only since November, 1953, and not very widely. It was especially useful in controlling thrombosis, and there was no agreement among doctors whether regular prothrombin estimations were necessary in controlling dosage.

The verdict was recorded that death was due to haemorrhage into the small intestine following anticoagulant therapy.

¹The Times, April 14.

Vital Statistics

Births and Deaths in First Quarter

Provisional figures for England and Wales show that this year for the first time since 1947 the number of births registered in the March quarter is greater than the number registered in the corresponding quarter of the previous year. Live births registered numbered 173,784, representing a rate of 16.0 per 1,000 population. Comparable figures for the first quarters of 1953 and 1952 were 171,705 (rate 15.8) and 173,338 (rate 15.9).

There were 153,116 deaths registered, representing a rate of 14.1 per 1,000 population, compared with a rate of 15.8 in the first quarter of 1953 (when influenza was widely prevalent) and 13.5 in the first quarter of 1952. Deaths of children under 1 year of age numbered 5,239, giving a record low rate for a March quarter of 31.0 per 1,000 related live births, compared with a rate of 33.8 in the corresponding quarter of 1953. In the first quarter of 1938 the corresponding figure rate was 69.3. There were 4,220 stillbirths, giving a rate of 23.7 per 1,000 total live and stillbirths, compared with a rate of 22.5 in the corresponding quarter of 1953. The rate for the first quarter of 1938 was 38.3.—*Registrar-General's Weekly Return No. 15.*

Week Ending April 17

The notifications of infectious diseases in England and Wales during the week included pneumonia 451, scarlet fever 994, whooping-cough 1,980, diphtheria 14, measles 1,912, dysentery 919, acute poliomyelitis 17, paratyphoid fever 5, and typhoid fever 1.

Infectious Diseases

The incidence of infectious diseases in England and Wales during the week ending April 10 declined. The largest falls in the number of notifications were 100 for scarlet fever, from 1,474 to 1,374, 88 for dysentery, from 1,642 to 1,554, 84 for whooping-cough, from 2,546 to 2,462, and 37 for measles, from 2,330 to 2,293.

Only small fluctuations were reported in the local incidence of scarlet fever. The largest variation in the returns for whooping-cough was an increase of 57 in Yorkshire West Riding, from 202 to 259. The largest falls in the local incidence of measles were 87 in Norfolk, from 433 to 346, and 86 in Cumberland, from 149 to 63, and the largest rises were 126 in Staffordshire, from 208 to 334, and 70 in Lancashire, from 429 to 499. 12 cases of diphtheria were notified, being 10 fewer than in the preceding week. The chief feature of the returns of diphtheria was a fall in Lancashire from 6 to 3.

Only 10 cases of acute poliomyelitis were notified. This was the smallest total for five years. The notifications were 7 fewer for paralytic and 4 fewer for non-paralytic cases than in the preceding week. Two cases were notified in the counties of Cheshire, Lancashire, and Yorkshire West Riding.

The largest centres of dysentery were Yorkshire West Riding 236 (Sheffield C.B. 42, Bradford C.B. 36, Brighouse M.B. 27, Keighley M.B. 21, Leeds C.B. 19, Hebden Royd U.D. 18, Wortley R.D. 11), London 230 (Islington 67, Chelsea 43, Lewisham 28, Shoreditch 20, Hackney 11, the other 61 cases were scattered through 18 boroughs), Lancashire 199 (Salford C.B. 22, Urmston U.D. 13), Bolton C.B. 18, Southport C.B. 15, Eccles M.B. 15, Manchester C.B. 14, Liverpool C.B. 13, Leyland U.D. 13), Leicestershire 121 (Leicester C.B. 118), Surrey 85 (Epsom and Ewell M.B. 30, Reigate M.B. 20, Bagshot R.D. 11, Croydon C.B. 10), Middlesex 85 (Edmonton M.B. 32, Hornsey M.B. 13, Willesden M.B. 10), Devonshire 53 (Exeter C.B. 45), Warwickshire 52 (Birmingham C.B. 44), Cheshire 48 (Ellesmere Port U.D. 42), Essex 46 (West Ham C.B. 15), Kent 37 (Chatham M.B.

14), Oxfordshire 35 (Oxford C.B. 35), Norfolk 35 (Norwich C.B. 34), Berkshire 33 (Maidenhead M.B. 27), Nottinghamshire 30 (Nottingham C.B. 24), Staffordshire 28 (Cannock U.D. 19), Lincolnshire 22 (Lincoln C.B. 9), Bedfordshire 20 (Luton M.B. 19), Gloucestershire 20 (Bristol C.B. 11), and Northumberland 20 (Hexham U.D. 15).

In Scotland the number of notifications of dysentery declined from 438 to 399. The largest returns were 211 in Glasgow, 100 in Lanark county, 22 in Edinburgh, and 15 in Dundee.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1945-53 are shown thus ———, the figures for 1954 thus ———. Except for the curves showing notifications in 1954, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending April 10 (No. 14) and corresponding week 1953.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Medical News

Rockefeller Grants.—During the first quarter of this year the Rockefeller Foundation disbursed nearly one and a half million dollars in grants. As usual, much of this money went to support medical projects. By a grant of \$125,000 to the Medical Research Council, the continuance of the Rockefeller travelling fellowships in medicine is assured until 1959. Biophysics is generously supported by a grant of £\$24,000 to London University for the purchase of an additional electron microscope for Professor J. T. Randall, F.R.S., and his colleagues at King's College, London, while Professor T. Caspersson at the Karolinska Institutet, Stockholm, receives \$30,000 for his studies of the effects of radiation on the cell. Perhaps of outstanding interest among the other medical projects receiving support are the study of the working of the Health Insurance Plan of Greater New York, and the central register of the Institute of Human Genetics at Geneva. Founded in 1950 with the help of a Rockefeller grant, the Institute has developed a central register for recording hereditary diseases by the medical profession in Switzerland, and it is hoped that the register will contribute to a better definition of the role of heredity in disease. A grant of \$12,000 has been given to University College, Dublin, to support Professor E. J. Conway's researches on the behaviour of tissue electrolytes. Recipients of individual grants, mostly for travel in America, include Professor H. J. Eysenck (Institute of Psychiatry, London), Miss Margaret B. Swann (Department of Psychological Medicine, Glasgow), Dr. J. R. Ellis (London Hospital Medical College), Professor F. W. Rogers Brambell (University College of North Wales), Dr. F. P. Glees (Department of Physiology, Oxford), and Dr. James Walker (Department of Obstetrics, Aberdeen).

European League for Mental Hygiene.—Under the presidency of Dr. Doris Odium, the European League for Mental Hygiene held a conference in Rome last month. The hosts were the Italian League for Mental Hygiene, and the meetings were held at the Institute of Research associated with the University Medical School. In her presidential address Dr. Odium defined the field of mental hygiene as twofold. On the one hand the treatment of those with mental disorder or arrested mental development and the education of the public about mental health; on the other the prevention of mental ill-health by attention to problems of human relations and development. The British delegation to the conference included Dr. Isobel Wilson, Dr. J. R. Rees, and Dr. E. Stengel.

Danish Medical Bulletin.—In its official organ, *Ugeskrift for Læger*, the Danish Medical Association has for many years published short English summaries of its original articles. Now it has gone a step further by the publication of *The Danish Medical Bulletin*, entirely in English, which is issued as a monthly supplement to the weekly *Ugeskrift*. The *Bulletin*, whose first number accompanies the April 8 *Ugeskrift*, is sponsored not only by the Danish Medical Association but also by the Danish Government through the Universities of Copenhagen and Aarhus and the National Health Service. Subscribers to *Ugeskrift* will receive the *Bulletin* free. Hitherto the *Index Medicus Danicus*, a bibliography of Danish medical papers, has been published by the University Library of Copenhagen. It will now be incorporated in the *Bulletin*, two of whose monthly issues will be devoted entirely to the *Index* so that it can be bound separately. The other issues of the *Bulletin* are expected to contain about 350 pages every year. In addition to original articles there will be short communications, annotations, and notices.

Mitchiner and Lady Cade Medals.—The first awards of of these medals for outstanding services to military and aviation medicine respectively were made by the Council of the Royal College of Surgeons on April 8. Brevet Colonel H. D. Chalke received the Mitchiner Medal for his outstanding

service over many years in improving the health of the Army, and Squadron Leader R. R. L. Pryer the Lady Cade Medal for meritorious service, and in particular for demonstrating that intra-arterial transfusion is readily practicable under Service conditions. These medals will be awarded annually.

Standards for Hospital Equipment.—The British Standards Institution has issued a Sectional List of British Standards for Hospital Equipment (P.D. 1821, March, 1954). It includes details of standards of medical and surgical apparatus, laboratory glassware and scientific apparatus, furniture and fittings, textiles and clothing, photographic and radiological material, testing materials, and electrical equipment. Copies may be obtained from the B.S.I., 2, Park Lane, London, W.1.

May "Family Doctor."—A 1s. 6d. pamphlet on "Slimming the Safe Way" (by Dr. Alan Porter) is given away with this month's *Family Doctor*. In the medical section, Sir Heneage Ogilvie writes about chest surgery and what it can achieve. Dr. T. Traherne explains the electroencephalogram, and Dr. Grey Walter contributes a note about children's "brain waves." Dr. T. Anderson gives plain advice on how long the infectious diseases stay infectious. The Birmingham City Analyst, Mr. H. H. Bagnall, is made the subject of an informative "profile." Professor Alvarez continues to tell us how to live with our blood pressure. No doctor can afford to skip the "Expert Advice" columns, where questions on such subjects as "drugs and mother's milk" and "inherited allergy" are answered.

Change of Address.—The Metropolitan Ear, Nose, and Throat Hospital has now moved to St. Mary Abbots Hospital. Its new address is: Metropolitan Ear, Nose, and Throat Hospital, at St. Mary Abbots Hospital, Marlborough Road, Kensington, London, W.8. (Telephone: WESTern 8201.)

Sir John McNee, lately Regius Professor of the Practice of Medicine at Glasgow, and **Professor J. H. Dible**, Professor of Pathology at the Postgraduate Medical School of London, are to receive the honorary degree of LL.D. at a ceremony at Glasgow University on June 16. Both graduated in medicine at Glasgow.

Dr. V. F. Hall, Dean of King's College Hospital Medical School since 1951, has been appointed a Fellow of King's College.

Dr. Dennis Geffen, M.O.H. of St. Pancras and Hampstead, is going to Greece, Cyprus, and Turkey to lecture on poliomyelitis and public health. His tour is sponsored by the British Council and the Cyprus Government.

COMING EVENTS

The Midland Tuberculosis Society and the North-western Tuberculosis Society will hold a joint meeting at the Cheshire Joint Sanatorium, Market Drayton, on May 8. The subjects to be discussed are "What is the Place, if any, of Mass Radiography?" and "An Analysis of the Place of Artificial Pneumothorax in the Treatment of Pulmonary Tuberculosis." Further particulars may be obtained from Dr. G. R. W. N. Luntz, Romsley Hill Sanatorium, Halesowen, near Birmingham.

Ciba Foundation Lecture.—The sixth annual lecture will be given by Sir Macfarlane Burnet, F.R.S., on May 11 at 5 p.m. in the lecture hall, Royal Society of Tropical Medicine and Hygiene, 26, Portland Place, London, W.1. His subject is "The Problem of Virulence in Virus Disease." Admission is by ticket only, obtainable free from the assistant secretary, Ciba Foundation, 41, Portland Place, London, W.1.

Dr. Evarts A. Graham will deliver the second Sir John Fraser Memorial Lecture on May 11 at 5 p.m. in the Surgery Lecture Theatre, University New Buildings, Teviot Row, Edinburgh. His subject will be "Cancer of the Lung, with Special Emphasis on the Aetiology."

French Cancer Film.—A French documentary film on cancer will be shown by the Institut Français du Royaume Uni and the Scientific Office of the French Embassy on May 12 at 8 p.m. at the Institut Français, 15, Queensberry Place, London, S.W.7. The film was prepared for the general public as part of the French anti-cancer campaign. Admission is by invitation, to be obtained in advance from the Scientific Office, French Embassy, 22, Wilton Crescent, London, S.W.1 (Telephone: SL. Oane 0797, Ext. 5).

Dr. Alfred Blalock, of the Johns Hopkins Hospital, Baltimore, will deliver the Moynihan Lecture in the Riley Smith Hall of the University Union of Leeds on May 14 at 3.30 p.m. His subject will be "The Expanding Scope of Cardiovascular Surgery."

Fourth Varrier-Jones Memorial Lecture.—Professor Harold G. Trimble, of Stanford University, California, will deliver a lecture on "Current Therapy in Pulmonary Tuberculosis" at Manson House, 26, Portland Place, London, W.1, on May 14 at 5 p.m.

Provincial Medical Exhibition.—A medical exhibition on similar lines to that held in London will be held at Victoria Rooms, Bristol University, from May 17 to 21. Further information may be obtained from the organizers, London Medical Exhibition, 194-200, Bishopsgate, London, E.C.2.

Professor H. F. Humphreys will deliver the Webb-Johnson Lecture at the Royal College of Surgeons of England on May 21 at 5 p.m. His subject will be "The Value of the Teeth as Evidence—Scientific, Clinical, and Forensic."

NEW ISSUES

British Journal of Ophthalmology.—The next issue (Vol. 38, No. 5) is now available. The contents include:

EFFECTS OF AREA AND INTENSITY ON SIZE AND SHAPE OF THE ELECTRO-RETINOGRAM. EXCLUSION OF STRAY LIGHT EFFECTS. A. Wirth and B. Zeppenfeld.
SLIT-LAMP STUDIES ON THE FLOW OF AQUEOUS HUMOUR. T. H. Hodgson and R. K. MacDonald.
OCULAR DISEASE DUE TO BRUCELLA. K. Dean Forgy.
EQUATORIAL CATARACT AFTER CORNEO-SCLERAL TREPHINING. H. E. Hobbs and Redmond Smith.
PRIMARY TUMOURS OF THE OPTIC NERVE IN VON RECKLINGHAUSEN'S DISEASE. W. A. Manschot.
EVALUATION OF THE WATER-DRINKING TEST. Wolfgang Leydhecker.
DEGENERATIONS OF THE DOG RETINA. IV. RETINOPATHIES ASSOCIATED WITH DOG DISTEMPER-COMPLEX VIRUS INFECTIONS. H. B. Parry.
INTRANASAL RHINO-DACRYO-CYSTOSTOMY FOR PERSISTENT EPIPHORA IN CHILDHOOD. H. S. Sharp.
CHOROIDAL CARCINOMA METASTATIC FROM THE MAMMARY GLAND. C. H. Greer.
LAMBLER KERATOPLASTY FOLLOWED BY CATARACT EXTRACTION IN MALIGNANT PAPILLOMA OF THE LIMBUS. P. Sivabramaniam and T. Hoole.

Issued monthly; annual subscription £4 4s.; single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Archives of Disease in Childhood.—The April issue (Vol. 29, No. 144) is now available. The contents include:

THE ANAEMIA OF PREMATURITY. B. L. Coles and Ursula James.
CONGENITAL ECTROPION OF THE UPPER LIDS. Robert J. Young.
CONGENITAL STRIDOR CAUSED BY AN ABERRANT PULMONARY ARTERY. T. M. Welsh and I. B. Munro.
THE RESPONSE OF INFANTS TO A LARGE DOSE OF WATER. R. A. McCance, N. J. B. Naylor, and E. M. Widdowson.
THE SERUM PROTEIN LEVELS OF NEWBORN AFRICAN INFANTS. M. W. Stanier and M. D. Thompson.
SOME DIFFERENTIAL CHARACTERISTICS OF CEREBRAL MOTOR DEFECTS IN INFANCY. Eileen Collis.
DIFFERENTIAL DIAGNOSIS OF FACIAL AND DENTAL MANIFESTATIONS IN CONGENITAL SYPHILIS. G. O. Horne.
HONEYCOMB LUNG AND XANTHOMATOSIS. A. M. MacDonald and Robert A. Shanks.
FEMALE PSEUDOPHYLLIDITIS WITH ADRENOCORTICAL FAILURE IN IDENTICAL TWINS. Sulamith Wolff.
EPILOIA AND ENDOCARDIAL FIBRO-ELASTOSIS. L. Crome.
BACTERIAL ENDOCARDITIS COMPLICATING SEPTICÆMIA IN AN INFANT. Ian C. Lewis.
THE AGE OF CHILDREN WHEN GROWTH IN STATURE CEASES. E. M. B. Clements.
TWO CASES OF PRIMARY TUBERCULOSIS AFTER IMMERSION IN SEWAGE CONTAMINATED WATER. F. J. W. Miller and J. P. Anderson.
TWELVE CASES OF LYMPHOBLASTOMA IN CHILDREN. George M. Maxwell.
SCROTAL GANGRENE IN A NEWBORN BABY. Nicholas Alders.
NEONATAL THROMBOCYTOPENIC PURPURA IN TWO INFANTS. M. L. Neville and L. M. Masterman.

Published six times a year; annual subscription £3 3s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Friday, April 30

CAMBRIDGE MEDICAL SOCIETY.—At Addenbrooke's Hospital, 3 p.m., Dr. L. B. Cole: Hexamethonium in the Treatment of Hypertension.

Monday, May 3

INSTITUTE OF CARDIOLOGY.—9.30 a.m., Dr. K. W. Donald: Exercise in Heart Disease.
INSTITUTE OF CHILD HEALTH.—5 p.m., Professor G. Frontali (Rome): Proteins in Child Nutrition.
INSTITUTE OF NEUROLOGY.—5 p.m., Professor Klaus Conrad (Homburg-Saar): New Problems of Aphasia.
INSTITUTE OF PSYCHIATRY.—5.30 p.m., lecture-demonstration by Dr. E. Stengel.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. E. S. Clarke: Cervical Spondylosis with Cord Compression.

Tuesday, May 4

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. E. J. Moynihan: Urticaria.
INSTITUTE OF NEUROLOGY.—5 p.m., Dr. I. Wickham (Gothenburg): Choice of Encephalography or Ventriculography for the Examination of Intracranial Tumours (with special reference to Posterior Fossa and Basal Tumours).
ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Croonian Lecture by Dr. J. F. Smith: Nutrition and Child Health.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Arnott Demonstration by Professor M. F. Lucas Keene: Development of the Pharynx.
ROYAL MICROSCOPICAL SOCIETY.—11 a.m. to 1 p.m.: 2.30 to 4.30 p.m.: 6 to 7.30 p.m., symposium on the Golgi Apparatus.
WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY.—5 p.m., Almroth Wright Lecture by Sir Wilfred Fish: Dental Research in the Inoculation Department.

Wednesday, May 5

EDINBURGH UNIVERSITY: FACULTY OF MEDICINE.—At Surgery Lecture Theatre, University New Buildings, 5 p.m., Macarthur Postgraduate Lecture by Professor H. K. Beecher (Massachusetts): Resuscitation and Other Early Care of the Severely Wounded Man.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Lichen Planus and Lichenoid Eruptions.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. M. Bodian: Hirschsprung's Disease and Chronic Constipation in Childhood.

Thursday, May 6

EDINBURGH UNIVERSITY.—At Anatomy Lecture Theatre, University New Buildings, 5 p.m., Cameron Prize Lecture by Professor Gerhard Domagk (Münster): Development of Chemotherapy in Tuberculosis.
INSTITUTE OF CARDIOLOGY.—9.30 a.m., Dr. Maurice Sokolow (California): Some Aspects of Quinidine Therapy.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Arnott Demonstration by Professor G. W. Causey: Sterno-mastoid Muscle; 5.30 p.m., Otolaryngology Lecture by Professor G. A. G. Mitchell: Sympathetic Nervous System in Relation to the Throat, Nose, and Ear.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., neurology demonstration by Dr. D. J. Williams.
ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.—4.30 p.m., clinical meeting.
●SOCIETY OF CHEMICAL INDUSTRY: MICROBIOLOGY GROUP.—At Microbiological Research Department, Experimental Station, Porton, near Salisbury, Wilts, 11 a.m., papers by Mr. R. Ellsworth and Mr. L. R. P. Meakin, Dr. D. Herbert, and Mr. E. O. Powell.

Friday, May 7

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. M. S. Thomson: Lichen Planus.
LEBANON HOSPITAL FOR MENTAL AND NERVOUS DISORDERS.—At Cora Hotel, Upper Woburn Place, London, W.C., 5 p.m., 55th annual meeting.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Mr. E. T. C. Milligan: Surgery of the Anal Canal and Fistula-in-Ano. 4 p.m., Dr. H. G. Miller: Allergic Disorders of the Nervous System.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Mr. R. A. Brews: Obstetric/Gynaecological Conference.
WHIPPS CROSS HOSPITAL MEDICAL SOCIETY.—8.30 p.m., clinical meeting.

Saturday, May 8

MIDLAND TUBERCULOSIS SOCIETY.—At Cheshire Joint Sanatorium, joint meeting with North-Western Tuberculosis Society.
SOUTH-EAST METROPOLITAN TUBERCULOSIS SOCIETY.—At Preston Hall, near Maidstone, 10.30 for 11 a.m., extraordinary general meeting. Dr. A. Stocker (Illinois, U.S.A.): Preferences in Surgery for Tuberculosis.
WEST MIDLANDS PHYSICIANS ASSOCIATION.—At Royal Salop Infirmary, Shrewsbury, 11 a.m., spring meeting.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Davies.—On April 7, 1954, at the R.N. Hospital, Trincomalee, Ceylon, to Elizabeth (formerly Rose), wife of Surgeon Lieutenant John M. Davies, R.N., a son.
Jacobs.—On April 6, 1954, at the Nottingham Hospital for Women, to Jean, wife of Dr. Brendan Jacobs, a daughter—Stella Jean.
Morgan.—On April 2, 1954, at St. Michael's Hospital, Lethbridge, Alberta, Canada, to Helen (formerly James), S.R.N., S.C.M., M.T.D., wife of John E. Morgan, M.B., B.S., M.R.C.O.G., a sister for Joanna and David—Susan Gail Margaret.

MARRIAGES

Zeitline.—Roberts.—On April 2, 1954, at the Paddington Register Office, London, W., L. L. B. Zeitline, M.R.C.S., L.R.C.P., of 16, Norfolk Place, London, W., to Miss Jane Roberts, of 30A, Sussex Place, Hyde Park, London, W.

DEATHS

Badcock.—On April 6, 1954, at Flodden Lodge, Cornhill-on-Tweed, Northumberland, Vincent Edgar Badcock, M.C., M.D.
Burgess.—On April 22, 1954, at 454, Perth Road, Dundee, William Leslie Burgess, C.B.E., M.D., F.R.C.P.Ed., D.P.H., D.T.M.&H., aged 68.
Carlisle.—On April 7, 1954, Henry George Carlisle, M.D., of Ardair, Hexwall, Cheshire.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

The Use of the Toothbrush

Q.—Is the regular use of the toothbrush really worthwhile? Does it not damage the gums as much as it saves the teeth? The best teeth I have seen have been in those who have never used a toothbrush.

A.—The use of the toothbrush is an essential habit for everyone who wishes to have healthy teeth and gums. Brushing the crowns of the teeth removes debris and keeps the surfaces polished, thereby minimizing the risk of decay. Places, such as the interdental spaces, where the bristles cannot reach are always the danger spots for the start of decay. There is good statistical evidence that toothbrushing immediately after meals reduces the incidence of caries.¹

But just as important is the good, not harm, derived from brushing the gum margin, provided it is done with a soft brush and a rotary motion so that the bristles pass from the gum to the tooth surface. Most individuals eating civilized diets need to use a toothbrush regularly to prevent gum diseases, which are caused by stagnation of food debris and tartar around the teeth. The correct use of a soft toothbrush is an essential part of the treatment of all gum diseases, though damage to the gums and teeth can be produced by the incorrect use of a hard toothbrush.

Sensitivity Tests before Radiological Investigations

Q.—Is there any real advantage in performing sensitivity tests before intravenous pyelography, bronchography, or cholecystography? If so, what tests are advised?

A.—It is very doubtful if sensitivity tests for intravenous pyelography, whether intravenous, subcutaneous, oral, or ocular, are of sufficient reliability to warrant their routine use, and they are probably best reserved for cases with a positive indication for their performance. To select these cases, a routine history should be taken from every patient before injection, directed to determine whether there is a history of any allergic phenomena (such as asthma or urticaria); whether there is any known sensitivity to iodine; and whether there has been a previous pyelogram, and if so whether there was any reaction. With this information a decision as to the necessary precautions can be taken, and a suggested scheme is as follows.

If the past history is clear, no special precautions are indicated.

If there is an allergic history, it is known there is an increased incidence of sensitivity reactions (Mullen and Hughes¹) and the injection should be given very slowly, with a pause of about two minutes after the first 1 ml. Restoratives, such as oxygen, adrenaline, and promethazine hydrochloride (for intramuscular use), should be immediately available. There is a certain amount of evidence (Inman²) that, in the presence of a history of allergy, iodoxyl is preferable to diodone.

If there is a history of sensitivity to iodine, or of a mild reaction to previous pyelography, it is as well to postpone the examination until sensitivity tests have been performed. As little as 1 ml. of diodone given intravenously as a test dose has proved fatal (Dotter and Steinberg³), so it is advisable to start with 1 ml. of 1/100 solution and proceed at ten-minute intervals to 1 ml. of 1/10 solution, 1 ml. of full-strength solution, and 5 ml. of full-strength solution. If there is no reaction then the full dose can be given.

If there has been a severe reaction to a previous pyelogram, desensitization to the medium should be performed. A suitable course of desensitization is to start with oral doses at three-hourly intervals, beginning with 0.25 ml. and increasing by about 50% each time, and then to proceed to intravenous desensitization (two-hourly injection, starting with 0.5 ml. of full strength and again increasing by approximately 50% with each dose).

In bronchography, consideration must be given to the local analgesic and to the contrast agent. Whichever local analgesic is used, a short-acting barbiturate should first be administered to combat the potential toxic effects on the cerebral cortex. The best local analgesic for bronchography is lignocaine; a sensitivity test is probably not necessary when using this drug. With amethocaine a sensitivity test is, perhaps, advisable (0.1 ml. of 2% amethocaine subcutaneously), although in many centres it is dispensed with. There is no indication for using cocaine in bronchography; if it is used, however, a sensitivity test should certainly be performed (0.2 ml. of 5% cocaine subcutaneously).

Before oral cholecystography sensitivity tests are not indicated.

T.A.B.T. Vaccine in Children

Q.—A child of 3 was given a first dose of 0.1 ml. of T.A.B.T. vaccine before going abroad. Two and a half hours later he had a reaction consisting in slight cyanosis, rapid respirations and pulse, and a temperature of 101.8° F. (38.8° C.). In view of this, do you advise a second dose of 0.2 ml. in one month's time, or what alternative do you recommend?

A.—T.A.B.T. (typhoid-paratyphoid vaccine and tetanus toxoid) was introduced for the immunization of adults and is unsuitable in its present form for young children. The dose injected into this child—that is, 0.1 ml.—contained a reasonable first dose of T.A.B. vaccine, but only one-fifth to one-tenth of the required dose of tetanus toxoid. It would be well to give these prophylactics separately to complete immunization.

Probably the T.A.B. constituent of the combined preparation caused the trouble reported, and not the tetanus toxoid, which is an exceptionally innocuous prophylactic at all ages. The dosage of T.A.B. vaccine for children is arbitrary, but in general young children tolerate injections of vaccines better than adults, and are therefore given larger doses in relation to body weight. Possibly this patient has an allergic personal or family history, or has been sensitized in some way to bacterial protein. Another and more probable explanation is that leakage occurred from the inoculation site into a vein, and caused symptoms which are unlikely to be repeated. It is suggested that further immunization might be attempted with two doses each of 0.1 ml. (or 0.2 ml.) of T.A.B. vaccine, spaced by four weeks. As a safeguard in this child, the injections might be administered in the evening, adrenaline and antihistaminic drugs being kept in readiness to control any allergic symptoms that develop. Care should also be taken to ensure that the route of administration is subcutaneous rather than intramuscular.

Protein and Resistance to Tuberculosis

Q.—What is the evidence that a diet rich in protein raises resistance to tuberculosis?

A.—There is experimental evidence that animals fed on diets adequate in protein and subsequently infected with tuberculosis survive longer, and with fewer lesions, than controls on diets poor in protein. In clinical and statistical studies it is often difficult to dissociate nutrition from other social factors, but there is much evidence which suggests

its importance. For instance, a world food survey showed an inverse relationship between animal food intake and tuberculosis mortality in European countries. There was a sharp rise in mortality from tuberculosis among French prisoners of war when Red Cross food parcels ceased. In the first world war the rise and fall of tuberculosis mortality in Denmark was closely associated with the supply of meat in the towns. A similar association with intake of first-class protein has been suggested in England and Wales in the second world war. This and much other evidence is reviewed in the chapter entitled "Food and Tuberculosis" in *Causes and Prevention of Tuberculosis*, Brice R. Clarke: E. and S. Livingstone, Edinburgh, 1952; in *Tuberculosis, a Global Study in Social Pathology* (pp. 359-373), John B. McDougall: E. and S. Livingstone, Edinburgh, 1949; and in *The Pathogenesis of Tuberculosis* (pp. 318-325), Arnold R. Rich: Blackwell, 2nd ed., Oxford, 1951.

Spermatorrhoea and Sexual Neurosis

Q.—What investigations and treatment are advised for a case of spermatorrhoea? At first there was an occasional loss of a drop or two of semen after urination, but now it happens regularly. The patient is worried about his symptoms.

A.—The drop squeezed out at the end of micturition is more likely to be prostatic than testicular secretion, although it will doubtless contain a certain number of spermatozoa. The genital tract should first be examined and the existence of any such lesion as a prostatitis excluded. The key to the case almost certainly lies in the words: "The patient is worried about his symptoms." He is probably a man with no sexual outlet who has not yet come to terms with his sexuality and who is in process of developing a sexual neurosis. In other words, he is more likely to be in need of psychological than of physical help. The physical symptom complained of is often associated with a sexual neurosis.

Arsenic and Bromide Rashes

Q.—As students we were taught that a small dose of arsenic prevented bromide rashes. Is this true? Could very small doses of arsenic, such as a few minims of liquor arsenicalis, taken over a long period have any harmful effect?

A.—The belief at one time widely held that small doses of liquor arsenicalis in a bromide mixture prevented bromide rashes rests upon no scientific basis nor on any controlled clinical trials. In the days when bromide was commonly taken over a prolonged period of time for the control, say, of epilepsy, the liquor arsenicalis usually given with it quite often caused hyperkeratosis and bronzing of the skin.

"Any Questions?" Book.—The second book of selected "Any Questions?" is available, price 7s. 6d. (postage 6d.). Copies may be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

AN APPRECIATION OF MITRAL STENOSIS*

PART I. CLINICAL FEATURES

BY

PAUL WOOD, O.B.E., M.D., F.R.C.P.

Physician-in-Charge, Cardiac Department, Brompton Hospital; Physician to the National Heart Hospital; Director of Studies, Institute of Cardiology

During the past three years mitral valve disease has been studied intensively at the Institute of Cardiology and at the Cardiac Department of the Brompton Hospital. It is the purpose of this paper to present a comprehensive review of the facts ascertained during this period. The work represents an elaboration of one of the papers opening the discussion on mitral stenosis at the European Congress of Cardiology held in London on September 9 to 12, 1952, and summarized in the Abstracts of Scientific Communications.

Material

The material comprises 150 cases submitted for operation, and another 150 which were considered unsuitable for surgical treatment. Amongst the surgical cases were four put up for repair of mitral incompetence; amongst the medical cases were 50 believed to have predominant mitral incompetence and another 32 in which mitral incompetence was thought to be as important as stenosis, if not more important. A further 50 patients have been studied, but are not included in the main series because they are awaiting either catheterization or valvotomy.

The material is analysed more fully in Table XXIII in the Summary, at the end of Part II. All cases were examined and assessed personally by the author, who was responsible for their medical care, including that before and after operation.

Method

These 300 cases were analysed in respect of 50 medical points, including those pertaining to radiography, fluoroscopy, and electrocardiography. Auscultation was often checked but rarely influenced by phonocardiography; and fluoroscopy was sometimes checked but never influenced by electrokymography. Where applicable, all cases were also analysed in respect of eight points relating to cardiac catheterization, 14 to valvotomy itself, and 20 to the subsequent course. Thus the great majority of those treated surgically were subjected to a 90-point analysis. All symptoms, measurements, and graphic patterns were graded from 0 (absent) to 4, the four positive grades representing the common English adjectives of degree—slight, moderate, considerable, and

*Delivered before the San Francisco Heart Association on October 29, 1953, and modified for the Strickland Goodall lecture of the Society of Apothecaries of London, March 24, 1954.

gross. If thought desirable, the moderate grade was divided into grades 2A and 2B, A being less severe than B.

Cardiac catheterization was carried out in 125 of the surgical cases, 42 of the medical, 17 of those with pure mitral incompetence, and in 23 awaiting valvotomy—that is, in a total of 207 cases. Pressures were recorded with reference to the sternal angle by means of a Sanborn electromanometer and polyviso, the oxygen consumption was measured by means of a Sanborn metabolator, and blood gas analysis using a Haldane type instrument. The left atrial pressure was obtained by wedging the catheter in a peripheral pulmonary artery as described by Lagerlöf and Werkö (1949). The tracing was accepted as an accurate record of the left atrial pressure if it was venous in form. This assumption has been proved valid in our laboratory at Brompton by Epps and Adler (1953). The data for calculating cardiac output and pulmonary resistance were obtained in quick succession, but not simultaneously. In one-third of the cases the left atrial and pulmonary artery pressures were also measured during and after standard exercise. The pulmonary vascular resistance was expressed in simple units obtained from dividing the mean pulmonary artery pressure minus the mean left atrial pressure (mm. Hg) by the pulmonary blood flow (l./min.), as explained in the section on resistance.

Nearly two-thirds of the surgical cases were operated on by Mr. R. C. Brock, who performed the first mitral valvotomy at Brompton on March 29, 1950. In the remainder, valvotomy was undertaken by Sir Clement Price-Thomas (5), Mr. Norman Barrett (14), Mr. Oswald Tubbs (3), Mr. W. P. Cleland (14), and Mr. Ian Hill (5) at the Brompton Hospital; by Professor R. Pilcher (13) at University College Hospital; and by Mr. Holmes Sellors (2) at the Middlesex Hospital.

The surgeons' observations with regard to the presence or absence of clot, mitral incompetence (before and after valvotomy), mitral calcification, mobility of the cusps, valve structure, and size of the mitral orifice before and after valvotomy were accepted without question. Direct pressures from the left atrium and pulmonary artery were recorded before and after valvotomy in about two-thirds of the cases. A biopsy from the left atrial appendage was obtained routinely, and from the lung in many cases. The post-operative physical signs and the general assessment of the situation and

operative achievement were recorded as a routine before the surgeon's report was read. Follow-up notes were then made at intervals of three, six, or twelve months.

Incidence

In his Harveian oration of 1945, Sir John Parkinson produced statistical evidence indicating that in 1942 there were approximately 144,000 men between the ages of 18 and 44 with established heart disease in Great Britain, and that 80% of these—that is, 115,200—were rheumatic. Since the incidence of rheumatic heart disease is higher in women than in men, and since there are rather more women than men in the country, the total incidence of rheumatic heart disease in both sexes between the ages of 18 and 44 must be not fewer than 240,000. At least two-thirds of these, or 160,000, are predominantly mitral.

It is clear from the material comprising this paper that about one-half of all mitral cases—that is, 80,000 in the age group stated above—require valvotomy. At a conservative estimate, therefore, there should be approximately 3,000 valvotomies carried out in Great Britain per annum in order to cope with the situation.

Incidence of Individual Valve Involvement

It has never been quite clear what determines the relative frequency with which each particular valve is involved in rheumatism. According to Cabot (1926) the mitral valve is involved in 85%, the aortic in 44%, the tricuspid in 10 to 16%, and the pulmonary in 1 to 2%. These figures would not be seriously disputed at the present time. Various attempts have been made to correlate them with the frequency with which each valve was vascularized—for example, Gross and Kugel (1931). But Wearn *et al.* (1936), using indian ink instead of a barium gel, were unable to demonstrate any such correlation; they found blood vessels in 66% of the mitral valves studied, in 64% of the tricuspid valves, in 28% of the pulmonary, and in only 16% of the aortic. It has long seemed obvious to me that there might be a much simpler explanation for the phenomenon under discussion—that it depended on the degree of stress to which each valve was subjected. In a child of 10 the systemic blood pressure is about 100/60, the pulmonary about 15/6. Thus the load against which the mitral, aortic, tricuspid, and pulmonary valves have to work is in the proportion of 100, 60, 15, and 6 mm. Hg respectively. If the mitral valve was involved in 80% of cases the expected frequency of aortic, tricuspid, and pulmonary valve involvement would be 48, 12, and 5% respectively. This approximates very closely to Cabot's figures.

Age and Sex

The average age of patients in various groups and sub-groups is presented in Table I. It was usually around 37.6 years, the average for the whole series. Surgical cases with simple mitral stenosis tended to be younger than their medical counterparts, although usually more severe; and patients with auricular fibrillation were usually considerably older than those with normal rhythm; but neither

TABLE I.—Age Incidence

	Groups			Total	M.S. Uncomplicated		M.S. M.I.		Extreme Resistance		Rhythm

All cases	1	2

that mitral incompetence has for men. The extraordinarily high proportion of women in the group with a high pulmonary vascular resistance (active pulmonary hypertension in the table) may be due partly to the same sex factor that operates in primary pulmonary hypertension and partly to the fact that it is stenosis rather than incompetence which favours the development of a high resistance (see below).

History of Rheumatic Fever, Chorea, or Growing Pains

A previous history of the active rheumatic state was obtained in 68% of the whole series. In relatively pure mitral stenosis, with or without a high pulmonary vascular resistance, a history of previous rheumatism was obtained in 60%; when there was a serious degree of mitral incompetence with or without clinical stenosis, the incidence rose to 71.7%, and when more than one valve was causing trouble it was as high as 96%. Thus pure mitral stenosis would seem to be the least florid form of rheumatic heart disease.

Of those giving a previous history of the rheumatic state 45.7% had had a single attack of rheumatic fever, 31.5% recurrent attacks, 12.5% chorea alone, 4.8% both chorea and rheumatism, and 5.5% had had only subacute rheumatism or growing pains. Cases with significant mitral incompetence or multiple valve lesions were ten times more likely to have had recurrent rheumatic fever than isolated chorea; in relatively mild cases of pure mitral stenosis, on the other hand, a previous history of chorea alone was twice as common as recurrent rheumatic fever. This supports the conclusion drawn from the previous paragraph.

Life History

The chief landmarks in the life histories of all patients with symptoms are presented in Table III. The cases were divided into two groups according to whether mitral sten-

TABLE III.—Life History

	Latent period			Duration of Symptoms					From Onset Symptoms to Total Incapacity (Years)
	Age at Onset (Years)	Latent Period (Years)	Age at Onset (Years)	Grade 1 (Years)	Grade 2 (Years)	Grade 3 (Years)	Grade 4 (Years)		
Mitral stenosis	12	19	31	2.7 (0-17)	2.7 (0-18)	1.94 (0.5-11)	2 (0.5-4)	7.3	
Mitral incompetence	12.5	20	32.5	2 (0-9)	1.1 (0-5)	2.25 (0-7)	>1 (0.3-3)	5.4	

osis or incompetence was predominant. The figures for each grade were computed only from those cases which had completed their period in the grade under consideration by deteriorating sufficiently to enter the next grade. Thus the duration of grade IV symptoms could be assessed only from those who died from medical causes.

The rapid deterioration shown in the table suggests that there can be little point in delaying mitral valvotomy long in anatomically suitable cases once unmistakable symptoms of stenosis have developed; to do so is to invite complications such as embolism and to deprive patients of good physical health at a time of life when they have the right to expect it. Against operating too soon, however, are the surgical mortality of 6%, the 24% incidence of poor or indifferent results, and the possibility that stenosis may recur.

Pregnancy

In the whole series there were 83 mothers who between them had had 140 pregnancies. Cardiac symptoms had developed or increased during pregnancy in 43, but not in the other 97. On account of these symptoms two cases had been terminated at three months, one had had a hysterotomy at five months, one had been medically delivered at eight months, and two had had caesarean section; the remainder had been delivered naturally at term.

Of the 43 patients who deteriorated during pregnancy, 19 subsequently regained their previous state of health and 24 did not. Thus 24 out of 140 pregnancies, or 17%, precipitated permanent disability. In those cases in which pregnancy caused no trouble, cardiac symptoms did not develop for an average period of 10.4 years afterwards (range 1 to 28).

Cardiac symptoms developing during pregnancy were always due to pulmonary venous congestion and consisted of cough, breathlessness, orthopnoea, paroxysmal cardiac dyspnoea, or pulmonary oedema; sudden haemoptysis (pulmonary apoplexy) occurred in 12 out of the 43 cases (28%). Auricular fibrillation, systemic embolism, and congestive failure were rare complications. There was no evidence that those patients who developed symptoms during pregnancy were more or less likely to present later with a high pulmonary vascular resistance (34%) than those who did not (28%).

SPECIAL SYMPTOMS

Dyspnoea and Grading

Effort intolerance commonly due to dyspnoea was graded according to its severity as mentioned in the introduction under "Method." Patients in grade 1 were able to lead normal lives, but could not keep up with their fellows physically, although they might not be deterred from attempting to do so. They became unduly breathless on hurrying, running, walking up hills, or playing games. Patients in grade 2 were unable to run or hurry and found walking up hills difficult; they could walk indefinitely on the level, and were not orthopnoeic. To clarify the situation further this grade was usually divided into 2a and 2b. In grade 3 patients could walk only a few hundred yards on the level, and shopping and housework were carried out only with difficulty. Walking up hill was almost impossible and stairs had to be negotiated slowly. Patients who were more or less totally incapacitated were placed in grade 4; they could hardly manage 100 yards on the level and had abandoned their shopping and housework; many of them were virtually confined to bed. The majority of patients with orthopnoea, paroxysmal cardiac dyspnoea, or pulmonary oedema were in grade 3 or 4; out of respect for custom, cases with indisputable congestive heart failure were arbitrarily placed in grade 4.

Of the 150 patients selected for surgical treatment 19% were in grade 2 (all but two in grade 2b), 41% in grade 3, and 39% in grade 4. One patient with no effort intolerance was operated on because of recurring systemic embolism.

There were many patients in the medical and mitral incompetent groups who were only slightly breathless on effort or not at all, and it may be observed here that when such patients were catheterized the left atrial pressure was usually well below 10 mm. Hg with reference to the sternal angle. In striking contrast is the fact that of all the patients treated surgically there was only one with a left

atrial pressure in this range, and that was the individual with recurrent embolism just mentioned. The belief that breathlessness in mitral valve disease is closely associated with pulmonary venous congestion is thus strongly supported.

Orthopnoea and Paroxysmal Cardiac Dyspnoea

Orthopnoea occurred in 69% of the surgical patients, in 30% of the medical, and in 44% of those with mitral incompetence—that is, in 53% of the whole series. The respective figures for paroxysmal cardiac dyspnoea were 49%, 16%, 32%, and 35%. It should be remembered that there were a number of relatively mild cases in the two medical groups.

In attempting to find out what particular factors governed the incidence of the major pulmonary venous congestive symptoms, patients with paroxysmal cardiac dyspnoea were compared with those who had neither paroxysmal cardiac dyspnoea nor orthopnoea, only cases with well-marked disability (grade 2b to grade 4) being selected for study, so that the two groups were matched in this respect. There were over 50 cases in each group.

The most important results of the analysis are shown in Table IV. It will be seen that the degree of stenosis was certainly not responsible for the difference in func-

TABLE IV

	Normal Rhythm (%)	L.A.P. mm. Hg	C.O. l./min.	Unusually Tight or Extreme Stenosis (%)	Resistance Units				
					1-3.9 %	4-5.9 %	6-9.9 %	10-30 %	Average
Pulmonary oedema (history of)	76	23	4.6	36	66.5	33.5	—	—	2.9
Paroxysmal cardiac dyspnoea (history of)	59	23	4.0	50	50	26	20	4	4.6
Cases without P.C.D. or orthopnoea	42	22	3.5	46	21	26	15	38	9.2
Whole surgical series	59	22.5	3.8	43	38.4	26	23	12.6	6.0

tional behaviour between the two groups. The left atrial pressure and the cardiac output at rest were both a little higher, and the rhythm was more often normal in those with paroxysmal dyspnoea, but these differences were not great. The pulmonary vascular resistance, on the other hand, showed a remarkable difference, the level in cases of paroxysmal dyspnoea being exactly half what it was in the others. If the figures are examined more closely it will be noticed that the important difference is confined to the extreme grade of resistance which was found nine times more frequently in those without paroxysmal dyspnoea or orthopnoea. Resistance lower than 10 units did not protect the lungs adequately.

It may be tempting to assume that in their natural life history all cases of tight mitral stenosis sooner or later develop orthopnoea and paroxysmal cardiac dyspnoea, and that they then either die from pulmonary oedema or are protected by developing a high pulmonary vascular resistance; by obstructing the circulation proximal to the pulmonary capillaries this prevents dangerous rises of pulmonary venous pressure, so that patients are saved from drowning at the expense of a low cardiac output, and symptoms of pulmonary venous congestion are replaced by fatigue and oedema. This attractive hypothesis, however, is not properly supported by the facts. In the whole series such a life history was encountered in only six instances, or in 22% of all those with a resistance of 10 units or more. On the contrary, 78% of patients with a really high pulmonary vascular resistance had never had orthopnoea or paroxysmal cardiac dyspnoea at any stage. One is forced to conclude that if an extreme resistance is going to develop in mitral stenosis it does so relatively early in the course of the disease.

Frank Pulmonary Oedema

Manifest pulmonary oedema occurred in 11% of the surgical cases, in 2% of the medical, and in 6.5% of those with mitral incompetence, or in 7.5% of the whole series. Nearly 80% of such cases had more or less pure mitral stenosis, 15% combined stenosis and incompetence, and only 5% pure incompetence. Amongst the cases with stenosis 94% were women; in the small group with incompetence 75% were men.

The series is analysed in Table IV. The patients were distinctly younger (average age 32) than those who had never had pulmonary oedema (average age 37), and normal rhythm was more frequent. At rest, when free from attacks, the left atrial pressure averaged 23 mm. Hg, which was no higher than in the other cases; but in two or three instances, when an attack was threatened during cardiac catheterization, it was between 30 and 35 mm. Hg. The average cardiac output was relatively high (4.6 litres/minute). The pulmonary vascular resistance was remarkably low, averaging only 2.9 units, and never exceeding 5.2 units. The mitral orifice at operation was a little less tight than in the surgical series as a whole, not more tight.

It is concluded that pulmonary oedema tends to occur in relatively young women with average stenosis, when the pulmonary vascular resistance is unusually low. Sudden surges of cardiac output are possible because the pulmonary blood flow is not damped by the pulmonary resistance, and this allows extremely high pressures to develop in the pulmonary venous system. Thus, although these cases are rightly given top surgical priority, they are not necessarily advanced cases of mitral stenosis—rather to the contrary.

Haemoptysis

There are five kinds of haemoptysis complicating mitral valve disease: (1) the sudden unexpected profuse haemorrhage (pulmonary apoplexy); (2) blood-stained sputum associated with attacks of dyspnoea due to acute pulmonary venous congestion; (3) blood-streaked sputum associated with attacks of winter bronchitis, presumably due to a combination of bronchial inflammation and pulmonary venous congestion; (4) pink frothy sputum accompanying acute pulmonary oedema; and (5) frank haemoptysis due to pulmonary infarction.

Pulmonary Apoplexy

This was never seen in truly mild cases of mitral valve disease. Its incidence is given in Table V. By "serious cases only" in that Table are meant all the surgical cases,

TABLE V.—Percentage Incidence of Haemoptysis

	Whole Series				Serious Cases Only			Resistance Units		
	Surg.	Med.	M.I.	Total	M.S.	M.S., M.I.	M.I.	1-5.9	6-9.9	10-30
Pulmonary apoplexy...	24	13	13	18.3	22	33	15	25	20	12.5
Congestive haemoptysis: All cases...	24	9	9	16.5	30	19	8.3	20	30	21
Recent cases								16	10	4
Pulmonary apoplexy, congestive haemoptysis, or both...	44	25	20	34						
Pulmonary infarction	6	11	2	8.5						

but only those of comparable severity in the two medical groups, so that the relative importance of stenosis and incompetence might be probed. This column does in fact reveal that persons with combined lesions are particularly prone to pulmonary apoplexy.

It has often been stated, though with little factual support, that haemoptysis (meaning pulmonary apoplexy)

occurs especially in cases of mitral stenosis complicated by pulmonary hypertension (e.g., Logan and Turner, 1953), presumably with the idea that it is akin to cerebral haemorrhage in essential hypertension. This statement is incorrect. Pulmonary apoplexy is rare when the pulmonary arterial resistance is really high, for the haemorrhage is venous and the high resistance tends to protect the pulmonary venous system from developing too high a pressure. This is shown in the third major column of the Table. Moreover, when haemorrhage was recorded in a case with extremely high resistance it had always occurred several years previously, at a time when the resistance may well have been lower. There was no single instance of pulmonary apoplexy occurring within a period of three years previous to the actual measurement of the high resistance. In the cases that have come to be regarded as being only partly protected (pulmonary resistance 6 to 9 units) pulmonary apoplexy had ceased in two-thirds.

Again, pulmonary apoplexy was a truly early symptom of mitral valve disease in 68% of the cases in which it occurred: it pre-dated the onset of grade I effort intolerance in 12.7%, initiated symptoms in 42.5%, and was an early symptom occurring within a year or so of the onset of effort breathlessness in 12.8%. It was a relatively late symptom in only one-third of the cases, occurring about half-way through the period of symptoms in 17% and being really late in 15%. The same truth was established in another way: the average duration of symptoms in all the cases with pulmonary apoplexy was 6.8 years; the average time of the onset of haemoptysis was one year after the onset of effort dyspnoea; and the average time at which haemorrhages ceased was three years before the patient was seen.

Pulmonary apoplexy was recurrent in 58% of the cases in which it occurred and was single in 42%; it was precipitated by pregnancy in 27%, and was sometimes provoked by physical effort.

This analysis suggests that sudden profuse haemoptysis in mitral stenosis is due to a venous haemorrhage occurring at a time when the pulmonary venous pressure has risen rather suddenly, and that such haemorrhages tend to cease when abrupt rises of pulmonary venous pressure are prevented by a high pulmonary vascular resistance, and also perhaps when the pulmonary veins and their anastomotic communications with the bronchial venous system have had time to hypertrophy in response to the raised pressure within them. It follows that pulmonary apoplexy is not a serious symptom, and this is borne out by the fact that it has never proved fatal in my experience. Indeed, this sort of haemorrhage may be regarded as a safety valve and is inevitably self-limiting, ceasing when the pulmonary venous pressure has fallen sufficiently. Whether the haemorrhage arises from rupture of a pulmonary vein or from rupture of a bronchial vein or broncho-pulmonary venous communication is beyond the scope of this paper (see Gilroy *et al.*, 1952).

Congestive Haemoptysis

This refers to blood-stained or blood-streaked sputum associated with attacks of severe dyspnoea. The haemoptysis is far less important than the dyspnoea. Its incidence is given in Table V. The second main column shows that, unlike pulmonary apoplexy, congestive haemoptysis favours mitral stenosis rather than combined lesions or pure mitral incompetence. In the third main column the lower set of figures refers only to cases with recent haemoptysis, and may correct a false impression that might be gained from the upper set, which refers also to blood-spitting many years ago.

It is worth noting that 44% of the surgical cases had either pulmonary apoplexy or congestive haemoptysis: one of the outstanding results of mitral valvotomy has been the abolition of these haemoptyses, which have occurred subsequently in only two cases. In one of these it was found impossible to perform a valvotomy, and in the other, which

was the first case operated on at Brompton Hospital, mitral stenosis has just recurred, the haemoptysis is very recent, and the patient has been advised to have a second operation.

Haemoptysis Associated with Winter Bronchitis

These cases were not separately analysed, because it was rarely possible to distinguish them from the congestive group. A few of them appear to have been included in Table V among the 25% with pulmonary apoplexy, congestive haemoptysis, or both, in the medical group.

Haemorrhage in Pulmonary Oedema

Whether acute pulmonary oedema is associated with pink frothy sputum or not is a matter of small moment, and such cases have not been specially studied.

Pulmonary Infarction

This was a less common cause of haemoptysis, as shown in Table V. It is invariably a late development, all such cases but two being totally incapacitated. Phlebothrombosis in the legs was nearly always responsible for the infarct; in only two was local thrombosis in a peripheral pulmonary artery or vein thought possible. In 58% of the cases with infarcts the pulmonary resistance was unduly high, usually extreme. Indeed, amongst the 100 medical cases there were eight deaths: seven of these were due to pulmonary embolism, and in six of them the pulmonary vascular resistance was over 10 units. Since this danger has been recognized, all high-resistance cases have been maintained on anticoagulants while awaiting valvotomy, and have been given high priority. The phlebothrombosis is attributed to the low cardiac output.

Angina Pectoris

Angina pectoris, indistinguishable in site, radiation, quality, duration of attacks, and relationship to effort from that encountered in occlusive coronary atherosclerosis, occurred in 12% of the surgical cases, 5% of the medical,

and in 3% of those with almost pure mitral incompetence—that is, in 8.4% of the whole series; all of the medical cases also had serious incompetence. The average age of these patients was 36 years, or about the same as those without angina. The sex ratio was 5.5:1 in favour of women. One-third of the cases had auricular fibrillation. No significant coronary atherosclerosis was found in the four that came to necropsy. Angina disappeared in all those who had a technically successful valvotomy.

The pulmonary vascular resistance was extremely high, averaging 19.5 units, in just over a quarter of the cases, an incidence twice that in the surgical series as a whole. It is clear from Table VI, however, that angina was by no means confined to that group; a high resistance seemed to contribute to the development of angina, but was certainly not solely responsible for it.

There was some correlation between angina pectoris and the size of the mitral orifice. Thus about 40% of the cases with angina had extreme stenosis, an incidence twice as high as in the surgical series as a whole. Combined stenosis and incompetence was also twice as frequent as expected. Angina was rare in cases with virtually pure incompetence, and was not encountered at all in mild cases of any kind.

The resting electrocardiogram did not show ischaemic depression of the ST segment in any of the cases, but an ischaemic graph was sometimes obtained after effort, and the depression was then seen in left ventricular surface leads or their equivalents, even in cases with an extremely high pulmonary vascular resistance (Fig. 1).

It is believed that angina pectoris in mitral stenosis is due to functional insufficiency of the coronary blood flow resulting from strict limitation of the cardiac output, and that it is the left ventricle which suffers most. A high pulmonary resistance may encourage angina more by limiting the cardiac output than by increasing the work of the right ventricle.

FIG. 1.—The electrocardiogram at rest and after exercise in a patient with angina pectoris complicating mitral stenosis with an extreme pulmonary vascular resistance. Note the changes in leads V₅ and V₆.

TABLE VI.—*Angina Pectoris*

	Resistance Units					Size of Mitral Orifice (mm.)				
	Average	1-3.9	4-5.9	6-9.9	10-30	M.I.	13×7	10×5	8×4	5×3
Angina pectoris	8	45	14	14	27	20	10	15	15	40
Whole surgical series	6	38	26	23	13	10	5	46	18	21
All groups (estimate)	4.2	60	20	12	8					

Systemic Embolism

A history of systemic embolism was obtained in 14% of the surgical cases, 11.5% of the medical, 9.7% of those with mitral incompetence, and in 13% of the whole series. The embolism was cerebral in 75%, peripheral in 33%, and visceral in 6%; 22% of the afflicted patients had both cerebral and peripheral emboli.

Auricular fibrillation was present in two-thirds of these cases, which is appreciably higher than in the rest of the series (Table VII). Just how often paroxysmal fibrillation was responsible for embolism in those who were regarded as having normal rhythm is unknown.

TABLE VII.—*Systemic Embolism. The Incidence of Auricular Fibrillation, Serious Mitral Incompetence, Left Atrial Dilatation, Left Atrial Thrombosis Found at Operation, and Operative Embolism in Cases Giving a History of Peripheral Embolism and in Cases Giving no such History*

History of embolism	Aur. Fib. %	M.S. M.I. %	Left Atrial Dilatation. Grade		L.A. Clot at Operation %	Embolism at Operation %
			Surg. Group	All Cases		
No previous embolism	66	44	1.74	1.86	21	10.5
History of embolism	42	28	1.48	1.79	22.6	8

A significant degree of mitral incompetence was present more often than in cases without a history of embolism (Table VII). The influence of regurgitation on the size of the left atrium or left atrial appendage might seem to explain this; but less correlation than expected was found between the incidence of embolism and the estimated size of the left atrium (Table VII), although the figures for the surgical group may be significant.

No correlation was found between the incidence of embolism and the pulmonary vascular resistance, the cardiac output, or the size of the mitral orifice. In 12.5% of the embolic cases embolism was the first symptom, occurring at a time when there was no effort intolerance, and when the rest of the data indicated that the mitral lesion was not advanced.

At operation a clot was found in the left atrium or left atrial appendage in 21% of those who gave a history of embolism and in 23% of those who did not. Embolism was an immediate complication of mitral valvotomy in 10% of the surgical cases. A clot was detected in the left atrium in two-thirds of these. The incidence of embolism at operation was not significantly higher in those who gave a history of previous embolism than in those who did not (Table VII). Of those cases in which a clot was found in the left atrium at the time of operation one-fifth developed an embolism. This was either noticed then and there or was discovered when the patient regained consciousness in the ward. Embolism occurred only once during the post-operative course, on the third day, and has not been recorded so far at the follow-up clinic.

Several interesting conclusions can be drawn from this analysis: (1) The risk of embolism occurring at operation is almost as high as the risk of spontaneous embolism (10% compared with 13%). It is therefore unwise to advise mitral valvotomy in order to prevent future embolism in

someone who has so far been free from this complication. (2) In advising mitral valvotomy to prevent a recurrence of spontaneous embolism there need be no special fear that the operation itself may cause a recurrence, the risk being no greater in those who have had previous emboli than in those who have not. (3) The infrequency of left atrial clots in patients who have given a history of embolism suggests that only fresh clots are thrown out into the circulation, and that once a clot is organized there is little danger of embolism from that source. Operative intervention alone is likely to dislodge a fragment of old thrombus.

Winter Bronchitis

Attacks of acute bronchitis, commonly in the winter, occurred in 28% of the surgical group. Its incidence was not dissimilar in medical cases of equal severity. No special correlation could be found between bronchitis and any of the other factors analysed, except that it was not a feature of mild cases. It was at first thought probable that the high incidence of bronchitis in advanced mitral valve disease depended on an excessive bronchial reaction to trivial upper respiratory tract infections because of the congested state of the bronchial mucosa. On this hypothesis the incidence of bronchitis was expected to be higher in patients with symptoms of pulmonary venous congestion than in those without. No special correlation, however, could be established. For example, the average left atrial pressure for the cases giving a history of bronchitis was 23 mm. Hg, which is practically the same as in the whole surgical group (Table VIII). Again, the incidence of bron-

TABLE VIII.—*Bronchitis*

	L.A.P. (Average) mm. Hg	Resistance Units			Aur. Fib. %	L.A. Size. Average Grade	Art. Oxygen Sat. %			C.O. l./min.
		1-5.9	6-9.9	10-30			96-92	91-88	87-83	
Bronchitis (surgical group only)	23	61	23	16	50	1.6	46	38	16	3.6
Whole surgical group	22.5	64	23	13	41	1.6	52	34	14	3.8

chitis was not influenced by the pulmonary vascular resistance, although this is known to prevent excessive pulmonary venous congestion. Finally, auricular fibrillation was present rather more often in cases with bronchitis than in the controls, and it has already been shown that auricular fibrillation does not encourage pulmonary venous congestion. These negative findings do not entirely invalidate the hypothesis defined above, but seem to demand some other determinant.

It is well known that great dilatation of the left atrium may compress either main bronchus and cause collapse of the lung. It was thought possible that partial bronchial compression might encourage bronchitis. The size of the left atrium in the bronchitic group was therefore compared with that in the rest of the series, but no difference was found (Table VIII); nor was bronchitis more common in cases of mitral incompetence with grade 3 dilatation of the left atrium than in cases of pure mitral stenosis with relatively small left atria.

No serious effects of recurrent bronchitis on the pulmonary circulation were detected in the majority of patients. Figures for the arterial oxygen saturation, cardiac output, and pulmonary resistance are given in Table VIII, where they are compared with figures compiled from the surgical group as a whole; there was no significant difference. It is clear that cor pulmonale does not ordinarily develop from recurrent bronchitis and emphysema associated with mitral stenosis.

One of the remarkable results of technically successful mitral valvotomy is the disappearance of winter bronchitis. This certainly supports the view that the bronchitis depends on a state of chronic pulmonary venous congestion in the majority of cases.

Auricular Fibrillation

Persistent auricular fibrillation (Table IX) occurred in 41% of the surgical cases, 40% of the medical, 30% of those with pure mitral incompetence, and 39% of the whole series; the respective figures for paroxysmal fibrillation were 5%, 7%, 6%, and 6%. Although auricular fibrillation was rather

TABLE IX.—*Auricular Fibrillation*

	Age (Yrs.)	+ve Biopsy (%)	Atrial Dilatation Grade	Resistance Units					C.O. l./min.	Stenosis	
				Average	1-5.9	6-9.9	10-30			Mild or Average (%)	Tight or Extreme (%)
Auricular fibrillation	41	13	1.78	7.0	52.5	35.5	12	3.6	66	34	50
Normal rhythm	33.6	24	1.45	5.9	72	18.5	9.5	4.1	50		

less common in those with pure mitral incompetence, it was most common when a significant degree of mitral incompetence was associated with mitral stenosis, being present in 69% of such cases.

Patients with auricular fibrillation tended to be older than those with normal rhythm, the average age for the two groups being 41 and 33.6 respectively (surgical cases only).

The relationship of auricular fibrillation to systemic emboli has been described in a previous section. Something more should be said here, however, about the relationship of auricular fibrillation to paroxysmal cardiac dyspnoea. It was stated, when discussing that subject, that normal rhythm rather than auricular fibrillation favoured attacks of paroxysmal dyspnoea. There is, however, a rider to that: seven out of ten surgical cases with paroxysmal auricular fibrillation had paroxysmal cardiac dyspnoea, and in three of these cases paroxysmal auricular fibrillation was known to have precipitated the attack of dyspnoea. There is reason to believe that the sudden onset of auricular fibrillation may precipitate severe dyspnoea or right ventricular failure, according to the response of the cardiovascular system to the altered haemodynamics and to the type of case in which it occurs. When the pulmonary vascular resistance is relatively normal a sudden increase of heart rate may interfere with left ventricular diastolic filling and so increase the degree of pulmonary venous congestion (Gorlin *et al.*, 1951).

On the other hand, when the pulmonary vascular resistance is high the right ventricle is more likely to fail, particularly since it is denied the auricular support which it needs under these circumstances. Again, if the rate is too fast, even with a normal pulmonary vascular resistance, the right ventricular output may fall and so relieve pulmonary venous congestion, or a grossly irregular rhythm may have a similar effect. In short, the symptomatic pattern that results from the onset of auricular fibrillation depends on several factors which include the pulmonary vascular resistance, the rate of the heart, and the degree of irregularity of the rhythm. In cases of relatively mild mitral stenosis with attacks of dyspnoea due to paroxysmal auricular fibrillation, symptoms may be abolished by permanent digitalis therapy. This does not prevent the rhythm change, but by controlling the ventricular rate when attacks do occur it prevents the dyspnoea.

It is often stated that if auricular fibrillation occurs under the age of 20 rheumatic activity may be safely assumed. Whether this is so or not, it must not be concluded that rheumatic activity is in any way responsible for auricular fibrillation in established mitral stenosis. In the present series only 13% of cases with auricular fibrillation had positive biopsies (Aschoff nodes in the left atrial appendage), compared with 24% of those with normal rhythm. The difference is no doubt due to the age factor. Even so, the two youngest patients with auricular fibrillation (aged 18 and 23) both had negative biopsies.

It would naturally be expected that auricular fibrillation in mitral stenosis might be related to the size of the left atrium. In fact, the average size of the left atrium in the group with fibrillation was grade 1.78 compared with grade 1.45 in those with normal rhythm. This is a significant difference, but does not indicate whether the enlargement caused the fibrillation or vice versa. It should be noted, however, that the grade of right atrial enlargement was also 1.78 in the group with fibrillation and only 1.04 in the group with normal rhythm, an even greater difference. Since the right atrium is not ordinarily enlarged in mitral stenosis unless the pulmonary vascular resistance is high, it follows that atrial enlargement is more likely to be the result than the cause of auricular fibrillation, unless the latter can be shown to be closely related to pulmonary hypertension.

The pulmonary vascular resistance averaged 7.0 units in those with auricular fibrillation and 5.9 units in those with normal rhythm. Further details are given in Table IX. It may be seen that a high resistance (6 to 9 units) was nearly twice as frequent with auricular fibrillation as with normal rhythm, but the relationship did not embrace extreme resistances. The paradox may be explained by the rarity of mitral incompetence in cases with an extreme resistance. Although these figures do not deny that a dilated right atrium from pulmonary hypertension may precipitate auricular fibrillation, they are not convincing. There is no doubt that the left atrium is apt to be greatly distended in cases of combined mitral stenosis and incompetence, and auricular fibrillation is particularly common in this group. This certainly suggests that atrial dilatation can cause fibrillation. The same conclusion may be drawn from the fact that in pure mitral incompetence grade 3 or 4 left atrial dilatation occurred in 75% of those with auricular fibrillation, and in only 16.6% of those with normal rhythm.

The cardiac output tended to be lower in patients with auricular fibrillation than in those with normal rhythm, averaging 3.6 litres a minute in the former and 4.1 litres a minute in the latter (analysed from the surgical group only).

Auricular fibrillation could not be correlated directly with the size of the mitral orifice. Cases complicated by serious mitral incompetence were excluded from this analysis, for these are particularly prone to fibrillate and would therefore load the figures in favour of auricular fibrillation being associated with a relatively large orifice. Despite this precaution, however, cases with auricular fibrillation had unusually tight or extreme stenosis less often than cases with normal rhythm (Table IX).

The chief conclusions from these observations are that auricular fibrillation in mitral valve disease tends to be provoked by age and distension of the left atrium especially as a result of mitral incompetence, but that it also causes dilatation of both atria; it is not related to rheumatic activity or to the degree of stenosis itself. Uncontrolled auricular fibrillation may cause intense dyspnoea or congestive heart failure in cases which would not otherwise develop serious symptoms at the time.

Essential Hypertension

Only 3% of the present series had a blood pressure of 160/100 or above, and only 1% had a diastolic pressure as high as 120 mm. Hg. This figure is in harmony with Bechgaard's (1946) converse finding that only 1% of cases of essential hypertension have mitral stenosis.

PHYSICAL SIGNS**Mitral Facies**

Peripheral cyanosis in the face and hands was common, and has been attributed to peripheral vasoconstriction secondary to a low cardiac output. In order to test this hypothesis, patients with the characteristic mitral facies of at least moderate degree were compared with cases in which there was no cyanosis of either face or hands. The

TABLE X.—Mitral Facies

	Pul. Vasc. Resistance Units	C.O. l./min.	Grade 4 Eff. Intol. (C.F.) (%)	Aur. Fib. (%)	Reduced Art. O ₂ Sat. 83-89% (%)
Mitral facies	11.7	3.3	73	68	52.4
No peripheral vasoconstriction	4.1	4.25	9.3	25	20

results are shown in Table X, and strongly confirm the hypothesis. An extreme pulmonary vascular resistance tends to keep the output low and fixed. Grade 4 effort intolerance or complete incapacity usually means congestive heart failure proper (low output type), and auricular fibrillation also tends to keep the output low. The only other factor which seemed to contribute to the mitral facies was an arterial oxygen saturation of less than 90%.

In three cases with an extremely high pulmonary vascular resistance a bright palmar flush and hot hands were observed instead of peripheral cyanosis. This unexpected finding was attributed to hepatic dysfunction.

Peripheral Pulse

The quality of the brachial pulse was noted carefully and recorded as a routine in all cases. Quality should not be confused with amplitude (quantity). The latter was small in the great majority of all groups, being considered normal in only 11.5% of the whole series. A water-hammer quality (abrupt and collapsing) was detected in 26% of the whole series; but, whereas it was present in only 8% of the surgical cases, it was found in 29% of the medical and 84% of those with pure mitral incompetence. Again, a water-hammer pulse was recognized in only 5% of the surgical cases which were proved at operation to have no significant incompetence, whereas it was recorded in 71% of all cases with a serious degree of incompetence. It is concluded that a small water-hammer pulse is an important sign of mitral incompetence. Cases complicated by aortic incompetence were excluded from this analysis.

A careful study of routine arterial pressure tracings in many cases of mitral valve disease has confirmed this clinical observation. In cases of more or less pure stenosis the arterial tracing was blunt; the upstroke was rarely abrupt and took at least 0.08 second to reach the beginning of the summit; the summit itself was rounded and occupied about 0.07 second. The down-stroke proper was not unduly steep and rarely began before 0.15 second after the onset (Fig. 2). In mitral incompetence, on the other hand, the upstroke was often abrupt and the beginning of the summit was usually reached within 0.07 second; the peak itself was sharper, and occupied only about 0.05 second; the down-stroke proper was earlier, usually within 0.12 second after the onset and was more precipitous (Fig. 3).

The characteristic pulse of mitral incompetence may be attributed to a combination of overfilling of the left ventricle, a systolic leak into the left atrium, and a low cardiac output. Left ventricular systole is hyperdynamic and im-

FIG. 2.—Intra-arterial pressure tracings from six unselected cases of mitral stenosis.

parts an abrupt wave front to the pulse; the low resistance at the mitral orifice causes systolic collapse; the poor cardiac output results in peripheral vasoconstriction, which diminishes the amplitude of the pulse.

FIG. 3.—Intra-arterial pressure tracings from two cases of serious mitral incompetence. Neither had aortic incompetence.

Jugular Venous Pressure and Pulse

The jugular venous pressure was raised in 25% of the whole series. This means that the top of the oscillating venous column in the neck was at least 5 cm. of saline above the sternal angle when the patient was propped up at 30 degrees.

A giant *a* wave (Wood, 1950, 1952; Abrahams and Wood, 1951) was seen in 12 cases (4%) and always denoted an extremely high pulmonary vascular resistance (9 cases) or tricuspid stenosis (3 cases).

A combined *va* wave followed by an *x* descent, necessarily associated with sinus tachycardia, was recorded as such in five cases. None of these had a high resistance, and it is doubted if any of them were in true heart failure.

FIG. 4.—Jugular phlebogram illustrating the steep *y* descent in a patient with heart failure secondary to mitral stenosis with an extreme pulmonary vascular resistance.

This sort of venous pulse was seen in cases of severe mitral stenosis with intense pulmonary venous congestion and passive pulmonary hypertension.

a and *v* waves of equal amplitude were found in nine cases (3%). When the venous pressure level was around 5 cm. above the sternal angle these cases did not differ from those in the previous paragraph. When the pressure was higher, however, around 10 cm. of saline, the *v* wave was followed by a steep *y* descent which was seen only in congestive heart failure proper (Fig. 4). An extremely high pulmonary vascular resistance was responsible for the failure in the few cases of relatively pure mitral stenosis that showed this type of venous pulse; four others, however, had dominant or pure mitral incompetence, and in these the pulmonary vascular resistance was not unduly high. It is believed that some other factor operates in mitral incompetence which causes congestive heart failure with a low cardiac output in the absence of extreme pulmonary hypertension.

Mackenzie's ventricular form of the venous pulse, which is characterized by a single systolic wave, was recorded in

right atrial pressure tracings in all cases of auricular fibrillation and was associated with a raised venous pressure, as previously defined, in 10% of the whole series: the pulmonary vascular resistance then averaged 9 units in those with mitral stenosis; the lowest resistance was 6.4 units.

In the same group there were eight cases with a serious degree of mitral incompetence and only one of these had a high pulmonary resistance. There were also two cases with tricuspid stenosis and one with coronary embolism; the resistance was relatively normal in each of these.

Tricuspid incompetence was diagnosed when the amplitude of the *v* wave was very much greater than that ordinarily seen in normal rhythm or auricular fibrillation.

FIG. 5.—Case of tricuspid stenosis showing a diastolic pressure gradient across the tricuspid valve.

and as a rule the top of the oscillating venous column was exceptionally high. A venous pulse of this kind was seen in 6% of the whole series. Tricuspid stenosis was excluded by means of cardiac catheterization (see below). The average pulmonary vascular resistance for this group was 14.5 units, being extreme in all but three of the 18 cases and between 6 and 9 units in the exceptions. Functional tricuspid incompetence associated with mitral valve disease clearly results from right ventricular stress of a high order.

When tricuspid stenosis was associated with normal rhythm, a giant *a* wave was seen in the venous pulse as described above; when auricular fibrillation was present, however, there was no clinical means of recognizing tricuspid stenosis from the character of the venous pulse, but it was suspected when there were no clinical, electrocardiographic, or radiological signs of a high pulmonary vascular resistance despite a really high venous pressure; in seven such cases the presence of tricuspid stenosis was subsequently established by means of cardiac catheterization, a diastolic pressure gradient across the tricuspid valve being demonstrated when the catheter was withdrawn from the right ventricle to the right atrium (Figs. 5 and 6).

The most important conclusions to be drawn from these observations are that (1) a giant *a* wave means extreme pulmonary hypertension if the clinical signs are in harmony, or tricuspid stenosis if they are not; (2) mitral stenosis does not ordinarily cause congestive failure in the absence of a high pulmonary vascular resistance—that is, passive pulmonary hypertension does not cause congestive failure; (3) tricuspid incompetence implies a pulmonary vascular resistance in the extreme grade; (4) a high venous pressure in the absence of signs of pulmonary hypertension may well mean tricuspid stenosis; and (5) some other mechanism seems to be involved in cases of congestive heart failure associated with mitral incompetence. As a corollary to all this is the very important fact that in mitral stenosis neither congestive heart failure nor tricuspid incompetence

was ever seen as the result of myocarditis itself. In other words, the so-called myocardial factor was conspicuous by its absence. In isolated or other forms of myocarditis proper, including gross rheumatic myocarditis in children, congestive heart failure is associated with a high venous pressure, a low cardiac output, and a relatively normal pulmonary vascular resistance. The only type of case in the present series in which a dominant myocardial factor has not been excluded as a cause of right ventricular failure is that with a serious degree of mitral incompetence. No further comment can be made about this possibility as yet.

Cardiac Impulse

A left ventricular thrust at the apex beat was recorded in 12% of the surgical cases, 38% of the medical, and 86% of those with pure mitral incompetence. Of the 18 cases in the surgical group, eight had a significant degree of mitral incompetence, and two had aortic stenosis. The sign was recorded erroneously in three cases in which a huge right ventricle occupied the apex of the heart; this error was suspected in view of the physical signs, but was not finally laid by the heels until the electrocardiogram was inspected. Thus there were only five cases (3.3%) in which a thrusting left ventricular impulse was unexplained. No further light was thrown on these cases as the result of valvotomy, but an enlarged left ventricle was confirmed by direct inspection of the heart. It is suspected that previous mitral incompetence may have been responsible.

Of the medical cases with this type of cardiac impulse three-fifths had a serious degree of mitral incompetence, and one-quarter had significant aortic valve disease. One patient had cardiac infarction from coronary embolism, and one had essential hypertension. There were only two cases (2%) in which the thrusting left ventricle was unexplained.

Little need be said about the 50 cases with relatively pure mitral incompetence, since 86% showed this sign. When all these cases of significant mitral incompetence in the whole series were reviewed it was found that 70% had a hyperdynamic left ventricular thrust. The importance of this sign cannot be overestimated.

There was close correlation between a left ventricular cardiac impulse and left ventricular preponderance in the electrocardiogram. Thus the electrocardiogram showed left ventricular preponderance in 48% of these cases and normal left ventricular dominance in 40%; in other words, it was left-sided in 88%. A right-sided electrocardiogram was found in 11% (only once in a case of pure mitral incompetence), and the electrocardiogram showed cardiac infarction in the case with coronary embolism.

A lift over the right ventricle, usually maximum in the third and fourth intercostal space in the left parasternal line, was appreciated in 79% of the surgical cases, in 45% of the medical, and in 36% of those with pure mitral in-

FIG. 6.—Four controls showing identical diastolic pressures in the right atrium and right ventricle.

competence, or in 61% of all cases. Since there has been a little uncertainty about the value and meaning of this sign, it was subjected to a searching cross analysis. Since the left atrium tends to be larger in cases with significant mitral incompetence than in those with pure stenosis, the figures themselves indicate that it is not the left atrium behind which is responsible for the parasternal lift in front. It was decided, therefore, to restrict the analysis to the surgical group, in which the evidence was more complete. The degree of right ventricular lift was recorded as a routine, and for the purpose of this particular analysis four groups were segregated, according to whether the lift was absent or grade 1, 2, or 3 in degree. There were 25 cases (chosen consecutively) in each group. In this way the degree of right ventricular lift was correlated with the degree of right ventricular preponderance in the electrocardiogram; the degree of dilatation of the left atrium, pulmonary artery, and right side of the heart as seen radiologically; the pulmonary vascular resistance; tricuspid incompetence; and congestive heart failure.

TABLE XI.—Right Ventricular Lift

R.V. Lift	R.V. Dominance (E.C.G.) Grade	Left Atrium Grade	Pulmonary Artery Grade	R. Atrium Ventricle Grade	Units of Resistance	T.I. %	C.F. %
0	0-35	1-5	1-0	0-6	2-6	0	0
Grade 1	0-8	1-4	1-5	1-1	4-4	12	12
" 2	1-8	1-6	2-1	1-6	6-8	12	28
" 3	2-5	1-5	2-9	2-2	12-0	32	48
" 3 or 4							

T.I. = Tricuspid incompetence. C.F. = Congestive heart failure.

The results are set out in Table XI. Each figure represents the average grade of the factor analysed as defined in the introduction. For example, the figure 2.9, at the bottom of the third column, represents the average grade of pulmonary artery dilatation in the 25 cases having a grade 3 (considerable) right ventricular lift. The table shows clearly that the right ventricular lift bears no relationship to the size of the left atrium, but is correlated closely with the degree of right ventricular preponderance in the electrocardiogram, with the degree of dilatation of the pulmonary artery and right side of the heart, and especially with the pulmonary vascular resistance; it was also related to the frequency of tricuspid incompetence and congestive heart failure. There can be no serious doubt that the fundamental factor which determines the degree of right ventricular thrust is the pulmonary vascular resistance.

AUSCULTATION

Presystolic Murmur

A presystolic murmur was heard in all but two of the surgical cases with normal rhythm, and there was a serious degree of mitral incompetence in the two exceptions. It was only just heard in one case in which there was an extremely high pulmonary vascular resistance. It was absent in one-third of the medical cases with normal rhythm; all but two of these had a serious degree of mitral incompetence, one had an extremely high pulmonary vascular resistance, and one was the mildest case of mitral valve disease in the whole series. It was absent in all cases classed as pure mitral incompetence. It is obvious from these figures that a presystolic murmur is excellent evidence against significant mitral incompetence. This conclusion was checked by analysing all cases of combined stenosis and incompetence in the surgical and medical groups. There were only 12 with normal rhythm, and of these only three had a presystolic murmur.

A presystolic murmur was heard in all of the six cases of mitral stenosis in which cardiac catheterization proved that the left atrial pressure (P.C.V.P.) did not exceed 10 mm. Hg with reference to the sternal angle; it was also present in all but one of the eight most trivial cases

of mitral stenosis in the medical group, the exception having already been referred to above. It follows that a presystolic murmur is a sign of mitral stenosis, but not of its degree.

Considerable interest is attached to the effect of mitral valvotomy on the presystolic murmur. When a presystolic murmur was present before operation it was still heard afterwards in 42% of the cases, but could not be heard in 58%. One-third of the cases in which the murmur was still present were classed as excellent results, whereas two-thirds of those in which the murmur disappeared were so classed. When those cases which lost their presystolic murmur as a result of a serious degree of mitral incompetence caused by the operation were excluded from this latter group as many as 90% were classed as excellent. The significance of this will be especially appreciated in the light of the previous finding that a presystolic murmur may occur with only a trivial degree of stenosis.

First Heart Sound

The first heart sound was loud (grade 3 or 4) in 90% of cases of uncomplicated pure mitral stenosis with normal rhythm in the surgical group (Table XII). Of the excep-

TABLE XII

	First Heart Sound		
	Normal	Accentuated	
		Grade 1-2	Grade 3-4
M.S. mild, L.A.P. < 10 mm. . .	0	42	58
" operated cases . . .	0	10	90
" M.I. . .	14	86	0
Pure M.I. . .	73	27	0

tions, only one case had but slight accentuation and this was the mildest in the series, the left atrial pressure measuring only 10 mm. Hg and the mitral orifice measuring 1.5 cm. in length at operation. In the medical group there were 26 cases classed as mild mitral stenosis with normal rhythm; the first heart sound was markedly accentuated in 15 of them, moderately so in 6, and only slightly so in 5. In this group there were nine instances in which a loud first sound was associated with a left atrial pressure proved to be less than 10 mm. Hg.

In the surgical group auricular fibrillation was present in only 14.5% of those with grade 3 accentuation of the first heart sound, but in 50% of those with grade 2 accentuation, indicating that auricular fibrillation tends to damp the intensity of the sound. In the majority of cases of auricular fibrillation the first heart sound was loud following a short diastolic period and soft after a pause, as described by Ravin and Bershof (1951). This is attributed to a tendency for the valve to close towards the end of diastole, when there is time for the ventricle to be properly filled. The absence of auricular systole favours such behaviour. In a limited number of cases, however, paradoxical accentuation of the first heart sound was noted—that is, it was softer after a short diastole and louder after a pause. No explanation for this phenomenon can yet be offered. In combined stenosis and incompetence there was usually little variation in the intensity of the first sound.

A high pulmonary vascular resistance also tended to damp the intensity of the first heart sound. Thus high or extremely high resistances were found in 25% of those with greatly accentuated first sounds, and in 41% of those with moderately accentuated first sounds. Nevertheless, extreme resistances never caused normal or soft first sounds.

Mitral incompetence was by far the most important factor modifying the first heart sound. Thus, of the surgical cases in which the degree of mitral incompetence was checked at operation, no case of significant incompetence had grade 3 accentuation of the first heart sound, 20% had grade 2 accentuation, and 66% grade 1. Again,

no case of significant mitral incompetence in the whole series had considerable accentuation of the first heart sound, 27% had grade 1 or 2 accentuation, and 73% had a normal or soft first sound. These figures were taken only from the cases without obvious calcification of the valve so that they would not be influenced by that factor. There were only three examples of marked calcification of the mitral valve without incompetence, and each of these had slight accentuation of the first heart sound. It follows that, although calcium alone may diminish the intensity of the sound, the soft first sound of mitral incompetence does not depend on its presence. As expected, there was a positive correlation between the intensity of the first heart sound and the presence and intensity of the opening snap.

It is believed that the first heart sound is loud in mitral stenosis because there is a sufficient pressure gradient across the mitral valve to billow the cusps deeply into the left ventricle right up to the moment when that chamber contracts. When there is no stenosis the left ventricle fills rapidly, so that towards the end of diastole, even when quite short, the mitral cusps tend to float into apposition, and therefore shut more quietly when the ventricle contracts (Dock, 1933). Normal rhythm favours accentuation of the first sound by increasing the pressure gradient across the valve at the end of ventricular diastole; a high pulmonary vascular resistance may damp the sound a little by encouraging the right ventricle to form the apex beat of the heart; mitral incompetence results in quicker left ventricular filling, and the rapid equalization of left atrial and left ventricular diastolic pressures may float mobile cusps into apposition before the ventricle contracts; moreover, mitral incompetence is often associated with rigid cusps, particularly in the presence of heavy calcification, and in these cases there may be little movement.

The effect of valvotomy on the intensity of the first heart sound was studied (Table XIII). When the first

TABLE XIII.—Post-operative First Heart Sound

First Heart Sound	Incidence	Functional Result		
		Excellent	Good	Fair or Poor
Intensity diminished by 2 or 3 grades. Now grade 1 or normal	30%	81.5%	18.5%	—
Intensity slightly diminished. Now grade 1 or 2	25%	30%	61%	9%
Unchanged	22%	20%	50%	30%
Now soft or normal due to mitral incompetence	23%	—	33.3%	66.6%

sound was greatly diminished after the operation 81.5% did excellently, whereas when it was unchanged or only slightly diminished only 20 to 30% did as well. When the first heart sound became soft as the result of mitral incompetence caused or increased by the valvotomy the result was poor or only fair in as many as two-thirds, and it was excellent in none. When it is remembered that the first heart sound is usually loud in trivial degrees of mitral stenosis the return to normal or near normal in about one-third of all cases operated on is remarkable.

It is concluded that a loud first heart sound is excellent evidence of mitral stenosis, but gives little indication of its degree; its presence is a talisman against serious mitral incompetence.

Mitral Systolic Murmur

A loud mitral systolic murmur (grade 3 or 4) was heard in all the cases of pure mitral incompetence except two in which the murmur was only moderate in degree; a thrill accompanied the murmur in 43%. A similar loud murmur was also heard in all the cases of combined mitral stenosis and incompetence in the medical group except two in which it was also only moderate in degree; a thrill accompanied this murmur in 14%. No case of significant mitral incompetence without a systolic murmur of at least moderate degree was encountered in the whole series. In

the surgical group there were naturally far fewer cases of significant mitral incompetence: here a loud mitral systolic murmur was heard in 11.4%, a moderate murmur in 9.3%, a faint murmur in 8.6%, and no mitral systolic murmur at all in 66.4%; in 4.3% of cases a tricuspid systolic murmur extending far out to the left was mistaken for a mitral murmur by some observers.

When the surgical cases were analysed in respect of the mitral systolic murmur there was close correlation between the incidence and grading of the murmur and the presence and degree of mitral incompetence recognized by the surgeon by direct palpation of the valve (Table XIV). For

TABLE XIV.—Mitral Systolic Murmur (Surgical Cases Only)

Mitral Systolic Murmur	Grade of Mitral Incompetence			
	0	1	2	3
Absent	98%	2%	—	—
Grade 1	42%	42%	16%	—
" 2	15%	70%	15%	—
" 3 or 4	12%	18%	12%	58%

example, when there was no mitral systolic murmur there was no incompetence at all in 98% of cases; on the other hand, when the murmur was loud mitral incompetence was found in 88%, considerable in 58%, and mild or moderate in 30%. It can no longer be seriously maintained that a mitral systolic murmur is of little value in determining the presence or absence of mitral incompetence.

The effect of valvotomy on the mitral systolic murmur was recorded in all the surgical cases and has been correlated with the functional results (Table XV). As would

TABLE XV.—Post-operative Mitral Systolic Murmur

Mitral Systolic Murmur	Incidence	Functional Result			
		Excellent	Good	Fair	Poor
Grade 3 or 4 before and after	9%	—	10%	30%	60%
Increased to Grade 3 or 4	22%	4%	29%	38%	29%
Increased slightly to Grade 1 or 2	21%	53%	39%	4%	—
No change Grade 0 to 2	41%	46.5%	38%	11%	4.5%
Diminished slightly	3.5%	50%	37.5%	12.5%	—
" greatly	3.5%	—	—	—	—

be expected, the development of a loud mitral systolic murmur (grade 3 or 4) was associated with an important degree of mitral incompetence in the great majority of cases in which it occurred (84%). The functional result was relatively poor in this group. Those cases with a loud systolic murmur before the operation nearly always had a loud murmur afterwards and did not do well, 90% of them being classed as fair or poor and none as excellent. Apart from these two groups the functional result was much the same whether a grade 1 or grade 2 mitral systolic murmur developed, whether such a murmur present before the operation diminished or even disappeared (which was rare), whether a grade 1 or grade 2 systolic murmur remained unchanged, or whether there was no murmur before or afterwards. As many as 41% of the whole surgical group had no mitral systolic murmur before or after the operation, and 55% of those without a pre-operative murmur did not develop one afterwards; since the functional result was excellent or good in 85% of such cases it is clear that mitral valvotomy is capable of restoring excellent valve function. Relatively few (14%) of those without a mitral systolic murmur before the operation developed a grade 3 or 4 murmur afterwards, and all but two of them then had other evidence of serious mitral incompetence.

The Pulmonary Second Sound

By the pulmonary second sound is meant the second or pulmonary element of the second heart sound; it is rarely heard beyond the pulmonary area. When the second sound seems single, splitting can nearly always be recognized

during rather deep inspiration. It was necessary to appreciate the split before the pulmonary element could be properly analysed. Table XVI shows the relationship between the intensity of this pulmonary second sound and the pulmonary vascular resistance. The correlation is not as close as might be expected, but cannot be ignored: thus

TABLE XVI.—Pulmonary Element of Second Sound

Pulmonary 2nd Sound		Resistance		
		< 6 Units	6-10 Units	> 10 Units
Normal	1	91%	8%	1%
Accentuated Grade 1	2	76%	16%	8%
"	3 or 4	42%	31%	26%
"	"	33%	33%	33%

when the pulmonary second sound was normal the resistance was relatively normal in 81%; on the other hand, when the pulmonary element was markedly accentuated (grade 3 or 4) the pulmonary vascular resistance was high in 66%. Further details may be studied in the table. Closer correlation might well have been obtained if the second sound had been auscultated while the pulmonary artery pressure was being recorded, but this was impracticable.

It is concluded that the pulmonary element of the second heart sound is an important but not infallible guide to the degree of pulmonary hypertension present in mitral stenosis.

Pulmonary incompetence was recognized in 10% of the surgical cases, but in only 1% of the medical and in none of the cases of pure mitral incompetence. It was associated with an extremely high pulmonary vascular resistance in 55%, and with a high resistance (6 to 9 units) in the other 45%; it was never encountered when the resistance was under six units. The pulmonary artery was conspicuously dilated in nearly all these cases, the average degree of enlargement working out at just over grade 3.

The Mitral Opening Snap

This occurred in none of the group with pure mitral incompetence, but this only means that if a snap was present pure mitral incompetence was never diagnosed. There was, however, ample collateral evidence supporting this attitude.

Of the surgical cases 16.5% did not have an opening snap, excluding four cases which were put up for surgical repair of mitral incompetence. The absence of a snap was attributed to the following factors: (1) associated significant mitral incompetence without calcification (four cases); (2) associated significant mitral incompetence with heavy calcification (9 cases); (3) heavy calcification with trivial mitral incompetence (4 cases); (4) an extremely high pulmonary vascular resistance over 10 units (5 cases); (5) massive left atrial thrombosis (1 case); and (6) moderate aortic valve disease (1 case).

It is uncertain whether the explanation in these last two instances is correct. Since the opening snap is certainly due to the abrupt backward billowing of the mitral cusps, particularly the aortic, when the pressure within the left ventricle sinks rapidly below that in the left atrium at the end of the period of isometric relaxation, it is suggested that aortic reflux may prevent the snap by interfering with the backward movement of the aortic cusp.

Mitral incompetence of sufficient degree prevents the snap because in these cases there is far more destruction and rigidity of the mitral cusps than in pure stenosis, so that the rigging is disorganized and, if one thinks of the cusps as sails, they are too matted down to flap back as the pressure gradient is reversed. It may also be true that with sufficient incompetence the lack of obstruction at the mitral orifice itself prevents the snap by allowing free filling of the ventricle as in normal hearts.

It has been suggested that mitral calcification may be responsible for the absence of a snap (Wynn, 1953), and the

findings here confirm this view. Conspicuous calcification is rare in the absence of incompetence, but it has occurred, and in addition to the four cases mentioned above two others have been seen recently both without a snap. Extreme rigidity of the cusps is assumed to be responsible. Of 13 additional surgical cases in which calcification was slight and in which there was no mitral incompetence, all had an opening snap.

An extremely high pulmonary vascular resistance obscured the snap in one-quarter of all such cases. Since the left atrial pressure was at a level which would certainly have been associated with a snap in uncomplicated cases of mitral stenosis, its relative lowering cannot be held responsible for the absence of the sign; moreover, the sign was in fact present in three-quarters of such cases, and was sometimes very loud. It is suggested that the snap may be masked by the very large pulmonary artery overlying the root of the aorta, so that sounds produced by the aortic cusp of the mitral valve are not readily heard at the base; also by a grossly distended right ventricle forming the apex of the heart, so that sounds transmitted through the left ventricle may be difficult to hear at the "mitral area." In one or two instances of extreme pulmonary hypertension the snap was recorded phonocardiographically when it could not be heard clinically; this was never so when a snap could not be heard in cases of mitral incompetence.

Amongst the 150 surgical cases there were only two instances of simple stenosis in which a snap was not recorded clinically. One of these had the largest mitral orifice in the series; in the other an error was suspected. Mitral valvotomy resulted in loss of the snap in 32% of the cases; half of these were associated with excellent results, the other half with the development of serious mitral incompetence.

In the medical cases an opening snap was not heard in 38%. The explanations were much as described for the surgical group, in that 16 had serious mitral incompetence without calcium, 10 had serious mitral incompetence with conspicuous calcification, one had conspicuous calcification without mitral incompetence, three had an extreme pulmonary vascular resistance, and one had moderate aortic valve disease. In addition, however, there were five cases in which the absence of a snap was attributed to the mildness of the lesion; in fact, 38% of really mild cases had no snap. It must be understood that in these the degree of stenosis approached the trivial. In relatively mild cases, in the sense that they were not severe enough to warrant valvotomy although otherwise quite well developed, a snap was always present. In the medical group also there was one case with predominant tricuspid stenosis in which a mitral opening snap could not be heard, and there was one instance in which failure to record a snap was believed to be a clinical error.

It is concluded that the opening snap is one of the most important signs of dominant mitral stenosis, and, like a loud first heart sound, is an excellent talisman against the presence of serious mitral incompetence. Although it signifies properly developed stenosis, being absent in many trivial cases, it does not necessarily mean that the stenosis is severe enough to warrant valvotomy.

The Third Heart Sound

This was never heard in cases of pure stenosis as noted by Bridgen and Leatham (1953). It was present in 85% of the cases of well-developed mitral incompetence (grades 2 to 4) and in 25% of cases of mild mitral incompetence. It was present in 74% of the medical cases in which a serious degree of incompetence complicated mitral stenosis, but in only 25% of the surgical cases of similar kind, probably because there was relatively more stenosis in this small group. Of the surgical cases with a third heart sound not one did excellently or even well; indeed, three-quarters of them died. A third sound was never heard when a trivial degree of incompetence complicated mitral stenosis.

The sound was closely correlated with a hyperdynamic left ventricle. Thus 78% of all cases having such a left ventricular action without aortic incompetence had a third heart sound; conversely, 95% of cases with a third heart sound had a hyperdynamic left ventricle. This could be recognized both clinically and radiologically. The third heart sound, of course, is attributed to rapid filling of the left ventricle. The third sound was very closely correlated with the presence of a loud mitral systolic murmur; indeed, it was never heard without such a murmur. In fact, it was closely correlated with all the other signs of mitral incompetence as discussed elsewhere.

The difference between an opening snap and a third sound is usually obvious when both are classical, the opening snap being closer to the second sound, shorter, sharper, and higher-pitched in quality, and being very well heard at the left sternal edge; whereas a third heart sound is later, longer in duration, dull, relatively low-pitched, and best heard over the left ventricle at the apex of the heart. Again, the snap is well heard on expiration, whereas the third heart sound usually comes out better on inspiration. Unfortunately, the character of the third sound may become much more like an opening snap in advanced mitral incompetence in the sense that it may be less delayed and much sharper and higher pitched in quality than usual. The classical description of the third sound is based on its occurrence in normal individuals, usually children, and in association with heart failure (left ventricular diastolic gallop). In mitral incompetence the left ventricle fills more rapidly than in these conditions, and this is probably responsible for the modification of the sound.

When present before the operation, the third sound never disappeared afterwards; on the contrary, it was always louder. In the cases with combined stenosis and incompetence without a third sound pre-operatively, 85% developed the sound after valvotomy. In other words, relief of stenosis accentuated the signs of incompetence. In cases operated on for mitral stenosis with a trivial degree of incompetence, as many as 60% developed a third heart sound after valvotomy, although these patients often did very well functionally, the incompetence being only of moderate degree. A third sound associated with mitral incompetence also developed after valvotomy in 7.5% of cases without previous incompetence at all.

It is concluded that the presence of a third heart sound is excellent evidence of at least moderate mitral incompetence. Its presence offers a strong reason for not recommending valvotomy even in those rare instances in which a clinical opening snap is heard in addition to the third sound.

Mitral Diastolic Murmur

Particular attention was paid to the length as well as to the intensity of a mitral diastolic murmur, and whether or not it was accompanied by a thrill; both length and intensity were graded. By grade 4 length is meant that no gap could be detected between the murmur and the first heart sound, or between a diastolic murmur and presystolic accentuation; a grade 3 murmur means that a gap could just be recognized; a grade 2 murmur was of moderate length, and grade 1 very short. When there was tachycardia the heart was slowed by means of carotid sinus compression in order to grade the length of a murmur. When there was auricular fibrillation the length of the bruit was gauged during the longer pauses; sometimes these had to be induced by carotid sinus pressure.

The mitral diastolic murmur was long (grade 3 or 4 in equal proportion) in 85% of the surgical cases. In 15% only was it relatively short; one-third of these had an extremely high pulmonary vascular resistance (abolishing the murmur altogether in one instance); one-third had significant mitral incompetence; no explanation could be found in the remainder (5% of the whole series). An extremely high pulmonary vascular resistance also abolished the murmur in one of the medical cases.

In the group with almost pure mitral incompetence the murmur was very short in 48% and only moderate in length (grade 2) in 24%. It was never long, and was absent altogether in 28%. Moreover, when a diastolic murmur was present in mitral incompetence a third heart sound could nearly always be heard.

A mitral diastolic thrill was appreciated in 38% of the surgical group, in 29% of the medical, and in 20% of the cases with mitral incompetence. An attempt was made to find some factor which might favour the development of a thrill, but with little success. In the cases with a thrill valve calcification was present in 29%, against 28% in the group as a whole; the left atrial pressure averaged 21.4 mm. Hg, the cardiac output 3.95 litres a minute, and the pulmonary vascular resistance 5.1 units, against respective control figures of 22.5, 3.8, and 6.5; the mitral orifice was less stenosed than usual in 22%, average in 46%, tighter than usual in 22%, and extremely stenosed in 10%, against control figures of 9%, 48%, 17%, and 26% respectively, omitting cases with significant mitral incompetence. As a rule, the cusps were mobile in cases with a thrill; a tough fibrous orifice was present in 27%; these anatomical findings were much the same in the series as a whole.

It will be discerned that the only points of difference between cases with a diastolic thrill and the surgical group as a whole were that the pulmonary vascular resistance was a little lower, and that the incidence of cases with extreme and relatively mild stenosis was reversed. On looking into the resistance more closely it was found that an extreme resistance was present less than half as frequently in those with thrills as in those without. This was confirmed by an analysis of the medical group, in which none of the few with an extreme resistance had a thrill. This damping effect probably explained the relatively few cases of an extremely stenosed orifice amongst the cases with thrill referred to above.

The intensity of the mitral diastolic murmur has not been analysed separately, for the loudest murmurs were usually associated with a thrill, soft murmurs never.

[Part II, with a list of references, will appear in our next issue.]

Scientific Film Review for March, 1954, includes descriptions of eight new medical films. "Analysis of the Effect of Vasoactive Substances on the Blood Vessels in the Mesorchium of the Rat" (Ciba Laboratories) is described as a superb example of cinemicrography. Although intended for pharmacologists and physiologists, it is also suitable for medical societies. "The Children's Vocabulary of the New Sign Language" (Department of Phonetics, University College, London) demonstrates some 330 moving signs in Sir Richard Paget's new sign language. It is intended for teachers of the deaf and otologists. "Cold Agglutination of Human Blood" (Ciba Laboratories), partly in colour, is for haematologists and physiologists. "The Cyto-diagnosis of Uterine Cancer" (Ciba) is a useful colour film dealing with the recovery of vaginal contents, the technique of Papanicolaou's staining procedure, and the appearance of cancerous cells. The first part is primarily of value to gynaecologists and the remainder to pathologists and laboratory technicians. "Lymph Vessel Movement Studies in the Mesentery of the Rat" (Ciba) is meant for pharmacologists and physiologists. "Nalorphine" (Wellcome Film Unit) demonstrates the antagonistic action of this drug to morphine, methadone, and thiambutene. "A New Approach to the Surgery of Peptic Ulcer" (Allen and Hanbury) is a demonstration in colour of the difference between Billroth partial gastrectomies and the jejunal replacement technique, with particular emphasis on the latter. It is likely to be of special interest to gastric surgeons and surgical societies. "Nydrazid in the Treatment of Tuberculosis" (E. R. Squibb and Sons) is a coloured film intended for chest physicians, tuberculosis officers, etc.

THE SURGICAL TREATMENT OF PECTUS EXCAVATUM (FUNNEL CHEST)

BY

E. F. CHIN, F.R.C.S.

Surgeon in Charge of Thoracic Surgical Unit, Southampton
Chest Hospital

AND

RICHARD H. ADLER, M.D.

Fellow of the Dazian Foundation for Medical Research,
U.S.A.

Pectus excavatum is a depression deformity of the anterior chest wall that has been recognized under a number of names: funnel chest, trichterbrust, chondrocostosternon, koilosternia, and others. Despite the considerable literature on this well-known entity many differences exist concerning its development and management. A brief review of the current concepts and the results of surgical treatment used in this unit are presented.

Aetiology

The exact aetiology is still uncertain. Of the many theories advanced none could serve as a fit basis of treatment until Brown (1939) demonstrated that the deformity was due to a short central tendon of the diaphragm. Brodtkin (1951) observed a diminished inspiratory sternal retraction on the homolateral side following procaine injection of the phrenic nerve. We have noticed an almost complete disappearance of inspiratory sternal retraction when the diaphragm has been paralysed by curare. It does seem likely that some congenital abnormality of the diaphragm is primarily responsible for the condition.

The deformity is noticed shortly after birth, but in some individuals it may not become apparent until later years, and it may be observed by the parents for the first time in early adolescence. That there is a strong genetic factor is well shown by the commonly reported occurrence of multiple cases within a single family and in lineal descent through several generations (Sainsbury, 1947). This has been confirmed in our series. It is characterized by a progressive posterior sternal depression and distortion of the adjacent costal cartilages that begins near the sterno-manubrial junction and reaches its deepest point at the xiphoid. In infancy this retraction may be apparent only with deep inspiration and is best seen when the child is crying, a severe degree of deformity then being produced which immediately corrects itself after the inspiratory effort is over. Unfortunately it often tends to progress to a permanent bony deformity, and there is no way of knowing in which individual this will occur. In one of our cases it progressed from a mobile deformity seen only on deep inspiration to a fixed deformity in a period of six months. The deformity is often symmetrical but not always so. In time a characteristic posture develops. The ribs acquire a lateral flare and the chest becomes flattened and pulled down upon the abdomen, a dorsal kyphosis develops, and the head tends to protrude forward. The appearance is that of a thin round-shouldered, hollow-chested, pot-bellied individual. The costal cartilages dip into the sternum at a steep angle and the xiphoid is often impalpable from the overcrowding of the sixth and seventh cartilages. The depression, which is often extreme, usually deepens on inspiration.

The thoracic viscera may be affected by compression and distortion. Although there is interference with respiration this is seldom at a critical level, and in many instances the commonly used clinical tests of respiratory function may fail to show any serious alterations. There is adequate evidence in the literature to show that symptomatic cardiac disturbances are not uncommon. Electrocardiograms, angiocardigrams, and cardiac catheterization have pro-

vided convincing evidence of disturbed cardiac function. Symptoms of tachycardia, palpitation, arrhythmia, and dyspnoea can occur at an early age. A systolic murmur may be heard, and on the basis of this some of these children have been labelled "heart disease" and precluded from many activities at school.

The purpose of surgical treatment is to correct the sternal and costal cartilage deformity. This is of no value unless persistent post-operative supervision is carried out to see that the patient corrects the kyphosis, which is, of course, secondary to the diaphragmatic and sternal abnormality. The younger the patient the easier this is, and we are reluctant to operate on patients over 20 unless they have symptoms. There is no doubt that these symptoms will be relieved in this older age group, but the bad posture will probably persist.

Infants under the age of 6 months should not have treatment, as inspiratory sucking-in of the sternum may be present in the newborn and gradually disappear during the first few months of life. Delay in treatment is to be condemned, because in the early stage, when the chest wall is still mobile and deformity is produced only on deep inspiration, the operation is a relatively minor one. When the sternum has become detracted down and the costal cartilages are permanently deformed then a more extensive procedure is necessary. Excluding those who are too old and too young, we feel that all cases should have surgery.

It is striking how the patients' and their parents' concern over this disability is masked. When first seen in the out-patient department and accepted for operation their true feelings become more apparent, though restrained. It is only after operation that their real feelings are manifest. There is a reluctance on their part to believe that surgery can offer anything because they have been repeatedly told that nothing can be done. Many of them have had prolonged treatment in physiotherapy out-patient departments with little or no improvement, and an attitude of *laissez faire* exists. These children are often very conscious of their defect. They are shy of their complaint; boys frequently undergo teasing at school and girls feel handicapped, particularly as they reach adolescence. It has impressed us in their first follow-up how they volunteer a sense of well-being and an improved exercise tolerance. This latter is very constant. The patient often states that he can now do far more than he did before and that he can keep up with boys of his age effortlessly, whereas prior to the correction of his pectus he had found difficulty in keeping up. Thus surgery is undertaken: (1) for cosmetic reasons; the penalty for this is a scar which can be hidden, but it is impossible to hide the bad posture in a well-established case; and (2) to alleviate symptoms; these may be severe. It is true that the percentage of cases with symptoms in our series is not representative, as we are more inclined to see cases who have symptoms.

Brown (1939) and Ochsner and De Bakey (1939) put surgical treatment of pectus excavatum on a sound basis. Many modifications and variations have appeared since that time (Sweet, 1944, 1950; Ravitch, 1949; Wahren, 1950; Brodtkin, 1951; Woods *et al.*, 1952; Johnson and Kirby, 1952). Techniques involving the use of plaster casts, various forms of external traction and fixation, grafts of bone and cartilage internally to support the sternum, and plastic operations upon the deformed costal cartilages are in current practice. It is understandable that such a state of confusion should exist, since the exact aetiology of the condition is not completely settled and no one method of treatment has been 100% successful.

Most present-day operations are based upon the principles of Brown. It is mainly in the method of maintaining sternal elevation and in dealing with the deformed costal cartilages that the various techniques differ. We have been impressed with the modification described by Ravitch (1949), and our present technique is based essentially upon this method. It requires no traction or added supports externally or internally.

Technique of the Operation

The anaesthetic consists of nitrous oxide, thiopentone, curare, and oxygen with an endotracheal tube. A midline incision is made from above the upper limit of the deformity to the epigastrium. The pectoral muscles are dissected laterally to expose the full length of the deformed costal cartilages. Because of the crowding and depression, the lowermost two costal cartilages on each side usually need to be resected to expose the xiphisternal junction. After dividing this a tough fibrous band may be seen running from the posterior rectus sheath to the back of the sternum. This is not always present. When this so-called substernal ligament is divided the xiphoid and rectus retract, sometimes with an audible snap. It is now possible to palpate the entire posterior surface of the sternum and to free all adhesions and remaining diaphragmatic attachments.

If the costal cartilages are deformed they must be completely removed to the level where the posterior angulation of the sternum begins (Fig. 1). The remaining intercostal

FIG. 1.—Diagram showing the third, fourth, fifth, sixth, and seventh cartilages removed on the left, and the fifth being enucleated on the right, leaving the posterior perichondrial layer intact. The xiphoid has been detached with the rectus after division of the substernal ligament. The upper line shows the usual site of the transverse osteotomy.

position of slight over-correction. The pectoral muscles are sutured to the periosteum of the anterior surface of the sternum near the midline and the wound is closed without drainage. A simple gauze dressing is used to cover the incision, and the patient is got up and dressed the following day. There has been no fixation in any case.

If the operation is done in infancy, before there is any fixed deformity of the sternum or the costal cartilages, only a small transverse incision is needed over the xiphisternum. The xiphisternum joint and the substernal ligament are divided and the sternum and the lowest costal cartilages are freed of any diaphragmatic attachments. We have abandoned subperichondrial resection of the costal cartilages, since it can be tedious and is felt to be unnecessary. A section of each side of the cartilage is freed from the intercostal insertions and a curved blunt periosteal elevator is inserted beneath the cartilage and elevated. This elevated cartilage is then easily divided with a knife and each end picked up in turn with a towel clip, stripped free, and removed. A narrow strip of posterior perichondrium is usually left. The chest becomes firm in two weeks.

In a case with fixed deformity it is essential to be radical. If the deformity of the third costal cartilage is present but not marked it is wrong to spare it. This mistake was made in Case 2; the cosmetic result has been spoilt by the overgrowth of this third cartilage and the patient has a mild degree of pectus carinatum.

The extent of the deformity in each individual must be carefully assessed clinically and at operation to ensure complete removal of all deformed costal cartilages. No harm follows accidental opening of the pleura with an endotracheal tube in place. The lung is kept inflated, the pleura is closed, and any small remaining pneumothorax is allowed to absorb. Occasionally fullness beneath the lower end of the incision will require aspiration, but routine drainage of this space has not been found to be necessary. Respiratory paradox of the anterior chest wall has not been a problem. It was seen in only one patient; she developed a lung infection two days after the operation and the paradox was rapidly brought under control by giving her four million units of penicillin a day. Diligent pre-operative and post-operative physiotherapy is most important in achieving a smooth convalescence and a good result.

The early results in this series of 10 patients is very satisfactory, the longest follow-up being 11 months. Concerning the question of later recurrence, we gain solace from the report of Ravitch (1951), whose patients, treated in this way, have been followed up for five and six years with no evidence of recurrence.

Case Reports

Full reports on all these cases are not given, as in many this would be repetitive; only cases with features of interest are discussed.

The age range of the patients was 2 to 17 years. There were seven males and three females.

Case 1.—A girl aged 15 had had severe symptoms for two years. She was afflicted by frequent attacks of giddiness, which were quite unrelated to any particular posture or

FIG. 2

FIG. 3

FIG. 2.—Case 1. This patient presented with symptoms of pain, dyspnoea, giddiness, and palpitation. Severe degree of deformity and paradoxical movement on inspiration. FIG. 3.—Case 1. Follow-up 11 months post-operatively. Correction maintained and symptoms alleviated.

movement. For 18 months she had noticed a persistent sense of constriction in the chest and on exercise experienced incapacitating discomfort along the subcostal margin, this being always associated with severe palpitations. At the end of a day at school her ankles were swollen. She had ceased all sporting activities because of pain and dyspnoea. On examination the typical deformity of a well-established funnel chest was seen (Fig. 2). Her kyphosis was not fixed,

and there was marked paradoxical movement of the sternum on inspiration. X-ray examination showed a rotation of the heart into the left chest. Angiocardiogram revealed no filling defect. E.C.G. was normal and the circulation time using dehydrocholic acid was seven seconds. In July, 1952, the deformity was repaired. The result is shown in Fig. 3. At her last follow-up, 10 months after operation, there was no recurrence of deformity, her posture was excellent, and she had no disability.

Case 2.—A boy aged 5 had been subject to "bronchitis" all his life. The deformity was first noticed when he was 2½, and it had progressed since. In all respects he seemed a healthy boy except for his recurrent chest infections. On examination a well-marked deformity was seen. On inspiration there was a severe degree of paradoxical movement of the sternum. Repair was carried out. He had a well-formed substernal ligament, and when this was divided the xiphoid and recti sprang away. The mistake was made of not being radical enough; the third costal cartilage should have been removed on either side. His follow-up from the cosmetic point of view was disappointing in that there was some overgrowth of the third costal cartilage. There was no paradox, and since his operation nine months previously he had had no further attacks of bronchitis; this was the longest period he had been free of chest infection.

Case 3.—A boy aged 10½ was completely symptomless. His parents requested the operation because they were a Service family and were anxious for the boy to go ultimately into the Services. Also, they lived in a families camp and

FIG. 4

FIG. 5

Fig. 4.—Case 3. This patient had no symptoms. Fig. 5.—Case 3. Photograph taken just before discharge.

had seen a previous case returned from the unit. Fig. 4 shows the degree of deformity. This boy had a marked paradox. Fig. 5 was taken immediately before his discharge and well illustrates the need for close supervision over the next three to five months.

Case 4.—A girl aged 13 complained of pain in the xiphisternal region associated with exercise. It was a sharp non-radiating pain. It had been present for one year. She became more breathless than her friends and at times found it difficult to keep up with them. Because of a murmur in her heart the school doctor had years previously told her that she had heart trouble. Examination showed typical funnel-chest deformity. There was a systolic murmur over the mitral area. The deformity was repaired; the murmur has now disappeared, and she indulges in full activities without any discomfort.

[Since this paper was submitted five additional cases have been repaired. They have all done well and no complications have arisen.]

Summary

The current concepts of pectus excavatum are briefly reviewed.

A prophylactic operation is advised at an early age to prevent a progressive and permanent deformity. The two main indications for surgery are cosmetic and symptomatic. The technique employed requires no external traction or added internal support. In infancy the dividing of the xiphisternal joint and freeing of the sternum from the diaphragm correct the deformity. Older subjects require the added resection of all deformed costal cartilages and a transverse wedge osteotomy of the sternum.

Ten patients treated by this method are presented. There were no deaths or complications. The early results are satisfactory and encouraging. It is necessary to be radical and to excise all the deformed cartilages.

ANTIHISTAMINE THERAPY

WITH SPECIAL REFERENCE TO SKIN DISORDERS

BY

R. P. WARIN, M.D., M.R.C.P.

Dermatologist, United Bristol Hospitals

During the past five years a separate out-patient clinic has been held twice a month for the purpose of studying the administration and overall value of the antihistamine group of drugs. Most of the patients attending the clinic have had urticaria. The main problems connected with the use of these drugs can be dealt with under headings of administration, ill-effects, and skin disorders affected.

The Drugs Available

The following drugs of the group are available for oral use in this country.

Official Name	Proprietary Name
Antazoline	Antistin (Ciba)
"	Histotab (Boots)
"	Ben-a-Hist (Bencard)
Bromazone	Ambodryl (Parke, Davis)
Chlorcyclizine hydrochloride	Histanin (Burroughs Wellcome)
"	Di-paralene (Abbott)
Diphenhydramine hydrochloride	Benadryl (Parke, Davis)
Mepyramine maleate	Anthisan (May & Baker)
Methaphenilene hydrochloride	Diatrin (Warner)
Phenindamine hydrogen tartrate	Theophorin (Roche)
Promethazine hydrochloride	Phenergan (May & Baker)
Tripeleannamine hydrochloride	Pyribenzamine (Ciba)
Meclozine dihydrochloride	Ancolan (B.D.H.)
None	Actidil (Burroughs Wellcome)
None	Synopen (Geigy)

"Dibistin" (Ciba) is a mixture of antazoline and tripeleannamine.

"Avomine" (M. & B.) and dimenhydrinate ("dramamine," Searle) contain antihistamines but are primarily used for travel sickness.

There is not much information available about the equieffective doses of the various drugs. In conjunction with Professor W. A. Bain, I carried out comparisons of various drugs in their effects on induced histamine weals in man. It was then found that for single doses 40 mg. of promethazine was equivalent to 275 mg. of mepyramine and 600 mg. of antazoline (Bain, 1949). With repeated doses the drugs with a long action, such as promethazine, will build up a greater effect; and after a week's therapy promethazine, 40 mg., was found to be equivalent to mepyramine, 560 mg., given in a 24-hour period.

The specific histamine antagonism is apparently the same with all the drugs, but the nature and degree of side-effects vary. It is the incidence of the latter, when equieffective doses of the drugs are compared, that usually determines which is the most suitable drug. In a clinical assessment (Bain, Hellier, and Warin, 1948) it was shown that the incidence of drowsiness was greater with diphenhydramine than with mepyramine. When promethazine given in a single dose at night was compared in this respect with mepyramine given three times a day, the side-effects were less, and most patients preferred promethazine (Bain, Broadbent, and Warin, 1949). Recently a similar comparison has been undertaken, using promethazine in a single dose at night and chlorcyclizine given twice a day. Forty-nine patients with persistent urticaria were treated with the drugs in turn, and the dose in each case was adjusted to a level giving approximately the same degree of reduction of the wealing. Nineteen patients had some side-effects with one or both drugs. In seven of these they were less or nil when on chlorcyclizine, in two they were less or nil on promethazine, and in 10 there was no difference. In this clinical comparison chlorcyclizine, 75 mg., gave approximately the same effect as promethazine, 25 mg.

From the preliminary tests it was shown that antazoline was a relatively weak antihistamine, and it has not been used in the clinical work. Tripeleannamine has a similar structure to mepyramine and its effects are about the same.

Meclozine, phenindamine, and methaphenilene do not appear to have any useful advantage over the others, but, together with the recent additions, bromazone, "actidil," and "synopen," my experience with these drugs has been limited, and no clear comparison seems to be available.

In the clinic the main drug used has been chlorcyclizine, but a few patients have had promethazine or mepyramine, and in some cases diphenhydramine has been used when the additional sedative action has been required.

Practical Points in Administration

The dose of the drugs required to suppress weals varies greatly. Apart from the question of body weight and age it has been shown that individual patients vary considerably in the degree of histamine antagonism given by the same dose of one of the drugs (Bain *et al.*, 1948). Thus the same degree of histamine antagonism given in one patient by, for example, 300 mg. of mepyramine a day may be given in another by 900 mg. If a patient shows a small antihistamine effect with one drug of the series, a small effect will generally be given by the other drugs. In the practical administration of the drugs the variation in response is usually overcome by giving the patient an average dose, and if the symptoms are not controlled the dose is raised until either the desired effect is brought about or side-effects become too great.

In addition to this variation in individual response to the drugs the strength of stimulus evoking the treated disorder will vary from patient to patient. If the tendency to urticaria is very great even in a patient relatively sensitive to the antihistamine, it may be impossible to reach a high enough dose of the drug to control the eruption. This is more often seen in the acute attacks of urticaria.

The strength of the stimulus may also fluctuate in the same patient. For example, urticarial weals satisfactorily

suppressed by certain doses of an antihistamine may suddenly reappear coincident with additional psychological stress, or other factor. In such a case higher doses of the drug may again suppress the weals (Warin, 1950a).

Judged by the response of the induced histamine weal, children are relatively insensitive to antihistamines, and consequently a larger amount than the usual proportional age reduction of the dose is necessary to get an effect on weal formation.

The frequency of administration will vary with the length of action of the drugs: promethazine has a long action, and if given in a single dose may control the urticaria throughout the 24 hours. However, in some patients on a single dose the weals return towards the end of the 24-hour period. This could, of course, be controlled by giving a second dose, but can also often be controlled by increasing the single nightly dose. Chlorcyclizine is relatively long-lasting and it seems satisfactory to give the drug twice a day. With mepyramine it is usually necessary to give the dose three or four times a day.

Chronic urticaria quite often fluctuates regularly throughout the 24-hour period, appearing or becoming worse in the evening or in the early hours of the morning. When this is so the drugs should obviously be given to allow the maximum antihistamine effect at this time. The time taken from ingestion to full effect is about two to four hours with most of the drugs. Therefore, for example, in a patient who has a persistent slight wealing but exacerbations in the late evening, the best method of administration might be to use chlorcyclizine, 50 mg. in the morning and 100 mg. at tea-time. In a patient requiring large doses of an antihistamine one may be able to avoid unpleasant side-effects at work or during the daytime by so adjusting the times of administration.

The antihistamine drugs vary in the rapidity of onset of action after ingestion. The new drug actidil apparently reaches its maximum effect more quickly than the others, and it may prove to be the drug of choice when a rapid effect is required.

Often the type of patient who suffers from a persistent urticaria does not sleep well, quite apart from any itching, and in these cases it may be worth while giving at night one of the antihistamine drugs, which usually produces a drowsy effect. Diphenhydramine and promethazine are perhaps the best for this purpose, and, indeed, recently they have been used deliberately as mild sedatives. The drugs can be mixed, and a quite useful combination is chlorcyclizine, 50 mg. twice daily, with diphenhydramine, 50 mg. at night.

The dose should always be gradually reduced before discontinuing treatment. Otherwise, if the tendency to urticaria remains unchanged, the patient may find a sudden and full return of the rash very distressing.

Sometimes the conditions treated are periodic, with intervals of a few weeks between attacks, and in these cases it may be as well to start off with a period of regular daily administration, but later on it is often satisfactory to give the patient a supply of the tablets to take for a few days as soon as the attack begins.

Ill-effects of Antihistamines

The main side-effect of the antihistamines is drowsiness. As has been discussed, this is commoner with some drugs, and is, of course, more often encountered when large doses are employed. It is very difficult to assess the overall incidence of drowsiness. On direct questioning practically all intelligent sensitive patients having average doses will have noticed a little drowsiness. The danger of drivers and workmen in hazardous occupations taking the drugs is of course present, but has probably been overemphasized. Under such circumstances the first dose should, if possible, be taken at a week-end or, if more urgent, in the evening after returning home. In the clinic a number of public transport drivers and a motor-cycle "speedway" rider have been treated for long periods.

Many other side-effects have been described; these include dryness of the mouth, headache, blurred vision, dysuria, nightmares, depression, and other mental changes.

A curious effect is that of a twitching sensation, which is usually felt more in the legs. The muscles ache and the patient is constantly moving and stretching the limbs. Restlessness and a desire to get up and walk about are often felt. This side-effect was first noticed with promethazine (Warin, 1950b), but during the past two years it has been noted with chlorcyclizine and also with diphenhydramine. The symptoms may not be described by the patient, but are not uncommon if specifically inquired about.

Mepyramine and tripeleminamine sometimes give rise to nausea, vomiting, abdominal colic, and diarrhoea. These side-effects are uncommon if it is remembered to give the drugs with or after meals. In potential epileptics the drugs occasionally produce fits (Churchill and Gammon, 1949).

Death associated with convulsions has been recorded in 14 cases when large overdoses have been swallowed accidentally by children. In only one of these children did the amount taken approach the therapeutic dose. This occurred in a child aged 14 months who died after accidentally taking mepyramine tablets, the dose of which was unknown, but assessed at 2-300 mg. (Prain, 1950).

Wyngaarden and SeEVERS (1951) mention reports of three cases of haemolytic anaemia and nine cases of agranulocytosis. In one of the latter the patient, who had mepyramine for three months, died (Glassmire, 1951). Bénard and others (1947) report the case of a patient who died with jaundice and anaemia, but this did not appear to be definitely related to the small dose of "anergan" administered.

Considering the vast amount of the drugs used throughout the world, these few cases have little significance, and it seems that in general these substances are relatively free from serious toxic effects in therapeutic doses, even when administered for prolonged periods. Some patients in the clinic have now received regular and continuous treatment for three to four years without any deleterious effects. There is no definite evidence that tolerance to the antihistamine effect of the drugs occurs. Certainly the drowsy side-effects often become less after a few days and patients may think that they are becoming tolerant to the drugs. It is also possible that the tendency to urticaria becomes greater and gives rise to an increase in weals in a patient in whom the rash was previously reduced, so creating an impression that tolerance was developing. However, the degree of reduction of the induced histamine weal after many months' treatment is unaltered (Warin, 1948).

Skin Disorders Affected

Acute chronic and papular urticaria, dermatographism, and the urticarial response from stings and bites can all be affected. The weals may be completely suppressed or they may just be reduced in number and size according to the level of antihistamine effect obtained. If the underlying stimulus to the urticarial reaction is considerable, as may occur with drug or food urticaria, or if the patient is relatively resistant to the drugs, as, for example, in children with papular urticaria, the weals may not be obviously affected by the doses commonly prescribed.

Although it is not intended here to discuss in detail the clinical value of suppressing or reducing the weals in urticaria, the main conclusions might be mentioned. When the attack is self-limited, as in acute or recurrent urticaria, symptomatic relief with the drugs will have an obvious place in treatment. In chronic urticaria the weals are reduced or suppressed only so long as the drugs are given, and treatment may have to be continued for many months. The period that the underlying tendency to wealing lasts is probably neither shortened nor prolonged by such treatment, but as in most cases considerable relief is obtained

it is thought that antihistamine treatment has an important place in the management of these cases.

It is very difficult to decide how much giant urticarial swellings are affected by antihistamines. In such giant urticaria (angioneurotic oedema or Quincke's oedema) the oedema is largely in the subcutaneous tissues. These swellings may or may not occur in association with chronic urticaria. Clearly they do not respond to antihistamines as well as the ordinary dermal weals, and when both conditions are present the dermal weals can often be completely suppressed while giant swellings may still occur. Fifty-two cases with recurrent giant swellings have been treated, and, although it is very difficult to institute adequate controls in a condition with such irregular manifestations, 40 patients have had a reduction in the number and size of swellings when on antihistamines. Furthermore, there was usually a reduction in the severity and length of time the swellings were present if the drugs were given only at the earliest possible stage in an attack. It therefore seems that, although not affected as much as dermal weals, subcutaneous swellings are reduced.

A type of wealing may occur in association with certain other eruptions, including dermatitis herpetiformis, erythema multiforme, and actinic prurigo. An attempt to assess the effect of antihistamines on these conditions has been made, the antihistamine effect being checked by noting the reduction of induced histamine weals and using a mild sedative in the control periods (Warin, 1950a). In 10 cases of dermatitis herpetiformis it was concluded that, although one or two patients appeared to be improved, in general no specific action on this condition could be demonstrated. Since then a number of cases have been treated, and it has appeared that the cases benefited have been those in which the weal element of the rash has been a prominent feature. Ten cases of actinic prurigo were also assessed in a similar manner; although conclusions were not definite there was apparently some effect from antihistamines. It has proved very difficult to decide whether or not erythema multiforme lesions are reduced.

The eczematous dermatitis reaction affects the epidermis chiefly, but in some cases the skin is raised and tense owing to an associated dermal oedema. In my experience it is only this latter type of the eczematous dermatitis reaction which is affected, and then only with regard to the dermal oedema. The drugs have been used to reduce pruritus from various causes, but it is only the type associated with wealing, as in urticaria, that can regularly be affected.

From time to time it has been claimed that certain other eruptions are affected by the drugs, but as experience becomes wider the number of conditions benefited becomes smaller and it may well be shown eventually that the only conditions affected are those in which wealing is part of the eruption. Halpern (1952) has suggested that the main effect of antihistaminic substances is on the neuromuscular mechanism of certain small vessels. As wealing is dependent on the dilatation of small vessels in the dermis, it would seem likely that the main action of the drugs is to antagonize the dilatatory action of histamine on the dermal vessels and to a less extent on the subcutaneous vessels.

Summary

The antihistamine drugs available in this country are listed and compared.

Certain practical points in administration of the drugs are mentioned.

Ill-effects of the drugs are discussed.

The skin disorders affected are discussed, and it would seem possible that the only conditions of the skin which are benefited by antihistamines are those in which wealing is part of the eruption.

I would like to express my thanks to Dr. C. D. Evans for so kindly referring many patients to me.

INCIDENCE OF ALLERGIC DISEASES IN GENERAL PRACTICE

BY

N. J. T. HAMILTON, M.B., B.Ch., B.A.O.

AND

B. BENDKOWSKI, M.B., Ch.B.

Barrow-in-Furness

The symptoms of allergic disorders depend upon the antigen-antibody reaction in the shock organ. Von Pirquet defined allergy as an "acquired specific altered capacity to react." Even after 50 years of research in this field, Pepys (1953) points out that this statement is still valid.

The findings of a collagen lesion in serum sickness, periarteritis nodosa, lupus erythematosus, and rheumatic fever, and the improvement in these conditions after cortisone or A.C.T.H. therapy, suggest that allergic reactions might play some part in their aetiology. We decided to investigate the incidence of five of the common allergic diseases in our practice—namely, bronchial asthma, allergic rhinitis, urticaria, atopic eczema, and drug allergy.

The practice, an industrial one comprising about 4,000 patients, is carried on from two surgeries. Details of attendances and treatment are recorded daily in each surgery. The period of this investigation was from September 1, 1952, to September 1, 1953.

Diagnosis of the Allergic Diseases

Only a brief account of the diagnosis and differential diagnosis of allergic diseases is given.

The general practitioner has the best opportunity of diagnosing common allergic diseases. A careful history-taking is most important, and should include the main complaints, details relating to the cause of illness, past medical history, family and social history, environmental background, and history of previous treatment. History-taking has been emphasized by Tuft (1949), Herxheimer (1952), Sheldon *et al.* (1953), and other allergists. The therapeutic application of adrenaline and ephedrine in acute attacks of asthma and antihistamines in allergic rhinitis and urticaria is helpful in establishing the diagnosis.

We agree with Freeman (1950) that x-ray examination of the chest in asthma is not essential. Laboratory investigations, skin tests, and estimations of vital capacity are more useful for the management of the patients than for diagnosis. Cases of chronic bronchitis and emphysema were excluded.

In allergic rhinitis a history of recurrent attacks of rhinorrhoea, sneezing, itching in the eyes, nose, and pharynx, and a general feeling of fatigue are the complaints. Examination reveals bluish oedema of the nasal mucosa and sometimes polypi. Sheldon *et al.* point out that sore throat and enlargement of cervical lymph nodes are not common

in allergic rhinitis. The finding of large numbers of eosinophils in nasal smears helps in doubtful cases.

Urticaria may be acute or chronic: the acute type generally disappears within a few days or weeks; chronic urticaria may continue for months or years (Tuft, 1949; Sheldon *et al.*, 1953). The patient complains of an itching or burning sensation. The diagnosis is made on the finding of weals, which may vary in size and shape.

Atopic eczema was diagnosed by the finding of superficial cutaneous eruptions involving the flexural surfaces; adequate history is very important (Vickers, 1952; Sheldon *et al.*, 1953).

Drug allergy presents a great problem. A memorandum on the sensitivity of antibiotics (*Med. Offr.*, 1953) emphasizes the importance of this subject. Reports of deaths attributed to phenylbutazone have appeared in the medical and lay press. Penicillin may cause dangerous or even fatal reactions (Pick and Patterson, 1953; Siegal *et al.*, 1953). Drug allergy may develop after ingestion, parenteral injections, or contact with the offending agent, and it may manifest itself in the immediate or delayed type of reaction (Rackemann, 1953; Pepys, 1953; Sheldon *et al.*, 1953). The manifestations of drug allergy are various, the commonest being the skin lesions. The most serious, however, are agranulocytosis and thrombocytopenia, and thiouracil is the common cause of the former and "sedormid" (Grant, 1953) of the latter. Diagnosis depends on history, general examination, and cessation of symptoms on stopping the offending drug.

Differential Diagnosis

The diagnosis of straightforward cases of allergic disease, like many other medical or surgical conditions, is not difficult. The elderly hypertensive and arteriosclerotic patient with incipient cardiac failure gets attacks of dyspnoea; the child with recurrent attacks of bronchitis and bronchiolitis presents wheezing and cough. Periarteritis nodosa or Löfller's syndrome (Rubin, 1947) brings on asthma-like attacks. Here the eosinophil count is of great value. Bronchogenic carcinoma is getting common, and we encountered one patient suffering from it who self-diagnosed asthma.

Septal deflections, enlarged turbinates, enlarged tonsils and adenoids, infective sinusitis, and the common cold are the conditions mistaken for allergic rhinitis.

Children like to scratch the itchy urticaria weals; urticaria should then be differentiated from scabies or chickenpox.

In atopic eczema the secondary changes resulting from scratching and infection may lead to a variety of skin abnormalities: erythema, papules, wealing, scaling, pigmentation, and lichenification. Cases of seborrhoeic dermatitis and contact dermatitis were excluded.

Results of Observations

Table I shows the age and sex incidence of the five allergic diseases. Table II gives the percentage incidence of allergic diseases. Table III shows the duration of symptoms for each group. Drug allergy is of special interest

TABLE I.—Age and Sex Incidence of Allergic Diseases

Age	Asthma		Urticaria		Allergic Rhinitis		Atopic Eczema		Drug Allergy

1	M	Atopic eczema	Urticaria
1	M	Allergic rhinitis	Atopic eczema
1	F	"	"

from the therapeutic point of view, and details of the patients suffering from it are given in Table IV. Table V shows the patients with collateral allergy—that is, suffering from more than one form of allergic disease simultaneously. Such patients have been listed once only. They are included in the group which covers the most serious of their complaints—for example, a patient with severe recurrent attacks of asthma and also hay-fever is listed with the asthma cases. This is done to avoid duplicating the figures and to keep a true picture of the incidence.

Discussion

The figures given in the tables may not represent the actual incidence of the allergic conditions in this country, but they do give the true figures for this section of the population who come to the average surgery for these complaints.

Asthma.—Of 68 asthma cases, 45 fall within the working-age group (20 to 70 years), and 37 suffered from asthma for over five years. Although we are not discussing the management of asthmatics we would like to mention that our attitude towards these patients was similar to that which

the average practitioner takes with his epileptic patients. They were encouraged to stay at work, kept under constant supervision, and invited to pay frequent visits to the surgery, not only for treatment, but to report their progress. The results were good, and most of them are usefully employed.

Urticaria.—Out of 72 patients 32 were under 5 years of age. As is well known, "spots" usually compel most parents to attend the surgery promptly, hence the high proportion of small children in this group. Table III shows that 53 cases were of the acute variety, lasting less than four weeks. Some mothers could trace the offending allergen to foods. Sheldon *et al.* (1953) explain the greater incidence of food allergy in children by the fact that small children appear to absorb undigested food particles more readily than adults.

Allergic Rhinitis.—As stated before, these figures may not represent a true picture of this condition. The general public tend to neglect or ignore the usual allergy, and the children who undoubtedly suffer from it are labelled as "tonsils and adenoids." Doctors often make this mistaken diagnosis. There were only 30 cases, and only one had the condition for less than six months. The rest had suffered for two years or more. One child under 5 was diagnosed, and only four patients aged 5 to 19. There were 23 cases over the age of 30. Table V shows that 20 allergic patients had allergic rhinitis as collateral allergy and were therefore not included in these figures.

Atopic Eczema.—This condition tends to occur with acute exacerbations, and the figures support this clinical finding. Only five children were affected by it, and 22 patients were over 20. Seventeen patients had this condition for less than one year, and only six had it for more than two years.

Drug Allergy.—In this group 12 patients suffered from definite drug allergy. In each case the symptoms lasted less than a month; 11 of the patients were over 20 years of age. The list of offending drugs becomes longer every day, and the incidence of drug allergy must vary with the habits of individual doctors in drug prescribing. The unjustified use of well-recognized potential drug allergens without clear indication will greatly alter these figures—for example, penicillin ointments and creams for all types of skin blemishes or sulphonamide tablets for elevation of temperature. We tend to avoid antibiotics in local applications, and do not use heavy metals and other drugs recognized to give a high incidence of drug allergy, especially if alternative measures will suffice. In fairness to the drug manufacturers it should be stated that certain drugs are often blamed as allergens when some inactive ingredient in the pill or medicine is the actual allergen. Indeed, some useful drugs have been banished into oblivion because of slight reactions which may have been wrongly attributed to their use. Lastly, drug allergy may give rise to some very serious and sudden reactions, and this should be kept in mind when drugs are given parenterally.

Summary

Observations were made for a period of twelve months on the incidence of five allergic conditions: asthma, urticaria, allergic rhinitis, atopic eczema, and drug allergy in a general practice.

Tables give the details of these observations.

The findings and their significance are discussed.

Special note is made of drug allergy.

EPIDEMIC OF INFECTIVE HEPATITIS IN AN OXFORD COLLEGE*

BY

G. A. BALLANCE, M.B., B.Chir.

Infective hepatitis has long been recognized as a disease due to a specific micro-organism. This was Cockayne's opinion in 1912, and during the first world war and the next few years much work was carried out confirming this opinion, and distinguishing the disease from leptospiral infection and from other bacterial causes of jaundice (Willcox, 1919; Morgan and Brown, 1927; Gardner and Brown, 1928). In the years between the wars it became generally recognized that infection was usually spread by means of personal contact of some kind (Booth and Okell, 1928; Findlay *et al.*, 1931), and in 1939 Pickles emphasized the important part probably played by droplets from the respiratory tract.

During the second world war the aetiology of infective hepatitis again became an important problem owing to the high incidence of jaundice in the Forces. A number of epidemics in this country were studied with the greatest care (Newman, 1942; Ford, 1943; Lisney, 1944); and special efforts were made to correlate the observations made by Service medical officers, both British and American (Spooner, 1944; McFarlan, 1945; Gauld, 1946). Information collected in this way confirmed the importance of personal contact in the transmission of infection; but it was recognized that this contact was often of an indirect kind, and that the virus could be transferred as readily by fingers and feeding utensils contaminated with faeces or droplets as by direct droplet infection. Also during the war it was considered justifiable to carry out transmission experiments on human volunteers, and, by using material from patients in the early stages of the disease, it was found that infection could be transmitted by inoculation with serum and by oral and nasal administration of faecal suspensions (MacCallum and Bradley, 1944; Havens *et al.*, 1944; Neefe and Stokes, 1945).

As might be expected, from the discovery of the virus in faeces, food-, milk-, and water-borne outbreaks of infective hepatitis have occasionally been reported (Neefe and Stokes, 1945; Gauld, 1946; *Hlth Bull., Edinb.*, 1943; Read *et al.*, 1946). An epidemic of this kind occurred in an Oxford college towards the end of the Hilary Term, 1950, and, owing to a fortunate combination of circumstances, it was possible to be reasonably certain when infection took place and what article of food conveyed the virus to its victims.

History of the Epidemic

The Main Wave of Infection

The outbreak first came to light on May 31, 1950, when three cases of infective hepatitis were diagnosed among undergraduate members of the college in question. Next day eight more cases were found, and on the day following another 12. These cases and all subsequent ones were distributed at random among those living in college, in college annexes, and in lodgings.

Once it was realized that an epidemic was in progress, inquiries were made, aimed at discovering any patients who had fallen ill before May 31 and who might be under the care of other practitioners. There were three such patients,

including one who had begun his illness as far back as May 22, and this date has therefore been taken as marking the onset of the epidemic. From June 2, the day on which 12 cases were discovered, cases continued to appear with decreasing frequency for another week. The last patient in this wave of infection began his illness on June 10.

Incidence of Cases: May 22 to June 10.

Date	Daily Total	Date	Daily Total	Date	Daily Total
May 22	1	May 29	7	June 5	0
" 23	0	" 30	6	" 6	0
" 24	3	" 31	2	" 7	0
" 25	1	June 1	2	" 8	1
" 26	4	" 2	0	" 9	0
" 27	6	" 3	3	" 10	1
" 28	11	" 4	1		

Between May 22 and this date—that is to say, during a period of 20 days—49 people had fallen ill with infective hepatitis, all connected in some way or other with the college, 47 of them being undergraduates. The table shows the number of cases occurring each day, and is accompanied by a histogram constructed from the figures.

Owing to its explosive nature the epidemic was regarded from the start as being due to a food- or milk-borne infection, and one of the first steps taken was to inquire among the kitchen and buttery staffs for any case of jaundice or "gastric flu" that had occurred four to five weeks previously. This inquiry proved fruitless, as did also all subsequent attempts to find an antecedent case that might have been the original source of infection.

Further light, however, was thrown on the problem on June 5 when a daughter of one of the college scouts and a patient of my practice attended surgery deeply jaundiced, having fallen ill seven days previously, on May 29—that is to say, at the height of the college infection. Next day I visited her in her home, and she admitted that she often had snacks of food in the college, and that about six weeks previously she had consumed a large plate of particularly delicious fruit salad and custard. She was quite sure that this was the only dish of food, apart from rolls and butter and pieces of cake, that she had eaten in the college during the previous few months. It seemed probable that she had acquired her infection from the same source as the undergraduate patients, and attention was therefore directed to the fruit salad and the custard as possible vehicles of the infective agent. On being questioned further, she remembered that she had eaten her helping of sweet on a Saturday evening, and that it had been left over from dinner on the previous day. Information was obtained from the college steward that fruit salad and custard had been served at dinner in hall on Friday, April 28.

At the suggestion of the medical officer of health, the problem of the date or dates of infection was next approached from a different angle. An attempt was made to discover a single meal or a small number of consecutive meals which had been eaten by all the undergraduate patients. It could be taken for granted that those living in college took their meals in hall regularly. So special attention was directed to the signing-in records of those patients who lived out of college, and who therefore lunched and dined in hall only occasionally. It was discovered that all patients in the living-out group either dined in hall on April 28 or lunched there on April 29. The menus showed that fruit salad and custard was served as a sweet on both occasions. These facts were consistent with the discoveries which had already been made about

Histogram of cases, showing distribution about a central peak.

*The Charles Oliver Hawthorne Clinical Prize essay for 1953.

the scout's daughter and her helping of sweet, and they contained the additional information that the custard was eaten on two consecutive days.

At this stage of the investigation the curious fact emerged that there were no cases of jaundice among the six members of High Table who dined in regularly, nor among the kitchen and butchery staffs, who were about 15 in number. No cases were in fact ever discovered among these groups, both of which included a proportion of young adults who, on the face of it, shared an equal risk with the undergraduates. Their escape was readily explained, however, when it was discovered that the dons had ice cream with their fruit salad, from a source outside the college; nor could there be much doubt that the kitchen and butchery staffs would have made the same choice also.

How the custard could have become contaminated was never discovered with any certainty. Presumably the virus might have gained access either to the milk from which the custard was made or to the custard itself at some stage while it was being prepared and handled. At any rate, contamination must have taken place inside the college, because had the milk been contaminated outside there would have been other outbreaks of infective hepatitis among those families and institutions which were supplied from the same source. From an inquiry carried out by the medical officer of health among general practitioners it was learnt that, although the incidence of infective hepatitis in the city was probably above the average, there was no widespread epidemic.

In order to account for the infection of those patients who missed dinner on April 28 and were presumably infected at lunch on April 29, it must be assumed that virus was carried over from one meal to the other. Custard was served at both, and it is probable that any left over from Friday's dinner would have been added to the fresh lot made for lunch on Saturday. Alternatively, receptacles which had been contaminated on the first day may still have contained sufficient virus, in spite of being washed up, to infect their contents on the second day. Although the washing-up arrangements in the college kitchen appeared to be very efficient, they may easily not have been thorough enough to destroy a relatively heat-stable virus.

A final piece of evidence in favour of the supposed dates of infection came to light later on, when it was discovered that an undergraduate guest from another college, who dined in hall on the suspected Friday night, fell ill with hepatitis on June 3—that is to say, near the peak of the college infection.

Secondary Cases

When infective hepatitis affects a closed community, a school for instance, it is common for a number of secondary cases to occur about a month after the primary wave of infection. The same thing often happens on a smaller scale in families. In the Oxford epidemic, however, probably owing to the fact that personal contact in a college is not very close, there were only three secondary cases, so far as could be discovered. One of these, the case of a patient who fell ill on June 30, came to light during the long vacation. The other two were reported during the following term after a notice asking for information on the subject had been displayed in the junior common-room. These latter were the cases of two friends who went on a hitch-hiking tour of France. One dated his illness from about June 20, and the other definitely from June 27, when he had an attack of "sunstroke," which was presumably the pre-icteric stage of infective hepatitis starting with acute febrile symptoms. Both these men were ambulant during most of the time they were jaundiced.

It could be argued that these three cases were a continuation of the main wave of the epidemic, and not due to secondary spread of infection. However, there was an interval of 10 days between the case already postulated as bringing the main wave of infection to a close and the first

case of this second group. In addition, all these later patients fell ill between 23 and 33 days after the peak of the main wave on May 28. They all admitted to having had plenty of contact with earlier patients during the term, and could easily have acquired their infection in this way.

Clinical Description

The 47 undergraduate members of the college who were affected by the main wave of infection form a conveniently homogeneous group of patients, and it seems worth while to comment briefly on the clinical aspect of their illness. The majority of them were under my own care, although some only to start with, because I had as many of them as possible transported home by car as soon as they were fit to travel. Of the remaining few who were not under my care, through the courtesy of colleagues I was able to interview and examine all but one, an undergraduate who fell ill while at home and wrote later to say that he became jaundiced on June 2.

Besides the 47 definite cases of infective hepatitis there were two others, which may have been examples of sub-icteric infection. Both patients were undergraduates who developed symptoms suggestive of the pre-icteric stage of infective hepatitis, but who never became jaundiced or passed bile-stained urine, so far as could be observed. It must be remembered that minor gastro-intestinal disturbances of a non-specific kind are always common among the undergraduate population of Oxford during the summer months.

The onset of the disease was abrupt in all the patients except two, who began their illness with an insidious malaise and a gradual loss of appetite. The great majority fell ill suddenly with shivering, sweating, and generalized aches, starting on a definite day and at a definite time which they could remember. These symptoms were usually accompanied by headaches, and in two cases the clinical picture at this stage raised a suspicion of early poliomyelitis. In neither, however, was the headache accompanied by neck stiffness or any other signs of involvement of the central nervous system, and it was not thought necessary to perform lumbar puncture. Two patients started their illness with diarrhoea and two by fainting. In one, the general constitutional symptoms were accompanied by a widespread urticarial rash. A single patient had nose-bleeds, and two complained of local joint stiffness, but neither had signs of effusion. Only two patients had symptoms of irritation of the upper respiratory tract.

Patients rarely complained of specific symptoms indicative of disturbed hepatic function at the onset of their illness. Nausea or vomiting, sometimes accompanied by abdominal discomfort, usually became their most prominent symptoms when they had already been ill for a day or two, and when fever and generalized aches and pains were beginning to subside. Shortly afterwards, darkening of the urine was usually noticed, and at this stage many patients began to feel much less ill in themselves; although in all but the very mildest cases gastric symptoms persisted and gradually became more severe. In two cases nausea improved temporarily with the subsidence of fever, but became more severe again when bile appeared in the urine. One patient denied that his appetite was ever affected, although at the onset of his illness he had a temperature of 103° F. (39.4° C.). It was often difficult to tell when bile first appeared in the urine because accuracy in this respect usually depended upon the patient's own powers of observation, or upon the stage in his illness at which he first happened to be seen by the college sister or myself. So far as could be determined, the urine became bile-stained some time between the second and eleventh day of the illness. Among four patients under close observation from the onset of their symptoms, three developed obvious bile staining when they had been ill for six days and the fourth when he had been ill for three days.

The clinical records of the icteric stage in a large number of cases are incomplete because, as already mentioned, as many patients as possible were taken home by their parents, once the nature of their illness had been established. The cardinal symptom of jaundice was present in all cases, and appeared between the fourth and the fourteenth day of the illness, with a mean about the seventh day. No cases were found in which there was bile-staining of the urine without some degree of jaundice. In 16 cases the urine, as tested by the salicyl-sulphonic acid method, gave a positive reaction for protein. In 21 cases the liver was palpable and usually tender as well. This unexpectedly low figure is probably accounted for by the fact that many of the patients were seen only in the early stages of their illness. In seven cases the spleen was palpable, and in one of these it was also noticeably tender. There seemed to be no correlation between the presence of an enlarged spleen in the early days of the illness and the subsequent development of a severe or prolonged attack. In no case was a generalized enlargement of the lymphatic glands detected. Three patients complained of generalized pruritus. Total white-cell counts were carried out on two patients early in the icteric stage, and gave figures of 5,000 and 8,000 with a film of normal appearance in each case. No other special investigations were carried out.

As a rule, by the time that jaundice had appeared the patient was afebrile and feeling better, but occasionally fever and other constitutional symptoms persisted during the first few days of the icteric stage. This occurred usually in the more severe cases, which in addition showed persistent vomiting, marked prostration, and rapid loss of flesh. In a few cases the illness was so mild that the patient experienced only a transient digestive disturbance, and had completely recovered in less than a fortnight. However, as judged by the standard of cases seen in the Middle East during the recent war, most patients had an illness of moderate severity. An attempt was made to follow up the course of each patient's illness by sending out a request for information on the following points: (1) date of return of urine to normal colour; (2) date of return of normal appetite; and (3) date when the patient considered himself perfectly fit again and/or had regained any weight lost. Thirty-nine patients sent in replies during the long vacation.

An inquiry of this sort has obvious limitations, but the results of this one were clear-cut and consistent with previous experience of epidemic infective hepatitis. In approximately a third of the cases return of appetite and the re-appearance of normal urine occurred after about two weeks' illness, and in another third after about three weeks. Among the remainder, a few took only a week to achieve normality, and the rest between four and six weeks. As was to be expected, convalescence was slow. About two-thirds of the patients took between three and five weeks to recover fully. Only three took a shorter time, and the rest between 14 and 16 weeks. Twenty-two patients reported loss of weight, two of them over a stone (10.9 kg.), and it was obvious that marked loss of weight was a feature of the disease in all but the mildest cases. The only notable symptoms reported as having occurred during convalescence were constipation and lassitude.

Two patients relapsed, one mildly and the other severely. The mild relapse was possibly precipitated by the consumption of alcohol. In the more severe case, relapse occurred four weeks after the onset of the initial attack, and while jaundice was still present. It began with an acute recrudescence of bilious symptoms. This patient took nine months to recover, but by the end of that time all tests of hepatic function were normal.

Discussion

Generally speaking, infective hepatitis is not a disease from which undergraduates suffer frequently. Apart from the victims of the epidemic described in this paper I have records of only six examples of the illness among rather

more than a thousand undergraduate cases of all kinds seen during the four years 1946-50. Not only was the occurrence of the epidemic itself an unusual event, but the features of the epidemic and the circumstances under which it occurred also raised a number of points of interest.

Mode of Infection

Although there is no doubt that infective hepatitis is usually spread by personal contact, the pattern of the Oxford epidemic was strikingly similar to that produced by other infections known to have been spread by food or drink. In particular, it was explosive, and the distribution of cases was that which would be expected if infection had taken place during a short period of time, such as one or two days; their wide "scatter" being related to the long incubation period of the disease. The circumstances of the epidemic make it improbable that all the cases could have acquired their infection by simultaneous contact, either with a patient already suffering from the disease or with a symptomless carrier of the virus. A considerable number of the victims visited the college only for the purpose of eating their meals in hall, and these occasions could hardly have provided the opportunity for sufficient personal contact to account for such widespread distribution of infection within such a short space of time.

In infective hepatitis it seems probable that infection can be transmitted either by personal contact or by the consumption of some article of food or drink containing the virus. In the epidemic under discussion all the evidence pointed to a food- or milk-borne infection, and to custard served at two meals as the particular vehicle concerned. It was never discovered how contamination might have taken place, and it is only possible to surmise that, among those handling the custard, there was a symptomless carrier of the virus, or a subclinical case of infection. Certainly, had there not been a special lookout for suggestive symptoms, some of the milder cases in the college epidemic might well have escaped detection.

Incubation Period

If it is accepted that all cases occurring between May 22 and June 10 resulted from infection that took place on April 28 and 29, the range of incubation period in this epidemic was between 23 and 42 days. These are exact figures, because fortunately both the first and last patients to fall ill consumed only one of the two crucial meals—namely, lunch on April 29. This range is consistent with the findings in other epidemics. Pickles (1939) for instance, in a batch of 40 cases, in which case-to-case spread could be accurately traced, calculated incubation periods varying between 26 and 35 days. Gauld (1946) found a rather wider range of 15 to 41 days in his small epidemic of 11 cases affecting a mountain infantry regiment drawing its water supply for a limited period from a contaminated well; while Neefe and Stokes (1945) found that incubation periods in their holiday camp epidemic varied between 14 and 39 days. Figures of the same order were found by MacCallum *et al.* (1951) to hold good for the epidemic in East Anglia studied by the Jaundice Committee of the Medical Research Council during the period 1943-7.

Attack Rate

The dean of the college kindly supplied the information that 103 graduates dined in hall on April 28, and 138 lunched on April 29. There would have been considerable overlapping between these two groups, and the dean estimated that the total number of men who consumed one or both meals would have been about 150. Out of this 150, 48 fell ill with jaundice—47 members of the college and one guest. Taking into account also the scout's daughter, this gives an attack rate of about one in three. The same figure can be obtained from the description given by Read *et al.* (1946) of their epidemic of 24 cases occurring among medical students living in a hostel.

Summary

During the summer of 1950 an explosive outbreak of infective hepatitis took place in one of the smaller Oxford colleges. The total number of cases was 52—49 occurred within a period of 20 days and comprised the main wave of the epidemic; and 3, occurring later, constituted a minor secondary wave.

Evidence was obtained from which it was reasonable to deduce that this was a food-borne epidemic, the vehicle of infection having been custard that was served at a dinner and a lunch on consecutive specified dates. No certain source of contamination of the custard was ever discovered.

The attack rate among those exposed to infection at the two meals was about 1 in 3; and the incubation period ranged between 23 and 42 days. A histogram constructed from the number of cases occurring each day shows an approximately symmetrical distribution about a single peak, and corresponds to a mean incubation period of 30½ days with a standard deviation of 3½ days.

The epidemic showed no unusual clinical features. In most cases the pre-icteric stage consisted of a well-marked febrile episode. No cases of hepatitis, without obvious bile-staining of the skin or urine, were detected with certainty. The icteric stage varied greatly in severity and duration. Convalescence was frequently prolonged. There was a relapse rate of 4%.

My thanks are due to Dr. J. F. Warin, Medical Officer of Health, City of Oxford, for his co-operation in the epidemiological investigation; and to Mr. R. E. Waller, of the Institute of Social Medicine, University of Oxford, for his help with the statistics.

"The precipitating cause of many malpractice actions is found in the unwise comments or criticism of physicians regarding treatment given to patients by other physicians. Commonly, it is criticism by a succeeding physician of the work of his predecessor on the case. Various authorities have estimated that 50 to 80% of all the suits for malpractice would be eliminated if such destructive criticism could be stopped. It is profitless to attempt to determine why physicians are so likely to criticize destructively and unethically, but the results of it are deplorable. Legitimate criticism can rest only on full knowledge of the facts as gathered from the physician who treated the patient, as well as from the patient."—Louis J. Regan, M.D., LL.B., *New Eng. J. Med.*, 1954, 250, 463.

MONDOR'S DISEASE (SUBCUTANEOUS PHLEBITIS OF THE BREAST REGION)

BY

G. M. LUNN, M.Chir., F.R.C.S.

Surgeon, Metropolitan and St. Leonard's Hospitals; Surgical Registrar, Royal Cancer Hospital

AND

J. M. POTTER, M.B., B.Chir., F.R.C.S.

Graduate Assistant, Nuffield Department of Surgery, Oxford

(Formerly of the Surgical Professorial Unit, St. Bartholomew's Hospital)

We should like to draw attention to an unusual condition characterized by the development of a subcutaneous cord in the breast region, usually along a line from the epigastrium to the axilla. The nature of this cord has given rise to speculation, but it appears to be of vascular origin, and we believe it to be a phlebitis and more particularly a periphlebitis.

The condition seems to be uncommon in this country, but, since it is self-limiting, medical advice may not be sought. Perhaps it is seen more in general practice than in hospital; some experienced general surgeons whom we have questioned have never met with it. It seems to be more common in France, where it is known as "maladie de Mondor," after Henri Mondor, who described cases in 1939, and who referred to it as "string phlebitis of the chest wall." Subsequent papers by Leger (1947), Kapitanoff, Touzard, Darbon, and Sicard (1950), and Kapitanoff and Küss (1950), all refer to it eponymously. But, in fact, the same condition was described in France in 1922 by Fiessinger and Mathieu, in America by Williams (1931) and Daniels (1932), and in this country by Robinson (1935). Adair (1950), in an article on cancer of the breast, stated that he had seen about 26 such cases over a period of 30 years, although most of them appear to have developed the lesion after a breast operation. He referred to it as a condition "which I have not found heretofore described" and which "has been confused with cancer." It is to Hughes (1952) that we owe the most comprehensive account of the disease in English. He gave details of five patients, on four of whom a biopsy was performed.

We describe five cases.

Case 1

An unmarried woman aged 50 attended hospital in July, 1951, having noticed, three weeks before, a tender cord below the breast. Her general health was good and she had had no recent illness, nor had there been a discharge from the nipple.

She was found to have a subcutaneous cord, approximately ¼ in. (6 mm.) in diameter, passing from the lower inner quadrant of the left breast to the left side of the epigastrium. Elevation of the breast made the cord stand out like a bowstring. In the breast, at the upper end of the cord there was indefinite induration, but this was not present when she was admitted a week later. The other breast and the regional lymphatic areas were normal. The breasts were well developed. We wondered whether this was an instance of lymphatic permeation from an occult carcinoma. A small portion of the cord and overlying skin were removed for examination.

Pathology.—In the subcutaneous fat there was a fibrous cord near the centre of which was a ring of smooth muscle. Within this ring was organizing tissue containing a few red cells. Outside the muscle there was connective tissue composed of collagen and fibroblasts with scattered elastic fibrils. In this tissue and around its edge were numerous capillaries. There was no suggestion of an elastic lamina. The cord was a blood vessel, probably a vein, containing thrombus, with marked fibrosis of the adventitia. Serial sections were cut and the cord was seen to divide. No malignant cells were seen. One near-by vessel also showed fibrosis of the adventitia.

When the patient was seen five months later no trace of the cord could be found.

Case 2

A married woman aged 54 was admitted to hospital in February, 1950. For two years the left nipple had been retracted. There had been pain under the breast for two weeks, but no discharge from the nipple.

The left nipple was indrawn and a little blood-stained fluid could be expressed. Passing down from the lower outer quadrant towards the costal margin was a cord attached to the skin and in the shape of an inverted Y. The breast tissue itself felt normal. The other breast was granular and there was a small mobile node in the left axilla. The cord was excised.

Pathology.—In two blocks taken from the specimen, one contained two small thick-walled blood vessels and the other a single larger vessel of the same type. The former were radicles of the larger vessel, which in serial sections was seen to divide. All lay in the subcutis and had narrow blood-containing lumina surrounded by a layer of plain muscle which was enveloped by a thick zone of cellular fibrous tissue containing scattered elastic fibres. No elastic lamina was present. Midway between the divisions of the affected vessel was a dilated lymphatic vessel, about which there were active inflammatory changes. In the subjacent breast tissue there was sclerosing adenosis.

The patient has been seen at frequent intervals, the last occasion being in January, 1953; no further lesion has developed.

Case 3

Mrs. E. K. Dawson, of Edinburgh University, very kindly sent sections from a similar case, and added that, so far as she could recall, it was the only example she had seen. We

FIG. 1.—Case 3. Showing a thin muscle band surrounded by a wide zone of fibrous tissue. The lumen is almost occluded by granulation tissue.

are indebted to her and to Mr. T. McW. Millar for details of the patient and for permission to record the case. We should add that we are responsible for the following interpretation of the sections.

A married woman aged 53 was seen by Mr. Millar in June, 1951. In the right breast there was a centrally placed carcinoma, with *peau d'orange* over the lower half of the breast. A firm

cord-like band, slightly tender, extended from the lower and outer angle of the breast and ran down the chest wall to the costal margin. On lifting the breast the band stood out, and it was obviously close to, and possibly adherent

to, the skin. The lymph nodes in the right axilla and supraclavicular fossa were enlarged. A simple mastectomy was performed and a portion of the cord removed for examination. The patient subsequently received radiotherapy.

Pathology (Fig. 1).—The subcutaneous fat contained a single thick-walled blood vessel of similar type to those described in the other cases. Its lumen was reduced to a narrow crescentic slit by cellular and vascular granulation tissue which lay within a thin band of plain muscle. The main thickness of the vessel wall was, as in the other cases, due to a wide enveloping zone of compact cellular fibrous tissue in which there were irregularly scattered elastic fibres and a few capillary blood vessels.

Two months after operation the cord-like structure was very much less obvious.

Case 4

An unmarried woman aged 51 attended hospital in December, 1951. For two years she had had recurrent trouble from a small area in the left breast, which would come up like a boil and then subside without discharging. She felt unwell when the lesion was inflamed.

Examination showed a reddened indurated area about the size of a shilling in the skin and subcutaneous tissues over the lower inner quadrant of the left breast. A small bead of pus could be expressed. A thickening cord, thought to be a thrombosed vein, was felt running downwards and medially to the epigastrium. There were enlarged nodes in the axilla.

Subsequently the inflammatory area was excised. Histologically this was reported by Dr. R. H. Cowdell to be a subcutaneous giant-cell granuloma, probably of sebaceous origin. There was no biopsy of the cord in this case.

By the following month, the cord had subsided and there had been no recurrence when she was seen in July, 1953.

Case 5

One of us, through the kindness of Mr. Reginald C. B. Ledlie, was able to see this patient, a married woman of 57, who was found to have a tender subcutaneous cord which passed downwards and somewhat medially just lateral to the left breast. Five weeks later the cord was barely palpable, but she had developed a similar lesion in the right upper forearm. Some years ago she had had, in the left upper arm, a tender cord which resolved spontaneously.

Clinical Features

The essential lesion develops in the region of the breast, more commonly in the female. It is a subcutaneous cord which is often at first painful and tender, and which usually runs along a part or the whole of a line passing between the anterior axillary fold and the epigastrium. Usually, as in all these cases, it is below the nipple. Occasionally the cord divides into two or even three, and a case has been described in which a plexiform pattern existed. Earlier authors have described cases in which these cords were found elsewhere on the chest-wall, sometimes extending far down on to the abdomen. This is not surprising if the condition is to be regarded as a phlebitis, for the subcutaneous veins of the region (Fig. 2) have the same distribution as the cords.

Sometimes there is a history of recent local trauma or muscular strain, or of some pre-existing febrile episode or malaise, with or without an obvious local focus of infection, such as was present in Case 4. Case 3 was associated with a carcinoma of the breast, but there may be no symptoms or signs other than the presence of the cord.

The cord itself may be confused with cancer, as mentioned by Adair, and as happened in Case 1. It is possible for such a cord to be associated with an early carcinoma of the breast and for the patient for this reason mistakenly to be placed in an advanced stage and denied radical treatment.

FIG. 2.—The subcutaneous veins of the anterior body wall. (Modified from C. W. Braune by Spalteholz, 1896.)

Pathology

The earlier authors (Fiessinger and Mathieu, 1922; Williams, 1931; Daniels, 1932; Robinson, 1935) attributed the lesion to a superficial thrombophlebitis, although in none of their cases was a histological examination made. Mondor (1939) described the histology in one case and concluded that the cord was either a lymphatic vessel or a vein, and favoured the former as no red blood cells were seen. Sicard (Kapitanoff, Touzard, Darbon, and Sicard, 1950) found a thrombosed vein without phlebitis. Hughes (1952), however, prefers the term "angiitis," and considers the essential lesion to be gross sclerosis around the vessel.

In the present series the three specimens examined all contained red blood cells, so that a lymphatic origin can be discounted, although it is of interest to note that in Case 2 a neighbouring lymphatic vessel was affected by the inflammatory change.

The distinction between an arteritis and a phlebitis is difficult to make, and Hughes prefers the wider term of "angiitis." However, we consider that from the thinness of the muscle band and the paucity of elastic fibres it is much more likely to be of venous origin; furthermore, analogy with similar lesions elsewhere and the location of the cords (Fig. 2) support the view that it is a phlebitis. A striking feature of the lesion is the wide zone of fibrosis around the vessel, a point stressed by Hughes.

Moschowitz (1933) gave details of six patients who presented a similar picture of a subcutaneous cord in the breast region. He examined the cord in one case and found an epithelial structure surrounded by leucocytes. He attributed the lesion to inflammation of a persistent mammary line and termed the condition "vestigial mastitis." We agree with Hughes that photomicrographs of the condition are difficult to interpret. In none of the other reported cases has such an epithelial structure been found.

No wholly satisfactory name has been found for the condition; among those suggested have been "string

phlebitis" and "phlébite en cordon," both of which are concise and describe the clinical features: Hughes favours "sclerosing peri-angiitis of the lateral thoracic wall," a term which describes the pathological features, but which is clumsy and leaves doubt about the type of vessel affected. Although Mondor was not the first to describe the condition, he was the first to study it in detail, and, as we have an affection for the eponymous, we have used the short term "Mondor's disease."

Aetiology

In three of our cases there was no apparent cause. In Case 4 it is difficult not to incriminate the infected sebaceous cyst, which was situated at one end of the cord. In Case 3 the connexion between the thrombosed vein and the breast carcinoma is not clear. Robinson (1935) attributed the lesion to muscular strain: one of his patients had been digging in the garden and the other moving heavy furniture. He compared it with the axillary "phlébite par effort." (It should, however, be mentioned that it is often the exercising of the arm that stretches the thrombosed vein and draws attention to its presence.) The French authors have also noticed the traumatic factor, and a pre-existing influenza-like illness in some cases. Adair (1950), noting the condition in post-operative cases, believes that in the majority it is "unquestionably due to too tight an application of the adhesive over the dressings, blocking the return circulation of the superficial breast veins to the axillary and subclavian veins." It is similarly possible for the breast support worn to impede the venous flow, especially when the breasts are well developed. The reason for the marked periphlebitis is not easy to determine. It is difficult not to postulate an infective agent, as was in fact present in the region in Case 4, and as was suggested by the spread of the inflammation to a lymphatic in Case 2. Clearly, many factors may be concerned in the production of phlebitis here as elsewhere in the body, and none of these factors may be obvious in a given case.

Progress and Treatment.—The lesion itself is self-limiting, and the "idiopathic" variety will resolve without treatment in a few weeks. There is no record of any case proceeding to suppuration. Any associated condition will naturally require the appropriate treatment.

Summary

Attention is drawn to the apparently little-known condition of Mondor's disease (subcutaneous phlebitis of the breast region), five cases of which are recorded.

The clinical features are described and the pathology and aetiology of the malady discussed.

The disease is in itself benign and self-limiting, and may be commoner than is supposed.

We are grateful to Sir James Paterson Ross for his help and encouragement, and for permission to publish Case 1; to Mr. C. E. Shattock for Case 2; to Mr. A. Elliot Smith for Case 4; and to Mrs. Dawson for her help. We should also like to thank Dr. J. W. Whittick and Dr. R. J. R. Cureton for considerable help with the histology.

PULMONARY OEDEMA DUE TO LATENT PHAEOCHROMOCYTOMA

BY

B. L. HARRISON, M.R.C.S., L.R.C.P., D.A.

AND

E. H. SEWARD, D.M., F.F.A.R.C.S.

Anaesthetists, Amersham General Hospital

The somewhat rare condition of phaeochromocytoma is occasionally diagnosed, but is all too often a necropsy diagnosis. Death is usually due to cerebral haemorrhage, pulmonary oedema, or ventricular fibrillation (Wood, 1950). In the case reported below an unsuspected phaeochromocytoma caused pulmonary oedema during a planned operation for repair of inguinal hernia.

Case History

A robust man of 60 complained of left sciatic pain, thought to be due to a truss he was wearing for a left inguinal hernia. He was admitted to hospital for repair of this hernia. He was robust and apparently in good health: his pulse rate in bed was 60 a minute and blood pressure 140/80 mm. Hg. For the operation he was given premedication morphine, 1/6 gr. (11 mg.), and atropine, 1/100 gr. (0.65 mg.), one hour before operation. Anaesthesia was induced with thiopentone, 0.4 g., and gallamine triethiodide, 80 mg., and maintained with cyclopropane, ether, and oxygen in a closed circuit. A No. 4 Waters airway was inserted. He was placed supine on a horizontal operating table. Respiration was almost adequate by the time he was on the table, and was assisted.

Some 20 minutes after the operation had begun the pulse became irregular at a rate of 80 and cyclopropane was discontinued. The pulse irregularity ceased almost at once, but the rate increased gradually to 120; in the course of a few minutes his skin colour changed from pink to blue and then to grey, the respiration rate increased and moist sounds were noticed, first in the trachea and then in the lungs. The face-mask was removed and mucus aspirated from nose and pharynx. When this had been done he was almost conscious and would not tolerate the airway. The operation had been completed, so he was returned to the ward. There he was conscious and reacted to questions, but cyanosis gradually increased, breathing became laboured, and he was distressed: his pulse rate was about 140 and irregular. It was realized that he had developed heart failure with pulmonary oedema of unknown cause. Oxygen was given by B.L.B. mask and from an Oxford inflator. Nikethamide was given intravenously, two doses of 2 ml.; aminophylline, 0.5 g. intravenously; morphine, 1/4 gr. (16 mg.) intravenously, with no improvement. Death occurred approximately three and a quarter hours after induction of anaesthesia.

At necropsy the lungs were congested and waterlogged, and blood-stained froth was present in all the passages. A haemorrhagic tumour, 2 in. (5 cm.) in diameter, was found in the left adrenal gland; this proved to be a phaeochromocytoma. The histological appearance was typical, the tumour consisting of sheets and columns of polygonal cells separated by a rich plexus of sinusoids with which the cells were in intimate contact. A weak chromaffin reaction was given by these cells when fixed in a solution containing potassium dichromate.

Comment

Macintosh and Mushin (1946) describe how pulmonary oedema may develop during anaesthesia in the presence of an obstructed airway. In this case there was no respiratory obstruction. Death was due to congestive heart failure and pulmonary oedema, which probably followed a sudden rise

in blood pressure and perhaps ventricular fibrillation due to outpouring of adrenaline or noradrenaline. It is uncertain why this developed during operation, but release of histamine at the site of operation may be concerned. Small injections of histamine lead to a fall in blood pressure, and following this there may be a rise in blood pressure above the normal, due to a compensatory secretion of adrenaline (Samson Wright, 1952). The mechanism in this compensation is probably the fall in blood pressure via the carotid sinus, thence via the nerve to the adrenal gland. During operation in normal subjects this complex would be unnoticed, there being no change in blood pressure, but in the presence of phaeochromocytoma it is possible that the secondary overaction of the adrenal glands may be exaggerated.

According to Graham (1951) a potentially fatal paroxysm may be induced by the anaesthesia or by the positioning of the patient. Ward, Riches, and Johnson (1952) discuss anaesthesia for removal of phaeochromocytoma. They advise against drugs which affect the myocardial irritability or cardiac rate, such as cyclopropane, trichlorethylene, and gallamine, and point out that high concentrations of ether may limit any rise in blood pressure. They recommend the use of benzodioxane to limit rise of blood pressure, and intravenous injection of procaine amide to control gross cardiac irregularity. Cobb *et al.* (1953) report the successful control of blood pressure by benzodioxane and L-noradrenaline during surgical removal of a phaeochromocytoma.

The tragedy in this case is that the patient's wife revealed after his death that for two years he had had attacks of palpitations, faintness, sweating, and pallor lasting a few minutes, followed by a sensation of exhaustion. These are very like the paroxysmal attacks described by Smithwick *et al.* (1950). The patient was ashamed of these attacks and did not mention them before operation.

Summary

A case is described in which death occurred due to pulmonary oedema which developed during a planned operation for inguinal hernia. Necropsy revealed a phaeochromocytoma of the left adrenal gland which caused the pulmonary oedema.

We would like to express our thanks to Mr. K. H. Taylor, under whose care the patient was admitted, for permission to publish the case; to Dr. L. E. Glynn for the necropsy report; and to Dr. H. J. Harris for assistance in the preparation of this article.

The hygiene of seafarers has been receiving attention from a joint International Labour Organization and World Health Organization committee in Geneva. The chairman was the vice-president of the International Shipping Federation, Norway, and Dr. W. M. Frazer, emeritus professor of public health at Liverpool, was vice-chairman. The main recommendations concern the provision of medical advice by radio, the equipment of medicine chests, and the examination of all new entrants to the Merchant Navy for tuberculosis. In general the radio facilities are considered now to be satisfactory. The committee drew up a list of minimum requirements based on the *International Pharmacopoeia* for the medicine chests of ships not carrying a doctor. The drugs in the chest are intended for use by the master on his own initiative in the case of minor ailments and after wireless advice in serious illness.

Medical Memorandum

Uterine Abnormalities in Sisters with Associated Android Features

Since the introduction of hysterosalpingography, and its increasing use in the investigation of infertility, the discovery of congenital uterine abnormalities has become increasingly common. However, uterine malformation in sisters is extremely rare, and with android features is of special interest.

CASE REPORT

A married woman aged 29 first attended the gynaecological out-patient department with a history of amenorrhoea and morning sickness for four months. The menarche occurred at 18. The menstrual cycle was 10-12/50-60 days. She had been married five years. There was involuntary infertility.

On examination a thick-set muscular female with marked hirsutism of face, trunk, and limbs, and male distribution of pubic hair, was seen. Her height was 5 ft. 2 in. (157.5 cm.). Blood pressure was 140/90. Her breasts were well developed, with prominent Montgomery tubercles. Vaginal examination revealed the uterus enlarged, consistent with a ten-weeks pregnancy, and there was moderate hypertrophy of the clitoris. She was referred to the antenatal clinic, where arrangements were made for her confinement in hospital.

At subsequent visits the uterus was noted to be asymmetrical, with a diffuse swelling to the right which could not be felt apart from the body of the uterus. At the 35th week of pregnancy she was admitted to hospital with the signs of mild pre-eclamptic toxæmia and an unstable presentation. As there was no cephalo-pelvic disproportion a uterine malformation was suspected. The toxæmia worsened in spite of rest and sedation, and, because of this and the unstable presentation, delivery by caesarean section was decided upon. At operation a bicornuate uterus was found with the pregnancy contained in the left horn. The adrenal glands were not palpated, but both ovaries appeared to be normal. A male child weighing 6 lb. 2 oz. (2.8 kg.) was delivered, and the patient made an uninterrupted convalescence, being discharged from hospital on the 17th day of the puerperium with the child breast-fed.

Further investigation was undertaken three months after delivery. By this time the child was no longer breast-fed and menstruation had been re-established. A hysterosalpingogram confirmed the presence of a bicornuate uterus, and intravenous pyelography showed a normal urinary tract. Urinary 17-ketosteroids amounted to 14.5 mg. in 24 hours. X-ray examination of the skull showed a normal pituitary fossa.

FAMILY HISTORY

On being informed that she had a double womb, the patient volunteered the information that her elder sister had been investigated at another hospital for a similar abnormality. Information from this hospital stated that this sister had been admitted with a threatened miscarriage, which had completed itself shortly after admission. Examination under anaesthesia had revealed a septate bicornuate uterus, a sound having been passed 9 cm. into the left horn and 11 cm. into the right, but hysterosalpingography had not been performed.

The elder sister agreed to attend the gynaecological out-patient department. She was 31; the menarche had occurred at 17, and the menstrual cycle was 6-8/35-40 days. She had been married nine years, and had had two pregnancies, both having terminated spontaneously at the 10th week.

Examination revealed hirsutism, but to a less degree than in the above case, and hypertrophy of the clitoris. Urinary ketosteroids were 8 mg. in 24 hours. A hysterosalpingogram showed a bicornuate uterus with non-patency of the right Fallopian tube.

The third and youngest sister, aged 22, also agreed to examination. The menarche had occurred at 14, and the menstrual cycle was 5-7/28 days. She was unmarried and nulliparous. Examination showed normal female hair distribution with normal external genitalia. Vaginal examination and hysterosalpingography, performed under general anaesthesia, revealed a normal uterus.

The three sisters had been born and brought up in Ireland and had no brothers. The mother, who still lived in Ireland, apparently had hirsutism, but unfortunately no record could be obtained of the uterus; it had been removed some 15 years previously for menorrhagia.

COMMENT

It does not seem unreasonable, in these cases, to assume a relationship between the uterine abnormalities and the presence of minor degrees of female pseudohermaphroditism, represented by the hirsutism and hypertrophy of the clitoris—the two conditions being produced by the action of androgenic hormones of adrenal cortical origin, in early foetal life, inhibiting normal fusion of the Müllerian ducts, and producing the android features. Greene (1944) produced female hermaphroditism experimentally in animals by subjecting the female foetus to the influence of androgenic hormones, and in these cases various uterine abnormalities also were produced. An example of this occurring in animal life is the sterile freemartin; here the androgenic hormone reaches the female foetus via the placental circulation. However, in experimental cases of intersexuality the earlier the influence of the androgenic hormones in foetal life the greater the degree of sex reversal. Also, as normal fusion of the Müllerian ducts has occurred by the 14th week of intrauterine life, one would expect a much greater degree of sex reversal than in the present case. In Young's (1937) series of female pseudohermaphrodites the uterus appeared either to be normal or to be absent.

Heredity.—That this factor plays a part in the production of female pseudohermaphroditism is well known, especially in its lesser degrees (Browne, 1950). Biggs and Rose (1947) were able to collect nine families affected in this way: two sisters were pseudohermaphrodites, and in four of these families both males and females were affected. That uterine malformations arising from failure of fusion of the Müllerian ducts may also be hereditary has been shown by Way (1945, 1947). In his series there were four cases in which the mother and female child both had uterine abnormalities of this type, and in one of these cases two sisters were so affected. Hunter (1950) recorded 32 cases of uterine abnormalities and added one in which the mother had a fundal depression and the daughter a uterus bicornis bicornis unicollis.

Unfortunately, in our three cases it was not possible to obtain information about the mother's uterus, but the fact that she was hirsute is suggestive that she may have been similarly affected.

Reviews

WAR SURGERY

Surgery of Trauma. Edited by Colonel Warner F. Bowers, M.C., U.S.A. With Forewords by Melvin A. Casberg, M.D., and Surgeons General of the Army, the Navy, and the Air Force. (Pp. 605; 284 illustrations. £6.) Philadelphia and London: J. B. Lippincott Company, 1953.

This book represents a considered review of war surgery based on the experiences of the medical officers of the armed forces of the United States in the second world war and the Korean war. It contains chapters written by 42 contributors, all but four of whom are officers or ex-officers of one of the fighting services.

As is inevitable in a composite work of this kind, the chapters vary considerably in their scope and their quality. The variation in scope is well seen in two adjacent chapters. Chapter 15 on vascular wounds occupies 34 pages, and, apart from a diatribe against tobacco, is chiefly concerned with peacetime technique. Chapter 16, on fractures occurring in war wounds, deals with the whole of this important subject in 17 pages, of which three and a half are devoted to reproductions of radiograms, yet succeeds in giving a lucid and admirable summary of the principles of treatment, illustrated by case reports.

There are four sections devoted respectively to the physiological aspects of the management of trauma, to regional wound surgery, to military considerations in wound management, and a short final one on research methods. Of these the second is by far the most successful. The writers on general principles know a good deal more about their subjects than about the art of clear writing, and they tend to dump down a mass of unsorted statements and unproved theories for the reader to sort out in his own time and in his own way.

Most of the chapters in the regional section are excellent; the best is Chapter 6, on cranio-cerebral trauma, by Donald Matson. He knows his stuff and knows how to write simply and clearly and to make every figure earn the space it occupies. Chapter 18 on amputations, by Leonard T. Peterson, makes a welcome retreat from the advocacy of guillotine amputations that was the official policy of the American army during the second world war. Dr. Peterson says, "The open amputation was known previously as the guillotine amputation." It was not. A war amputation, with or without flaps, should always be open, and no surgeon with any knowledge of warfare has ever advocated primary suture of an amputation stump. A guillotine amputation was one with no flaps. The fault of the guillotine amputation, and of many of those illustrated in this chapter, is that it involves needless sacrifice of tissue and usually two operations, and offers no additional safety. One of the most detailed, as well as one of the best, chapters is that on genito-urinary wounds, by Colonel James Kimbrough, who during Hitler's war made many friends in Britain. The pages on the management of the neurogenic bladder are admirable.

The book is well produced and contains an immense number of facts and figures. It is a work of reference rather than a guide for the young surgeon, but to the expert, knowing what he wants and where to look for it, it will prove a mine of factual information.

HENEAGE OGILVIE.

PREVENTIVE MEDICINE

Textbook of Preventive Medicine. By Professor Hugh R. Leavell, M.D., Dr.P.H., and Professor E. Gurney Clark, M.D., Dr.P.H. With the assistance of 19 collaborators. (Pp. 629; 28 figures. 68s.) London: McGraw-Hill Book Publishing Co., 1953.

This book is not a textbook according to the generally accepted meaning of the term in this country. Indeed, the authors specifically state that it should be used as a compendium, that it is not a textbook of epidemiology or of

biostatistics, and that it is not intended as a course in public health administration. The chief aim is to advance a philosophical concept and methods of approach to preventive medicine. It is designed mainly for the doctor entering private practice. Dr. Leavell is professor of public health practice at Harvard School of Public Health and Dr. Gurney Clark is professor of epidemiology at Columbia University. Those collaborating are drawn from many American universities and state and city health departments.

The authors wisely decline to attempt to distinguish between "public health" and "preventive medicine." They prefer to consider how the public health officer practises preventive medicine and how the family practitioner applies it—a neat, sound, and subtle distinction. The main sections of preventive medicine are all considered with great care—epidemiology, infectious diseases, nutrition, chronic illness, cancer, maternity and child welfare, mental health, and occupational health. There is an excellent chapter on biostatistics—a subject not too easily assimilated by most doctors, but this makes applied mathematics easier. The few pages on tests of significance provide a most useful and salutary restraint on enthusiasm in assessing ascertained facts.

There is much in this book about American agencies and services, and it is therefore naturally of more use to the American than to the European doctor, but even so a general knowledge of administrative arrangements in the States is useful to us for reference. But most of the chapters are of direct interest and will supply valuable stimulation in all countries where English is read or translated. The extensive references and indications for additional reading give guidance to the reader who may wish to pursue any of the extraordinary variety of special subjects referred to. The paper and binding are superlative. The printing is so unusually good that the middle-aged presbyope may enjoy the unusual experience of reading comfortably without spectacles subject to suitable remoteness of the volume. The British reader who can afford the price will be the fortunate possessor of a book which will be less useful for reference than the standard British textbooks on public health and than at least one American textbook. But it will certainly set him off on new lines of approach to preventive medicine.

C. METCALFE BROWN.

TEXTBOOK OF GYNAECOLOGY

Textbook of Gynecology. By John I. Brewer, B.S., M.D., Ph.D. (Pp. 532; 146 illustrations. 76s. 6d.) London: Baillière, Tindall and Cox, 1953.

Dr. Brewer's previous book was entitled *Gynecology* and presented the subject entirely from the standpoint of symptoms, thus reflecting the teaching plan of the gynaecological department in the medical school of the Northwestern University of Chicago. It now forms the basis of Part 2 of this new work, the first part having been added to supply the undergraduate with a more systematic account of disease to which he can refer when he leaves the bedside. Both sections are neat and compact, but the reasonable size of the book is mainly explained by the omission of embryology, anatomy, physiology, and operative treatment, and by the proper restriction of the place given to endocrine therapy. While expressing views on the pathology of certain diseases which differ from those held by most gynaecologists in Britain, the author impresses the reader by his simple common-sense advice on the handling and treatment of the patient and her complaint. The illustrations are nearly all photographs and do full justice to the art of modern photography.

The main criticism which might be levelled against the book is that the allocation of space fails to indicate or misrepresents the relative importance and frequency of various diseases. Thus Paget's disease and hydradenoma of the vulva receive as much, if not more, attention than does Bartholin cyst; and cervical pregnancy and amoebic vaginitis appear to be as important as adenomyoma of the uterus.

The dual approach to the same subject inevitably means some repetition, but this has its advantages. It is unfortunate, however, that the layout makes it necessary to consult four different chapters in order to get a composite picture of the treatment of fibroids and their complications. The selection and arrangement of subjects for an undergraduate textbook of gynaecology is extraordinarily difficult, and most of the problems can be solved only at the expense of creating others. No author can hope to do more than achieve a credit balance, and Dr. Brewer has certainly succeeded in doing this.

T. N. A. JEFFCOATE.

DIABETES AND ASTHMA

Zur Genese des Diabetes Mellitus und des Bronchialasthmas. By Professor M. Bauer. (Pp. 113. M. 9.60.) Stuttgart: Georg Thieme, 1953.

This is a difficult book to appraise and is concerned with the genesis and nature of diabetes and asthma. It appears to be the forty-ninth book produced in a series on "Work and Health," under the aegis of the German "Ministry of Work." One rather feels that this Ministry must have said to the appropriate authors, "Keep writing and we will publish."

The major part of this book is concerned with diabetes. First, the relation of trauma to the production of diabetes is discussed and no clear connexion found. The relation of the total endocrine system is then considered, and the well-known cycles of carbohydrate metabolism adequately described. Clear, but nothing new. Asthma is treated under two similar headings: is it of pure allergic origin, or does trauma (*schadigungsfolge*), including infections, and particularly bronchial ones, give the answer? The answer is elusive.

Only two sections have a reference section, fairly international. But when the writer of the introduction quotes seven German writers by name "as well as Banting and Best and others" as concerned in the discovery of the relation of the pancreas to diabetes, it leaves a blatantly Germanic and sour taste in my mouth.

R. D. LAWRENCE.

FORENSIC MEDICINE

Forensic Medicine: A Textbook for Students and a Guide for the Practitioner. By Douglas J. A. Kerr, M.D., D.P.H., F.R.C.P.(Ed.), F.R.S.(Ed.). Fifth edition. (Pp. 362; illustrated. 28s.) London: Adam and Charles Black, 1954.

This popular Scottish students' textbook appears in a fifth edition after an eight-year interval. It will be most welcome to a wide circle of both students and general practitioners who desire a concise practical guide to the subject, yet never intend to practise the art themselves. The author writes this time with the newly vested authority of the regius professorship at Edinburgh. Kerr's book has always been sound, lucid, and remarkably well illustrated: we find no change in the easy digestibility of any subject he sets out so succinctly, whether on the dry bones of legal procedure in case of death or on the more arresting subjects of wounds, asphyxia, or the sex offences: Kerr has obviously seen them—and taught on them.

This book, already distinctly fatter than its predecessors, must not grow larger. It is not a comprehensive guide to the subject, and to become voluminous would be to court disaster. It covers a remarkably large field, and Kerr has incorporated new legislature (Cremation Act, 1952, Coroners' Rules, 1953, and newer Poisons Regulations) in order to keep abreast of the times. An interesting short chapter on the history of the subject appears in this edition. A few minutiae are still dated—like the reference to "veronal" as "the most common soporific to cause poisoning," and "deaths from chloroform occur under surgical anaesthesia." We note, too, an anachronism on the wording of the English coroners' suicide verdict—which no longer uses the words "temporarily insane"—and uncertainty on the spelling of M'Naghten and even Romberg. The references for further reading must have attention next time,

for they do not appear to have taken adequate notice of the many contributions to the literature in the subject that the last 10 years have brought. But, by and large, Kerr has done a good job on the text, largely by leaving it well alone, modernizing only its law and statistics. It can be strongly recommended to the student and the general practitioner who wants everyday guidance.

KEITH SIMPSON.

HERNIA

Anatomy and Surgery of Hernia. By Leo M. Zimmerman, M.D., and Barry J. Anson, Ph.D.(Med.Sc.). (Pp. 374; 204 figures. 76s. 6d.) London: Baillière, Tindall and Cox, 1953.

This volume is the result of collaboration between a surgeon and an anatomist, both of the highest standing and wide experience. It is finely produced and superbly illustrated, and it may be taken as the last word in American experience. Naturally it deals for the most part with familiar material and with established methods, but these are well presented and illustrated with quite remarkable accuracy. Every class of hernia is described in elaborate detail, but we do not think that sufficient stress is laid on the importance of the neck of the sac. It is our own belief (we may be wrong) that when strangulation occurs it is invariably at the neck of the sac and physically due to abnormal thickening at this point. In the case of femoral hernia this is of vital importance, for if it is true the femoral ring itself is of quite secondary import. However this may be, the anatomical drawings here presented are of a very high order and worthy of close study.

The chapter by Bettman on diaphragmatic hernia deserves special mention. It gives a full and clear account of this difficult and important condition, and again the illustrative drawings are a pleasure to study and are of real value.

HENRY SOUTAR.

NEUROLOGY AND PSYCHIATRY

Progress in Neurology and Psychiatry: An Annual Review. Volume VII. Edited by Professor E. A. Spiegel, M.D. (Pp. 604. 75s.) London: George Allen and Unwin, 1953.

The association of neurology and psychiatry is closer in the United States than in Great Britain, where co-operation between the two disciplines is exceptional. Professor Spiegel, however, believes that "there is hardly a field of medicine in which the interrelationship between clinic and laboratory work is as obvious as in neurology and psychiatry."

This comprehensive book is the work of 73 contributors; the only non-American authors are Professor Sjögren and Dr. Hallgren (Stockholm), who write on genetics. The book is in four parts: the basic sciences (neuro-anatomy and neuro-physiology), neurology, neurosurgery, and psychiatry. Each contributor, an authority in his own sphere, surveys the abundant literature with a critical eye. The weekly, monthly, and quarterly spate of papers is so great that the postgraduate student finds it difficult to separate the wheat from the chaff. The chaff of this book is negligible, and although the wheat has a particular flavour it is nevertheless genuine wheat.

The psychological aspects of psychiatry receive less prominence in the volume than the physiological. While there are chapters on the neuroses, psycho-analysis, group psychotherapy, and rehabilitation, the book nevertheless gives the impression that the psyche as such is not of vital interest to the editor. The contribution on clinical psychiatry is particularly good, and there are notable chapters in Part I on general and regional physiology.

No one will read this book from cover to cover, for it is essentially a book of reference for the hospital or medical library. Few librarians—provided funds permit—would care to be without it. The general arrangement is clear and the index is good, although it omits the names of the writers mentioned in the host of references given with each chapter.

E. A. BENNET.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MAY 8 1954

SOCIAL INCIDENCE OF RHEUMATIC FEVER

For many years it has been recognized that the incidence of acute rheumatism is in some way related to poor social and environmental conditions, and attempts have been made to determine what are the important factors and how they operate. Traditionally, living in damp houses and the influence of damp climate were considered important, but there has been little consistent evidence in support of these suppositions. That overcrowding plays a part was suggested by the experience of Dudley¹ in training ships and of Bradley² in a residential school, and Perry and Roberts³ showed that the incidence of rheumatic heart disease in different wards of Bristol was highly and significantly correlated with overcrowding, as measured by the number of persons per room. Daniel,⁴ in a more detailed study in the same city, confirmed this, and in addition concluded that low family income was associated with high incidence. A study of children in Glasgow and London hospitals⁵ suggested that, although the disease was rare among the children of the well-to-do, the artisan class was subject to the greatest risk. Morris and Titmuss,⁶ on the other hand, showed that among males aged 20–35 years in England and Wales there was a steady increase in mortality from heart disease, assumed to be principally rheumatic at this age, on descending the social scale from the Registrar-General's Social Class I, the professional occupations, to Class V, the unskilled workers, and they considered that "the whole complex of poverty" was involved. They did not consider that urbanization or overcrowding as such were important influences. Knowelden,⁷ analysing mortality from heart disease at ages 15–34 years in thirty county boroughs, found a significant correlation with the proportions of the employed population in the lower social classes, but little association with overcrowding.

A major defect of many of these studies has been that they were concerned with morbidity and mortality from rheumatic heart disease and not with the incidence of the underlying condition, rheumatic fever. A factor which increases the prevalence of rheumatic heart disease might act either by increasing the frequency of attacks of rheumatic fever or by facilitating the development of heart disease in patients so attacked. Which of these two possible mechanisms is responsible cannot be determined from information on the end-result, heart disease, alone. Still further does this argument apply to studies based on heart disease mortality in which another variable, fatality from heart disease, is introduced. Since 1947, however, acute rheumatism has been notifiable in certain specified areas in England, making available for the first time routine information on the frequency of first attacks of rheumatic fever. In an analysis of these records received in the first three years of the scheme, Hewitt and Stewart⁸ conclude that, though children of unskilled workers are far more commonly affected than are children of professional and skilled workers, bad housing conditions or poverty are not the responsible factors. They emphasize the greater risk of infection in large families compared with small, and in children just attaining school age compared with children of pre-school age.

The approach to the epidemiology of rheumatic fever has changed with the wider acceptance of the fundamental part played by preceding streptococcal infections. Clinical observations of epidemics of rheumatic fever following epidemics of streptococcal infection have been supplemented by studies of anti-streptolysin titres in rheumatic children, and *Streptococcus pyogenes* has been obtained from a high proportion of throat swabs in children suffering from rheumatic fever. Some trials of prophylaxis by sulphonamide or penicillin in children who have had previous attacks of rheumatic fever have shown that a reduction in streptococcal carrier and infection rates has been associated with a reduction in the incidence of recurrences,^{9,10} but this has not always been confirmed.^{11,12} It is suggested, therefore, that the social incidence of rheumatic fever is the direct result of the social incidence of streptococcal infection.

A recent paper based on observations in Melbourne helps to clarify the picture. Holmes and Rubbo¹³ show that in the years 1938–48 the attack rate of rheumatic fever, based on hospital cases, in children living in low rental areas was three times that in high rental areas, the rate in medium rental areas occupying an intermediate position. Investigations carried out in certain schools in 1947 and 1948 revealed that the carrier rate for *Str. pyogenes* and the proportion of Dick-negative

children were both greatest in the low rental areas and least in the high rental areas. They also observed a social pattern in tonsillectomy similar to that seen by Glover in England,¹⁴ with greatest tonsillectomy rates in the higher rental areas. Within each school the streptococcal carrier rate was considerably greater in children who still had their tonsils present than in those who had undergone tonsillectomy. The authors come to the conclusion that tonsillectomy protects against rheumatic fever by reducing the streptococcal carrier rate and also the infection rate.

Holmes and Rubbo propound an interesting theory to account for the social distribution of rheumatic fever, but they have far from proved their case. For example, to clinch their argument they observed that the tonsillectomy rate for rheumatic children, 26%, was even less than that for schoolchildren in the low rental area, 35%. However, this proportion is based on information on only 250 rheumatic children out of the total of 1,469 observed in the whole period, and the effect of this selection cannot be determined. Further, although a precise age distribution is not given, there is evidence to suggest that these rheumatic children may have been younger than the school groups investigated, and this would make any comparison of tonsillectomy rates invalid.

Epidemiology is the art of welding together evidence from many sources. The many investigations into the social incidence of rheumatic fever illustrate this by the contributions of clinical observation, of field studies, of vital statistics, and of laboratory investigation. The story, by its contradictions and uncertainties, also shows that epidemiology demands clear interpretation of precise data.

PENSIONS AND THE COMMUNITY

A great deal has been heard in recent years about the burden the growing numbers of old people will throw upon the community. For this reason an authoritative study showing that the burden can be shouldered without undue strain is reassuring. Such a study was recently undertaken by a research group of the Institute of Actuaries and the Faculty of Actuaries, whose report¹ was published last week. The problem the actuaries set themselves to examine was this. At any given period the country's national income has to maintain a certain number of people who for one reason or another are not contributing to that income—because they are too young or too old, unemployed, or sick and disabled. But in twenty-five years' time those who will have to be maintained because they

are old will have increased in numbers by 50%. Not only this: they will have acquired, in the shape of pensions of all kinds, rights to consume goods and services that will have to be honoured. But if the amount of goods and services produced remains stationary, the old people's rights can be honoured only by compelling, mainly through severe taxation, the earning members of the community to consume less. If this reduction in their standard of living does not take place, if everyone is allowed to try to consume as much as before of a constant amount of goods and services, then prices will be pushed upwards and the people to suffer will be those on fixed incomes and pensions.

The best answer to this problem is a steady rise in the national income—and thus in the amount of goods and services available—large enough for the pensioners' claims on it to be met without reducing the share of others. Before the war, productivity per head is thought to have increased at the rate of 1½% per annum, and since the war there have been years when the rate was as high as 3%. If merely the lower rate is maintained over the next thirty years it will bring about, the actuaries estimate, an increase in the national income of 56%. If, in the same period, pension rights continue to grow so that everyone eventually receives a total retirement pension (including the National Insurance pension) equal to two-thirds of his average earnings, pension payments, according to the actuaries' calculations, would absorb 11% of the national income—or 14% if widows are allowed half their husbands' pensions. The estimated rise in the national income will therefore easily provide for this and for a higher standard of living for other members of the community.

The actuaries' conclusion is reassuring. But is it over-optimistic? One comment that may spring to a professional man's mind is that, even if the national income has been steadily increasing since the war, it does not seem to have improved his standard of living. A bigger national income can always be redistributed according to the fancies of the Government in power, and the heavily taxed middle-classes may well feel that they have seen precious little of the rise since the war. Are they to bear more than their fair share of the amount to be raised by taxation to meet the growing cost of State pensions—as well as any claims on the higher national income that the other social services may stake? Secondly, although it is perfectly realistic to assume that productivity per head will increase at its pre-war rate, this cannot be taken as inevitable. Since there are

¹ *The Growth of Pension Rights and Their Impact on the National Economy* 1954. London.

now virtually no unemployed resources, as there were before the war, a rise in productivity depends on more capital investment and continued technological progress. The actuaries maintain that pension schemes, by enforcing savings, will help capital investment, but they agree that they only do so indirectly. It remains to be seen whether, with all the disincentive of heavy taxation, the country's economy is flexible enough to make the constant adjustments necessary if the national income is to expand indefinitely.

The actuaries were concerned only with the burden of pensions. But old people cannot be guaranteed a certain income and then allowed to get on with it. Their health is frailer, for one thing, and they need more medical care than the younger members of the community. There is no doubt that they will throw an ever bigger burden on the National Health Service, which means that it, in its turn, will have to demand a higher share of the national income. The burden of old people cannot indeed be measured solely in money terms. They raise all sorts of problems—of where and how they should live and who should be responsible for them. The burden will have to be accepted, and the actuaries have shown that, provided there is no national disaster, the next generation of old people need not fear real poverty. But that is only the beginning.

ANTHRAX PROTECTIVE ANTIGEN

The Pasteurian method of producing active immunity against anthrax by means of a living avirulent vaccine has hitherto not been superseded in the seventy years since it was introduced. Killed vaccines are ineffective. On the other hand it is also fifty years since Bail¹ showed that the anthrax bacillus liberates a substance in the body which has an immunizing action; filtrates of fluid from the lesion were shown to have this effect. The antigen responsible was first obtained from cultures by Gladstone,² the medium used containing serum or serum albumin. In order to concentrate or isolate the antigen it would be preferable to cultivate the organism in a protein-free medium, and such cultivation on an extensive scale has now been highly successful in the hands of Belton and Strange³ at the Microbiological Research Department, Porton. The medium used contained, apart from minerals and other basal constituents, certain amino-acids, a casein hydrolysate, yeast extract, and charcoal. The antigen was obtained from culture filtrates by lyophilization or alum precipitation. Satisfactory yields were given by cultures not only of a virulent but of the avirulent "Weybridge" strain.

¹ *Zbl. Bakt., 1904, I Abt., Orig.*, 38, 266.

² *Brit. J. exp. Path.*, 1946, 27, 394.

³ *Ibid.*, 1954, 35, 144.

⁴ *Ibid.*, 1954, 35, 153.

⁵ *Z. Immunforsch.*, 1938, 94, 436.

The material was non-toxic, and in small doses produced solid immunity in rabbits and monkeys against inoculation by injection and inhalation respectively with many times the minimum lethal dose of virulent organisms. Immunization of horses with the alum-precipitated antigen (length of course unstated) yielded a serum the protective power of which was at least equal to that obtained by the usual method of immunization with a living spore vaccine.

In a second paper Strange and Belton⁴ describe attempts to purify the antigen. It may be true to say that large amounts of this material can be produced "with normal laboratory equipment" if normal is understood in a qualitative but not quantitative sense: 1,000 litres of culture were used per week, and the filtration system dealt with 230 litres in five hours. Alum precipitates from this filtrate were the starting material for a process of fractionation which yielded a protein, apparently the protective antigen itself, and a polysaccharide resembling that described by Ivanovics.⁵ The sedimentation pattern and other properties of the protein were consistent with its being a single substance. A single dose of as little as 25µg. of a good batch gave 100% protection in rabbits against challenge with 250 average lethal doses of spores.

It is by methods of this kind, feasible only in an institution with lavish and large-scale equipment, that future progress in obtaining immunizing material of a high degree of activity is likely to be achieved. This antigen has an unexampled potency and may already have been obtained in a state approaching purity. If so, it is the first of its kind, and makes the materials used for most other forms of active immunization look very crude by comparison. There appears to be no reason why it should not replace avirulent living spore vaccines for all purposes for which they are used and for any others which may suggest themselves. The duration of the immunity produced will require further study. These workers mention only that tests on monkeys after one year showed no evidence of waning resistance.

A WIDER VIEW OF EPIDEMIOLOGY

Epidemiology is usually defined as the science of epidemics, and since the term epidemic has been largely confined to the communicable diseases the uninitiated might expect the "epidemiological method" to be the technique of studying the group prevalence and incidence of infections. The term has no such restriction for Dr. John Gordon, of Harvard, who addressed the Epidemiological Section of the Royal Society of Medicine on April 30 on "The Epidemiologic Method in Modern Perspective" and hardly mentioned communicable diseases. He maintains that the techniques developed for the investigation of epidemic diseases can profitably be employed in a far wider field. Although epidemiology still has its immediate practical use as the diagnostic method of public health—its analyses and tabulations are the clinical signs on which health

officers can base diagnosis and prognosis of the mass prevalence of disease—Dr. Gordon was more concerned with its fundamental contribution to knowledge of the diseases (and also of the health) of a population.

The cause of any disease can be sought by three approaches: the clinical investigation of particular patients; the study of possible aetiological factors in the microbiological, pathological, or physiological laboratory; and the epidemiological study of the disease as it affects a number of patients and as it occurs in different geographical or social groups. The three methods of study must continuously interact. The clinician and the laboratory worker can direct attention to possible aetiological agents; and the epidemiologists in investigating them may find correlations that have little real meaning until confirmed by direct experimental study. No wonder that, as Dr. A. M. McFarlan recalled at the R.S.M. meeting, Dr. Gordon's ideal epidemiologist is one who has clinical responsibility for his patients, carries out the field as well as the laboratory investigations, and finally performs the statistical analyses. No wonder too that such an ideal individual has usually to be replaced by a team of specialists.

Dr. Gordon said little about what really constitutes the epidemiological method, and Dr. Ian Taylor's suggestion that the chief characteristic of its practitioners is an attitude of mind that can see beyond the patient in the bed still does not offer very precise guidance to the newcomer. Professor R. Cruickshank¹ gave more helpful detail in his presidential address to the Epidemiological Section two years ago. It seems that what the epidemiologists consider their method (and it differs little from what the practitioners of "social medicine" or of "preventive medicine" regard as theirs) comprises the cumulation of experience from a number of cases, and the treatment of this material by statistical methods, with particular emphasis on possible correlations with environmental or social conditions. Although the early stages of an investigation may often be based on a series of patients suffering from the disease, it is rare for one to be concluded without study of "controls," or indeed of whole population groups.

Clinicians are sometimes scornful of statisticians because their method has to be selective, and because it is not possible to describe the whole of a patient's condition in numerical terms. The epidemiologist retorts² that it is only by abstracting the data in this way that it is possible, physically or psychologically, to arrive at an unbiased assessment in studying the aetiology of disease. The wise epidemiologist will rarely hope that his work will give a final answer to the problems of aetiology. Dr. Gordon's^{3,4} own studies on the causes of death from accidents in Massachusetts are the sort that could lead to immediate remedial methods. But more often—as with current epidemiological studies of cancer, diabetes, heart disease, congenital defects such

as mongolism, and with most nutritional problems—the hope is to restrict the field within which the clinician or pathologist has to seek.

ANTIHISTAMINE DRUGS IN DERMATOLOGY

In recent years there has been a striking increase of dermatitis venenata from the use of topical applications to which the patient is sensitive: it is perhaps the most important skin disease for the practitioner to be able to recognize. Many substances of complex chemical structure have been put on the market, and the suggestion of a rational scientific purpose behind their use has made them attractive to doctor and patient. The antihistamine drugs are an outstanding example and may be assumed to have been a great commercial success. Their use has, however, been much abused. Introduced to medicine by Bovet,¹ these drugs are not the least spectacular or important of the many remarkable chemical discoveries of the last two decades. The antihistamines are of importance in experimental pharmacology and have a wide range of application in general medicine. The antihistamine effect is one common to local anaesthetics, analgesics, and the quinidine type of drug, and the antihistamines themselves share the properties of all these drugs. The range of usefulness in clinical practice may not yet have been fully explored, and it would be foolish and harmful to condemn a drug of obvious importance because of the common fault of abuse.

Because of their local anaesthetic and general sedative effects the antihistamines tend to be used for any and every itching affection of the skin and are prescribed as general sedatives internally. To apply a local anaesthetic for a local disturbance of function is as reasonable or unreasonable as to give a general anaesthetic for a more general disturbance of function. Unfortunately the local anaesthetics, and with them the antihistamines, stand high in the list of sensitizing agents, and much suffering results from the application of antihistamine drugs to the skin for the relief of itching and of eczematous dermatitis. Having become sensitized by local application, the patient will have a relapse of the dermatitis after taking antihistamine drugs by mouth and sometimes also after taking drugs of related chemical structure through cross-sensitization. The American Council on Pharmacy and Chemistry—acting upon the opinion of experienced dermatologists—has recently agreed to discontinue the acceptance of dermatological preparations of all antihistamine drugs and to omit from *New and Nonofficial Remedies* all currently accepted products in that category.² This decision would seem to be a wise one, for dermatological practice would lose little if the antihistamine drugs were entirely withdrawn. Though their use is not essential, they have a specific therapeutic effect in allergic urticaria when taken by mouth. Elsewhere in this issue Dr. R. P. Warin discusses the treatment of skin disorders, particularly urticaria, with antihistamine drugs

administered by mouth, and he concludes that probably the only conditions of the skin which are benefited by them are those in which wealing is part of the eruption. These drugs have no other legitimate place in the treatment of skin disorders, and as local applications are better avoided altogether.

ALGAE AS FOOD

In the twentieth century man is faced by two contrasting perils. He may be burnt to cinders by a hydrogen bomb, or he may succumb to slow starvation through the overcrowding of the world by his ever-increasing progeny. It was the second of these that engaged the attention of the House of Lords last week, and several of the speakers showed their awareness of the urgent need to increase greatly the production of food. Much scope still remains for improving the production of crops and livestock in many parts of the world. Scientists have long been impressed, however, by the potentialities of the sea as a source of food. All denizens of the deep, from whales downwards, depend ultimately for their nutriment on the photosynthetic activities of microscopic algae or diatoms. Would it not be possible to forestall the whale, and to collect diatoms for direct use as human food? Viscount Samuel told their Lordships, for instance, that the blue whale, feeding on plankton alone, can in two years grow to a length of sixty feet and a weight of fifty tons. In the great extent of the oceans the whales are rather sparse, however, and it would be necessary to pass about thirty tons of sea water through a fine sieve in order to collect enough diatoms to weigh one ounce when dried.

According to H. W. Milner,¹ who has recently reviewed the subject, the artificial cultivation of diatoms seems a much more hopeful proposition. Extensive studies, which have already reached the pilot plant scale both in Britain and the U.S.A., have been made with the alga *Chlorella*. This unicellular organism is remarkable both for the rapidity of its growth and for the ease with which its chemical composition can be varied by modifications in the cultural conditions. Thus it may be made to contain 7 to 88% of its dry weight as protein, 6 to 38% as carbohydrate, and 1 to 75% as fat. Unlike most land plants it is entirely edible, without the necessity of discarding a husk or stalk. According to some accounts the taste is insipid, but others suggest a similarity to anchovy paste. Obviously the palatability will depend greatly on the methods of growth and preparation. Terrestrial plants cover the ground only for part of the year, and use only about 2% of the light falling on the area which they cover. *Chlorella* can be made to cover the ground for the whole year, and can use a much higher percentage of the available light. On the sun-lit roof of a factory at Cambridge, Mass., the organism is grown in a large polyethylene tube curved into an oval ring 160 ft. in circumference. The *Chlorella* is suspended in a culture medium containing nitrate, or some other form of combined nitrogen, and air mixed with a high proportion of carbon dioxide

is forced through the system. A pump keeps the *Chlorella* moving round, and a centrifuge removes the crop when the concentration exceeds the optimum for rapid growth. A cooling system is incorporated to prevent the development of excessive heat in the culture medium.

For the manufacture of one ton of dried *Chlorella* about two tons of carbon dioxide and 1.1 tons of potassium nitrate are needed. The degree of "supercharging" to which the organism is subjected may be judged from the inclusion of 5% of carbon dioxide in the circulating air, as compared with only 0.03% in the natural atmosphere. In one year an area of one acre could provide forty tons of dried material, which when cultivated at this rapid rate would contain 50% of protein and 7% of fat. According to current estimates the price under conditions of mass production would be 25–30 cents per lb. If the yield could be doubled and the cost cut in half *Chlorella* would immediately become highly competitive with farm produce in a free market. This might well come about by the selective breeding of new strains, a point made in the House of Lords debate by Lord Stamp, who is professor of bacteriology at the Postgraduate Medical School of London. It would appear that the artificial provision of food by unicellular algae may soon leave the realms of fantasy and become solid fact.

THE ANNUAL MEETING

If the programme of the Annual Meeting published in the *Supplement* this week describes the mingled fare, both grave and gay, offered to visitors, it must perforce omit from the list that unfailing ingredient of Annual Meetings—the hospitality of the hosts. As Dr. A. L. Goodall wrote last week,¹ "Perhaps the most pleasing of the commonly heard remarks of the visitor to Glasgow is that the people are amongst the kindest and most hospitable in the world," and a warm welcome awaits those many doctors who have made arrangements to attend the meeting. Those who have not yet done so would be well advised to make them soon. The plenary sessions, which have proved so popular in previous years, are to be on sleep, food and disease, and pulmonary tuberculosis, subjects of wide interest on which it is hoped many of the visitors will speak. A scientific exhibition is again to be a feature of the meeting, and here technical ingenuity comes into its own. At least one exhibit is to be so up to date that the exhibitors, who are illustrating their current research, are not sure yet what the scope of their exhibit will be. The Scientific Sections will range over clinical medicine, and many excursions have been arranged. Moreover, in the city of Glasgow and its 500-year-old university there is much to see of special interest to medical men. It was here that Lister devised his antiseptic system of surgery, and William Hunter's museum recalls to memory the genius of an earlier pioneer in our profession. The President-Elect is Sir John McNee, for seventeen years regius professor of practice of medicine at Glasgow until his retirement last October.

CLINICAL PATHOLOGY IN GENERAL PRACTICE

PITUITARY FUNCTION

BY

G. A. SMART, M.D., B.Sc., F.R.C.P.

Reader in Medicine, University of Durham

Developmentally the pituitary body can be divided into two parts: that which derives from Rathke's pouch in the buccal cavity and which in the fully developed gland forms the anterior and intermediate part of the gland, and that developing from nervous tissue, represented by the posterior part. The intermediate part is vestigial in man, and its function, if any, has not been satisfactorily elucidated; it is not considered in this article. The anterior pituitary has quite different functions from those of the posterior pituitary and no reason is apparent why the two parts should be joined to form one anatomical structure.

Laboratory tests alone are not always sufficient to diagnose abnormal pituitary function. They can usually only be interpreted by a simultaneous consideration of the clinical findings. In particular a search for evidence of a space-occupying lesion in the region of the pituitary should never be omitted.

Posterior Pituitary

The posterior pituitary is connected by nervous pathways to centres in the hypothalamus, notably the supraoptic and paraventricular nuclei. Its secretory activities seem to

FIG. 1.—Diagrammatic illustration of the regulation of extracellular osmotic pressure by antidiuretic hormones.

depend upon the integrity of these pathways. Extracts of the gland have three main actions. In the first place, they cause a great diminution in urinary output, which has been shown to be due to increased reabsorption of water by the renal tubules; secondly, they cause generalized vasoconstriction and increased peristalsis of the intestine; and, thirdly, they produce contraction of the pregnant uterus. Only the antidiuretic activity is considered here.

It has been shown by Verney that there exist certain cells, called by him "osmoreceptors," which are probably situated in the supraoptic nucleus of the hypothalamus, and which are sensitive to changes in the osmotic pressure of extra-

cellular fluid—in other words, to the concentration of dissolved particles. Whenever this rises above normal, nervous impulses from the osmoreceptors to the posterior pituitary result in the secretion of increased amounts of "antidiuretic hormone" (A.D.H.). This causes an increase in the amount of water reabsorbed by the distal tubules of the kidney, with the consequent production of a more concentrated urine and a fall in the osmotic pressure of extracellular fluid. The system is represented diagrammatically in Fig. 1.

In contrast to the above, lack of secretion of the posterior pituitary will result in the passage of large quantities of very dilute urine and consequently in intense thirst. This is the syndrome of diabetes insipidus.

Diagnosis of Diabetes Insipidus

Clinically, deficiency of posterior pituitary secretion should be suspected whenever a patient complains of intense thirst and polyuria, and when it is found that the urinary specific gravity is never above 1005. Differentiation from diabetes mellitus should present no difficulty because of the presence of glycosuria and a high urinary specific gravity in this condition. In chronic nephritis there are proteinuria, a specific gravity of the urine fixed at about 1010, and a raised blood urea. There are, however, two conditions which can only be differentiated from posterior pituitary deficiency with more difficulty—namely, nephrogenic diabetes insipidus and polydipsia of psychological origin. The first of these two conditions is a rare familial disorder in which the renal tubules do not appear to respond to A.D.H. Differentiation can be made by the following test.

At some specified time—for example, 8 a.m.—the patient is instructed to empty his bladder and the urine obtained is discarded. Any urine passed during the next hour is placed in a bottle labelled "8 a.m. to 9 a.m." At 9 a.m. the bladder is again emptied and the urine placed in this first bottle. Another bottle labelled "9 a.m. to 10 a.m." is provided for urine passed during the second hour, and at 10 a.m. the bladder is emptied into this bottle. Pitressin, at a dosage level of 0.1 unit per 1 kg. body weight, is given subcutaneously at this time. Two further one-hourly samples of urine are obtained in the same manner as the others. The specific gravity and the volume of each of these samples is measured. There should be no restriction of water during this test unless a considerable fall in urinary output after the injection of pitressin is found; in this event, large quantities of water should not be taken until the urinary volume increases. In normal subjects who have not been on restricted fluids, in patients with true diabetes insipidus, and in those with psychological polydipsia the injection of pitressin will be followed by a considerable diminution in the rate of urinary secretion (to less than 1 ml. a minute) and by a marked increase in the specific gravity of the urine. No such change will be found in those with nephrogenic diabetes insipidus.

The following test will differentiate true diabetes insipidus from psychological polydipsia. It should only be carried out with the patient under carefully controlled conditions, otherwise the interpretation may not be satisfactory, and, furthermore, the patient may become seriously dehydrated.

Water is allowed freely, and, there being no evidence of dehydration, two one-hourly samples of urine are collected as in the above test. Water and food are then completely withheld for the next six hours and urine is collected during this period in one-hour samples. In normal subjects and in those with psychological polydipsia the specific gravity of the urine will increase considerably during the water deprivation (to above 1010) and its volume will fall. In those with true diabetes insipidus, however, and in those with nephrogenic diabetes insipidus there will be little change in the urinary specific gravity and volume.

A further test, proposed by Lewis and Chalmers, depends upon the observation that nicotine will stimulate the production of A.D.H.

Urine is collected at 10-minute intervals, and if the urinary flow does not exceed 10 ml. a minute the patient is instructed to drink more water until this level is reached during two consecutive intervals. Cigarettes are then smoked and the smoke inhaled until severe malaise or nausea and perhaps vomiting occurs (this may require up to three cigarettes), the urine being continuously collected at 10-minute intervals. In normal subjects and in those with polydipsia of psychological origin there will be a considerable diminution in urine flow and a rise in urinary specific gravity. There will be little or no effect in patients with true diabetes insipidus, nor presumably in those with nephrogenic diabetes insipidus.

Occasionally a patient with diabetes insipidus will have only a partial lesion of the A.D.H. mechanism, and in this event all these tests may have rather equivocal results.

Anterior Pituitary

On the basis of staining reactions there are three types of cells in the anterior pituitary—basophil cells, which stain with basic dyes; acidophil cells, which stain with acid dyes; and chromophobe cells, which do not stain readily at all. There is no definite evidence that the chromophobe cells secrete any hormone; it seems more likely that they are early forms of both acidophil and basophil cells.

The acidophil cells probably produce a hormone which has been called pituitary growth hormone or somatotrophic hormone (S.T.H.); and hyperplasia or a tumour of the eosinophil cells, producing excessive quantities of this hormone, gives rise to the clinical picture of gigantism or of acromegaly; conversely, lack of this hormone contributes to the picture of pituitary dwarfism. There is a considerable amount of evidence that S.T.H. is very closely allied to, if not identical with, the pituitary substance which will produce diabetes mellitus (diabetogenic hormone).

The basophil cells probably secrete many different hormones, and these seem mainly to control the activity of other endocrine glands. Because of the action of this group of hormones the pituitary has been called the "leader of the endocrine orchestra." They are (1) thyrotrophic or thyroid stimulating hormone (T.S.H.); (2) the hormone which stimulates the adrenal cortex (A.C.T.H.); (3) a substance which stimulates ovarian follicles in the female and the seminiferous tubules in the male (F.S.H.); (4) interstitial cell stimulating hormone (I.C.S.H.) or luteinizing hormone (L.H.); (5) lactogenic hormone—prolactin, which is probably identical with luteotrophic hormone (L.T.H.); Nos. 3, 4, and 5 are collectively termed the gonadotrophins. It seems certain that the

FIG. 2.—Diagram to illustrate the internal regulating arrangements of the pituitary-thyroid axis.

output of these hormones is controlled, possibly through chemical mediators, by centres in the hypothalamus. In addition, in the case of T.S.H. and A.C.T.H. the output of these substances is suppressed by thyroid hormone and by the steroids derived from the adrenal cortex, respectively. This system of control is very important and is represented by the pituitary-thyroid relationship (the so-called pituitary-thyroid axis) in Fig. 2.

It will be seen that externally administered thyroid hormone, provided the dosage is within the controlling limits of the system, will not result in any increase in thyroid hormone in the body, since there will be a suppression of

T.S.H. and a diminished output of endogenous thyroid hormone. Similarly, when cortisone is given there is a suppression of A.C.T.H. production, with consequent diminution in the activity of the adrenal cortex. This is very important, since, if cortisone which has been given therapeutically is suddenly discontinued, there is a period before the resumption of endogenous production of A.C.T.H. and consequent stimulation of increased adrenocortical activity when the patient may suffer from acute insufficiency of adrenocortical activity and may die as the result of what would normally be trivial trauma.

F.S.H. in the female stimulates the development of follicles in the ovaries, and, in conjunction with further stimulation by L.H., oestrogens are produced and maturation of the follicle with ovulation and the formation of a corpus luteum occurs. Further stimulation with prolactin or L.T.H. maintains the corpus luteum for about two weeks and results in progesterone formation. It seems probable that the oestrogens inhibit F.S.H. and stimulate L.H. production, and that, by contrast, progesterone stimulates F.S.H. and inhibits L.H. production. In addition to its action on the ovary L.T.H. will initiate lactation in mammary glands which have undergone the appropriate development associated with pregnancy.

In the male the relationship of these gonadotrophic hormones is by no means so clear, but it seems that F.S.H. stimulates the development of the seminiferous tubules, and that L.H. stimulates the Leydig cells, which, as a result, secrete androgens or masculinizing hormones.

Assessment of Anterior Pituitary Function

It can be seen from the foregoing that direct estimations of the hormones of the anterior pituitary would by themselves give no precise information about whether there was a primary pituitary disorder or not. There are, in any case, no methods of assay of these hormones available for general routine clinical use, though estimations of some are carried out in certain centres. Gonadotrophins are measured in the various tests for pregnancy, but these are derived from the placenta and are present in very much greater quantities than pituitary gonadotrophins.

Tumours of one type of anterior pituitary cell may either stimulate or depress the activity of the other cells. Thus chromophobe tumours, which in themselves have no secretory activity, usually cause a diminution in anterior pituitary function; on the other hand, eosinophil adenomas may be associated with evidence of increased or of decreased activity of the basophil cells.

Thus pituitary abnormalities must be assessed on clinical grounds and by tests of function of those peripheral endocrine glands which are under pituitary control.

On Clinical Grounds

1. By neurological and radiological evidence of a space-occupying lesion in the region of the pituitary. Such a lesion should always be looked for, although of course it is often absent.
2. By a preceding history of an obstetrical catastrophe or intense shock from haemorrhage, followed by symptoms and signs suggestive of deficient pituitary function resulting, as shown by Sheehan, from necrosis in the anterior pituitary.
3. By inference from a combination of clinical signs of various endocrine disturbances—for example, gain or loss of weight, failure of lactation, amenorrhoea, feeling of the cold, loss of libido, loss of axillary and body hair, and atrophic vaginal mucosa on the one hand, and acromegaly, masculinization, Cushing's syndrome, hirsutism, etc., on the other.
4. In childhood, by a consideration of the development of puberty, of growth rate, and of the appearance and union of epiphyses, all taken in conjunction with the patient's age.

By Tests of Function of Peripheral Endocrine Glands under Pituitary Control

The Adrenal Cortex*

(a) *Urinary 17-Ketosteroid Excretion.*—The most direct test of adrenocortical activity in common use is the estimation of the daily output of 17-ketosteroids in the urine. These substances, which stimulate the laying-down of body protein and which may also induce masculinization, are produced both by the adrenal cortex and by the interstitial cells of the testis. The whole of the urinary output in the female is thus derived from adrenal activity, whereas in the male about two-thirds of the total is derived from the adrenals and the remainder from the testes.

A quantitative 24-hour collection of urine is made and 10 ml. of concentrated hydrochloric acid is added as a preservative. This is assayed chemically for 17-ketosteroids; the normal output for 24 hours is roughly as follows, but the figures vary slightly in different laboratories: Adult males, 8 to 22 mg.; adult females, 5 to 14 mg.; children under 8 years, below 1 mg.; subjects between 8 and 20 years a gradual rise to the adult levels of the appropriate sex. In the female, values lower than the above indicate deficient secretion by the adrenal cortex. In the male, low values also usually indicate deficient function of the adrenal cortex (since this produces the major part of the 17-ketosteroids); deficient interstitial testicular secretion may result in somewhat low figures, though often they are in the normal range. If 17-ketosteroids are very low (absent or almost so) then it is probable that both the adrenal cortices and the testes are deficient and this will almost certainly result from anterior pituitary deficiency. Deficient secretion of adrenal 17-ketosteroids in both male and female may be due to a primary abnormality of the adrenal cortex or it may be secondary to anterior pituitary dysfunction. These can be differentiated by finding out whether 17-ketosteroid output varies after several days of treatment with A.C.T.H.—for example, 25 I.U. six-hourly (see below).

Increased amounts of 17-ketosteroids may result from increased stimulating activity of the anterior pituitary or from tumours of adrenal or testicular tissue.

(b) *Estimation of 11-Oxysteroids in the Plasma or Urine.*—These are the hormones secreted by the adrenal cortex, which are concerned in carbohydrate metabolism and in protecting the body against the non-specific effects of injury; cortisone and hydrocortisone are members of this group. Adequate routine methods for the estimation of these substances in plasma are not generally available, but when they do become so they will be extremely important and valuable. Routine methods for urine are in existence, the urine being collected quantitatively for 24 hours, as for the 17-ketosteroids. It will be appreciated, however, that these urinary substances are largely metabolic end-products and an exact interpretation of the findings is still not possible.

(c) *Adrenal Response to A.C.T.H.*—A final diagnosis between pituitary deficiency and adrenal cortex deficiency can be made by following the effect of injections of A.C.T.H. upon 17-ketosteroid output. Obviously, if there is no functioning adrenocortical tissue, there will be no increase in 17-ketosteroid output when A.C.T.H. is given. By contrast, when the lesion is one of the anterior pituitary, the injection of A.C.T.H. will, after an interval, result in an increased secretion of 17-ketosteroids. Details of this test vary in different centres; the one I use is as follows:

Twenty-four hour samples of urine are collected from 6 a.m. to 6 a.m. on each of two control days when no A.C.T.H. is given, and the 17-ketosteroid content of each is estimated. At 10 a.m. and 4 p.m. on each of these days blood is taken and the number of eosinophils per c.mm. is estimated. Starting at 6 a.m. 25 I.U. of A.C.T.H. is then given intramuscularly every six hours for four to seven days. On each of these days the 24-hour output of

17-ketosteroids is determined, and also at 10 a.m. and 4 p.m. blood is taken for enumeration of the eosinophils.

When there is insufficiency of the adrenal cortex—for example, in Addison's disease—there is no change in the urinary output of 17-ketosteroids and no change in circulating eosinophils. By contrast, when there is diminished function of the anterior pituitary, the output rises, usually on the second day of A.C.T.H., and even more on the third and fourth days; at the same time there is a fall in the number of circulating eosinophils and these are usually absent by the end of the third day. In cases of marked pituitary deficiency of long standing it may take five or six days before a significant response is obtained. The eosinophils are counted, because it has been found that the number of these cells per c.mm. of blood is decreased by 11-oxysteroids, and a decrease in their numbers forms a convenient index of increased secretion of these hormones.

(d) *Tests Associated with the Electrolyte- and Water-Regulating Effect of the Adrenal Cortex.*—The water diuresis test presupposes that there is no abnormality of renal function and no liver disease. The patient drinks 1.5 litres of water in the course of 15 minutes, and the excretion of urine hour by hour is recorded. Normally, over 1,000 ml. should be secreted within five hours. With decreased activity of the anterior pituitary and with primary lack of function of the adrenal cortex there is only a small diuresis or none at all during the five-hour period. If the test is repeated on the fifth or sixth day of A.C.T.H. therapy at a dosage of 25 I.U. intramuscularly six-hourly a normal response will be obtained if there is primary pituitary deficiency; in primary adrenal deficiency water diuresis will remain deficient.

(e) *Tests of Carbohydrate Metabolism.* A glucose-tolerance test carried out in the usual way shows a flatter curve than normal in hypopituitarism. In acromegaly and in other syndromes resulting from increased activity of the anterior pituitary the curve is often diabetic in type, in the former because of the diabetogenic effect of S.T.H. and in the latter because of associated overactivity of the adrenal cortex. An insulin-tolerance test carried out by following the change in blood sugar at 30-minute intervals following the intravenous injection of 0.1 unit of insulin per kg. body weight shows an abnormal degree and an abnormally prolonged period of hypoglycaemia in hypopituitarism, whereas in increased pituitary activity there may be no fall in the blood-glucose level. Care should be taken when this test is performed, since in hypopituitarism there is a risk of profound and possibly irreversible hypoglycaemia.

The Thyroid†

Thyroid function is estimated by the basal metabolic rate or by the uptake of radioactive iodine. These may show deficient function either in hypopituitarism or in primary lack of thyroid function. It is possible to stimulate thyroid activity by injections of T.S.H., and this can be used for differentiation. However, no test of this type is yet in general use.

The Gonads‡

In the female the lack of oestrogen production which accompanies hypopituitarism may be detected by the appearance of the cells in smears from the vaginal mucosa.

A small amount of vaginal secretion is aspirated into a glass tube by means of a rubber bulb. In hypopituitarism the vaginal mucosa is characteristically free from secretion and it may be very difficult to get material for a smear. However, if anything is obtained it is then spread thinly on to a clean microscope slide which is immediately plunged into a mixture of equal parts of ether and ethyl alcohol for fixing. It is of great importance that the smear should not dry before being plunged into the fixative, since this results in distortion of the cells and in alteration of their staining

*See also Dr. Russell Fraser's article on "Tests of Thyroid Function" (March 20, p. 696).

†See also Dr. G. I. M. Swyer's article on "The Assessment of Gonadal Function" (April 10, p. 866).

reactions. After fixation for at least two hours the slide can be posted, if necessary, to a suitable laboratory for staining and interpretation, but it is probably preferable to keep it in the fixing solution. It is stained with the special stain devised either by Papanicolaou or by Shorr. Interpretation should be attempted only by someone thoroughly conversant with the technique.

The chemical estimation of oestrogens in the urine is difficult and not usually necessary in the diagnosis of hypopituitarism.

In the male, testicular biopsy is sometimes used to differentiate diminution in function resulting from decreased activity of the anterior pituitary from that due to some primary testicular disorder. It is a very simple procedure and can be carried out under local analgesia. It is only occasionally necessary, and if F.S.H. estimation can be carried out will usually be unnecessary, since with primary pituitary deficiency F.S.H. output will be absent or low, whereas it will be abnormally high with primary testicular deficiency.

Conclusion

It can be seen that there is no simple test which can be applied to determine whether the anterior pituitary is functioning normally or not. Most of the tests are indirect and non-specific, pituitary function merely being inferred from their results. Such inferences cannot usually be made on the basis of one test alone, more information, either clinical or from other tests, being required. For this reason the diagnosis of anterior pituitary dysfunction can be made only by a consideration of the clinical data, taken in conjunction with the results of one or more of the tests outlined above.

ROYAL SANITARY INSTITUTE CONGRESS THE IMPORTANCE OF PREVENTIVE MEDICINE

The annual congress of the Royal Sanitary Institute was held at Scarborough from April 27 to 30. The attendance was reckoned at about 2,000, and included representatives from more than a thousand local authorities. The EARL OF FEVERSHAM, in his inaugural address as president, acclaimed the achievements of the National Health Service, which, he said, had now silenced frivolous criticisms even among the most prejudiced. At the same time he drew attention to some perils. Centralization of the hospital services had brought about a separation between preventive and curative sections of the public service, and this, unless it was checked, might deteriorate into a divorce. The great service of voluntary effort which used to centre around the hospital was also in danger of being lost. He urged that there was a great opportunity at this stage to strengthen the links between the work of hospital boards and medical officers of health by a greater concentration on preventive medicine.

The Public Health Team

The Congress met in ten sections, and there were four special conferences for workers in the public health field. Presiding over the Section of Preventive Medicine, Sir ALLEN DALEY said that the preventive services must do all in their power to make the curative services redundant, as had already been largely done in those fields which were first subjected to direct attack. For example, fever hospitals were now largely available for other hospital pur-

poses, and tuberculosis of bones and joints had become a rare disease. But the burden of ill-health was still very heavy. Typhoid fever might appear again, as it did in Croydon some years ago; smallpox might slip through the barrier; apathy might develop about immunization against diphtheria, and new diseases might appear, or old ones, like poliomyelitis and hepatitis, might become more prevalent.

Dr. HENRY VAUGHAN, former Health Commissioner of Detroit, and now Dean of the School of Public Health, University of Michigan, described the steps taken in his country to train non-medical workers for the public health team, and pointed out the need for harmonious working on the part of all concerned, down to the least experienced technical assistant.

General Practitioners and Research

The relations between general practitioners and medical officers of local authorities were declared by Dr. HUGH PAUL, M.O.H., Smethwick, to be steadily growing more cordial. Much of the work of each was now dovetailed into the work of the other. The recent inauguration of the College of General Practitioners was noteworthy from the public health point of view, and even in its infancy the new College was showing a deep and intelligent interest in research. Could not medical officers of health harness its activity to their own, and by team-work find out much more of the real causes of disease? Many general practitioners were both eager and competent to carry out research work in this field, and could be enormously helped by the staff of the health departments. What about the study of diabetes? The medical officer of health might find out from the practitioners in his area a few who would co-operate in a study of the sociology of the disease.

"The family doctor is in a unique position to know the intimate family history of his patients, and a small committee of family doctors and public health medical officers, guided perhaps by a bio-statistician, could, in the course of time, bring together a mass of useful information which might well have a bearing on the causation, the course, and the prevention of the disease."

Again, the social pathology of peptic ulcer was another urgent problem, and here the team would include the hospital, with a health visitor to follow through her inquiries in the home and in the hospital and in the home again after discharge.

Spectacular successes, Dr. Paul added, must no longer be expected. "We no longer can hope to save hundreds of lives by removing the village pump handle." Future success would be hardly won, by lengthy processes and organized team-work.

Flaws in the Health Service

Dr. C. METCALFE BROWN, in presiding over the Conference of Medical Officers of Health, took as his main subject the administration and cost of the Health Service. Nearly all responsible people, he said, rightly supported the principle of a National Health Service, but forthright criticism was needed to secure necessary adjustments. It was no comfort to a patient to be assured that poverty was no bar to a hospital bed if he found, as many did, that no hospital bed was free for him within a reasonable time. In the future administration of hospitals there was a choice between the English voluntary hospital system of employing lay administrative officers and the local government and Scottish voluntary hospital system of relying on medical superintendent administration. Gradually, slowly at first but rapidly recently, it had become apparent to most people actively concerned with hospitals that the medical superintendent was indispensable, not only for smoothing inter-departmental relations but for the protection and assistance of the patient and his family.

Strong criticism had been levelled by many knowledgeable people at the regional hospital boards on the grounds that they are unwieldy, remote, soulless, inefficient, and uneconomical. It had to be faced that the hospital service

*See also Dr. F. T. G. Prunty's article on "The Assessment of Adrenal Cortical Activity" (March 27, p. 751).

was in general no better than it was before 1948 and the cost had increased fantastically. General practitioners and public health officers in many areas had to deal daily with patients needing hospital accommodation for whom beds were not available. A multiplicity of meetings of a variety of committees were nowadays necessary for action which formerly would have been taken simply and swiftly by a local government medical officer. Administrative dynamite was required to bring about what in bygone but recent years was achieved by friendly official letters or even telephone conversations. The only remedy was to entrust hospital administration to local health authorities. Regional arrangements for consultants would still be necessary, but that could be achieved, as it had been before in some areas, by means of Hospital Joint Advisory Boards.

Examining the rising cost of the Health Service, Dr. Metcalfe Brown said that the general-practitioner service was in the main well administered, and it was not the general practitioners' fault that far too many and far too expensive drugs were absorbed by their patients. "Some contributors to the National Insurance Scheme believe they were promised and entitled to the medical earth, and they intend to get it." The public health service offered no scope for economies, as it had always been conducted on the basis of obtaining the best value for money spent. The hospital service provided the only field for far-reaching economies. There appeared to be no limit to the huge cost of the hospital service, he said, and it was difficult to see what remedy could be applied so long as the extraordinary system persisted under which policy and costs were determined by people who had no direct responsibility to the taxpayer and ratepayer. There must be a balance struck between demands for treatment and its cost, and the local authorities in whose councils the voice of the local elector was heard were the best equipped for settling this delicate problem.

Dr. Metcalfe Brown concluded his address with some brief references to research and other activities in the public health field.

Epidemiological Aspects of Poliomyelitis

The discussion at the Conference of Medical Officers of Health was on poliomyelitis, Dr. W. H. BRADLEY discussing the epidemiological aspect and Dr. J. STEVENSON LOGAN the application of present epidemiological concepts to the management of outbreaks. The latter said that in his area (Southend-on-Sea), since the beginning of July, 1952, the incidence of confirmed disease had been 1 per 1,000 of population. A few years ago it could have been said with confidence that no path of infection had been traced and that multiple cases in the same household were unknown. In 1947 a tendency to some geographical grouping of cases was noticed, and it was considered worthy of comment that an adult should develop the disease eight days after its onset in a child living next door. From that time the distribution pattern seemed progressively to become a little clearer, but it was not until 1952 that school and district spread and multiple cases in the same households were seen.

As a result of his experience Dr. Logan said that an obvious first step in prevention was the exclusion from schools and nurseries of household contacts and other children who had been in close and regular association with a notified case of poliomyelitis. Three weeks' exclusion was probably the best general rule, a period which might with advantage be extended in specific cases where there had been vague illness in the immediate environment of a notified case. It was also reasonable to exclude from their occupations all those whose work brought them into regular and sustained contact with young children. These included school-teachers and other school employees and nursery nurses and nursery attendants. At one time he had taken less stringent action with adults in these employments, but the events of 1952 had led him to alter his views. In the infected school all unnecessary re-groupings of children were clearly to be avoided. Playtime recesses should be

"staggered" for different classes, and among younger children particularly the volume of organized physical activity ordinarily included in the curriculum should be reduced.

The Disabled Child

A symposium on the disabled child, in the Section of Maternal and Child Health, was preceded by an address by Professor A. G. WATKINS, the President of the Section, on the way in which the medical schools and hospitals of the country had entered the field of preventive paediatrics. During the last ten years the schools and hospitals had broadened their outlook a great deal and the study of the healthy child had been brought within their province. Infant mortality had fallen steadily, methods of immunization had improved, preventive measures had become almost routine, and the chronic illnesses of childhood had almost disappeared.

Dr. A. R. SOUTHWOOD, Director-General of Public Health, South Australia, gave an account of Australian ways with handicapped children. Much valuable work was being done by both official and voluntary bodies, but more could be achieved with better co-ordination, and it was in that direction that progress was being made. Dr. J. D. KERSHAW, M.O.H., Colchester, made some constructive criticism of the special schools for handicapped children. The special school took the child out of the social milieu in which he had been brought up and to which he would have to return. There should be no prejudice either in favour of the special school or against it, and the decision should be made in each case on its merits. Moreover, no school placement should be final. Dr. JEAN PARKER gave an account of what is being done in Sheffield for the disabled child, especially in occupation centres for mental defectives.

Prevention in the Mental Health Field

Three important addresses were given in a symposium on problems of prevention in the mental health field. Dr. J. A. FRASER, M.O.H., North Riding, speaking from the point of view of the medical officer of a local health authority, urged that such authorities should have restored to them the powers to house defectives in residential accommodation instead of having to rely on regional hospital boards to provide so-called "hospitals." These were, he said, in the main simply hostels for defectives where no real medical treatment was carried out. Professor T. FERGUSON RODGER dealt with the relationship between social change and the prevalence of mental illness and posed certain questions which might be taken into account in any survey:

Is the speed of social change a factor in explaining the increased prevalence of mental and nervous illness?

Is the increase in psychiatric illness related to the fact that people move about the country far more than formerly?

Is mental illness more common among those who have to live in an alien culture?

Is psychiatric disorder less frequent among those who have been brought up in and remained attached to religious belief?

What effect has the economic status of a family on the probability of one of its members succumbing to mental disorder?

Dr. J. A. HADFIELD discussed the principles of parenthood in relation to mental health and made the suggestion that homes should be established where children to the number of twelve to fifteen in separate houses could be placed under house mothers. In such homes the ordinary behaviour and disorders of children could be observed and studied by one or two whole-time trained psychiatrists who would work out the natural phases of maturation and reactions to varying types of treatment. These homes would not only be research stations but training schools, where medical officers, health visitors, and others could have experience in the handling of children.

A wide range of subjects was discussed in other sections of the Congress, including housing technique as affected by modern science, hospital planning, port health, rural

sewerage, health education, animal sources of food infection, polluted watercourses, food hygiene and preparation, and the problems of young people during the transition from schoolchild to adult worker.

IMPERIAL CANCER RESEARCH FUND

The annual general meeting of the governors of the Imperial Cancer Research Fund was held at the Royal College of Surgeons on April 29. Professor H. R. Dean, chairman of the council, said that two years had passed since the Fund celebrated its jubilee, and during those two years much had happened. The Fund was formed in 1902, when the first director of the laboratory, Dr. Bashford, formulated a scheme for an inquiry into the nature, cause, prevention, and treatment of cancer. The Fund's laboratory was one of the first to be established for the study of cancer, and during the years it had made many contributions to knowledge. In the last century the knowledge of cancer was almost limited to its appearance in human beings, but with the new century and the work of their laboratory it had been recognized that cancer occurred frequently among many varieties of animals, that it could be transmitted by grafting from one animal to another, and that cancer could actually be initiated by chemical substances, by ultra-microscopic viruses, and other means. Cancer thus became a branch of experimental biology.

New Laboratories in Lincoln's Inn Fields

It was for these long-term investigations that their laboratories at Mill Hill existed, and a report on the work above the name of Dr. James Craigie, F.R.S., director of the central laboratories, was before the governors. In 1951, Professor Dean continued, the council made a very important decision. At its request the Royal College of Surgeons provided two laboratories in Lincoln's Inn Fields, especially for the investigation of problems concerning cancer in human beings. These were under the general direction of Professor Geoffrey Hadfield. The council decided that larger premises were necessary, and once more a request had been made to the Royal College, which promptly helped them by giving them a ten years' lease of No. 48, Lincoln's Inn Fields. This house had been adapted as a laboratory for the clinico-pathological research unit, and here a number of new appointments had been made, including a senior and two junior biochemists and a junior research pathologist. A consultant service in diagnostic cytology would in the course of the year be set up at No. 47, Lincoln's Inn Fields, which had also been leased from the Royal College of Surgeons. Still other problems were coming forward for investigation, and it was hoped that it might be possible to increase the facilities for long-term investigation. It was essential that this work should be carried on in Central London, within easy reach of the great London hospitals; and here Professor Dean thanked the surgeons and pathologists of the London hospitals for their ready co-operation.

Current Research

Professor Dean went on to refer to certain investigations which are set out in more detail in the annual report.* Dr. Craigie had been concerned in an investigation to discover how tumour cells managed to survive freezing and thawing. A special refrigerating unit had been installed for the preservation of experimental tumours, and this had facilitated certain kinds of work for which transplantable tumours of animals were required. Tumour material kept in a frozen state for nearly five years had shown a remarkable degree of survival. The ability to survive in the frozen state was not, of course, peculiar to cancer, but was shared by various normal mammalian cells. Dr. A. M. Begg had started research on the induction of lung cancer in mice following the introduction of carcinogens by the

*Imperial Cancer Research Fund: Fifty-first Annual Report, 1953-4.

respiratory route, and Mr. H. G. Crabtree had extended his investigations, previously reported, on chemical carcinogens. Certain azo-compounds which yield sulphanilamide on metabolic breakdown were found to delay the development of butter-yellow liver tumours in rats by 6-7 weeks. Dr. L. M. Franks had carried out an inquiry into cancer of the prostate, especially from the point of view of two neglected factors, old age and the adrenal cortex, using hamsters, which aged rapidly, and guinea-pigs, which had an exceptionally large adrenal gland. Drs. G. Lumb and J. Stretton Young had been working on the morbid histology of established breast cancer. Much other work of a miscellaneous nature had gone forward.

Mr. A. Dickson Wright, Hon. Treasurer of the Fund, presented a financial statement, showing that the total receipts from investments, contributions, and other sources amounted to just over £60,000, a slight increase on the previous year's figure. This year, for the first time, legacies not exceeding £1,000 had been credited to revenue, bringing in a further sum of over £30,000. The Fund was in the happy position of being able to point to the very high proportion of expenditure incurred in its research work and the care of its laboratory buildings. Of the £91,000 income, only £4,517 was spent on administration and £6,739 on publicity.

Viscount Halifax was re-elected President and Mr. Dickson Wright treasurer.

PROBLEMS OF THE RHEUMATIC DISEASES

SEVENTEENTH MEETING OF EMPIRE COUNCIL

The 17th annual meeting of the Empire Rheumatism Council was held at the Royal College of Surgeons on April 28, Dr. W. S. C. COPEMAN, chairman of the Executive Committee, presiding. A message was read from H.R.H. the Duke of Gloucester, the President, in which he spoke of his pleasure on learning that the Council had initiated and was financing the first Chair of Rheumatology to be established in the Commonwealth, and that Dr. J. H. Kellgren, a member of the Council, had been appointed to the professorship.

First British Chair of Rheumatology

Dr. Copeman, presenting the annual report, said that this chair—perhaps the most important development in the whole orbit of rheumatology since the Council was formed in 1936—had been established in the University of Manchester. It was in fact only the third such chair in the world, the other two being in France and in Holland. It was an important and far-reaching accomplishment, and they all had the utmost confidence in Professor Kellgren. Another event of the year had been the invitation received by the Council to submit evidence to the committee of inquiry (the Piercy Committee) of the Ministry of Labour and National Service into the provision for the rehabilitation, training, and settlement of disabled persons. A person much overlooked and ignored in considering the problems of rehabilitation was the chronic arthritic, especially the arthritic housewife, whose return to a normal way of life was one of the most rewarding, though not one of the most dramatic, concerns of modern medicine. The securing of ministerial recognition of rheumatology as a specialty within general medicine and the institution of registrarships in rheumatology in its own right had been pursued, and it was hoped that the Minister would shortly receive another deputation on the subject, when final approval would be given to proposals on these lines.

Mr. W. R. C. HALPIN, chairman of the Finance Committee, presented a report which showed that the net income for the year (exclusive of legacies) was just over £10,000; the decrease of £3,434 on the previous year was accounted for almost wholly by a decrease in donations. Medical expenditure amounted to £8,127. The Finance Committee was very anxious to increase expenditure on research projects of merit, but could do no more than funds permitted.

Dr. Copeman was re-elected chairman, and Lord Webb-Johnson vice-chairman. The hon. medical secretary (Dr. Oswald Savage), his deputy (Dr. R. M. Mason), and the parliamentary representative (Sir Hugh Linstead, M.P.) were all re-elected, together with the various committees. The meeting closed with a vote of thanks to Dr. Copeman, proposed by Mr. C. G. Izard, seconded by Dr. Dudley Hart.

Clinical Research

The annual report, which was adopted at the meeting, stated that certain work on steroid metabolism, including clinical trials of A.C.T.H., cortisone, and other steroid substances, at the Council's "Maclean" laboratory at the Hospital of St. John and St. Elizabeth, had terminated last year with the appointment of Dr. A. A. Henly to another position, but the Council's laboratory was not to be left without a successor and would continue to be used by an Empire Rheumatism Fellow for research work, for which new equipment and apparatus were now being obtained. Two clinical trials were in progress in which a number of hospitals were participating. One was to assess the value of cortisone and aspirin, and the other that of "hydrocortone." The report contained an account of completed and current researches under the Council's Fellowships. Two Fellowships had been recently instituted for specific research problems. Under one of these work had been undertaken at Sheffield on the oxidation of corticosteroids with sodium bismuthate, and had led to the development of an analytical method for the simultaneous determination of formaldehydogenic and 17-ketogenic steroids, and a routine procedure for the estimation of 17-ketogenic steroids in urine. Under the other, at St. Mary's Hospital, the examination of some enzymological aspects of connective-tissue metabolism was being conducted. Some basic research into the long-term treatment of rheumatoid arthritis, undertaken under the "Philip Gray" Fellowship, would shortly be published.

Preparations and Appliances

AN IMPROVED TYPE OF CORONARY SCISSORS

Dr. GEOFFREY SHERA, of Eastbourne, writes: The conventional type of coronary scissors has many faults: a clumsy, blunted tip unsuitable for very narrow coronary vessels and likely to disturb a small clot; the loops are too small for the average gloved hand; leverage is feeble; and the absence of any "angling" tends to tear a brittle vessel.

The new pattern illustrated here attempts to meet these defects. The tip is only just blunted, without increasing

its size. The loops are now adequate and eminently comfortable. Overriding is prevented by a "pin and socket" stop when strong pressure is required, and leverage is both powerful and effective. The "angling" allows the coronary vessels to be cut with the blade strictly in line with the lumen, and this ensures rapid and easy exposure thereof. One is much less likely to disturb a coronary clot with these scissors, and calcified vessels present no trouble owing to powerful leverage.

I am indebted to Messrs. Down Bros. and Mayer & Phelps, 32-34, New Cavendish Street, London, W.1, for their skill in executing the manufacture to my design.

Reports of Societies

Devon and Exeter Medico-Chirurgical Society

At a meeting on March 18 the president, Mr. Norman Capener, spoke of "The Hunterian Influence in Exeter," relating his talk to the development of a medical school there which had flourished during the first half of the nineteenth century. The school failed to survive the Medical Act of 1858, but while it lasted it had included amongst its teachers some outstanding figures. Dr. John Sheldon, F.R.S., had spent his last twenty years in Exeter, having retired owing to ill-health from the Westminster Hospital. He had gained notoriety through keeping the embalmed body of his mistress in his bedroom, as a pioneer of ballooning, and as an explorer for whales. But he deserved recognition for his early work on the lymphatic system. Nurtured in the Hunterian tradition was John Haddy James. He was a native of Exeter, and with Samuel Barnes was a leader in the development of the Exeter school. He joined the staff of the Devon and Exeter Hospital after serving with Wellington at Waterloo, and two years later won the Jacksonian prize for an essay on inflammation. He invented many interesting mechanical devices and was noteworthy for having introduced continuous traction in the treatment of fractures. He was one of those who assisted Charles Hastings, of Worcester, in the foundation of the Provincial Medical and Surgical Association, which later became the British Medical Association. James became its president in 1842, and the next year was one of the original Fellows of the Royal College of Surgeons of England under its new charter.

Liverpool Medical Institution

Sir Henry Cohen read a paper on "The Collagen Diseases and their Response to Cortisone and A.C.T.H.," at a meeting on March 26. Reviewing their pathology, Sir Henry discussed the ways in which fibrinoid degeneration was related to collagen. Damage to the collagen system led to disturbance in the lubrication of tissue and the transport of metabolites. He then described four collagen diseases: diffuse lupus erythematosus, periarteritis acuta nodosa, temporal arteritis, and dermatomyositis—and pointed out that similarities of pathological findings did not necessarily imply similar aetiology. He thought that periarteritis nodosa and temporal arteritis were different entities. The discovery of A.C.T.H. and cortisone had helped in the unification of collagen diseases, since it was in them that their greatest effect was found. Great, however, as had been their benefits in these diseases, they were toxic drugs, of great theoretical interest, but which would soon be superseded by newer forms of therapy. After Sir Henry's paper the annual meeting of members was held. Sir Henry Cohen was elected president for the ensuing year and was installed by the retiring president, Mr. J. B. Oldham.

Manchester Medical Society

Discussing cancer of the breast at an ordinary meeting on March 24, Mr. Hedley Atkins said that at the Guy's Hospital Breast Clinic they were searching for criteria that would enable them to predict whether the response to hormone therapy was likely to be favourable or not. Although this foreknowledge was not essential in treatment with endocrine preparations, it would be almost indispensable if the operations of adrenalectomy and hypophysectomy were shown to have definite value. An investigation to compare the results of adrenalectomy and hypophysectomy was now proceeding.

North of England Otolaryngological Society

On March 20 Mr. J. M. Wishart was installed as president at a meeting held at the Blackburn and East Lancashire Royal Infirmary. Afterwards clinical cases were shown and discussed.

Correspondence

A New Oral Diuretic

SIR,—I had the opportunity of reviewing the January 16 issue of the *Journal* and was impressed with the annotation entitled "A New Oral Diuretic" (p. 144). I was intrigued by the statements made on behalf of the new diuretic "mercloran" ("neohydrin"), which in my experience has proved to be almost as good as the parenteral diuretics. In fact, maintaining patients oedema-free with mercloran has been consummated with less difficulty than with the more potent parenteral mercurials. Therefore I was somewhat puzzled by your rather high incidence of reactions. I could not imagine that severe gastro-intestinal symptoms "develop in about two-thirds of patients after effective doses," as you report.

In my experience there have been fewer reactions with mercloran (about 10%) than with other diuretics. Moreover, the reactions when they occurred were usually mild. Considering the relationship between an effective diuretic dose and a dose large enough to provoke reaction, I have found that mercloran in nearly all instances will provide satisfactory diuresis in a dose far below the reaction level. This has been established in a report by Gold and his co-workers.¹ In addition to the high degree of tolerability which was observed in studies of over two years, I had also noted a psychological improvement in the patients. Apparently the lack of drastic response which the patients formerly experienced with the parenteral diuretic has improved the patient's attitude and nutritional status.

The Cornell University authorities, who have bioassayed this product and reported it to be unusually effective, had pointed out that in their tests the dose was necessarily administered *in toto*, even as high as nine tablets at once, and therefore some of the patients experienced gastro-intestinal reactions. The authorities also claimed that these reactions would certainly be less frequent if the doses were divided. This has been my experience and that of other investigators. It was more important to administer enough of the diuretic per day than per one dose. It is also well to point to the misconception clinicians have frequently entertained that mercurial diuretics give off metallic mercury. I believe that a review of the pharmacology texts will allay such fears. Organic mercurial diuretics do not give off free mercury. This also applies to mercloran.² According to this monograph,³ in the test for purity on this agent, the results indicated absence of ionizable mercury and other heavy metals.

Kidney function tests are being done on all of the patients attending the cardiac clinic who have been taking mercloran for a duration of from one to two and a half years. At the present time, we have not found a single patient who has presented any clinical or laboratory evidence of impairment of kidney function due to the oral mercurial mercloran. This study will be published in the near future. Through my own experience and that of other investigators in the United States, we have gained full confidence in the oral mercurial diuretic such as mercloran. I believe the British clinicians will experience similar favourable and unequivocal results.—I am, etc.,

Congenital Tuberculosis after Pleural Effusion in the Mother

SIR,—The case described by Dr. Neil Mason (*Journal*, April 24, p. 970) is of great interest from the point of view of the pathogenesis of tuberculous infection generally, and of demonstrating a special need to distinguish primary from secondary tuberculous disease in pregnant women. The

pleural effusion in the mother when five months pregnant was obviously a perifocal reaction associated with the benign primary complex. This condition does not benefit by chemotherapy as a general rule unless there are evident bacillaemic metastases (meningitis, bone and joint disease, etc.), but it may give rise in pregnant women, as in this case, to the fatal malignant primary complex in the foetus. As this condition in the foetus cannot be diagnosed until delivery, it follows that all pregnant women contracting the benign primary complex should have chemotherapy as a preventive of foetal tuberculosis.

In Dr. Mason's case the mother did not have chemotherapy during pregnancy, and she recovered clinically without it. The lesions found in the infant at death, eight days after full-term delivery, included a large caseous mass of lymphatic nodes in the area of the porta hepatis, and acute miliary foci of two distinct sizes in the lungs, spleen, and liver. These are the lesions of the malignant primary complex, complicated by acute miliary dissemination, and are invariably fatal without chemotherapy. The conditions in this case were entirely different from that of the pregnant women with any form of secondary tuberculosis, such as advanced fibro-caseous disease, where acquired resistance is strong throughout the course of pregnancy and constitutes an effective protection to the foetus, which in these circumstances is usually born healthy.

An interpretation of the sequence of events in Dr. Mason's case, based on the known facts relating to natural and acquired resistance in tuberculosis, is as follows. The mass of caseous lymphatic nodes could hardly be other than the lymphatic component of a malignant primary complex of which the primary focus in the stomach or duodenum was no longer to be seen macroscopically. The upper mesenteric site of these nodes strongly suggests infection of the foetus by the alimentary route, probably by swallowing infected amniotic fluid. Since the duration of the disease appeared to be approximately the same in mother and child, the amniotic fluid was probably infected at a very early stage in the pregnancy, and most likely during the incubation period of the infection in the mother. At this stage, a preclinical bacillaemia regularly occurs in tuberculosis, as in so many other infectious diseases, and this is usually brought to an end by acquired resistance which rises only after the primary complex is established. Infection by means of the amniotic fluid is usually massive in contrast with that by inhalation, and this would account for the large caseous mass of lymph nodes (malignant primary disease) with two later invasions of the foetal circulation giving rise to the two sizes of acute miliary foci in lungs, spleen, and liver.

A case like this is rarely observed and it should become classical. Its lesions are most important: (1) the danger to the foetus not only from malignant primary tuberculosis (acute miliary) but from benign primary tuberculosis in pregnancy; (2) the necessity to distinguish primary tuberculosis from secondary in general, and particularly because of the need for preventive chemotherapy for the foetus in the former; and (3) the neat demonstration of the operation of two fundamental factors in pathogenesis, quantity of bacilli, and acquired resistance.—I am, etc.,

Neomycin in Pyogenic Skin Diseases

SIR,—The reports by Dr. R. E. Church (*Journal*, February 6, p. 314) and by Dr. I. W. Caldwell (*Journal*, April 10, p. 871) suggest that neomycin may be the drug of first choice in the superficial pyoderms. But I would suggest that there may still be a place for other antibiotics. During the past 15 months, 304 cases of impetigo contagiosa all responded within a few days to treatment with 3% aureomycin cream. Of these cases 135 were sigilliform, and 169 were bullous and mostly widely generalized. It appears unlikely that insensitive organisms will develop in the course of rapid and successful treatment. Furthermore,

although it is generally agreed that neomycin may be applied topically with safety, it has been shown that systemic absorption may occur from topical application.¹ Although the serum concentration of neomycin was slight, this factor may have to be considered if local applications are adopted on a wide scale.

With regard to treatment of sycosis barbae, assessment is difficult but aureomycin and terramycin both appear to be of some value. Of 18 cases treated with 3% terramycin cream, 5 remained well when reviewed from 2 to 11 months after treatment had ceased, 4 cases cleared rapidly but did not report back, 3 cases continued to have occasional pustules, 1 case recurred 4 months after treatment had ceased, and 5 cases failed to improve. Six cases of seborrhoeic type showed temporary improvement. Of 28 cases treated with 3% aureomycin cream, 8 remained well when reviewed 2 to 18 months after treatment had ceased. Eight cases cleared rapidly but did not report back, 6 cases continued to have occasional pustules, 1 case recurred 11 months after treatment had ceased, and 5 cases failed to improve. Five cases of seborrhoeic type showed temporary improvement. As might be expected, duration of treatment was longer than in the cases of impetigo. In this connexion, the development of insensitive strains is of some moment also in treatment with neomycin, since neomycin may be required as an intestinal antiseptic and as a parenteral²⁻⁴ antibiotic in selected cases. It has also been shown that, *in vitro*, increase in resistance develops more regularly and rapidly to neomycin than to aureomycin, terramycin, and chloramphenicol,⁵ and that strains which have increased in resistance to neomycin also increase significantly in resistance to streptomycin.⁶—I am, etc.,

Appointment with Fear

SIR.—Dr. P. R. Saville's timely letter (*Journal*, April 17, p. 932) entitled "Appointment with Fear" deplores the increase of unhealthy, and often unfounded, fears among the British public in recent years. In a clinical lecture, the late C. B. Lockwood stated: "The human being fears death above all things; after death he fears pain, and after pain, parting with his possessions."¹ Had he been speaking to-day he might have added the fear of official infringement of his rights and liberties.

There is little doubt that most people fear the idea of pain, although they will usually bear it stoically enough when they actually have to endure it. They also fear the loss of their possessions or the ability to earn their living, but I would dispute the categorical statement that they fear "death above all things." In health, most of us dislike the contemplation of our own demise, but when people are faced with its inevitability they generally do not seem to be afraid. It has been stated that even condemned prisoners become philosophical enough once they come to realize that their fate is inevitable. It is certainly the general experience that the mortally sick and the aged generally face the end with little apprehension and sometimes even with a sense of relief. This may also be the case with those who retain their full faculties throughout.

I believe that what most people dread is a sense of uncertainty and the unknown. They fear "the shadow of uncertain ill." When they know exactly what to expect they generally cease to be fearful. Even in such a dreaded disease as cancer, I have generally found that patients are quieter in their minds once their doubts have been resolved and when they have been frankly told the truth, particularly where some method of treatment can hold out a reasonable prospect of cure or amelioration. I have never found it

advisable to attempt to delude patients into a sense of false security: they generally don't believe one if one does, and doubts as to the truthfulness of their medical adviser only tend to increase their general anxiety and augment their fears. On the other hand, no good purpose is served by proffering unasked-for information of an unpleasant character. A patient or his relatives should not generally be told bad news of this kind, unless the direct question is asked: exceptionally such information may become necessary in the patient's interests, particularly where there is hesitation to undergo some favourable line of treatment with a prospect of success.

We, as doctors, also have our especial fears, which have greatly increased in recent years: fear of the power of those authorities who now so largely control our professional lives; fear of irresponsible litigation, and, in view of some of the more recent decisions of the courts, a doubt that we may receive a full measure of justice; fear of the activities of other medical men who may be tempted to undermine our interests for their own advantage in the altered circumstances in which we now practise our profession. The most serious feature of these special medical fears is the unfavourable effect that they are having on the younger men and on entrants to the profession; this is evident from their increasing unwillingness to take appointments which carry any risk and their reluctance to undertake clinical responsibilities which should be well within their capabilities. Soon the most able types of men and women may cease to be willing to enter the profession at all. We may free our patients from unnecessary fears, to some extent, by clearing their minds of superstitions and by telling them the truth when we can, for ignorance is often the basis of fear; but neither we nor they can hope for freedom from fear unless we also regain some of those other freedoms which we seem to have lost. The public should remember that the doctor whose professional conduct is unduly influenced by the fear of personal consequences is lost, as may his patient be also.—I am, etc.,

SIR.—The letter by Dr. Paul R. Saville (*Journal*, April 17, p. 932) sounds a welcome note of sanity. He has, however, omitted to point out that we should eat nothing but raw food to be entirely safe, for we have little, if any, notion of what happens to it during cooking. What thermal decomposition products, potentially lethal, has man been consuming for many thousands of years? We have no idea; nor have we a complete list of all the essential nutrients destroyed during cooking. Needless to say, this goes not only for cooking, but also for factory processing. How do we know, indeed, that many of the "thousand natural shocks that flesh is heir to" do not in fact come from producing slow poisons by simply cooking food or from the destruction in it of things we need?

Presumably the truly cautious should not eat anything cooked, processed, or manufactured before trying it on the dog—or at least on the laboratory rat. This, it seems, is the procedure being advocated in the field of food additives. Do we know what risks we run not just from preserving and sterilizing, but even from Mum's best kitchen practices? The answer is that we don't, any more than we know fully the hazards of crossing Piccadilly at mid-day; if we did, we should not get run over there, because we'd stay on our side.

There seems to be growing a pusillanimity that is a caricature of "safety first" in food, and the nation is, I submit, at present in serious danger of suffering from acute hyper-toxic consciousness—to coin a word. Scientists, whether medical or non-medical, surely have a responsibility for preventing the spread of this condition. Unfortunately, many of them seem to be doing exactly the opposite.—I am, etc.,

A. L. BACHARACH.

Smoking and Lung Cancer

SIR.—The considerable suggestive evidence of a positive relationship between lung cancer, heavy cigarette-smoking, and urban residence may mean that (leaving out of account the possibility that city people smoke more than countrymen) excessive cigarette-smoking develops some abnormal mechanism which allows the ingestion not merely of possible carcinogens from the cigarettes themselves but, in addition, known potential carcinogens polluting the surrounding atmosphere. In short, two seemingly highly important factors—cigarette-smoking and urban residence—may operate synergistically. Heavy cigarette-smoking appears sufficient to irritate the mucosa of the respiratory tract to cause catarrh, bronchial wheezing, and reflex coughing, which continue for as long as the smoking habit persists. In industrial areas particularly, the discharge is impregnated with dark particles, including atmospheric soot. Pipe-smokers who do not inhale deeply through either mouth or nostrils appear generally to avoid this irritation and discharge.

The present writer found that a chronic "smoker's cough" which developed after heavy smoking (20 to 40 cigarettes per day) ceased immediately he gave up cigarettes. It did not reappear after pipe-smoking. Yet a mere ten cigarettes per day, even without deep inhalation through the mouth, was enough to start it off again together with a characteristic bronchial wheezing and discharge. It was believed that voluntary and involuntary inhalation of cigarette-tobacco fumes through the nostrils into the nasopharynx and bronchi might be the cause. When a cigarette-holder (with or without filter) was used, the cigarette end, as with the bowl of a pipe, was projected far enough from the nostrils to avoid nasal inhalation. Thereafter an abnormal experimental number of cigarettes (50 to 60 per day) was smoked for a week without the reappearance of the former symptoms.

It is probable, therefore, that nasally inhaled tobacco smoke caused nasopharyngeal and perhaps bronchial irritation, hypersensitivity of the mucosa, and a relatively copious watery discharge from neighbouring glands. It is not impossible that if a sufficient flow of fluid was generated by nasopharyngitis and bronchitis, this would cascade over the cilia of the respiratory trees, defeat their cleansing mechanism, and thus allow the carriage of tobacco soot and, in addition, inspired atmospheric soot into the bronchioles and alveoli. There is already experimental evidence^{1,2} that radio-opaque dusts mixed with fluids and introduced into the trachea of cats did penetrate right into the alveoli. The cilia were rendered inoperative by the fluid.

Although it is more reasonable to assume that a nasopharyngeal secretion would be blocked at the epiglottis and pass down the oesophagus, the wheezing and bubbling in the bronchi of habitual cigarette-smokers suggest that fluid (unless it is all produced by a local bronchitis) may indeed creep into the bronchi at night without operating a cough reflex. The matter was attacked experimentally by the introduction into the nasopharynx of "dionosil" in successive evening dosages of 6, 10, and 12 minims (0.3, 0.6, and 0.7 ml.) respectively after heavy cigarette-smoking without holder. Radiography showed a negative result—the material apparently went down the oesophagus, although rales and rhonchi could be detected with the stethoscope each morning. It is possible that the oily suspension used was insufficiently dilute to pass over the epiglottal bridge. A second attempt, involving the like ingestion of radio-active gold colloid, was projected, but this has not been made since there appears to be already available clinical evidence that a post-nasal drip does sometimes overcome the cough reflex and result in a mucous creep into the bronchi. Among children in particular lipid pneumonia can occur in healthy individuals after "the prolonged use of an oil spray or the instillation of oil in the upper respiratory passages."³

Even if the irritation induced by inhaled smoke is confined to the bronchi, the working hypothesis that inspired particles of atmospheric soot, as well as those of burnt tobacco, may be caught up in a mucus discharge and carried deep into the lungs is not invalidated. It matters little whether the abnormal flow of mucus is produced in the nasopharynx or in the bronchi so long as it is sufficiently copious to entrap inspired foreign particles, to overflow the cilia in such a way as to carry injurious substances into the bronchial terminations, and to prevent the cilia from expelling them.

The present contribution is made in the hope that the problem raised will be attacked experimentally by others directly interested in cancer research. It should be possible to achieve hypersensitivity and a chronic respiratory tract discharge in a series of experimental animals and to introduce, over a period, concentrates of tobacco soot, atmospheric soot, and mixtures of both. The writer of course makes no claim to the validity of the present hypothesis, but at the same time he now proposes to use a pipe, or a cigarette-holder at least three inches long, to avoid unnecessary future irritation of his respiratory tract epithelium.—I am, etc.,

Skin Cancer and Burns

SIR.—It is desired to correct a statement in your annotation "Skin Cancer and Burns" (*Journal*, January 23, p. 204). The paragraph, which could be misinterpreted, reads: "Cancer of the skin, after years of actinic rays, is common in such countries as Australia, where it is found that European settlers are most susceptible."

In our statistical survey¹ of patients with cancer of the skin, the following facts emerged: (1) The average age of patients with cancer of the skin, born in Australia, is 61. (2) The average age of patients with cancer of the skin who have migrated to Australia (of these 99% come from Great Britain and other European countries) is 71. (3) The average length of residence in Australia (of the non native-born) before the development of skin cancer is 44 years.

In our opinion, the development of skin cancer is far more common among people of British descent than people of any other race, including the Scandinavian and North German.—I am, etc.,

Cancer Resistance

SIR.—The article on neuropathies associated with carcinoma by Dr. P. L. de V. Hart (*Journal*, March 13, p. 606) makes fascinating reading. I have under investigation at present a patient with foot drop and radiological evidence of bronchial obstruction, who "feels well" yet nevertheless may be doomed; but it raises wider and perhaps fundamental issues of practical importance. The far-flung effects of cancer are not always due to metastases. Multiple venous thromboses in areas remote from the growth may appear and disappear after a short interval (Trousseau's syndrome). I have seen small, slightly tender thromboses in the elbow appear and pass in a week or so, followed by similar episodes in the leg and chest (transitory pleurisy), heralding the major symptoms of a carcinoma of the tail of the pancreas. The rare myoclonus of the palate is said to be a pointer to lung neoplasm, without actual bulb involvement. There is undoubtedly a biochemical factor in these cases, perhaps some change in the serum producing remote effects. Now all experienced practitioners have met the occasional case of carcinoma that surprisingly seems to come to terms with the neoplasm and lasts many years,

I recall a lady who had a carcinoma of the caecum removed, to be followed 12 years later by a carcinoma in the colon, also excised (both dealt with by the late Mr. B. J. Ward). She developed a large irregular liver years later and was alive over 26 years after the first operation, despite the hepatic enlargement. Of course, long-standing cases of breast carcinoma are much commoner, and are usually explained by "fibrosis," but I am by no means certain that either the scalpel or the scirrhus explains away these cases. In my view there is a resisting factor in the serum in certain favoured individuals, and I am sure there are sufficient cases up and down the country to warrant an investigation of the serum of these carcinoma-resistant people.

I wrote to the *B.M.J.* some years ago on this matter, but it raised no interest. The high incidence of certain types of carcinoma in the same family (I have seen uterine cancer in a mother, later followed by the same type of neoplasm in three daughters, all the latter in the early 40's), suggests that there might even be an association between particular types of carcinoma and blood groups (the latter, of course, in the widest sense).

The effects of the endocrines in the treatment of some forms of malignancy suggest that the body could produce some defensive response, albeit too weak to be effective unless considerably enhanced artificially, in parallel fashion to cortisone. The answer to smallpox and scurvy was found long before virus and ascorbic acid deficiency were associated as causal, and the answer to neoplastic disease could possibly be found on these lines long before the scientists give us chapter and verse.—I am, etc.,

London, S.W.2.

A. WISEMAN.

Cortisone and Infection

SIR,—Your leading article entitled "Cortisone in Infection" (*Journal*, February 13, p. 381) is of very real interest. I shall be most obliged, however, if you will publish this letter as, in a sense, rebuttal of one sentence—namely: "It seems that, whenever cortisone has been administered to a vertebrate host parasitized by an invertebrate, the course of events has been altered to the detriment of the host."

There is no question that administration of large amounts of corticoids (A.C.T.H., cortisone, or hydrocortisone) to patients or to experimental animals with a variety of infections will tend to cause a dissemination of such infection usually to the detriment of the host, unless suitable means are employed to counteract such detrimental effects. There is, however, a very real place for the use of these hormones in the clinical management of infectious disease. This use is limited, for the most part, to infections for which thoroughly adequate antibiotic agents are available. Specific indications for the addition of intensive hormonal therapy to appropriate antibiotics consist in an overwhelmingly severe infection, with particular reference to generalized peritonitis, unusually virulent forms of pyogenic meningitis, with or without obvious blood-stream infection. If one employs A.C.T.H. and cortisone in a suitable manner in such individuals, using the hormones for their "non-specific antitoxic and anti-shock effects" to tide the individual over until the antibiotics have a chance to take effect, significant improvement in mortality and morbidity will result. Such therapy was undertaken on an investigative basis almost four years ago in this institution, and has now become routine in infections of more than usual severity.

Incidentally, it is our feeling that there are very few of the untoward effects of the corticoids, in so far as infection in the human subject is concerned, which cannot be reasonably well explained on the basis of inhibition of the inflammatory reaction. On the other hand, such inhibition can be highly desirable in the case of inflammatory involvement of the central nervous system, assuming that one has available an antibiotic capable of destroying the organism. A paper giving a comprehensive review of our total experience to date appears in the current volume of the *Journal of Pediatrics*.—I am, etc.,

Oakland, 6, California

LAURANCE W. KINSELL.

Elderly Psychiatric Patients

SIR,—Why do psychiatrists (and psychologists) habitually misuse their own special language? In the *Journal* of April 10 (p. 876) there is a letter in which a psychiatrist discusses the case of "elderly psychiatric patients" (though you, Sir, or the Assistant Editor, are, I fear, responsible for the actual headline). What is an "elderly psychiatric patient"? The answer should be "an elderly patient practising psychiatry"—so odd a combination that, of course, we reject it as the writer's meaning.

One is constantly reading of "psychiatric disorders," "psychiatric disability," "psychiatric symptoms"; but the writers do not mean disorders affecting the treatment by a psychiatrist, or affecting the psychiatrist himself—or a disability affecting the psychiatrist or affecting his treatment—or symptoms affecting the psychiatrist. No, what the writer means by "elderly psychiatric patients" is "elderly patients with mental disease under treatment by a psychiatrist." The term "psychiatric" is transferred from its proper subject, the psychiatrist, to his patient. But if psychiatrists habitually misuse their own language one begins to question the soundness of their reasoning.

I do not venture to suppose that this protest will avail anything. The misuse of the word "psychiatric" constantly recurs even in textbooks on psychological medicine by authors of acknowledged authority. Medicine is full of terms habitually, though wrongfully, misused. To name only a few there are "the acute abdomen," "the acute ear," T.B. (for "tuberculous" or "tuberculosis"), etc., etc. Very many years ago the Editor of the *B.M.J.* published a short leading article on the last of these abuses above-mentioned following a letter from me pointing out that it was sometimes impossible to say whether "No T.B. found" in a report on a demobilized soldier (after War I) meant "No tubercle bacilli found" (on sputum examination), or "No tuberculosis found"—a difference of vital importance. Did the kindly intervention of the Editor result in any change for the better? No. "T.B." stands triumphant. I have, in the past, even been referred to—through ministerial channels—as "T.B. officer." What chance for "psychiatric"? Still, let the protest stand; it can, at least, do no harm.—I am, etc.,

Folkestone.

E. WEATHERHEAD.

Psychiatry and General Medicine

SIR,—Having read the excellent article by Sir David Henderson (*Journal*, April 17, p. 889) I feel sure that he will be the first to admit that much of the disrepute enjoyed by the psychiatrists is of their own manufacture. The acceptance of a form of therapy by the medical profession as a whole depends ultimately on the response of patients to treatment. It has always surprised me that psychiatrists never seem to discuss treatment. As a rule they can always find a cause for a symptom or a syndrome which satisfies them, even if no one else, but, in most cases, that is as far as it goes. They wish to be accepted by all as openly as general physicians and surgeons, yet their form of treatment is nebulous and shrouded in mystery. Even standard textbooks devote little space to the management of cases except for those ill-understood forms of therapy, such as insulin, which even Sir David Henderson states are too readily used.

I would willingly send more of my patients with anxiety neurosis (and all doctors see large numbers of them) to the psychiatrist were he more helpful to me. We certainly need help with these cases, but little real improvement seems forthcoming. We get numerous labels for their inadequacies and weird causal agents for their symptoms, but their future seems quite unpredictable, except in so far as it will be the same as their past. The psychoses seem to be largely incurable, though some change may take place as a result of an empirical form of therapy or destructive brain operation. Any improvement seems usually to be short-lived. The psychoneuroses seem even less amenable

to psychiatric treatment, and it is with this group in particular that I plead for more constructive help from the psychiatrists. There is certainly enough material for them to treat.

I have stated elsewhere¹ that in my opinion the child psychiatrist is not always as helpful as the paediatrician. As an example, one may take the favourite topic of enuresis. My own view, being that of a person who likes a convenient "organic" basis for disease, is that it is usually due to a disordered sleep mechanism in which control by the higher centres is so completely lost during too deep a sleep that the reflex emptying of the bladder occurs. Fundamentally, the process is similar to that occurring in incontinence in organic disease, for example paraplegia. Treatment of childhood enuresis with the amphetamine group of drugs produces remarkable results—far better than does the delving of the psychiatrist who searches for emotional factors. He does not seek such factors in the bed-wetting of paraplegics. Whilst doctors are investigating the fascinating field of psychosomatic medicine, it is becoming more evident that many so-called functional diseases have an organic basis. It may well be that the psychiatrist will be called on to become more of a physician than the converse.

Finally, to Sir David Henderson, I would tell him of the most recent instance when I asked the help of a psychiatrist. It was concerning an obsessional neurosis, and the patient would 'phone me repeatedly during the night to explain his fears. After being examined carefully by the psychiatrist and the cause of his symptoms being discovered, he came the question of treatment. I was advised that the only solution would be to remove the patient from my list and let him plague the life of some other unfortunate doctor. Is it surprising that we are not yet all endeared to the science of psychiatry?—I am, etc.,

London, S.E.24.

CYRIL JOSEPHS.

REFERENCE

¹ *British Medical Journal*, 1952, 2, 881.

SIR,—As one who has come into the field of psychotherapy from a fairly broad background of hospital medicine and general practice, I would like to make a few comments on Sir David Henderson's address (*Journal*, April 17, p. 889). Much of my work is at a clinic for the out-patient treatment of neurotic disorders, where analytical psychotherapy is used, and where lay therapists are employed under supervision by the medical staff. Even though there are other out-patient clinics staffed by doctors, between 700 and 800 new patients are referred to us each year, mainly by general practitioners. Over a number of years I have not come across a case of a patient refusing treatment from a lay therapist, or complaining at being allotted to one. Nor have there been any instances where a lay therapist's lack of medical knowledge has been a stumbling block to satisfactory treatment.

As a healer, the lay therapist seems to possess several advantages over many doctors in the treatment of the neuroses. His professional status does not act as a screen between himself and his patient. His understanding of the patient is not limited by the narrow, mechanistic training of the medical curriculum, with its emphasis on factual and textual knowledge. His vision of the whole person is not obscured by anxiety concerning disease that the patient may have. His treatment does not tend to be applied *secundum artem* after a diagnosis, but rather according to his understanding of the patient's needs. He has no professional overhead expenses, and therefore the amount of time he can give to each patient is not limited primarily by economic considerations. In general, patients referred to clinics would seem to require treatment over a period of a few or a great many months with an average of two sessions per week; and it is difficult to see how, under the conditions of general practice to-day, a doctor can give adequate treatment to his neurotic patients. Undoubtedly many physicians help and support their patients in their difficulties, but that is not the same as curing them and rendering them independent of their doctor's help.

In regard to the proper training of medical students "to deal intelligently and skilfully with patients as persons," I wonder whether lectures and scientific knowledge are the best means of achieving these aims. There is a danger in the over-development

of the intellectual function, so that the natural intuitive understanding becomes stultified. Probably one of the most important things of all is to be able to listen to patients—to the unspoken as well as the spoken word, and to the unconscious. The Chinese emphasize this in their proverb, "If you want good advice, go to a man with four ears." Many of our patients who have been under psychiatric care have had no opportunity to be listened to, and this often is their greatest need.

Surely the needs of our patients should be our primary consideration, and until the supply of physicians is sufficient to meet their needs, both in mental hospitals and in out-patient clinics, many patients will fail to get the help they require unless the lay therapists are valued for what they can do.—I am, etc.,

Edinburgh, 4.

PHILIP SCOTT.

Second Attack of Chicken-pox

SIR,—We were interested to read the extract from Dr. J. I. Lyons's letter (*Journal*, April 10, p. 878). We have in fact seen only two instances of second attacks of chicken-pox this year, but the history of one is, we feel, worthy of note.

The patient is a healthy girl, now aged 8, who developed chicken-pox on June 23, 1953. This ran a normal course and she quickly recovered. On January 27, 1954, one of us again saw her with a mild but again quite typical chicken-pox rash, ushered in by a mild systemic upset and a temperature of 99° F. (37.2° C.). Again she recovered quickly. We were therefore amazed and indeed not a little suspicious when in April 1 we were asked to see M., who "had another rash." Sure enough she had chicken-pox. On each occasion the rash has been preceded by a mild systemic disturbance; the elements of the rash are typical, the centripetal distribution, the intraoral vesicles, and the "cropping" have been present on each occasion, and indeed in the third attack she even showed a concentration of vesicles at the site of a recent abrasion on the left elbow.

We are at a loss to explain these three attacks in so short a space of time and can only postulate different strains of the virus, immunologically distinct, or alternatively a complete failure to develop immunity to the virus. This latter theory would explain individual cases, but would not account for Dr. Lyons's observation of second attacks.—We are, etc.,

London, E.11.

Herpes Zoster and Chicken-pox

SIR,—That there is a very close association between the viruses of herpes zoster and chicken-pox is well known, but the following case is, I think, something of a rarity and therefore merits recording.

On April 10 a woman aged 58 consulted me for an eruption which had appeared on the previous day. This was situated on the right hip, the right flank, and the upper and outer part of the right thigh, and consisted of typical papulo-vesicles of herpes zoster. She had had no pre-eruption pain and the rash was not troubling her much at the time, and so I prescribed a placebo mixture and an occlusive varnish. On April 15 I received a message asking me to call and see her as she was not so well. She told me that she had had little sleep during the previous two nights owing to pain having developed in the eruption. She also said that she had developed more of the eruption in various places. When I asked to be shown these fresh lesions she exhibited to me scattered papules and vesicles on the face, trunk, and limbs, more or less symmetrically arranged, and which were indistinguishable from the lesions of chicken-pox—there was no grouping about these fresh lesions such as was present in the earlier zoster eruption—and I have no doubt whatever that this patient had developed an outbreak of true chicken-pox within a week of the appearance of her zoster eruption.

I have not heard or read of a similar case and I certainly have never seen one like this previously, and I should be most interested to learn if any other of your readers has had any experience of this double eruption, which appears to me to be strong evidence in favour of the viruses of zoster and chicken-pox being identical.—I am, etc.,

Birmingham, 18.

Appendix in Hernial Sac

SIR,—I am not a little surprised to see from recent case reports in the *Journal* how uncommon it is to find an appendix in a hernial sac. I remember having removed two appendices whilst I was a senior registrar in the Royal Liverpool United Hospital. However, I observe that no one has reported an appendix in a left inguinal hernial sac. The patient, a Fijian aged 30, was admitted to Lautoka Hospital on September 21, 1953. He had developed acute pain in the left inguinal hernia, which he had had for three years. He was shocked, and he had a swelling in the left side of his scrotum "the size of a mature coconut." As soon as possible I operated and found in the left sac strangulated caecum, appendix, and 15 cm. of small bowel. He also had a hydrocele. Owing to the tenseness of the caecum it was not possible to exteriorize both ends of gut in the hernial sac and await recovery for a second operation: the gut was punctured by inserting a catheter fastened with a purse-string suture. After this collapse had been effected the neck of the sac was dilated and the whole mass was handed through to another incision in the right iliac fossa and exteriorized. After removal of the testis and hydrocele the hernia was closed with drainage. The gangrenous bowel was removed and the peritoneum was also drained. As might be expected, the patient died, but not until the fourth post-operative day.—I am, etc.,

Suva, Fiji.

ROBERT I. COHEN.

Fatal Bronchial Asthma

SIR,—The article by Drs. C. Kelman Robertson and Kenneth Sinclair (*Journal*, January 23, p. 187) interested me considerably, as, in 26 years in practice, I have seen only three deaths from asthmatic attacks, and they all occurred in the year 1947.

Without records available, I can only write from memory. Case 1 was a man of 50, Case 2 a man of 35 approximately. Both these men had had repeated injections of adrenaline over more than 24 hours without much relief, and were given morphine. What part the latter played in the deaths is uncertain, but I have never used it in this complaint since. Case 3 was a young woman, aged 17, slightly built, very intelligent, working as a newspaper reporter, who had had asthma since infancy. She had been in good health and free from asthma for several months. About 15 minutes after a normal meal she developed an attack of asthma, presumably no worse than her usual ones. When the attack had been in progress for half an hour she suddenly collapsed. I was sent for and arrived within five minutes to find her pallid, pulseless, and with only an occasional sighing respiration. Intracardiac adrenaline had no effect, and she was dead within five minutes more.

My impression at the time was that she died of right heart failure, brought on by the strain of the attack. The views of Drs. Robertson and Sinclair on the possible mode of death in this case would be appreciated.—I am, etc.,

Wellington, N.Z.

A. RYDER-LEWIS.

Clinical Aspects of Bronchial Obstruction

SIR,—On reading the article by Dr. Robert N. Johnston *et al.* (*Journal*, April 3, p. 799) I was reminded of a sign of bronchial obstruction which I have recently observed and which is not mentioned by these authors, probably because it is rare or even unrecognized. It is a sign of partial obstruction in the sense that while it is complete in full expiration the dilating bronchus during inspiration allows air to pass at a certain stage. On auscultation before this stage air entry is absent, but when it is reached there is an accelerated rush of air past the obstruction due to the increased negative pressure built up beyond it, so that a rather sudden, loud, but short, soufflé results towards the end of the inspiratory phase.

I have heard and demonstrated to my registrar this unmistakable finding in two children, in each case over

a lower lobe; the mechanism was demonstrated by bronchoscopy showing polypoid tuberculous granulations completely obstructing the bronchus in expiration, but incompletely in full inspiration. As mobility of the bronchus is so important in the production of this finding, it is evidently much less likely to occur when the obstruction is due to a carcinoma. I provisionally labelled the sign "delayed inspiration" and wondered what relation it might bear to the "veiled puff" described by Skoda in bronchiectasis. While such cases could well give a similar finding with a plug of sputum as the obstructing agent, forced coughing should easily differentiate this group by causing disappearance of the sign.—I am, etc.,

Bristol.

J. E. G. PEARSON.

Diabetes Insipidus Associated with Pulmonary Disease

SIR,—I was very interested in Dr. J. E. G. Pearson's description (*Journal*, March 20, p. 704) of the diagnostic use of the serum tuberculin-neutralizing factor in sarcoidosis. However, I note that in order to carry out the test he injected his patient's serum into five other (tuberculin-positive) patients. May I most strongly urge him, or anyone else intending to carry out the test in the future, to keep for the purpose a small stock of guinea-pigs rendered tuberculin-positive with B.C.G.? It seems to me unwise to submit other patients to the risk of the transmission by means of a test of this kind of the virus of "serum hepatitis"—or even of a hypothetical sarcoidosis-causing agent.—I am, etc.,

London, S.W.1.

G. R. F. HILSON.

Photic Convulsions

SIR,—I was interested in your annotation on "Photic Convulsions" (*Journal*, April 17, p. 925). I have found from a clinical point of view that glare and also the flicker from cinema screens will precipitate migraine in a number of cases, and I am hoping to be able to get more controlled evidence on this point in the near future. A main source of trouble is fluorescent tube lighting when the tube is parallel to the desk instead of at right-angles to it. It happens occasionally that glare is the predominant factor among other precipitating factors in a given case of migraine, and all that is required is to deal with this by the use of "polaroid" glasses, etc. It would appear that there are many industrial processes where the lighting conditions are such as to be excessive and to constitute a state of glare.

Certainly the visual experiences described by Dr. Grey Walter in *The Living Brain*¹ using flicker in phase with the alpha rhythms would seem to be similar to the scintillating scotomata of migraine. One of my patients, an industrial research physicist, volunteered the information to me that headaches were induced by the flicker of light through the trees by the wayside while motoring; which has features in common with a case mentioned by Dr. Grey Walter in the same book. The effect of glare and light on various forms of psychosomatic disease has been noticed in days gone by, and Liveing, in his book on "megrim,"² discusses it as a precipitating factor in asthma as well as migraine.—I am, etc.,

Birmingham, 27.

Weight-lifting

SIR,—I have a practice within a few hundred yards of London and Katherine docks, and see many stevedores suffering from "sprung back" or prolapsed disk. Questioning those injured in lifting suggests: (a) Breathing is an important factor. If the lifter exhales during effort this decreases intra-abdominal tension and relaxes any "antagonist" muscles. This tip is well known to professional weight-lifters. (b) The centre of gravity must be as near

to and as far below the object to be raised as is possible. (c) If two people are lifting they must act as "mirror" images. The Safety Health and Welfare Museum in Horseferry Road, London, S.W.1, shows the posters Dr. J. H. Cyriax mentions (*Journal*, April 17, p. 933), and also some models.

Packing-case manufacturers could do some research into the placing and use of inset metal handles in their products of standard-size soft wood.—I am, etc.,

London, E.1.

N. D. WAYNE.

SIR,—Your recent correspondence under the heading, "Advice on Weight-lifting" (*Journal*, March 20, p. 703, and April 17, p. 933) prompts me to mention that, in collaboration with the Central Council for Physical Recreation, this Society has for two years been running courses in manual lifting and handling all over the country. The original point of contact—and this is typical of our work—was that the knowledge and experience behind the training of the weight-lifter in the field of sport might well be applied to weight-lifting at work. From this purely speculative idea developed a joint interest in human kinetics, the physiological details being medically approved. The basic lessons taught in these courses are summarized in a fully illustrated pocket book, *Manual Lifting and Handling*, which is bought by industrial firms in sufficient numbers to justify the belief, which we share with your correspondents, that the preventive approach is both necessary and appreciated.—I am, etc.,

London, W.1.

Industrial Welfare Society.

Conjoined Twins

SIR,—I read with great pleasure Professor Ian Aird's account of the conjoined twins of Kano (*Journal*, April 10, p. 831), and I was interested in his statement that it has never been completely proved that conjoined twins are, in fact, invariably monovular. If conjoined twins were, on occasion, the result of fusion of binovular embryos would we not sometimes find that the twins were of opposite sexes? There is no mention of any such case in Professor Aird's paper, and I would be interested to know if conjoined twins of different sexes have ever been reported. It may, of course, be that the circulatory connexion between the two partners, with the resultant mixing of sex hormones, would render the development of normal sexual characteristics impossible, and some bizarre effects might result.

I understand from a veterinary colleague that authentic cases have been recorded of conjoined twins in other mammals where the partners are male and female, but I am afraid I can trace no written authority for this statement.—I am, etc.,

London, W.C.1

D. A. BAILEY.

Weber-Christian Disease

SIR,—The point of interest to me in Dr. H. R. F. Macdonald's medical memorandum on Weber-Christian disease (*Journal*, February 13, p. 377) was the admission of the patient to hospital as a case of coronary artery thrombosis. No evidence of myocardial infarction was found. Similar cardiac symptoms developed in a patient whom I saw recently with the same condition.

An obese woman aged 54 developed the typical lesions on her legs on January 10, 1954. She was seen by Dr. Alice Carleton on January 20, to whom I am indebted for the diagnosis. She was admitted to hospital for investigation and biopsy of one of the skin lesions, which confirmed the diagnosis. She showed a low grade pyrexia. This is her first attack, so that her condition cannot truly be termed "relapsing" nodular panniculitis. The skin lesions had resolved, when, on February 8, she suddenly "collapsed" and became breathless and cyanosed. She denied any pain. On examination auricular fibrillation with a ventricular rate of 150 per minute was found to be the cause of her symptoms. The blood pressure was 180/110. Treatment with digitalis was given, and the ventricular rate was reduced to 90

per minute. Sinus rhythm had returned when she was seen on February 15, and this has been maintained. An electrocardiogram could not be taken during the acute phase, but the tracing on March 12 was normal. A chest x-ray showed moderate generalized cardiac enlargement with unduly prominent pulmonary vascular shadows.

Lesions of the internal adipose tissue have been reported,¹ and it has been suggested that nodular panniculitis in the bone marrow can disturb normal haemopoiesis. Is it possible that similar lesions in the epicardial and pericardial fat may cause cardiac irregularities?—I am, etc.,

Wroughton, Wilts.

Treatment of Threadworm Infestation

SIR,—When faced with cases of threadworm infestation many of us seem to be preoccupied with giving medicinal vermicides, necessary though they may be, and ignore the underlying causes. The literature is confused on the subject, and I would welcome the views of other practitioners on the following questions.

What are the conditions which favour the hatching of threadworms in the bowel? Donald Paterson¹ says: "It is the opinion of the author that most people are constantly ingesting the ova of worms. Those who are below par and run down have a low hydrochloric acid content and therefore fail to digest and kill off the swallowed ova." Has any work been done to prove or disprove this theory, or to establish what are the conditions in the digestive tract which favour the hatching and growth of the worms? Unless the problem is tackled at this level the tendency to infestation cannot be cured, however efficient the vermicide may be for each attack.

Is threadworm infestation detrimental apart from the anal irritation and the very rare blocking of the appendix? My own experience among well-cared-for children leads me to think that the appearance of threadworms is the result of debility rather than the cause of it. But what do others think? If, indeed, the condition is not detrimental there is no point in making the treatment more troublesome than the worms. Such fearsome and bothersome procedures are sometimes prescribed that mothers naturally get the impression that threadworms must be very dangerous, and become almost neurotic in their frantic efforts to eradicate the pests. I have recently heard of a mother who, when one of her family is infested, nightly gives enemas to her five children, including a baby, with goodness knows what psychological effects. She doses them and purges them and starves them, she daily boils their bed-linen and pants, and I am sure she would boil the children too if she could, so frantic and determined are her efforts to eradicate what she has been led to consider as a disgraceful and dangerous infestation. The tragic thing is that these efforts are largely in vain, because the worms appear again a few weeks later.—I am, etc.,

Obituary

Dr. H. U. GOULD died very suddenly on April 14 in the grounds of his home at Walton-on-Thames, where he had been living in retirement, at the age of 78. Harold Utterton Gould was born at Worcester Park, Surrey, on February 18, 1876, the son of Charles Gould, Q.C., and was educated at Winchester, Trinity College, Cambridge, and St. Bartholomew's Hospital. He qualified in 1902 and graduated M.B., B.Chir. in the following year. After holding the appointment of assistant house-surgeon at the Gloucestershire Royal Infirmary and Eye Institution, he returned to St. Bartholomew's as resident midwifery assistant and house-physician. In 1906 he settled in practice at Shaftesbury, in Dorset, where he became medical officer to the Westminster Memorial Cottage Hospital and medical officer of health to the Shaftesbury Rural District Council. He took a prominent part in local affairs and was elected mayor of Shaftesbury. Dr. Gould returned to Surrey in 1926, living first at Surbiton and then in the adjoining Royal Borough of Kingston-upon-Thames, where he designed and had built a central surgery for the use of himself and his two partners. For many years a member of the honorary medical staff of the Kingston Victoria Hospital, he was much concerned about the closing of the hospital three years ago. He was also on the honorary staff of the Surbiton Hospital. A tall man, with the physique of an athlete—he rowed for the Leander Club and won the Colquhoun sculls while at Cambridge—he was remarkably gentle in treating his patients, who quickly found that his seemingly off-hand manner masked a keen interest in their welfare. Dr. Gould retired from practice two years ago, but made many return visits to the Kingston district to call on former patients who had become his friends. A widower, he is survived by two sons and a daughter.

Dr. MABEL G. BRODIE died suddenly on April 21 at Port Dickson, Malaya, at the age of 64. Mabel Garland Cowper was born on May 28, 1889, and was educated at the Universities of Aberdeen and St. Andrews, graduating M.B., Ch.B. from St. Andrews in 1914. After graduation she was resident for a short time in 1914 at the Birmingham General Dispensary, whence she went to the Brownlow Hill Infirmary, under the Select Vestry, at Liverpool. In this post she proved herself an able clinician, but her chief interests were in maternity and child welfare and in ophthalmology. She took the D.P.H. at Liverpool in 1917. After about two years she was appointed to one of the Liverpool fever hospitals, where her work and ability attracted the attention of the then medical officer of health, the late Dr. E. W. Hope, and he asked that she be appointed as first medical officer in charge of maternity and child welfare work for the city of Liverpool. Her broad view of the duties of such a post, along with her advanced outlook and ability, soon showed how far-sighted had been the choice of the Liverpool City Council. Her next appointment was to the staff of the Ministry of Health, but on her marriage to Dr. William Hugh Brodie she resigned from the Ministry. Shortly afterwards she became senior medical officer to the maternity and child welfare department of the Durham County Council. Later both she and her husband joined the Colonial Medical Service in Malaya. In 1933 she took the D.T.M.&H. of the English Royal Colleges. Dr. Mabel Brodie had very deeply at heart the interests of mothers and children, both in England and Malaya. She returned to England soon after the outbreak of the last war and was employed as a medical officer in an ordnance factory in Yorkshire, and later undertook public health work in Willesden and Islington. After the war she went back to Malaya, and her sudden death has deprived the Colonial Medical Service of a very capable and conscientious practitioner and administrator. She was a most generous and sympathetic person

and will be missed by many of her colleagues and by those who worked under her and to whom she gave of her best. All who knew her will wish to extend their sympathy to her husband and their daughter and to her mother and sister.—W. M. G.

Medical Notes in Parliament

WORLD POPULATION AND FOOD SUPPLIES

Viscount SAMUEL invited the House of Lords on April 28 to consider the continuing and rapid increase in world population and the consequent need for increasing production of food and raw materials if living standards were to be maintained and improved.

He said that in 1850 the world population was rather over 1,000 million; to-day it was 2,500 million; and, if present trends were continued, by the early part of next century it would be 5,000 million. These figures had given rise to great anxiety, and the question was asked whether the human race was heading to sheer disaster. Dr. A. V. Hill said, in his presidential address to the British Association the year before last, that the rapid lowering of death rates all over the world meant that unless there was a deliberate restriction of birth rates in many countries there would be an inevitable fall in living standards.

The proposition that Lord Samuel put was that science, which had brought about the danger, brought also the means for preventing it, and that it was a fallacy to suppose that a mere increase of population must be a sheer liability. There were enormous opportunities for extending the areas of cultivation and vastly increasing the yields. Long-range possibilities included the development of nuclear energy, which might bring economic salvation to countries short of other sources of power; and the reaping of a greater harvest from the sea, including plankton, which for the next generation might be familiar as a main source of human food supply—it was only a question of the mode of preparation and availability. Plankton could be had for the asking; it contained millions of tons of proteins and quantities of vitamins. If the human race had been clever enough to grasp nitrogen out of the air and convert it by means of artificial fertilizers into bread and milk, surely it would be clever enough to take plankton from the sea and make it available in one form or another for human sustenance.

Lord BOYD-ORR said it was easy enough in theory to increase food, but not so easy in practice. In the Eastern countries—the food-deficit countries—there were social, religious, and economic difficulties. The food and economic problems might cancel each other out, because if food production was to be doubled an enormous increase in industrial equipment would be needed, and increased purchasing power and markets result from it.

The ARCHBISHOP OF YORK said that in asking the medical staffs of tropical hospitals what were the chief illnesses with which they had to deal, he had been struck that so often the answer had been, "With the exception of malaria, there is no particular tropical illness that causes us trouble, but the ordinary illnesses which you have at home are intensified and made more serious through malnutrition." He mentioned that one of the results of the eradication of malaria in British Guiana had been a decrease in infant mortality from 250 a thousand to 67 in a year, and the birth rate had also gone up. Birth control must be discussed and considered, but first things must be taken first, and he had found in the West Indies the opinion that the immediate need was to raise the standard of living, and that when that had been done people would have a greater appreciation of the necessity for parental responsibility.

Birth and Death Control

Lord BEVERIDGE said that what had been called "death control," the saving of lives through the development of science, had become one of the major factors in the world

population problem. It was clear that it automatically required birth control in some form or other.

Lord SIMON of Wythenshawe said that when this country started death control nearly 200 years ago medical and sanitary science was in its infancy. It took us nearly 200 years to get the death rate down to 40 a thousand. But recent inventions like penicillin and D.D.T. had produced remarkable results. If India, for example, applied Western health measures with comparable efficiency she would have an increase in population not of five million a year but ten million, and would not have time to get birth control going or industry developed. The Indian Government's five-year plan included, for the first time in history, he thought, the initiation of a campaign to limit the increase of population and as early as possible to stabilize it.

Lord HADEN-GUEST said that a world survey in much greater detail was required before any conclusions were drawn, and the necessity for control of the birth rate must be faced.

Lord STAMP said that as a medical microbiologist he was particularly interested in the contribution that research in the biological sciences might make. Further research was needed into the nutritive value of yeast for man and animals, and the methods of improving its palatability. Another group of organisms which appeared to have considerable potentialities as food was the algae, in particular the chlor-ella or green algae often seen as a green scum on the surface of ponds. These plants had high yields of fats and protein of nutritive value. There were many others which might prove of equal or greater value, and there was also the possibility of utilizing further the photosynthetic action of sunlight in building up proteins of nutritive value by devising methods for the extraction of proteins from leaves of plants that were at present largely wasted.

Earl DE LA WARR, for the Government, said the real problem was that agriculture must keep pace with medicine. It could do so only with a great effort. Birth control was primarily a matter for the countries concerned, and interference of that sort from this country would not be welcomed. He recounted the aid which was being given to the Food and Agriculture Organization and the United Nations technical assistance programme and through the Colombo plan. He agreed that the subject was one of great importance, and assured the House that the Government saw it as such and was prepared to do something as well as talk about it.

INQUIRY INTO HOMOSEXUALITY AND PROSTITUTION

It was announced in the House of Commons on April 29 that the Home Secretary, having given careful and anxious consideration to various representations that had been made on homosexual offences, and also close attention to the parallel problem of the law relating to prostitution and solicitation generally, had decided—in conjunction with the Secretary of State for Scotland—to appoint a committee to study both these questions.

Sir HUGH LUCAS-TOOTH, Under Secretary at the Home Office, added that he was anxious to secure the services of able and experienced men and women to serve on the committee, and therefore it might be some little time before he was able to announce the membership and terms of reference. The Home Secretary believed that a thorough investigation by a well-qualified body would throw useful light on the scope and nature of these difficult and controversial matters, and would make a valuable contribution to the problem of how the criminal law should deal with them.

Mr. DESMOND DONNELLY (Pembroke, Lab.) proposed the appointment of a Royal Commission to investigate the law relating to and the medical treatment of homosexuality, on the motion for the adjournment of the House. He said it was important that if such a commission was appointed it should look into the matter with a view to seeing what medical treatment could be provided. He was advised

that this was not mainly a glandular problem; it was a psychiatric problem, and the answer could often be found in psychiatric treatment where this was possible, or more particularly in studying the treatment of young people in their nursery years, because that was the crux of the whole matter. A Royal Commission should go into the matter and see that there was widespread public knowledge of how this sort of thing could be avoided.

Sir ROBERT BOOTHBY (Aberdeenshire, East, Con.) said that all the laws relating to this subject were enacted before any of the discoveries of modern psychology, and in any event were out-moded. The duty of the State was to protect youth from corruption and the public from indecency and nuisance. What consenting adults did in privacy might be a moral issue between them and their Maker, but it was not a legal issue between them and the State. What were called infanto-homosexuals should be segregated unless and until they were cured—as indeed must all those who committed offences against children and young people of either sex. But to send confirmed adult homosexuals to prison for long sentences was not only dangerous but madness. The prisons in their present overcrowded condition were factories for the manufacture of homosexuality. Recent cases established the need for an authoritative inquiry to furnish Parliament with the necessary expert knowledge and guidance for appropriate legislative and administrative action.

Sir HUGH LUCAS-TOOTH, replying, said that three main questions had emerged: What was the prevalence of homosexual activities? What was the impact of the law on such activities, and was any amendment of the law desirable? And what could be done by way of curative treatment, apart from punishment, for those who offended? There were no reliable means for assessing the prevalence of homosexual practices, but it was right to say that there had been a serious increase. Between 1938 and 1952 indictable offences known to the police had increased between four- and five-fold. He thought it could be said with complete truth that the reasons for the increase were simply not known. There would be general agreement that the criminal law ought to provide effectively for the protection of the young and the preservation of public order and decency. The question was whether the law should confine itself to securing those two objects, or whether it should be amended to permit unnatural relations between consenting adults in private. Such activities were no crime in many countries.

What medical science could do for those prisoners who were willing and able to be helped by psychological treatment was done to-day. Visiting psychotherapists had been appointed at certain prisons. Elsewhere prison medical officers submitted to the Prison Commissioners the names of any prisoners serving substantial sentences whom they thought were likely to benefit by treatment from psychotherapists with a view to their transfer. There was a scheme for prisoners serving shorter sentences to be seen by visiting psychiatrists from regional hospital boards with a view to continued treatment after release. The Prison Commissioners proposed to build a special establishment for mentally abnormal prisoners, and sexual and homosexual cases would be included. But those who could benefit were in a minority.

Cancer Registration

Mr. S. AWBERY (Bristol, Central, Lab.) asked if the Minister of Health, as a means of combating cancer, would give powers to local authorities to register all persons suffering from this disease; and if he would promote schemes to educate patients through general practitioners and other means on the best form of treatment. Miss PAT HORNSBY-SMITH replied that hospital boards were encouraged to arrange for the registration of all cases treated in hospital, and to provide information about incidence and results of treatment. The Minister had already invited local authorities to promote educational schemes, in co-operation with hospital authorities and general practitioners.

Mr. AWBURY said that many people who suffered from the disease were afraid to go to their doctors in the initial stages, and asked if the Minister would carry on a campaign through medical officers of health to encourage people to see their doctors at a stage when they could be helped. Miss HORNSBY-SMITH said that she shared his concern. They were working on the advice of the standing advisory committee on cancer and radiotherapy, and carrying out a scheme recommended by them.

Emphysema Research

Sir JOCELYN LUCAS (Portsmouth, South, Con.) asked the Minister of Health on April 29 if he would set up a special centre for research into the cause and cure of emphysema, and if he would give an estimate of the number of sufferers affected. Miss PAT HORNSBY-SMITH said that research into the lung conditions with which emphysema was usually associated was in progress in a number of centres. There was not information available to form an estimate of the number of sufferers.

Sir J. LUCAS urged that, as neither the cause nor the proper cure of this complaint had yet been discovered, the Minister should do all he could to step up research, with a view to relieving sufferers. Miss HORNSBY-SMITH said that research into diseases of the lung was already carried out at such centres as Hammersmith, the Brompton Hospital, and Sheffield, which covered research into emphysema.

World Health Organization

Sir RICHARD ACLAND (Gravesend, Lab.) asked the Minister of Health on April 29 whether he would instruct the British Government to press for a substantial increase in the regular budget of the World Health Organization, and to pledge this country to pay its fair share in the increase. Miss PAT HORNSBY-SMITH stated that the proposed regular budget of the Organization for 1955 showed a substantial increase over that approved for 1954, but the Minister was not satisfied that this increase was justified. The matter would be further considered at the next World Health Assembly. The United Kingdom contributed to the budget on a scale approved by the Assembly.

Sir RICHARD ACLAND asked that Britain should press for an increase in the budget so that the Organization could overcome its many problems. Miss HORNSBY-SMITH: "Not unless we are satisfied that the increase is justified."

Mr. A. BLENKINSOP (Newcastle-upon-Tyne, East, Lab.) asked for an assurance that there would be a long-term guarantee of funds to the Organization so that it could recruit the technical and qualified staff urgently needed for long-term contract work. Miss HORNSBY-SMITH said that was a much wider question, which she could not possibly answer.

Hospital Private Beds

Mr. A. MOYLE (Oldbury and Halesowen, Lab.) asked the Minister of Health on April 29 what steps were taken to ensure that private beds were not reserved for the use of fee-paying patients when there were urgent or chronic cases on the general waiting-list. Miss PAT HORNSBY-SMITH replied that the National Health Service Act specifically provided for patients in urgent medical need of treatment to be admitted to a pay-bed without charge if no alternative accommodation was available. The Minister had brought this to the notice of hospital authorities, and had also asked them to ensure that pay-beds not in full use for private patients were used for other patients, whether urgent cases or not.

Mr. MOYLE asked what view the Minister took of the heavy fees paid by private patients for minor operations, like the removal of tonsils, for which they were able to get attention within a week, whereas children had to wait as long as six months. Miss HORNSBY-SMITH said she hoped he would not exaggerate these claims. In the hospitals in which he was interested the Minister had assured him that whereas 25 tonsillectomies were done in a week under the Health Service there were only four in a year on private fee-

paying patients. If M.P.s had any evidence the Ministry would be glad to go into it to ensure that there was no abuse. It was not fair to suggest there was widespread abuse.

Medically Unfit for Service

Mr. IAN HARVEY (Harrow, East, Con.) was informed by Mr. HAROLD WATKINSON, Parliamentary Secretary, Ministry of Labour, on April 27, that it was estimated that 20% of the men medically examined on registering for national service in the first quarter of this year were not fit for service, on medical grounds. Mr. HARVEY said there was some concern about evasion of national service through men obtaining doctors' certificates, which were then honoured by the board, and asked that the matter should be looked into. Mr. WATKINSON said he did not think so. The medical boards did as the House had asked and were careful to see that they did not call up men who were medically unfit for military service. That sometimes meant delay in conferring with consultants, and so on, but he did not think many people evaded service for medical reasons. Mr. GEORGE THOMAS (Cardiff, West, Lab.) asked if the percentage was rising or falling, as 20% seemed a high figure for people unfit, and Mr. WATKINSON replied that it had been about the same over the past 12 months.

Antidotes to Poison

Lieutenant-Colonel W. SCHOFIELD (Rochdale, Con.) asked the Home Secretary if, where the law provided that any poisonous fluid or substance must be marked and labelled "poison," he would make it compulsory that the antidote to the poison should also be clearly stated. Sir DAVID MAXWELL FYFE replied on April 29 "No." The Poisons Board had advised against the introduction of such legislation. There were great dangers, because undue emphasis on antidotes might result in the loss of valuable time in obtaining medical help.

Contaminated Oranges.—Miss PAT HORNSBY-SMITH informed Mr. R. W. SORENSSEN (Leyton, Lab.) on April 29 that the Ministry of Health had received no reports from medical officers of health or any general practitioner of intestinal or other ill effects suspected to be due to the contamination of oranges by thiourea.

Sanitary Inspectors.—The Minister of Health stated on April 29 that he and other Ministers concerned had considered the report of the working party on the recruitment, training, and qualification of sanitary inspectors, and he proposed to discuss it with the interested bodies with a view to implementing the working party's proposals. It should not be inferred that he necessarily accepted all the detailed recommendations of the working party.

Medico-Legal

AN UNCERTAIN WILL

[FROM A SPECIAL CORRESPONDENT]

A recent decision in the courts has been of great moment to the two principal medical charities, and is therefore of importance to the whole profession. A Miss X, daughter of a long-deceased doctor, made a will in which, after various bequests, including annuities to be paid by her executors to four female friends, she left the residue to be divided (not quite equally) between the Royal Medical Foundation of Epsom College and the Royal Medical Benevolent Fund. One of the legacies was a bequest of £250 to her usual medical attendant.

So far all was plain sailing, but shortly before her death she executed a codicil in which she empowered her executors at their discretion to allow her doctor to buy her house, should he want to do so, "not necessarily at its full probate value but for such an amount as he can afford." The house was valued for probate at £700 at the time when Miss X died, about two years ago. The doctor then offered the

executors £100 for the house. Both the charities, naturally enough, protested emphatically against the acceptance of this offer. Various attempts to arrive at a compromise solution of the dilemma broke down, so finally the executors sought the direction of the court on the course they should follow. The clause was declared to be void for uncertainty. For once the strict letter of the law and natural justice seem to have coincided, which, to laymen, does not appear always necessarily to be the case.

HYPNOTIST LECTURER ACQUITTED

Believed to be the first person to be prosecuted under the Hypnotism Act of 1952, Mr. D. T. Watson, aged 46, was acquitted at Northampton on April 28 on a summons brought under the Act. Watson was a lecturer at a meeting arranged by the International Friendship League at a Northampton café, and he was accused of giving a public demonstration of hypnotism on a young man, a journalist, at a place which was not licensed for it. The Act says that "no person shall give an exhibition, demonstration, or performance of hypnotism on any living person at or in connexion with an entertainment to which the public are admitted," unless authorization has been given. The defence claimed that the lecture was not an entertainment, and that the purpose of the Act was to prevent the prostitution of hypnotism by people who wanted to make money from it in theatres. The magistrates were satisfied that the demonstration was not an entertainment.

Manchester Guardian, April 29.

Universities and Colleges

UNIVERSITY OF OXFORD

In Congregation on January 21 the degree of B.M. was conferred on J. G. Bateman and B. C. Morson.

The Board of the Faculty of Medicine has re-co-opted Dr. A. M. Cooke and co-opted Dr. E. M. Buzzard for the statutory period of two years from the first day of Hilary Term, 1954.

UNIVERSITY OF ST. ANDREWS

The degree of M.D. has been conferred on Norman Levinson. The following candidates have been approved at the examination indicated:

FINAL M.B., CH.B.—W. Chaplain, I. M. Sutherland, Mary E. Woods.

UNIVERSITY OF GLASGOW

The following degrees were conferred on January 16:

M.D.—J. Bruce (with commendation), Helen I. W. Kerr-Taylor, R. Lamb (with commendation), J. M. McBride (with high commendation), H. Thompson, R. M. L. Weir.

M.B., CH.B.—Florence M. D. McC. Adams, D. MacF. R. Adamson, W. G. Aitchison, J. A. H. Aitken, Elizabeth H. Arklie, W. G. Barbour, J. Bolland, Evelyn M. Borland, R. H. Boyd, Elizabeth J. B. Buchanan, J. M. Cameron, W. S. Campbell, J. A. Chapman, W. H. Cochrane, J. A. Dand, W. A. Dawson, Marion R. H. Donald, R. G. Dryden, D. Duncan, Stella E. G. Gibson, Katherine M. Girdwood, A. I. M. Glen, I. B. Hall, Margaret A. Hart, G. S. Henderson, M. Holmes, G. M. Jesner, J. H. Lawrie, Myra Leatham, W. J. Leishman, E. S. Livingstone, Isobel McClung, G. T. MacCulloch, A. McCutcheon, A. J. McDonald, I. G. MacFarlane, J. A. McCarry, W. G. MacIntosh, J. C. MacIntyre, A. Mackintosh, Marion T. McKissock, J. S. MacLean, J. H. McLean, J. D. Mabon, W. Mitchell, R. S. Moir, J. B. Morris, J. M. Neilson, J. M. Newton, R. A. H. Newton, W. A. Nicol, G. H. Parker, A. Patrick, Flora K. Prentice, Euphemia Quigley, Helen A. Ritchie, A. Robertson, J. T. Robertson, A. W. B. Russell, I. D. Sanderson, R. W. Sharp, I. R. Sherret, C. E. Simpson, N. J. Skelton, W. D. Smith, W. McA. Speirs, D. A. Stalker, Doreen Steel, Anne M. Stewart, Jean O. Struthers, Margaret A. Timmins, P. G. M. G. Walker, Margaret Wallace, A. S. Wilson, W. Young.

UNIVERSITY OF LONDON

D. P. Walther, M.R.C.S., L.R.C.P., L.D.S.R.C.S., senior hospital dental officer, orthodontist in charge of the orthodontic clinic department at the Eastman Dental Hospital, and senior hospital dental officer at the Hospital for Sick Children, has

been appointed to the University Readership in Orthodontics, tenable at the Royal Dental Hospital of London School of Dental Surgery.

UNIVERSITY OF SHEFFIELD

Dr. J. Wilkie has been appointed part-time Lecturer in Radio-diagnosis.

UNIVERSITY OF BRISTOL

The following candidates have been approved at the examinations indicated:

M.D.—J. D. Sheward.

FINAL M.B., CH.B.—P. B. Bailey, M. J. Betty, G. A. Bond, M. L. Cox, R. W. Digby, R. D. Doyle, R. I. Eastwood, Monica M. Gurnhill, K. W. Moulding, A. E. Nesling, T. F. J. Parker, W. E. Smith, D. G. Trott (with distinction in public health), R. Winstone. In Group I completing the examination: J. P. Bishop, Christine F. Boulter, Margaret V. Brown, J. Royle, Catherine M. Stephen. In Group II only: K. G. Collins, Janet H. Keevil, E. C. Skeens.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—Part II: L. W. Bowen, D. E. Jarman, S. Prus.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council of the College held on December 10, 1953, with Sir Reginald Watson-Jones, Vice-President, in the chair, Dr. Fred W. Rankin, President of the American College of Surgeons, was awarded an Honorary Fellowship.

Hunterian Professorships were awarded to Mr. R. C. Evans, and Dr. Michael Ward for a lecture on "The Ascent of Mount Everest—Medical Studies."

The Begley Prize was presented to Margaret M. Heley (Royal Free).

It was decided to proceed at once with the building of the Nuffield College of Surgical Sciences.

Diplomas of Fellowship were granted to the following candidates: J. A. James, K. L. Barnes, C. M. Phillips, R. B. McGrigor, D. B. Moffat, R. M. Harvey, G. F. Hird, J. S. J. Morley, J. E. Oliver, L. G. Fison, K. Till, A. S. Falconer, A. E. Platt, R. A. Daws, J. A. G. Holt, Betty M. L. Underhill, J. Bihari, P. B. Foxwell, S. Panikkar, B. G. Reynolds, Agnes R. D. Bartels, J. A. Snyder, K. S. E. MacRae, Margery Scott-Young, C. J. S. Sergel, M. Shaffi, G. C. Pritchard, K. G. Malcomson, J. M. Ellis, I. M. Grant, H. D. W. Powell, F. H. Gamali, J. D. Glanville, W. Grundill, P. A. P. Joseph, A. M. Akram, A. Benjamin, R. F. Burton, J. K. Craig, W. S. Foulds, P. E. Ohadi, B. Goldman, R. J. Hart, K. W. Hinrichsen, G. S. Karai, J. S. Lekias, Elaine Lister, E. A. McVerry, K. D. J. Vowles, K. H. Abdel-Ghaffar, A. K. Das, I. Sober, J. B. R. Wells, C. G. Wilson, W. S. Wilson, F. J. Hall, H. C. Jones, J. Klely, B. V. Kyle, E. D. McIntyre, S. A. Mellick, D. J. Retief, J. E. S. Scott, N. J. Way, R. F. Zacharin, A. F. G. Anderson, R. R. Barnett, J. G. Brice, A. F. Ferguson, H. R. McCoy, M. K. Mehra, A. G. Morgan, P. J. Mortensen, G. T. Smedley, T. K. Thorlakson, M. Wynyard, J. Chalmers, D. Davies, L. R. De Jode, E. S. P. Ferguson, R. S. Gupta, C. H. MacLaurin, B. Shandling, K. K. Sinha.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

The following were admitted to the Membership of the College on February 5: K. H. Anderson, E. E. Doyle, K. C. Finkel, L. G. McElearney, M. F. McParland, J. B. O'Dullivan.

SOCIETY OF APOTHECARIES OF LONDON

The diploma of L.M.S.S.A. has been granted by examination to the following successful candidates: J. M. Goyder, T. J. Gallivan, I. Dollond, T. J. Taylor, T. G. Wadsworth, E. Dayan, J. Curtis, J. K. Anderson, J. G. Robertson, M. W. L. Davis, B. Clarke.

The following candidates have been awarded the Diploma in Industrial Health: W. R. Brown, S. Chakravorti, K. P. Duncan, B. K. Ghose, R. Makin, P. B. Nicol, J. D. Pickford, M. K. Qureshi-Ul-Hashmi, A. W. W. Robinson, T. Simpson, H. Stott.

APOTHECARIES' HALL OF IRELAND

At recent examinations the following candidates received the diploma of L.A.H. Dublin: S. M. Abba, E. Allan, A. Azike, J. F. L. Barry, Evelyn Blake, E. W. Burke, D. R. Chiney, G. G. Dibue, P. P. Gallagher, W. H. Hamilton-Deane, P. J. A. Horan, J. M. Langan, Chew Seng Lau, J. M. Mangan, Erminie Marazzi, D. Martin, Bridget Moylan, P. D. Moylan, H. McCarthy, O. L. McGuinness, D. C. O'Sullivan, Maire Quigley, J. A. Quigley, T. F. Regan, Constance Strickland, J. D. Steele, T. E. Winckworth, R. Whyte.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending April 17 (No. 15) and corresponding week 1953.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1954					1953				
	Eng. & Wales	London	Scot.	N. Ire.	Eire	Eng. & Wales	London	Scot.	N. Ire.	Eire

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Vital Statistics

Hospital In-patient Statistics

A further contribution to the study of morbidity statistics published this week includes figures of cases admitted to certain hospitals in England and Wales in 1949 analysed by sex, age, disease, length of stay, and social class. The volume also includes some figures from wartime E.M.S. hospital records. The significance of many of the figures tabulated is not easy to interpret, because the population at risk is problematical. Hospital administrators, however, may find useful guidance on the proportions in which groups of beds should be set aside for different diseases. Some of the sex ratios of disease incidence obtainable may usefully be compared with those obtained from mortality statistics. Table H2 shows that the average stay in hospital is lower in the provincial teaching hospitals than in either the London teaching hospitals or the regional board hospitals. The figures for the last-named are influenced by the relatively high proportion of old people admitted.

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in March, 1954, was 118, compared with 114 in the previous month and 122 (revised figure) in March, 1953.

The number of cases of industrial diseases in the United Kingdom reported during March was as follows: lead poisoning 2, other poisoning 0, anthrax 4, epitheliomatous ulceration 12, and chrome ulceration 27; total 45. There was 1 death from epitheliomatous ulceration. *Ministry of Labour Gazette*, April, 1954.

Venereal Diseases

In England and Wales during the quarter ending December 31, 1953, 1,557 new cases of syphilis were reported as attending the clinics. Of these, 276 were classified as primary, secondary, or latent in the first year of infection. 24 cases of congenital syphilis in children aged under 1 year were reported, and 213 cases in persons over that age. New cases of gonorrhoea numbered 4,697, of chancroid 83, and of non-gonococcal urethritis (males only) 3,253. *Monthly Bulletin of the Ministry of Health*, April, 1954.

Infectious Diseases

The incidence of infectious diseases fell in England and Wales during the week ending April 17. The largest declines in the number of notifications were 635 for dysentery, from 1,554 to 919, 482 for whooping-cough, from 2,462 to 1,980, 381 for measles, from 2,293 to 1,912, and 380 for scarlet fever, from 1,374 to 994.

A decrease in the incidence of scarlet fever was recorded in most areas; the largest falls were Lancashire 30, from 166 to 136, Durham 24, from 44 to 20, and Derbyshire 21, from 31 to 10. The largest declines in the number of notifications of whooping-cough were 92 in Yorkshire West Riding, from 259 to 167, 54 in Norfolk, from 83 to 29, and 47 in Lancashire, from 237 to 190, while the only rise of any size was 36 in Gloucestershire, from 39 to 75. 14 cases of diphtheria were notified, being 2 more than in the preceding week. The largest falls in the notifications of measles were 119 in Staffordshire, from 334 to 215, 92 in Lancashire, from 499 to 407, and 45 in Cheshire, from 132 to 87, and the largest rise was 43 in Durham, from 65 to 108. 3 of the 5 cases of paratyphoid fever were notified in Anglesey, Beaumaris M.B.

17 cases of acute poliomyelitis were notified. These were 3 more for paralytic and 4 more for non-paralytic cases. *Registrar-General's Statistical Review of England and Wales for the Year 1949: Supplement on the Hospital In-patient Statistics*. H.M.S.O., 15s.

than in the preceding week. 3 cases were notified in Somersetshire and 2 in each of the counties of Devon, Warwick, Lancashire, and Yorkshire East Riding.

The largest returns of dysentery were Yorkshire West Riding 148 (Sheffield C.B. 42, Dewsbury C.B. 18, Leeds C.B. 17, Bradford C.B. 10, Wortley R.D. 10), Lancashire 133 (Salford C.B. 22, Liverpool C.B. 15, Bolton C.B. 11), London 121 (Islington 42, Lewisham 17, Wandsworth 15), Leicestershire 88 (Leicester C.B. 83), Middlesex 48 (Edmonton M.B. 12, Willesden M.B. 11), Nottinghamshire 40 (Nottingham C.B. 32), Essex 31, Norfolk 28 (Norwich C.B. 26), Gloucestershire 27 (Bristol C.B. 24), Warwickshire 26 (Birmingham C.B. 23), Kent 25, Staffordshire 23 (Cannock U.D. 15), and Surrey 22 (Croydon C.B. 17).

In Scotland the largest returns of dysentery were 147 in Glasgow, 40 in Lanark county, and 39 in Edinburgh.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1945-53 are shown thus -----, the figures for 1954 thus ————. Except for the curves showing notifications in 1954, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Week Ending April 24

The notifications of infectious diseases in England and Wales during the week included pneumonia 478, scarlet fever 789, whooping-cough 2,133, diphtheria 12, measles 2,196, dysentery 711, acute poliomyelitis 10, paratyphoid fever 3, and typhoid fever 1.

Not Smallpox

A Briton who returned by air from Spain on April 24 developed a rash which was reported to have aroused suspicion of smallpox, but further observation has excluded this diagnosis.

Medical News

World Health Assembly.—The seventh World Health Assembly opened in Geneva on May 4.

Clinical Science Institute at Belfast.—The most ambitious extension to Queen's University, Belfast, since its foundation in 1845 is the Institute of Clinical Science which was opened on May 7. It comprises two buildings on the hospitals site at Grosvenor Road, Belfast, which are directly linked with each other and with the adjacent Institute of Pathology and the Royal Victoria Hospital. Other hospitals in the vicinity are the Royal Maternity Hospital, the Royal Belfast Hospital for Sick Children, and the Musgrave Clinic. The new Institute will house the departments of medicine, surgery, therapeutics, obstetrics and gynaecology, child health, and social and preventive medicine, and one for research. In addition there are a medical library, lecture and reading rooms, operating rooms, laboratories, a photographic studio, and workshops. The design of the research department has been based on that at the Mayo Clinic in America. It is expected that the Institute will provide magnificent facilities for both undergraduate teaching and postgraduate research.

Nuffield Scottish Committee.—The first meeting of the Scottish Advisory Committee of the Nuffield Provincial Hospitals Trust was held in St. Andrew's House, Edinburgh, on April 28, with Sir George H. Henderson in the chair. The new committee will advise the trust on applications for grants towards projects in which either the Trust or the Nuffield Foundation may be interested. The medical members of the committee are Dr. May D. Baird, Mr. P. Martin Brodie, Professor Thomas Ferguson, Professor Ian G. W. Hill, and Professor C. F. W. Illingworth.

Eugenics Quarterly.—The American Eugenics Society has commenced publication of *Eugenics Quarterly*, which replaces *Eugenical News* as the official organ of the Society. Subscription to *Eugenics Quarterly* is \$3 per annum.

British Association of Physical Medicine.—The annual meeting was held on April 30 and May 1 at King's College Hospital Medical School, London, by kind permission of the Dean. The opening session was devoted to a discussion on "The Scientific Approach to Physical Medicine," the

principal speakers being Dr. A. C. Boyle, Dr. A. J. Richardson, and Dr. Richard Doll. Each of them emphasized the vital necessity of applying rigid statistical criteria before any new form of physical treatment was accepted. Failure to "control" clinical impressions in the past had led to much empirical therapy, the scientific basis of which was now being challenged. Subsequent speakers stressed some of the ethical and technical difficulties in carrying out an impeccable clinical trial. The second morning session took the form of a conference on industrial and social rehabilitation, organized by Dr. F. Cooksey, in which twelve illustrative cases were discussed by medical staff, almoner, occupational therapist, local disablement resettlement officer, and other interested officials. On one of the afternoons a clinical meeting was held, and on the other short papers were read. The annual dinner was held at the Grosvenor House, with Lord Horder presiding. The toasts were given by the Minister of Health (Mr. Iain Macleod), Lord Horder, Dr. A. C. Boyle, and Sir Cecil Wakeley, P.R.C.S.

Medical Women's Federation.—Dr. Annis Gillie has been elected president of the Medical Women's Federation. Her induction by the retiring president, Dr. Mary Esslemont, was announced as the final ceremony at the annual general meeting held on May 6 at Sheffield. The title of Dr. Gillie's presidential address was "Motive and Momentum."

Hunterian Society.—Dr. W. S. C. Copeman has been elected president of the Hunterian Society of Great Britain in succession to Sir Heneage Ogilvie.

Smokeless Zone for Bolton.—The Minister of Housing and Local Government has approved an Order creating the first smokeless zone in Bolton. The zone is an area of 86 acres in the centre of the city. The Order will come into force on November 1.

Professor Otto Loewi, the distinguished German pharmacologist, who now lives in New York, has been made a Foreign Member of the Royal Society. In 1936 Professor Loewi shared a Nobel Prize with Sir Henry Dale for their work on the transmission of nerve impulses.

Sir Landsborough Thomson, second secretary of the Medical Research Council, has been elected president of the Zoological Society of London.

Dr. J. W. Landells has been appointed to the University readership in morbid anatomy tenable at the London Hospital Medical College.

COMING EVENTS

Cavendish Lecture.—Lieutenant-General Sir William MacArthur will speak on "Pepys and the Plague" on May 10 at 8.30 p.m. at the Royal Society of Medicine, 1, Wimpole Street, London, W.1.

Medical Association for the Prevention of War.—A public conference will be held on May 15 from 2.30 to 5.45 p.m. at 45, Russell Square, London, W.C.1. The theme of the meeting is "The Concept of Race," and the speakers will include Professor Lionel Penrose, F.R.S., Dr. N. A. Barnicot, Mr. E. S. Sachs, and Dr. Duncan Leys.

William Blair-Bell Memorial Lecture.—Dr. Ian Donald will lecture on "Atelectasis Neonatorum" on May 21 at 5 p.m. at the Royal College of Obstetricians and Gynaecologists, 58, Queen Anne Street, London, W.1. Admission is by ticket only, obtainable from the secretary of the College.

Bristol Medical Exhibition.—The exhibition will be held at the Victoria Rooms, Bristol, from May 17 to 21 from 11 a.m. to 6.30 p.m. daily (7.30 p.m. on May 19). It will be officially opened at 11.30 on May 17 by Professor C. Bruce Perry. It is expected that the film of the Siamese twins operation will be shown in each day's programme. Further information may be obtained from the organizer of the exhibition, Victoria Rooms, Bristol.

Meeting of American College of Surgeons in London.—The American College of Surgeons is holding a three-day sectional meeting at the Royal College of Surgeons, Lincoln's Inn Fields, on May 17, 18, and 19. The programme for the meeting has been prepared by the American College on the lines of one of their typical sectional meetings, while the local arrangements are in the hands of the Royal College. The American College of Surgeons has issued invitations to all Fellows of the Royal College of Surgeons and to all members of the Association of Surgeons of Great Britain and Ireland. The programme is as follows:

Monday, May 17

9.00-12 noon.

The Great Hall, Royal College of Surgeons: Film and Lectures.

12.15-2.15 p.m.

Luncheon and Panel Discussion on: "Intestinal Obstruction," at the Connaught Rooms, Great Queen Street.

2.30 p.m.-6.00 p.m.

The Great Hall, Royal College of Surgeons: 2.30 p.m., Symposium on Gynaecology. 3.20 p.m., Panel Discussion on: "Pre- and Post-operative Care." 5.00 p.m., Presentation of Honorary Fellowship. 5.05 p.m., Hunterian Lecture on: "Progressive Exophthalmos."

6.30 p.m.-7.30 p.m.

Various Receptions. Reception by President and Council at Royal College of Surgeons.

9.30 p.m.

Tuesday, May 18

9.00 a.m.-12 noon

The Great Hall, Royal College of Surgeons: Symposium on: "Cardio-vascular Surgery." Room 1, Royal College of Surgeons. Symposium on: "Cancer."

2.00 p.m.-6.00 p.m.

Visits to London Hospitals.

7.30 p.m. for 8.00 p.m.

Banquet at the Dorchester Hotel, Park Lane.

Wednesday, May 19

9.00 a.m.-12.20 p.m.

The Great Hall, Royal College of Surgeons: Film and Lectures.

9.00 a.m.-12.15 p.m.

Special Programmes for otolaryngologists and urologists at the Royal College of Surgeons, and for ophthalmologists at the Institute of Ophthalmology, Judd Street, W.C.1, and Moorfields Westminster and Central Eye Hospital.

12.35 p.m.-2.30 p.m.

Luncheon and Panel Discussion on: "Massive Gastrointestinal Tract Haemorrhage," at the Connaught Rooms, Great Queen Street.

2.45 p.m.-5.30 p.m.

The Great Hall, Royal College of Surgeons: 2.45 p.m., Moynihan Lecture on: "Pancreatitis, Fundamental and Clinical Aspects." 3.45 p.m., Expression of Appreciation. 3.55 p.m., Panel Discussion on: "Hand Surgery."

Newsholme Lectures.—Professor W. M. Frazer will deliver three lectures on "State Medicine in the Nineteenth Century" at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1, on May 24, 25, and 26 at 5.15 p.m.

Demonstrations for Consultants on Modern Aspects of Thyroid Disease.—A week's course will be held at the Postgraduate Medical School, Ducane Road, London, W.12, from September 20 to 24. Further details are given in our advertisement columns at page 40. Applications for places, which are limited to 40, should be made to the Dean before September 1.

American Geriatrics Society.—The eleventh annual meeting will be held at the Hotel Fairmont, in San Francisco, from June 17 to 19. Dr. Laurence W. Kinsell, Highland Alameda County Hospital, 2701, Fourteenth Avenue, Oakland 6, California, is in charge of arrangements for the meeting.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Monday, May 10

MEDICAL SOCIETY OF LONDON.—8.30 p.m., second general meeting. Annual Oration by Mr. G. L. Keynes: Second (and Third) Thoughts on the Surgery of the Thyroid Gland.
WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—At Royal Society of Medicine, 8.30 p.m., Cavendish Lecture by Lieutenant-General Sir William MacArthur: Pepys and the Plague.

Tuesday, May 11

CHELSEA CLINICAL SOCIETY.—At South Kensington Hotel, annual dinner.
EDINBURGH UNIVERSITY.—At Surgery Lecture Theatre, University New Buildings, 5 p.m., Second Sir John Fraser Memorial Lecture by Dr. Ewart A. Graham (American College of Surgeons): Cancer of the Lung, with Special Emphasis on the Aetiology.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. O. Oliver: Antibiotics.
ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Croonian Lecture by Dr. J. F. Smith: Nutrition and Child Health.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Imperial Cancer Research Fund Lecture by Dr. L. M. Franks: Latent Carcinoma.
WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY.—5 p.m., Almoth Wright Lecture by Professor P. B. Medawar, F.R.S.: Wound Healing, with Special Reference to the Skin.

Wednesday, May 12

DUBLIN UNIVERSITY.—At Physiology Theatre, 4.30 p.m., John Mallet Purser Lecture by Professor E. B. Verney, F.R.S.: Water Diuresis.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. A. Dudgeon: Virus Diseases.
INSTITUTE OF ORTHOPAEDICS.—At Brockley Hill, Stanmore, 8 p.m., senior clinical pathological conference.
OXFORD UNIVERSITY.—At Physiology Theatre, 12 noon, Professor Z. M. Bacq (Liege): Actions of Cystamine and Cystamine.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Dr. G. W. B. James: lecture demonstration in psychiatry.

Thursday, May 13

ALFRED ADLER MEDICAL SOCIETY.—At 11, Chandos Street, W., 8 p.m., Dr. Franklin Bicknell: Diet and Behaviour.
FACULTY OF HOMOEOPATHY.—5 p.m., Dr. Pierre Schmidt (Geneva): Hidden Treasures of the Last Organon.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. A. Dudgeon: Virus Diseases.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Professor M. L. Rosenheim: Treatment of Nephritis.
ROYAL EYE HOSPITAL.—5 p.m., Mr. H. B. Jacobs: Relation of Nasal and Ocular Diseases.
ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Dr. R. W. G. Wyckoff: Use of the Electron Microscope in Biology and Medicine.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., psychiatry demonstration by Dr. M. A. Partridge.
SURREY INTER-HOSPITAL PSYCHIATRIC ASSOCIATION.—At Roffey Park Rehabilitation Centre, Horsham, Sussex, 5.30 p.m., clinical meeting. Papers by Dr. V. W. Wilson, Dr. L. S. Davies, and Dr. T. M. Ling.

Friday, May 14

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. P. F. Borrie: Vascular Anomalies.
LEEDS UNIVERSITY.—At Riley Smith Hall, University Union, 3.30 p.m., Moynihan Lecture by Dr. A. Blalock (Baltimore, U.S.A.): Expanding Scope of Cardiovascular Surgery.
LONDON UNIVERSITY.—At Anatomy Lecture Theatre, University College, 5.30 p.m., special university lecture in psychology by Dr. M. Ray Denny (Michigan): Learning Theory and Experimental Extinction.
PAPWORTH VILLAGE SETTLEMENT.—At 26, Portland Place, London, W., 5 p.m., Fourth Varric-Jones Memorial Lecture by Dr. H. G. Trimble (California, U.S.A.): Current Therapy in Pulmonary Tuberculosis.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Mr. E. P. Brockman: Disabilities of the Foot: 4 p.m., Professor R. B. Hunter: Control of Anticoagulant Therapy in Myocardial Infarction.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Mr. L. H. W. Williams: Obstetric/Gynaecological Conference.
SOCIETY OF MEDICAL OFFICERS OF HEALTH: WELSH BRANCH.—At B.M.A. House, 195, Newport Road, Cardiff, 6.30 p.m., annual meeting.

Saturday, May 15

ASHTON, HYDE, AND GLOSSOP HOSPITAL MANAGEMENT COMMITTEE.—At Physiotherapy Department, Lake Section, Ashton-under-Lyne General Hospital, 2.30 p.m., clinical meeting.
BIOCHEMICAL SOCIETY.—At Department of Physiology, The University, Bristol, 11 a.m., 329th meeting, scientific papers.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Heyland.—On April 2, 1954, at the London Hospital, London, E., to Joanna (formerly Poynton), and Dr. Ralph Heyland, of Hermon House, Faversham, Kent, a son.
Mather.—On April 15, 1954, at Ashmount, Lonsborough, York, to Dr. Maud (formerly Buchanan), wife of Dr. John S. Mather, a daughter.
O'Brien.—On April 27, 1954, at Leeds, to Elizabeth (formerly Craig), M.B., B.Chir., wife of Richard O'Brien, Wakefield, a brother for Alison—David Charles.

MARRIAGES

Fleischl-Quinton.—On May 1, 1954, at St. Paul's, Portman Square, London, W., Peter Fleischl, M.B., Ch.B., of Wellington, New Zealand, to Charmian Quinton, M.B., B.S., of London, W.

DEATHS

Fitter.—On April 1, 1954, Clara Ann Shipley Fitter, M.D., late of Streatham, London, S.W., and Hindhead, Surrey, aged 93.
Starforth.—On March 31, 1954, in hospital, William Percy Starforth, M.B., Ch.B., of London, S.E., formerly of Durham.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Vaccine Trial in General Practice

Q.—I am aware of the recent Medical Research Council trials of whooping-cough vaccines, but I want to test for myself over a period of years the efficiency in general practice of a combined diphtheria-pertussis prophylactic. My difficulty is to find a suitable control group with which to compare my results. What control group would you advise?

A.—It is difficult to see how a satisfactory trial of such a vaccine could be conducted in a general practice nowadays, it being presumed that the doctor is bound to vaccinate any child whose parents request it. The vaccinated children will form a "volunteer" group, and their home background, the size of family they come from, and other factors may make their risk of exposure to infection different from any "non-volunteer" control group. It might be of interest, however, to keep careful records of every occasion in which pertussis occurs in the vaccinated child's own family. An unvaccinated child of pre-school age without a known history of pertussis infection probably runs an 80% risk of himself becoming infected in such circumstances. With efficient vaccines this secondary attack rate is reduced to about 10%.

I am not optimistic that within the bounds of one practice the questioner will be able to collect sufficient data to calculate these secondary attack rates. Only children will rarely be of use to him, and even if efficient vaccines have not been widely used in his area the brothers and sisters of children offered for vaccination will often have been vaccinated already.

Infection from the Chalice

Q.—In certain churches the chalice at Holy Communion is passed from person to person. What are the risks of infectious diseases being spread by this means?

A.—Scattered observations dating back to the last century have been made on this subject, although none of them are fully conclusive by modern standards, and authors who condemn the use of the chalice as insanitary do not appear to have been free from bias against the practice itself. Burrows and Hemmens,¹ who review this evidence and describe what appears to be the only recent study of the subject, begin by emphasizing that they "are concerned with neither the theory of the sacrament nor the relative ecclesiastical merits of the various methods of its administration."

A superficial resemblance between this problem and that of "sanitizing" drinking utensils in general leads them to point out that "ordained clergymen are highly educated persons whose administration of the sacrament would appear hardly comparable to the activities of the usual soda fountain employee, restaurant dish washer, or bar keeper." The hygienic precautions taken are described as "rotation of the chalice so that successive persons do not drink from the same place, and the wiping of the chalice both inside and out before the same place is used again, with a purifier or a series of purifiers which are freshly laundered and ironed prior to use." It is also pointed out that in the Book of Common Prayer the directions for Communion of the Sick read "... the Minister shall first receive the Communion himself, and after minister unto those who are appointed to communicate with the sick, and last of all to the sick person."

These authors' actual experiments consisted in contaminating the rim of a silver chalice either with sterilized saliva to which pure cultures of various bacteria had been added or by drinking from it with or without an indicator organism

(*Chr. prodigiosum*) in the mouth, and studying the fate of the bacteria so deposited by subsequent quantitative culture. Silver is itself bactericidal, and a rapid fall in the numbers of bacteria recoverable was observed in comparison with their behaviour when similarly deposited on a glass slide. Moreover, the wiping of a smooth surface with a fine linen fabric mechanically removes anything deposited on it with a high degree of efficiency, and reductions in bacterial counts of 90% were observed to result from this process alone. From these and other experiments the authors were satisfied that the risk involved is very small, and it is said that in fact no instance of the transmission of infection by this means has ever been substantiated. Their least satisfactory evidence concerns *Myc. tuberculosis*. Experiments with this species were not quantitative, and were concerned only with survival on the surface of the chalice without wiping, but all guinea-pig tests up to 40 minutes after contamination were positive.

Idiosyncrasy to Procaine

Q.—Following a subcutaneous injection of 5 ml. 2% procaine, a pregnant woman had a severe reaction which came on within 10 minutes and lasted for half an hour. It consisted in tachycardia and collapse. No adrenaline was given with the procaine. What is the nature of this reaction, and can the diagnosis be confirmed by patch test or other means? If the diagnosis is confirmed, can the patient be desensitized to procaine, or are there other local analgesics that may safely be used?

A.—True allergic reactions to procaine usually manifest themselves as a local dermatitis to direct contact with the drug or urticaria and angioneurotic oedema from injections. The present reaction is due to the toxicity of the drug—that is, it is an idiosyncrasy rather than an allergy. The diagnosis cannot be confirmed by patch tests, but the reaction could be reproduced on further injections. Desensitization is thus not to be expected and I have not seen it reported. It is quite possible that a patient may show toxic reactions to procaine and have no reactions to such drugs as stovaine or supercaine which do not contain a para group. Buff¹ has found that a subcutaneous or intravenous dose of 0.5 to 1 mg. neostigmine methylsulphate will prevent collapse and dramatically reduce the cardiac rate to normal in cases with a toxic procaine tachycardia.

Sodium Glutamate in Food

Q.—Sodium glutamate seems to be a frequent constituent of the prepared foodstuffs being imported into this country, and recently in an American method of cooking rice it was recommended as an addition. It is said to be used as a condiment in the East, but I wonder if it has any other value in the cooking of rice and if it is entirely innocuous?

A.—Sodium glutamate is usually made from wheat gluten by acid hydrolysis followed by neutralization with soda, but it can also be obtained as a by-product in the sugar beet industry. It is favoured as a means of obtaining a strong meaty flavour from cheap vegetable sources. Under the name "aginomoto" it is used extensively in Japan and China. It is very effective in reinforcing the taste of chicken in dishes consisting mainly of rice. Food manufacturers use it to improve the taste in canned and dehydrated meats. There is no evidence that it is harmful, and it is presumably metabolized in the same way as glutamic acid eaten in combined form in ordinary foods.

Stability of Antibiotics

Q.—How stable are the commoner antibiotics in the refrigerator and at room temperature?

A.—A full answer to this question occupies 12 pages and constitutes Chapter 4 of *Antibiotics: A Survey of their*

Properties and Uses. London: Pharmaceutical Press, 1952, to which the inquirer is referred for details. The question presumably refers to solutions, and the stability of these depends not only on the temperature at which they are held, but on other factors such as pH. For example, penicillin is most stable at pH 6.0, and, if the trouble is taken to buffer the solution at this pH, it will last longer.

The only antibiotic so unstable as to cause serious difficulty is aureomycin: solutions of this for laboratory purposes should be made daily. Streptomycin, chloramphenicol, and terramycin are more stable than penicillin, and any of these four will suffer no significant loss of potency in one month or more if the solution is frozen, or in one week at about 4° C. These times may be extended if a loss of potency of the order of 10% is of no consequence.

NOTES AND COMMENTS

Drugs for Hypertension in Pregnancy. Mr. JOHN SOPHIAN (London, W.1) writes: In the answer to "Any Questions?" of February 13, regarding the place hypotensive drugs have in the treatment of hypertension in pregnancy, you touch on the merits of (1) hexamethonium and tetraethylammonium compounds and on (2) hydrazinophthalazine, thiopranium, and veratrine. In connexion with the neurogenic factor in hypertension Mendlowitz has classified the site of therapeutic action of hypotensive drugs at four levels: (a) The cortical, where barbiturates and rauwolfia serpentina act; (b) the hypothalamic, affected by protoveratrine and 1-hydrazinophthalazine corresponding to group (2) above; (c) the ganglionic level which reacts to the hexamethonium compounds, equivalent to the classification (1) above; and finally (d) the sympathetic nerve endings themselves. Rothlin¹ has shown that some portion of the pharmacological activity of the ergot derivatives is directed to the peripheral blocking of sympathico-adrenergic vasoconstrictor stimuli and that they have proved most useful for this purpose. The value of hypotensive drugs essentially needs to be considered along with the electrolyte NaCl, whose depletion appears to affect the non-neurogenic or intrinsic factor in hypertension, helping to reduce the blood pressure. The therapeutic agents in group (b) and (d) have a noticeable effect on the kidney. According to Moyer et al.,² 1-hydrazinophthalazine increases the renal blood flow in anaesthetized dogs. Simultaneous exhibition of adrenaline or noradrenaline showed that this was a preferential decrease in peripheral resistance in the kidney to that in the extremities, in which there was no change in blood flow; while Willson and Smith³ found that intravenous veratrine in the vagotomized animal heightened the perfusion rate of the isolated kidney. It is not improbable that the effectiveness of these therapeutic agents in toxæmia lies in the relief of an underlying renal ischaemia. Work on the ergot derivatives supports this view, as I mentioned recently in a letter in the *Lancet*.⁴ I therefore feel that the barbiturates and the ergot derivatives should find inclusion in the reply and that the corollary of salt restriction needs emphasis.

A New development providing CONTROLLED antacid therapy

Prodexin is a new product containing aluminium glycinate, and belongs to the buffer group of antacids. It depends for its action upon the slow release, on hydrolysis, of active aluminium hydroxide gel and glycine (amino acetic acid). Glycine rapidly raises the pH to 2, sparing the aluminium gel for the later stage of raising it into the "safe zone" of pH 3.5 to 4.5. Prodexin maintains an equable gastric environment for long periods without alkalisation.

Prodexin provides a convenient, economical and safe treatment for HYPERACIDITY and PEPTIC ULCER.

The tablets, sucked one at a time, maintain the pH of the stomach contents within the "safe zone" for up to two hours. With Prodexin there is no risk of acid rebound or alkalosis. Prodexin tablets are pleasant to suck and they do not form gritty particles in the mouth or give rise to constipation.

PRODEXIN

Each tablet contains:—

Aluminium glycinate.....0.9 gramme.
(dihydroxy aluminium aminoacetate)
Light magnesium carbonate.....0.1 gramme.

The basic N.H.S. cost of treatment at the rate of 6 Prodexin tablets daily is 83d.

New

plasticized

cream

provides

LONGER-LASTING

PROTECTION

against occupational

and allergic dermatoses

A single application daily will maintain effectiveness of COVICONE Cream's protective coating, following initial application three times a day for a week to 10 days. Longer-lasting because it is not removed by ordinary washing, COVICONE is ideal for prolonged protection against frequently encountered contact sensitizers as in industrial, professional and household circumstances.

Easily applied. COVICONE forms an invisible physical barrier against irritating and sensitizing substances. Imperceptible to patient, coating won't interfere with work or other activities.

Not greasy or sticky. COVICONE is a unique, plasticized combination of silicone, nitrocellulose and castor oil suspended in a cream base.

Premature application on rash and wet, exudative lesions should be avoided. COVICONE is as close to a universal product as you will find wherever protection is desired from environmental substances. Available in one ounce tubes, and one pound jars.

AND

M. E. FEARNLEY, D.S.C., M.D., M.R.C.P.
Dan Mason Research Fellow

(From the Rheumatism Department, West London Hospital)

After three years' experience at the West London Hospital in the treatment of a series of cases of rheumatoid arthritis with cortisone, we feel that it may be of interest to summarize our results to date. In a previous publication (Copeman *et al.*, 1950) we reported a short study of the effect of cortisone and other steroids in rheumatoid arthritis, and described certain methods for clinical assessment. We later published a longer study of the effects of continuous cortisone administration in the same disease (Copeman *et al.*, 1952). The present paper is a continuation of those studies.

This report is on 20 cases of rheumatoid arthritis, 14 of which have received cortisone for more than two years, and all for at least a year continuously (Table I).

TABLE I.—Duration of Cortisone Treatment

Months:	36	35	34	33	32	31	30	29	25	22	18	17	16	Total
No. of cases	2	3	1	2	1	1	2	1	1	1	2	1	2	20

All the patients selected had previously suffered from active rheumatoid arthritis for at least two and a half years, and the majority for much longer, the average duration of the disease before cortisone treatment being 6.8 years. None of them were able to carry out their normal occupations, and all were regarded as severe cases. They had lost their independence, and described themselves as "crippled." These patients had been under observation and treatment for some time, and the more standard methods, such as adequate rest, salicylates, and gold salt injections, had failed to suppress the progress of their disease.

From this series of 20 cases 17 have now been returned to a working life in their various spheres, although, as the analysis in this report will show, the actual degree of functional improvement varies from case to case.

*This work has been aided by grants from the Dan Mason Research Foundation of the West London Hospital Medical School, the Empire Rheumatism Council, and the Medical Research Council.

Realizing that a real cure in any case was unlikely, we decided to assess our results on a practical functional basis. Accordingly, if the disease was suppressed sufficiently to enable normal work to be resumed and maintained we regarded the result as satisfactory; if the patient was able to return to work but still complained of considerable pain we termed the result moderate; and if the patient could not resume work it was held to be unsatisfactory.

Analysis of Results

Any opinion concerning the value of a particular form of treatment must depend on whether the emphasis is placed

Chart showing the effect of long-term cortisone administration on the different components of rheumatoid arthritis (Case 7). Note the marked improvement in functional capacity, moderate improvement in signs of activity of the disease, and deterioration in radiological involvement.

The practical value of such improvement obtained through cortisone must, however, be weighed against the possible dangers resulting from long-term treatment with this drug.

TABLE II.—Results

Case No.	Description	Condition Before Treatment	Present Condition	Time on Cortisone	Daily Maintenance Dose of Cortisone	Results as Assessed by Functional Improvement
1	Housewife aged 48. R.A. 8 years	Doing only very light housework	Working. Cooking and housework	36 months	100 mg.; or 60 mg. hydrocortisone	Satisfactory
2	Army officer aged 33. R.A. 5½ years	Partly bedridden; could walk 30 yards	Full-time clerical work. Drives invalid chair. Considerable pain from secondary osteoarthritis of hips	36 "	100 mg.	Moderate. Walks with difficulty
3	Housewife aged 40. R.A. 4½ years	Unable to dress herself or do housework	Working, and leading a normal life	35 "	50 "	Satisfactory
4	Housewife aged 36. R.A. 12½ years	Unable to dress herself or run her home	Working. Can do housework with difficulty. Only partial suppression	35 "	62.5 "	Moderate. Oedema and some pain
5	Housewife aged 43. R.A. 5 years	Unable to do housework, lift anything, do her hair, or get out of a bath	Working. Leading a busy social life entertaining for her husband; much hampered by her knees	35 "	100 "	Moderate. Much pain
6	Superintendent water inspector aged 45. R.A. 14 years	Unable to work	Working full-time with much travelling	34 "	62.5 "	Satisfactory
7	Treasury official aged 35. R.A. 7 years	Just managing to work with long periods of sick leave. Unable to dress himself	Working full-time without difficulty	33 "	37.5 "	"
8	Clerk aged 34. R.A. 8 years	Unable to work or do housework	Working. Has completed training as a dressmaker. Arthrodiesis of left wrist	33 "	75 "	"
9	Housewife aged 36. R.A. 5½ years	Able to do light cooking only	Working. Able to do much more in her home, but hampered by her knees from walking any distance	32 "	50 mg., plus fortnightly injections of 50 mg. hydrocortisone into both knees	"
10	Housewife aged 31. R.A. 11 years	Unable to do housework or look after children. Walked with a stick	Working and leading a normal life, hindered only by deformed feet	31 "	62.5 mg.	"
11	Typist aged 21. R.A. 3½ years	Unable to work	Working full-time and leading a normal life	30 "	62.5 "	"
12	Chiropodist aged 54. R.A. 10½ years	Unable to work and permanently in hospital	Full-time clerical work in spite of much permanent damage	30 "	87.5 "	"
13	Railway maintenance worker aged 44. R.A. 4½ years	Bedridden. Much muscle-wasting and joint effusion	Not working, though mobile and independent and capable of light employment	29 "	75 "	"
14	Housewife aged 51. R.A. 4½ years	Unable to do housework or shopping	Working and leading a normal life. Some tenderness and swelling of right wrist and left knee	25 "	75 "	"
15	Gold blocker aged 50. R.A. 2½ years	Unable to work	Working full-time	22 "	37.5 "	"

20	Housewife aged 23. R.A. 5 years	Unable to do housework or look after child	Working and leading a normal life	16 "	75 "	Satisfactory

In order, therefore, to assess the true value of this therapy we have analysed in each case the effect of cortisone on various important components of the disease process, such as the objective joint changes, the patient's functional capacity, clinical and laboratory evidence of activity, and the radiological changes. Table II shows the results of this analysis in the whole series, and the Chart gives a graphic representation of the changes in a particular case.

These cases have been examined in detail every few weeks since the start of treatment, and the various components of the disease process assessed according to the following categories (Table III).

TABLE III

	Joint Involvement	Activities of Daily Life	Functional Tests	Systemic Signs and Lab. Tests	Radiological
Marked improvement	—	7	8	—	—
Moderate improvement	14	11	7	15	—
Unchanged	1	1	3	3	12
Deterioration	5	1	2	2	8
Total No. of cases	20	20	20	20	20

Objective Joint Involvement.—This was measured by examination of the joints for swelling, tenderness, and range of movement; the recordings were charted each month.

Activities of Daily Life (Functional Capacity).—At the outset of this trial a set of test questions was drawn up to estimate the patients' chief limitations in the conduct of their everyday life—for example, ability to dress, speed of dressing, ability to shave or do hair, ability to bath themselves, ability to walk, speed of walking, ability to climb stairs, ability to work, number of analgesics needed daily, how often awakened by pain.

Functional Tests.—Ten functional tests were adapted for each patient, depending on the joints involved. Among these were the power of grip, using a baumanometer cuff, starting at 30 mm. Hg (normal 260 mm. Hg +). Certain common functions, such as taking off a jacket, jumping, or standing on the toes, were also timed. These tests can be arranged to give a composite picture of the patient's functional abilities and can be carried out in a few minutes.

Systemic Signs and Laboratory Tests.—The clinical signs of activity apart from joint changes are fever, loss of weight, and muscle-wasting. The laboratory tests we have used consistently are the sedimentation rate (Westergren) and estimation of the haemoglobin level.

Radiological.—X-ray films taken before treatment included all the main joints involved at that time. The points particularly observed for change subsequently were soft-tissue swelling, osteoporosis, cartilage and joint erosions, and loss of joint space. A number of our cases have shown evidence of radiological progression in spite of the fact that their functional ability has none the less improved with cortisone.

Dosage Schedule

To find the optimum maintenance dose it is necessary to employ some method of assessing the clinical activity of the disease, and we have found that by measuring joint tenderness and function, together with the patient's own account of his pain and mobility, at regular intervals this can be achieved with reasonable accuracy. The patients in this series were seen and assessed weekly or fortnightly in the early stages, and once there was evidence that the symptoms and signs were being adequately suppressed the maintenance dose was found by reducing the initial dose by small amounts at intervals of not less than five days. A maintenance dose of 50 mg. a day or less was aimed at, but could by no means always be achieved. When the maintenance dose had been established the patients reported as out-patients every four or six weeks for observation.

In some cases a low maintenance dose will successfully suppress the inflammatory signs in all but one or two joints, often knees. We have found that by the use of hydrocortisone (compound F) as an intra-articular injection every few weeks, or occasionally at longer intervals, we can suppress this residual inflammation, and we have in addition sometimes been able to lower the patient's oral dose of cortisone.

In our early cases we adopted the scheme of dosage originally suggested by Hench *et al.* (1949), in which on successive days 300, 200, 100 mg. were used. We soon found, however, that the response provoked in this way tended to be too dramatic, and so led to subsequent disappointment on the part of the patient if this rate of progress did not continue. We therefore adopted a routine initial dose of 100 mg. daily, and with this it proved possible to measure the patient's response after about five days. In more recent cases in this series we have lowered the initial dose still further to 75 mg. daily; a level which has proved to be equally satisfactory in most cases.

Variation of Maintenance Dosage

The maintenance dose may have to be increased temporarily when conditions of extra stress occur, but should be lowered again as soon as possible. The average maintenance dose by the oral route in this series has been 69 mg. a day, which is the same as that reported by Fischer and Brøchner-Mortensen (1953) in Denmark.

Fourteen of our patients have received cortisone continuously for over two years, and during this period their dose requirements have not altered to any large extent, although in two cases the dose had to be increased somewhat. In Cases 6 and 8 the dose was progressively reduced during the first few months of treatment to 25 mg. cortisone a day, and was maintained satisfactorily at that level for some months. It was then thought probable that patients who need such a low dose might be able to dispense altogether with the drug, so it was stopped, with the unfortunate result that the disease relapsed at once. In neither of these cases were we ever able to lower the maintenance dose down to 25 mg. a day again.

We believe that the dose of cortisone should never be altered on account of surgery. Healing has proceeded normally after all operative procedures undertaken on our patients, notably in emergencies such as strangulated hernia (Case 12) and evacuation of a haematoma (Case 1), and in planned surgery such as an arthrodesis (Case 8). In the three cases of peptic ulceration which occurred (Cases 4, 7, and 12) the dose of cortisone was lowered slightly, but in each instance the lesion healed normally with ordinary medical treatment.

Side-effects

It is important to try to estimate the likelihood of the occurrence of side-effects in each case. Such an assessment often fails because the maintenance dose required cannot be accurately foretold. Experience has shown that in general men can tolerate a higher dose than women with-

out developing side-effects, and that obesity and "moon-face" are particularly apt to occur in women near the menopause. Most of the side-effects we have encountered were mild and could be controlled by merely lowering the dosage and supervising the diet, or adjusting the sodium or potassium intake; but over a long period they may sometimes become troublesome enough to offset the functional improvement gained.

We have divided the side-effects observed in this series into two groups: (1) those which were serious in the sense that they might endanger the patient's life; and (2) those which were merely inconvenient, aesthetically displeasing, or transitory.

Group 1. Side-effects Dangerous to Life

Depression.—The most serious reported complication of hormone treatment is psychosis. We have taken particular trouble in our series to exclude patients with psychological incidents in their history, and we have not encountered this complication. We have, however, one patient (Case 16) who suffers such severe depression on the minimal dose needed to control her arthritis that, although she has no family or previous history of psychological disturbances, we have decided to withdraw the drug.

Hypertension.—In all but three of our cases the blood pressure remained unaffected by treatment; in one (Case 19), however, hypertension became evident early in treatment and the blood pressure rose from 120/80 to 200/105 on the eighteenth day. The condition was symptomless, but, as it has so far proved impossible to find a dose which will control arthritis without further increasing the hypertension, cortisone is being withdrawn. In the other two cases the blood pressure rose slightly at the onset of treatment, but has not increased during the past year. Both these patients are working full time, and we have not felt it necessary to withdraw the hormone (Cases 2 and 15).

Gastric Complications.—There have been three gastric complications in the present series. Case 7 developed a duodenal ulcer after thirteen months on cortisone. This healed normally on medical treatment with slight reduction of the cortisone dosage whilst in hospital, and he has now been symptom-free for fifteen months. Case 4, who had a previous history of gastric ulcer, complained of retrosternal pain referred to the back. On investigation this was found to be due to an oesophagitis associated with a hiatus hernia, which responded to ordinary medical treatment with slight reduction in cortisone dosage. Continued medical treatment keeps her free from oesophageal pain. Case 12, after two years' continuous cortisone, complained of exhaustion, which was found to be due to anaemia secondary to melaena. On admission to hospital the haemoglobin had fallen to 4.23 g. Without alteration in the dose of cortisone she became symptom-free after transfusion and medical treatment. There was no x-ray evidence of peptic ulcer three weeks after the melaena stopped, but she has continued on an ulcer dietary regime.

Miscellaneous.—In the earlier cases, before the drug could be given by mouth, we encountered a great deal of trouble with injection abscesses. We have not encountered any intestinal intolerance to administration by the oral route. One case (No. 2), which has been reported fully elsewhere (Bishop and Glyn, 1952), has concurrent diabetes. He has been satisfactorily maintained on continuous cortisone therapy, however, whilst his diabetes has been controlled by insulin. We have already reported (Copeman *et al.*, 1952) the death from cerebral haemorrhage of one of our long-term patients. This was not, however, thought to be attributable to cortisone, and as she received the drug for only nine months her case is not included in the present series.

Group 2. Less Important Side-effects

Obesity.—The most common side-effect in female patients on cortisone has been a tendency to accumulate fat, both local and general. In nine cases there has been some rounding of the face; in two the development of localized

deposits of fat over the lower cervical vertebrae ("buffalo hump"), and in six cases some weight increase, due partly to fluid retention as evidenced by peripheral oedema, and partly to the voracious appetite which such patients occasionally develop. These effects were controlled with difficulty in some cases, by reduction of dosage, a salt-free diet, and fluid restriction.

Miscellaneous.—Minor skin abnormalities have occurred on high dosage: acne in three cases, excess sweating and hypertrichosis in two, and pigmentation in a single case. All these have disappeared on dose reduction. Minor psychiatric symptoms were occasionally noted, and were fairly evenly divided between those who showed apathy and exhaustion and those who complained of tension and irritation. In no case were they severe or disabling, and it seems that in such cases the drug merely tends to accentuate the normal personality trends.

Discussion

It is universally agreed that cortisone in adequate dosage will suppress the symptoms and signs of rheumatoid arthritis in a relatively short period, and it is recognized that when the drug is withdrawn a rapid relapse generally follows. It is, however, argued by some that because of this necessity for prolonged or even indefinite administration cortisone does not constitute practical therapy, and that owing to the danger of side-effects its use is not justified in practice.

Published reports of long-term treatment with cortisone and A.C.T.H. have now appeared from various parts of the world. Holbrook (1953), reporting on a group of 36 patients with rheumatoid arthritis treated with cortisone, found that at the end of twenty-four months only 10 of these were still getting worth-while improvement, and that all showed some clinical and x-ray advance in their disease. West and Newns (1953) reported a study of 27 patients with rheumatoid arthritis treated for an average of nineteen months with a maintenance dose between 50 and 75 mg. a day. They compared their series with other patients who had not received cortisone, and concluded that this drug does not have a favourable effect on the course of rheumatoid arthritis, and because of the danger of complications do not recommend its administration on a long-term basis.

In New York Freyberg *et al.* (1951) studied 44 patients who received cortisone uninterruptedly for more than a hundred days. In many patients a good partial remission could be maintained with 50–75 mg. daily. These authors note the less point out that prolonged use of cortisone is not practical treatment for all patients with rheumatoid arthritis. They advocate its use mainly for definite purposes, such as to check rapidly worsening disease or to facilitate certain stages in physical therapy or rehabilitation.

In Copenhagen Fischer and Brøchner-Mortensen (1953, 1954) have treated 50 patients suffering from rheumatoid arthritis with both cortisone and A.C.T.H. In their first report on 24 patients these authors were unwilling to commit themselves on the practicability of this form of treatment. In their second paper they report the study of 50 cases. In five cases treatment was abandoned because of an unsatisfactory response, whilst in another five cases complications necessitated stopping these drugs. In four cases treatment was stopped after five to twelve months because remission had occurred. The remaining 36 were maintained with an average dose of 69 mg. of cortisone a day from five to thirty-three months. Measurement of the joint-movement index and the general functional ability showed an improvement in 84% of the group when compared with the pretreatment values. Of the group in remission or continuing treatment only two had been capable of work before treatment started, compared with 31 during therapy; whilst the number of totally disabled subjects in this series was reduced from nine to one. Those authors now conclude, therefore, that this form of treatment is of practical value in the therapeutic management of selected cases of rheumatoid arthritis.

From Paris, Coste *et al.* (1953) reported 20 cases of rheumatoid arthritis treated continuously for many months. In three cases remissions occurred and they were able to stop treatment without relapse; in a further three cases the results were poor and cortisone was discontinued; whilst in the remaining 14 patients the results were satisfactory enough to make continued therapy worth while. Like most recent workers they preferred continuous to intermittent courses of treatment, and they believe that this method can be used as a practical therapeutic measure in this disease, save perhaps in early cases which might anyhow be expected to go into remission spontaneously. They estimated the risk of psychotic side-effects at 1% in their series.

Clark *et al.* (1953) reported on 35 patients with this disease treated with cortisone for from three to twenty-four months. Major subjective improvement was obtained in 74% and major objective improvement in 38%, although minor complications were common. They did not consider that hormone therapy should be employed until maximum benefit from conservative measures has been established, and that it should always be combined with such measures.

A study of long-term cortisone treatment was reported by Ward *et al.* (1953) in which 65 patients were treated. In 57 (88%) of these cortisone controlled the symptoms adequately, and in 8 (12%) the drug was stopped because the dose required for significant relief of symptoms also produced side-effects. In 46 patients the drug was given continuously for from eight to twenty-four months. In 44 of these patients there was moderate to great improvement; in the remaining two cases the relief was only mild. Nine cases showed mild side-effects. These authors concluded that long-term cortisone is a practical and useful method of treatment in rheumatoid arthritis, and is the treatment of choice in certain phases.

Conclusion

As the result of our experience with a well-observed group of 20 cases of rheumatoid arthritis, we consider that cortisone therapy is a practical addition to treatment in selected cases.

As cortisone is not actually curative, and since we have seen radiological progression of joint damage in patients in whom the symptoms were being suppressed, we consider that more conservative methods of treatment, such as adequate rest, salicylates, gold salts, and physiotherapy, should generally be tried first, as these will themselves in some cases produce adequate remission of the disease.

Absolute contraindications to cortisone therapy are recent or active tuberculosis, present or past psychosis or psycho-neurosis, diabetes, hypertension, and severe osteoporosis; while long-standing cases with much permanent irreversible deformity and joint damage are also unsuitable for cortisone therapy.

Evidence is adduced to show that the functional improvement of the patient under cortisone treatment is greater than the actual degree of suppression of the activity of the disease. The most suitable cases are therefore those in which the functional disability exceeds the anatomical joint damage.

It is our experience that, although previously incapacitated, a number of patients can be restored to and maintained in relatively normal activity by long-term cortisone treatment. Such patients, however, require careful and constant supervision if this result is to be achieved.

Summary

Twenty cases of rheumatoid arthritis have been treated with cortisone; 14 of them received this drug for over two years.

All were previously incapacitated, but 17 have been able to return to their occupations with the help of this treatment, as the result of varying degrees of functional improvement, the extent and nature of which have been analysed.

The dosage and management of these cases, and the side-effects seen in the course of their treatment, are discussed.

The cortisone used in this study was partly provided from a generous gift made jointly to the Medical Research Council and the Nuffield Foundation by Messrs. Merck & Co. Inc., and partly from the Ministry of Health. We wish to acknowledge the valuable assistance given to us by Dr. B. Gottlieb, consultant physician, St. Mary Abbots Hospital, and his assistants, and by the following pathologists and biochemists and their assistants: Dr. H. E. Archer, Dr. J. D. Robertson, and Dr. R. G. L. Waller, West London Hospital; Dr. A. G. Signy, St. Mary Abbots Hospital; and Dr. A. E. Kellie, Middlesex Hospital.

AN APPRECIATION OF MITRAL STENOSIS*

PART II. INVESTIGATIONS AND RESULTS

BY

PAUL WOOD, O.B.E., M.D., F.R.C.P.

Physician-in-Charge, Cardiac Department, Brompton Hospital; Physician to the National Heart Hospital; Director of Studies, Institute of Cardiology

THE ELECTROCARDIOGRAM P Mitrale

The P mitrale may be defined as a widened P wave of normal or only slightly increased voltage, usually notched, bifid, or flat-topped. It was present in all but four of the surgical cases with normal rhythm. The exceptions included three instances of the P pulmonale (due to extreme pulmonary hypertension in two and to tricuspid stenosis in one); there was only one instance in which the P wave was normal, and this was the mildest in the series. In 10 cases the auricular complex was a mixture of the P mitrale and the P pulmonale: the pulmonary vascular resistance was in the extreme grade in two of these, between 6 and 9 units in three of them, and relatively normal in three; tricuspid stenosis was responsible in the other two. The P mitrale was at least 0.12 second wide in 79% of the whole surgical group.

In the medical series with normal rhythm, the P mitrale was absent in three-quarters of the trivial cases of mitral stenosis and in 10% of the relatively mild cases in the sense that they were not severe enough to warrant valvotomy. It was present in all

the cases in which mitral incompetence was associated with stenosis, although usually of only moderate degree; there was no presystolic murmur in 80% of these cases. A P pulmonale was present in the most extreme example of pulmonary hypertension and in two cases of tricuspid stenosis, but in only one other. Excluding the trivial cases, a well-developed P mitrale, at least 0.12 second in duration, occurred in half of all the medical cases with normal rhythm.

In the group with almost pure mitral incompetence the P wave was normal in all trivial and mild cases; it was present in relatively mild degree (0.10 to 0.11 second) in half of those of moderate grade. It was seen, also in relatively mild degree, in 80% of the severe cases (grade 3 or 4).

A conspicuous P mitrale (grade 3 or 4) could not be correlated with a dominant a wave in the left atrial pressure tracing: thus only one-third of the cases showing such a waves had a grade 3 or 4 P mitrale; conversely, only a similar proportion of cases having a conspicuous P mitrale had an a wave higher than v in the left atrial tracing. The grade of the P mitrale could not be correlated with the size of the left atrium, this fact being best illustrated by the relatively mild grades found in mitral incompetence, which favours left atrial dilatation. Nor could it be correlated closely with the size of the mitral orifice found at operation, the great majority of those with conspicuous P mitrales having an orifice either in the average grade (1 by 0.5 cm.) or in the slightly tighter grade (0.75 by 0.4 cm.); in only one was the stenosis extreme (0.5 by 0.3 cm.).

It is concluded that the P mitrale is a good sign of well-developed mitral valve disease, and that if it is well marked (grade 3 or 4) it strongly favours stenosis rather than incompetence; also that it should be present in all cases of stenosis that are severe enough to warrant valvotomy.

Right Ventricular Preponderance

The degree of right ventricular preponderance in mitral stenosis based on a conventional interpretation of the six routine V chest leads was closely related to the pulmonary vascular resistance (Fig. 7). An important practical fact noticed in the analysis was that any degree of right ventricular preponderance in mitral stenosis meant that the case was severe enough to warrant valvotomy: the converse, of course, was not true.

Left Ventricular Preponderance

Left ventricular preponderance was very rare in pure mitral stenosis, and when present was only of slight degree. In the mitral incompetent group, on the other hand, it occurred in 82%, excluding trivial cases, and in degree averaged slightly over grade 2. Grade 3 left ventricular preponderance always meant severe mitral incompetence in the absence of aortic valve disease. In the medical group with significant mitral incompetence, left ventricular preponderance, averaging a little under grade 2, occurred in one-third, ventricular balance being normal in half and

FIG. 7.—Relationship between right ventricular preponderance and pulmonary vascular resistance.

*The second part of a lecture delivered before the San Francisco Heart Association on October 29, 1953, and modified for the Strickland Goodall lecture of the Society of Apothecaries of London, March 24, 1954. Part I appeared in last week's issue (p. 1051).

the right ventricle predominating in the remainder. Amongst the surgical cases with combined mitral stenosis and incompetence, slight left ventricular preponderance (averaging grade 1) occurred in one-third, the ventricular balance being normal in one-third and the right ventricle preponderating in one-third.

It is concluded that left ventricular preponderance is excellent evidence of mitral incompetence in the absence of aortic valve disease. In the whole surgical series there was only one patient with more than slight left ventricular preponderance, and she did not do at all well. Since the results of valvotomy were poor in half the cases of mitral stenosis complicated by more than trivial incompetence, and only fair in another quarter, and since only one-third of this group had left ventricular preponderance at all, and that of only grade 1, it follows that higher grades of left ventricular preponderance are a direct contraindication to mitral valvotomy.

X-RAY APPEARANCES

Small Aorta

Diminution in the size of the aortic knuckle, often to the extent of its being invisible in the antero-posterior view, was noticed in two-thirds of the surgical cases. A normal aorta was attributed to concomitant aortic valve disease, to atherosclerosis associated with age (over 45), to a relatively mild degree of stenosis, or to the maintenance of a normal rather than a low cardiac output at rest (4.5 to 6 litres a minute), each of these factors occurring in 30%, sometimes in varying combination. Their respective incidences in the surgical cases with a small aorta were 7%, 12%, 19%, and 20%, so that aortic valve disease and age were more likely to have been responsible than the degree of stenosis and the measured cardiac output; few of the cases were mild enough for the last two factors to be important. In addition, 6% of those with a normal aorta had a slightly raised blood pressure (about 160/110) against 1% in those with a small aorta. No obvious cause for a normal-sized aorta could be found in 15%.

In the mitral incompetence group, omitting trivial cases and those of grade 1 severity, 50% had a normal aortic shadow, but of these 58% were between 45 and 69 years old. In the cases with a small aorta only 17% were in this age group. If these relatively old patients are also omitted from the analysis, two-thirds of the mitral incompetence group had a small aorta, which is more comparable to the findings in mitral stenosis.

In the medical series two-thirds of those with significant mitral incompetence had a normal aortic shadow. This was attributed to associated aortic valve disease in half of them. On the whole the findings did not implicate mitral incompetence as one of the factors which tend to preserve a normal aortic shadow.

Left Ventricular Enlargement

Radiological evidence of left ventricular enlargement in cases of mitral valve disease proved less reliable than either clinical or electrocardiographic evidence, and deserves no further comment.

FIG. 8.—Relationship between size of pulmonary artery and pulmonary vascular resistance.

Dilatation of the Pulmonary Artery

There was a close relationship between the size of the pulmonary artery and the pulmonary vascular resistance (Fig. 8). The figures were compiled from the

medical and surgical groups, omitting cases of pure mitral incompetence. When the pulmonary artery was normal or only slightly dilated the pulmonary vascular resistance was normal or only slightly increased in 95%, being high in only 5%; on the other hand, when the pulmonary artery was considerably or grossly dilated the resistance was normal or only slightly increased in 17%, whereas it was high or extreme in 83%. No doubt the correlation would have been closer still if there were not so much variation in the radiological appearances of the pulmonary artery in normal individuals.

In the group with pure mitral incompetence considerable dilatation of the pulmonary artery was seen in only one instance; the vessel was normal in 73%, slightly dilated in 21%, and moderately so in 4%. The lack of enlargement was attributed to the relatively low pulmonary vascular resistance found in this group (see below).

Dilatation of the Right Atrium and Ventricle

It was rarely possible to decide which of these chambers was chiefly affected radiologically, either in the antero-posterior or in the oblique positions, and they have therefore been taken together. The clinical and electrocardiographic findings usually make it clear whether or not the ventricle is involved. In any case, isolated dilatation of the right atrium is seen only in tricuspid stenosis.

The presence and degree of right-sided cardiac enlargement was closely related to the size of the pulmonary artery (and therefore to the pulmonary vascular resistance). Thus in the whole series the grading of the two was the same in 55% and within one grade of each other in 35%, being out of harmony in only 10%. In the surgical group, when there was any discrepancy it was usually the pulmonary artery that was relatively larger than the right side of the heart. In the medical group it was the other way round. When the pulmonary artery was conspicuously dilated and the right heart only slightly so, a high pulmonary vascular resistance was present in half the cases; no explanation could be found in the other half. When the shadow of the right side of the heart was conspicuously enlarged and the pulmonary artery normal or only slightly dilated, tricuspid stenosis was present in 44%, pericardial effusion in 12.5%, and "congestive heart failure" without an unduly high pulmonary vascular resistance in 25%; no explanation other than auricular fibrillation could be found for the remainder.

Left Atrial Dilatation

The size of the left atrium was graded so far as possible from the x-ray appearances in the antero-posterior view. When it could not be seen at all in this view, but deflected the oesophagus backwards in the first oblique position, enlargement was considered to be slight (grade 1); a similar grading was applied when the right border of the left atrium could be seen through the shadow of the right atrium but did not overlap it in the antero-posterior view. Grade 2 enlargement meant that the left border of the atrium or the appendage itself formed a separate arc between the shadows of the pulmonary artery and left ventricle, or that the right border of the left atrium formed the upper part of the right border of the heart, but did not extend further laterally than the right atrium; in grade 3 dilatation the left atrium bulged conspicuously on both sides of the heart, and extended beyond the shadow of the right atrium on that side; gross enlargement was reserved for aneurysmal dilatation.

The average size of the left atrium in the surgical group worked out at grade 1.62, for the medical 1.92, and for mitral incompetence 2.35; for the whole series it was grade 1.8. These figures confirm the fact that mitral incompetence is a more important cause of left atrial dilatation than mitral stenosis.

In the surgical group no correlation could be found between the size of the left atrium and the degree of stenosis. Omitting the cases complicated by significant

Incompetence, grade 1 dilatation was found in 42%, grade 2 in 52%, and grade 3 in 6%; aneurysmal dilatation was not seen. The incidence of each grade of dilatation was much the same in each grade of stenosis. Similarly there was no correlation between the size of the left atrium and the left atrial pressure, provided that a critical degree of stenosis had been reached—as in the surgical group; those with grade 1 dilatation had an average left atrial pressure of 22.9 mm. Hg; those with grade 2 dilatation 21.8 mm. Hg.

In the medical group the size of the left atrium worked out at less than grade 1 for trivial cases, at grade 1.5 for the average case of stenosis not yet severe enough to warrant valvotomy or so severe that death supervened before operation could be undertaken, and grade 2.5 for combined stenosis and incompetence. This confirms the conclusion already drawn.

In the cases in which the pulmonary vascular resistance was extreme (10 units or above) the average size of the left atrium was a little under grade 1.5.

The relationship of the size of the left atrium both to auricular fibrillation and to systemic embolism has been discussed under those headings.

Pulmonary Venous Congestion

Pulmonary venous congestion is of course closely related to dyspnoea, but from time to time intense congestion may be noted radiologically in a patient who is hardly breathless at all, and vice versa. In these unusual cases individual idiosyncrasy in respect of the nervous reflex involved in the mechanism of this type of dyspnoea is incriminated.

As expected, the degree of pulmonary venous congestion judged radiologically was proportional to the left atrial pressure (Fig. 9). This chart shows that the vast majority of cases with radiological signs of pulmonary venous congestion had left atrial pressures between 10 and 30 mm. Hg.

Pulmonary venous congestion was also proportional to the degree of stenosis, provided the pulmonary vascular resistance was not too high. This is shown in Fig. 10, a to d, which have been compiled from the surgical cases without significant incompetence. When the mitral orifice was less

FIG. 9.—Relationship between the radiological signs of pulmonary venous congestion and the left atrial pressure.

stenosed than usual, venous congestion was slight or moderate in degree and was never modified by the pulmonary vascular resistance, for the latter was never raised; in the most common type of case, with an orifice of about 1 by 0.5 cm., congestion was usually moderate or considerable, provided the resistance was not above six units, but fell off sharply when the resistance was higher; when the mitral orifice was tighter than usual, around 0.75 by 0.4 cm., but not yet extreme, the findings were similar; in extreme cases in which the orifice did not exceed 0.5 by 0.3 cm., congestion tended to be considerable or gross and, although modified by resistances between 6 and 10 units, usually required a greater degree of vasoconstriction for its efficient

FIG. 10.—Relationship between the intensity of pulmonary venous congestion judged radiologically, the pulmonary vascular resistance, and size of the mitral orifice. In A the orifice was larger than usual, in B it was average, in C it was tighter than usual, and in D it was extreme. In B, C, and D the damping effect of a high resistance is seen.

relief. It may also be noticed from Fig. 10 that there was a higher incidence of cases with a high resistance in the group with extreme stenosis than in the other groups; life may well have depended on it.

Good objective evidence of a functionally successful valvotomy was afforded by relief of pulmonary venous congestion judged by radiological standards.

Haemosiderosis

Incontrovertible haemosiderosis, distinct from pulmonary venous and lymphatic congestion, was observed in 10% of the surgical cases and in 6% of the medical; it did not occur in a single instance of pure mitral incompetence. In the few examples in which serial skiagrams had been taken over a prolonged period haemosiderosis had been present for many years; indeed, the time of its onset was never detected, for it was always present in the first film obtained and did not change subsequently either before or after operation.

Orthopnoea or paroxysmal cardiac dyspnoea occurred in 60% of the cases with haemosiderosis, which is about the same as its incidence in the combined surgical and medical groups as a whole, so that pulmonary venous congestion cannot be the only factor concerned. Normal rhythm and a normal pulmonary vascular resistance were each present in 80% of the cases with haemosiderosis, which is a little higher than in those without. But by far the most important factor correlated with haemosiderosis was *pulmonary apoplexy*, as previously defined, for this had occurred in 55%, which is four to five times higher than its incidence in cases without haemosiderosis (12%). Since haemosiderosis is believed to be due to multiple recurrent haemorrhages from the broncho-pulmonary anastomoses in the mucosa of the terminal bronchioles the relationship was expected (Laubry *et al.*, 1948; Lendrum, 1950).

No correlation could be established between haemosiderosis and mitral incompetence, the left atrial pressure, or the size of the mitral orifice; nor, of course, had it anything to do with pulmonary hypertension.

Calcification of the Mitral Valve

The association between heavy calcification of the mitral valve and a serious degree of mitral incompetence has been emphasized repeatedly, and the point is strongly confirmed in the present series. Thus, 40% of the group with relatively pure well-developed mitral incompetence, 52% of the medical cases of mitral stenosis complicated by serious incompetence, and 62% of similar surgical cases had heavy calcification; in fact, 50% of all cases with a significant degree of mitral incompetence had heavy calcification.

In the surgical group 28% of all cases had some degree of mitral calcification, but it was trivial and in no way influenced the findings, operative technique, or results in over half of them; only 12% of the surgical cases had heavy or moderate mitral calcification, and significant incompetence was present in all but three of them.

Valvotomy was undertaken in these cases because the patients' symptoms were attributed to stenosis despite the leak, or in the hope that the valve could be repaired. The results in this small series were never excellent; they were good in 41%, fair in 12%, and poor in 47%. The chief cause of the bad results was the development of an even greater degree of mitral incompetence. Of three cases in which the pre-operative mitral leak was trivial, two did badly in this way.

In the medical group as a whole 87.5% of those with mitral calcification had moderate or considerable mitral incompetence.

It is concluded that heavy mitral calcification is a serious drawback to valvotomy, not only because it favours too great a degree of mitral incompetence, but because it is likely to result in such incompetence if not already present. It is not merely the calcium which causes the trouble, but the severe destruction of the valve mechanism which leads to its deposition.

Cardio-Thoracic Ratio

Although this was measured and recorded in most cases, it has not been analysed separately, for an increased cardio-thoracic ratio meant little unless the dilated chambers causing the enlargement of the heart shadow were identified. When there appeared to be true general enlargement without a mechanical cause, pericardial effusion proved a more likely explanation than active rheumatic carditis.

CATHETER STUDIES

Cardiac catheterization was carried out in 125 of the surgical cases, 42 of the medical, 17 of those with mitral incompetence, and in 23 awaiting valvotomy—a total of 207 cases. No serious technical difficulty was encountered in any of them; there was no mortality, and no complications other than the occurrence of pulmonary infarction when diiodone was injected through a catheter wedged in a distal branch of the pulmonary artery, so that that method of studying the anatomy of the pulmonary circulation had to be abandoned.

Right Atrial Pressure

Tracings obtained from the right atrium confirmed clinical observations on the jugular venous pressure and pulse described under that heading. Little further information was gained by analysing the central tracings themselves. When there was normal rhythm *a* and *v* were usually about equal in amplitude in uncomplicated cases. The *a* wave was usually dominant, measuring 3 to 5 mm. Hg above *v*, in cases with severe pulmonary hypertension, and was occasionally of giant proportions. Giant *a* waves were also recorded in tricuspid stenosis. In advanced heart failure the *v* wave became more prominent and was followed by a steep *y* descent. In tricuspid incompetence the *x* descent was minimal, and in auricular fibrillation it was never seen.

Right Ventricular Pressure

The systolic pressure was of course always the same as the pulmonary artery systolic pressure; this is discussed in the next section. The right ventricular pressure at the end of diastole was raised in 50% of patients with congestive heart failure, lying between 4 and 14 mm. Hg above the sternal angle; that the other 50% with failure did not show high readings was attributed to the fact that patients with heart failure were commonly treated by means of rest, digitalis, a low-sodium diet, and mercurial diuretics, and were not catheterized until they had improved. For this reason few of the figures represent the situation in severe failure.

The right ventricular end diastolic pressure was not raised in tricuspid stenosis. The diagnostic pressure gradient across the tricuspid valve in this condition has already been described and illustrated (Fig. 5, in Part I).

Pulmonary Artery Pressure

In the surgical group the pulmonary artery pressure averaged 64/33, with a mean of 45 mm. Hg. It will be noted that the diastolic level averaged about half the systolic, and that the mean pressure averaged the diastolic plus two-fifths of the pulse pressure. The pulmonary systolic pressure was 100 to 130 mm. Hg in 13%, between 60 and 95 mm. Hg in 40%, between 50 and 59 mm. Hg in 22%, and below 55 mm. Hg in 27%.

The relationship between the pulmonary systolic pressure and the pulmonary vascular resistance in the combined surgical and medical series is shown in Fig. 11. The critical systolic levels were 100 mm. Hg, above which the resistance was always raised, and 50 mm. Hg, below which the resistance was very rarely raised. The resistance varied considerably, however, when the pulmonary systolic pressure lay between 50 and 100 mm. Hg. Nearly all patients with pressures below 100 mm. Hg and an extreme pulmonary vascular resistance had congestive heart failure.

The relationship between the pulmonary pressure gradient (mean P.A.P. - mean L.A.P.) and the pulmonary vascular resistance is shown in Fig. 12. The critical gradient was about 25 mm. Hg, above which practically all cases had a resistance over 6 units. The majority of patients with

FIG. 11.—Relationship between the pulmonary systolic pressure and the pulmonary vascular resistance.

resistances between 6 and 10 units had gradients between 20 and 30. Practically all cases with an extreme resistance (10 to 30 units) had pressure gradients between 30 and 70 mm. Hg.

The pulmonary artery pressure always rose during effort, often very considerably. When the resistance was relatively normal the rise in pressure tended to run parallel with a normal rise in left atrial pressure, and in some instances the latter reached unexpectedly high levels, well above 35 mm. Hg. Clinical pulmonary oedema did not develop in these cases, but the effort was maintained for only three minutes. When the resistance was high the pulmonary artery pressure tended to rise disproportionately, often to an extreme degree. Precise figures cannot be given, because neither the work done nor the cardiac output during effort was measured, and unless these factors are known the findings can do no more than indicate the general trend. Since Dexter and his group (Gorlin *et al.*, 1951) showed that the resistance did not in fact change during effort, we have abandoned the test as a

FIG. 12.—Relationship between the pulmonary pressure gradient and the pulmonary vascular resistance.

diagnostic procedure, for it did not seem to provide any information beyond that already obtained in other ways.

Left Atrial Pressure

This was measured indirectly by wedging the catheter in a distal pulmonary artery as described in the introduction under "Method" in Part I. Tracings were considered valid only when venous in form.

The left atrial pressure ranged between 0 and 10 mm. Hg in all the trivial and several of the mild cases in the medical group, but was under 10 mm. Hg in only one of the surgical cases. This man had no effort intolerance, but was operated on for recurrent systemic embolism. The valve orifice was found to be less stenosed than usual.

The average left atrial pressure in the surgical group was 22.5 mm. Hg above the sternal angle, and, as previously mentioned, tended to be only slightly if at all higher in patients with orthopnoea or paroxysmal cardiac dyspnoea than in those without such symptoms; this also applied to patients giving a history of pulmonary oedema (Table IV). The relationship between the left atrial pressure and pulmonary venous congestion judged radiologically has already been discussed and illustrated in Fig. 9.

Pulmonary oedema was a rare complication of cardiac catheterization, and no physiological observations were made during an attack. On two occasions it occurred before the catheter was introduced into the vein. It is clear, however, that left atrial pressures up to 35 mm. Hg with reference to the sternal angle might be tolerated without pulmonary oedema, and that much higher pressures, even up to 50 mm. Hg, were maintained for short periods during the effort test without distress. On the other hand, pulmonary oedema never occurred with a left atrial pressure below 30 mm. Hg at the time, which agrees with the observations of Dexter's group (Gorlin *et al.*, 1951), and with current theory.

The relationship between the left atrial pressure and the pulmonary vascular resistance is shown in Table XVII. It

TABLE XVII.—Left Atrial Pressure and Resistance

	Pulmonary Vascular Resistance Units				
	Mild Medical Under 4	Surgical Series			
		Under 4	4-5.9	6-9.9	10-30
Average left atrial pressure (mm. Hg)	9.2	19.6	22.2	23.2	22.4

may be seen that there was some correlation between these two factors up to resistances in the critical range of 6 to 9.9 units, but when the resistance was in the extreme range (10 to 30 units) the left atrial pressure tended to fall off.

The left atrial pressure, as expected, was related both to the size of the mitral orifice and to the cardiac output, as shown in Fig. 13. The ratio C.O./L.A.P. offered a useful index of the degree of mitral stenosis, averaging 45% (range 33 to 66%) when the stenosis was less tight than average, 20% (range 12.5 to 50%) when the stenosis was average or a little tighter than average, and 12.5% (range 10 to 15%) when the stenosis was extreme, as previously defined. Gorlin's formula (Lewis *et al.*, 1952) could not be utilized, because the heart rate was omitted from the analyses.

FIG. 13.—Relationship between left atrial pressure, cardiac output, and size of mitral orifice.

Form of the Left Atrial Pressure Tracing

The form of the pulmonary venous pulse has already been discussed in relation to the P mitrale of the electrocardiogram. Only 32% of all cases with reliable indirect left atrial pressure tracings showed a waves higher than v; a and v were about equal in amplitude in 39%, and v was taller than a in 29%.

Giant a waves towering more than 5 mm. Hg above v were uncommon. In this respect left atrial behaviour is different from right atrial behaviour in tricuspid stenosis. This rather unexpected finding requires further study.

Although v was taller than a in nearly one-third of the cases of pure mitral stenosis, the difference was usually only a matter of 2 to 4 mm. Hg. In mitral incompetence with normal rhythm, on the other hand, v towered above a, the average difference in well-developed cases being as much as 14 mm. Hg, the range being 5 to 25. The expression giant v wave would not be out of place in these cases. When there was auricular fibrillation the amplitude of the v wave in mitral stenosis infrequently exceeded 10 mm. Hg and averaged nearer 5 mm. Hg; in well-developed mitral incompetence, on the other hand, it ranged between 5 and 30 mm. Hg. Thus, although there was considerable overlapping, it is fair to say that a v wave over 15 mm. Hg in amplitude nearly always means mitral incompetence, and a v wave under 5 mm. Hg nearly always excludes it.

Arterial Oxygen Saturation

The arterial oxygen saturation averaged 91.5% for the whole surgical series, being within the normal range (92 to 96%) for our laboratories in 52%, slightly reduced (88 to 91%) in 34%, and moderately reduced (83 to 87%) in 14%.

An attempt was made to find some factor common to the cases with the lowest range of arterial oxygen saturation. Pulmonary venous congestion could not be inculcated when patients with paroxysmal cardiac dyspnoea were compared with patients without orthopnoea, but appeared to be a significant factor in the group with orthopnoea only (Table XVIII). This suggests that patients with orthopnoea only

TABLE XVIII.—Relationship Between Arterial O₂ Saturation and Symptoms of Pulmonary Venous Congestion

	Arterial Oxygen Saturation		
	92-96%	88-91%	83-87%
No orthopnoea or P.C.D.	58%	31%	11%
Paroxysmal cardiac dyspnoea	52%	36%	12%
Orthopnoea only	38%	35%	27%

may be more advanced than patients with paroxysmal cardiac dyspnoea (a hypothesis which is not as improbable as it might seem), or that the factor chiefly responsible for a low arterial oxygen saturation tends to prevent paroxysmal cardiac dyspnoea: such a factor might well be the pulmonary vascular resistance.

In the small group of cases in which the arterial oxygen saturation ranged between 83 and 87% the pulmonary vascular resistance was extreme in 46%, between 8 and 9 units in 39%, and normal in 15%; in these last instances pulmonary oedema was present at the time. Conversely, 35% of all cases with an extreme resistance had an arterial oxygen saturation under 88%.

In the group with the lowest arterial oxygen saturation the left atrial pressure averaged 22.5 mm. Hg, which is the same as in the rest of the series. The cardiac output averaged 3.3 litres a minute and was below 4 litres a minute in all but one instance. The low cardiac output was probably the result of the high resistance.

Coincidental cor pulmonale, due to emphysema, the result of repeated attacks of winter bronchitis, was a very rare complication of mitral stenosis, as previously mentioned, and certainly played no part in lowering the arterial oxygen

saturation in the cases analysed; in the most florid instance, in which independent bronchial asthma was believed to be at least partly responsible for the symptoms, the arterial oxygen saturation was 94%.

Just why a high pulmonary vascular resistance should reduce the arterial oxygen saturation is unknown. The same phenomenon occurs in the later stages of primary pulmonary hypertension. That frank pulmonary oedema lowers the arterial oxygen saturation is well known and requires no explanation; pulmonary venous congestion alone is exonerated.

Arteriovenous Oxygen Difference and Cardiac Output

The relationship between the arteriovenous oxygen difference and the cardiac output in the present series is

TABLE XIX.—Arteriovenous Oxygen Difference

A-V Difference (ml./litre)	Incidence	Average Cardiac Output (l./min.)	Range (l./min.)
21-30	1.5%	9.3	7.3-11.3
31-40	6.5%	6.2	4.5-7.8
41-50	18%	4.8	3.7-5.7
51-60	30%	4.0	2.7-5.5
61-70	15%	3.4	2.5-5.25
71-80	17%	3.2	2.4-5.0
81-90	5.3%	3.0	2.2-4.0
91-100	3.3%	2.9	2.5-3.7
101-110	3%	2.3	2.0-3.1

shown in Table XIX and is illustrated in the shape of a curve in Fig. 14. If for any reason the oxygen consumption cannot be measured at the time the samples are obtained, it may be as accurate or more accurate to estimate the output from the arteriovenous oxygen difference by reference to such a curve than to measure the oxygen consumption subsequently.

The cardiac output averaged 3.8 litres a minute in the surgical cases, being higher in those with normal rhythm (4.1) than in those with auricular fibrillation (3.6), and higher in those with paroxysmal cardiac dyspnoea (4.0) and pulmonary oedema (4.6) than in those without (3.5 in the group also without orthopnoea); it was especially low (3.3) in cases with the typical mitral facies, and was above average (4.2) when there was no peripheral cyanosis at all.

The relationship between the cardiac output and the pulmonary vascular resistance is shown in Fig. 15. The pulmonary resistance is perhaps the most important of all the factors limiting the cardiac output. Certainly the output is restricted by the mitral stenosis itself, but if the resistance did not rise there would be little to prevent the output being maintained at the expense of an extremely high left atrial pressure, which would result in death from pulmonary oedema. This state of affairs has in fact been observed, although death was prevented by prompt treatment. Surges of output in pregnancy, during effort, on excitement, and as the result of other factors in patients with normal resistance may cause paroxysmal cardiac dyspnoea or pulmonary oedema in this way. Such patients may have no orthopnoea under basal conditions; indeed, one of these dramatic attacks may be the first symptom of mitral valve disease in certain circumstances.

The cardiac output was of course low in patients with congestive failure, but this group also had a high pulmonary vascular resistance; nevertheless, it was probably lower in those with failure than in those without, but precise figures are not available because catheterization was usually deferred until congestive failure had responded to treatment.

FIG. 15.—Relationship between the cardiac output and the pulmonary vascular resistance.

Pulmonary Vascular Resistance

Adapting the Poiseuille equation—

Resistance (R)=

mean P.A. pressure—mean L.A. pressure (mm. Hg)
pulmonary blood flow (cardiac output in l./min.)

the result may be expressed in units as in this paper. If it is desired to express resistance in fundamental units of force, as described by Gorlin and Gorlin (1951), pressures in mm. Hg must be converted into dynes/cm.², and flows expressed in litres a minute must be converted into cm.³/sec. The equation thus becomes—

$$R = U \times \frac{0.1 \times 13.59 \times 981.17 \text{ dynes/cm.}^2}{1,000 \text{ cm.}^3/60 \text{ sec.}}$$

where U stands for the simple unit already described. The figure 13.59 is the specific gravity of mercury, and 981.17 cm. per second per second is the g factor—that is, the acceleration force of gravity. The dividend thus becomes 1,333.4 dynes/cm.². The equation may now be rewritten—

$$R = U \times \frac{1,333.4 \text{ dynes} \times 60 \text{ sec.}}{1,000 \text{ cm.}^3}$$

$$= U \times 80.004 \text{ dynes sec./cm.}^3$$

Thus it is only necessary to multiply the unit by 80 to express the resistance in dynes sec./cm.³.

In the 200 cases in which it was measured the pulmonary vascular resistance averaged 6 units for the surgical group, 4.2 units for the medical, and 3.5 for those with mitral incompetence, or 5.4 for the whole series. Further details are given in Tables XX and XXI. The estimates for the

TABLE XX.—Pulmonary Vascular Resistance

	Average Resistance (Units)	Incidence of Each Grade of Resistance			
		Normal 1-3.9 Units	Transitional 4-5.9 Units	High 6-9.9 Units	Extreme 10-30 Units
Surgical	6.0	38.4%	26%	23%	12.6%
Medical	4.2	63%	15%	12%	10%
Mitral incompetence	3.5	56%	31%	6.5%	6.5%
Total catheterized	5.4	45%	24%	19.5%	11.5%

" all cases	79%	21%	—
M.I. serious	84%	13%	3%
" all cases	90%	8%	2%

whole series were contrived by including the 100 cases that were not catheterized, arbitrarily giving to each the average resistance of the group to which it belonged on clinical and other grounds. This was desirable because high-resistance cases were more likely to have been selected for physiological investigation than the others.

It may be added that predictions concerning resistances were rarely far wrong once the principles outlined in this paper were understood.

Although high resistances were rare in pure mitral incompetence they were not uncommon in combined lesions; extreme resistances, however, were very rare in anything but pure stenosis (Table XXI).

The behaviour of the pulmonary vascular resistance is perhaps the most important physiological event in mitral stenosis, and to a large extent determines the course and pattern of the disease. Thus a high resistance puts a considerable strain on the right ventricle and causes that chamber to enlarge with or without functional tricuspid incompetence; it prevents the pulmonary venous system and left atrium from developing unduly high pressures, and so diminishes orthopnoea and abolishes paroxysmal cardiac dyspnoea and pulmonary oedema; it limits the cardiac output directly and also indirectly by tending to reduce the pressure gradient across the mitral orifice. In other words, a high pulmonary vascular resistance saves the patient from drowning at the expense of a low cardiac output; a high venous pressure, hepatic distension, oedema, and fatigue replace haemoptysis, severe breathlessness, paroxysmal cardiac dyspnoea, and pulmonary oedema. Most of the evidence upon which these conclusions are based has already been presented in previous sections. It remains to be shown that congestive heart failure itself occurs only as a result of a high pulmonary resistance. That this was so in mitral stenosis is clear from Fig. 16. This omits

FIG. 16.—Relationship between congestive heart failure and the pulmonary vascular resistance. ●=Mitral valve disease without failure. ○=Congestive failure in mitral stenosis. ○=Congestive failure in mitral incompetence. * = Failure due to thyrotoxicosis.

transient congestive failure provoked by auricular fibrillation with uncontrolled ventricular tachycardia. There was no single instance in which a primary myocardial fault was responsible for failure. In mitral incompetence, on the other hand, there were as many cases of heart failure with relatively normal resistances as with high, and either a myocardial fault or some other factor must have operated. This question needs further study.

It might be thought that a high resistance developed in mitral stenosis gradually over the years in all well-established cases and that it depended on structural changes in the pulmonary arteries resulting from passive pulmonary hypertension secondary to a rise in left atrial pressure; that it was an inevitable end-result which must occur sooner or later if the patient did not die prematurely from pulmonary oedema, systemic embolism, or other complication of mitral stenosis. This hypothesis was not supported

by the facts. On the contrary, the average age of the group with an extremely high pulmonary vascular resistance was the same as in the rest of the series, as already mentioned; indeed, in the whole series the three most florid examples of extreme pulmonary hypertension were aged 27, 23, and 27. Again, no case of irreversible pulmonary hypertension has yet been encountered, and there is good reason to believe that the pulmonary vascular resistance falls after technically successful mitral valvotomy in practically all these cases, even if the operation is undertaken only in the very last stages and in the presence of gross heart failure. Finally, only 20% of the really high-resistance cases gave a previous history of pulmonary congestive symptoms, the great majority presenting the clinical picture of active pulmonary hypertension from the start. Just what determines this vasoconstrictive response is unknown. Much the same problem is encountered in cor pulmonale and the Eisenmenger syndrome (Wood, 1952).

Operative Findings

These have already been correlated with the pre-operative findings, and will therefore be reviewed here only briefly.

1. Atrial Thrombosis.—A clot was found in the left atrial appendage or sometimes in the left atrium itself in 23% of cases, as described in the section on systemic embolism, to which its relationship has been fully discussed. Brock has stressed the importance of allowing blood to gush momentarily from the incised auricle when a clot is detected or suspected, with the object of washing it out, and this manoeuvre has been successful in a number of cases (Baker *et al.*, 1952). Even so, systemic embolism complicated valvotomy in 10%.

2. Mitral Incompetence.—A regurgitant jet was appreciated by the surgeon in 24%, being slight in just over half of them, moderate in nearly a quarter, and considerable in nearly a quarter. Some degree of incompetence was predicted in 90% of these cases, as a rule with reasonable accuracy in respect of degree. Thus the prediction was correct in all but one of those with considerable regurgitation; in fact, half of them had been put up for surgical repair rather than valvotomy. Some were put up for valvotomy at a time when an attempt was being made to see what could be done for combined stenosis and incompetence, usually at the repeated request of the patient. The results were uniformly poor or fair; the degree of mitral incompetence was never less after the operation, and as a rule it was worse. Nevertheless, one-third of these patients improved enough to have made valvotomy worth while, and from being totally incapacitated they were comfortable and able to get about, though scarcely well enough to work.

Of the cases in which a moderate regurgitant jet was found, one had been predicted to have considerable incompetence and two mild incompetence—the rest were accurately assessed. Of those with a small jet, a trivial degree of incompetence had been predicted in 72%, the leak had been overlooked in 17%, and a moderate leak had been diagnosed in 11%.

Mitral incompetence of trivial degree was diagnosed clinically in 9% of the series, apparently in error. In one-third of this small group—that is, in 3% of the whole series—it was expected to be moderate in degree; but no instance of serious mitral incompetence was predicted erroneously. The final results in those with trivial or moderate leaks were not quite as good as in the rest of the series, there being fewer graded as excellent, and in over one-third of them mitral incompetence became considerable in degree.

Calcium.—Mitral-valve calcification has already been discussed in the radiological section. Only trivial calcification was sometimes overlooked on screening, important calcification practically never.

Size of Orifice

The orifice was commonly described as a small oval 1 by 0.5 cm. (Brock, 1952); it was about this size in 46% of the surgical cases, but was tighter (0.75 by 0.4 cm. approxi-

mately) in 18%, and extremely stenosed (0.5 by 0.3 cm. approximately) in 21%; in only 5% was the orifice a little larger, and it never exceeded 1.5 cm. in length in cases of simple stenosis. When there was a serious degree of associated mitral incompetence the orifice usually measured from 1.25 to 2 cm. by 0.75 to 1 cm. in length. In these cases the valve was severely disorganized and commonly heavily calcified, as described by Brock (1952). There were too few cases of pure incompetence examined to form any opinion about those.

The relationship between the size of the orifice and the symptoms, physical signs, and physiological findings has been discussed in other sections. It need only be said here that extreme stenosis tended to have more dire consequences than an average-sized opening, and that the grade of stricture should not be considered less important than the physiological reaction to the obstruction. Certainly pulmonary oedema was just as likely to occur in a patient with an average or relatively large orifice (provided it was within the critical range) as with extreme stenosis; auricular fibrillation, haemoptysis, and systemic embolism were also indifferent to the size of the orifice; but the pulmonary vascular resistance was undoubtedly influenced by the degree of stenosis, never being raised with a relatively large orifice, and never being normal with extreme stenosis (Fig. 10, a-d); angina pectoris, the left atrial pressure, the degree of pulmonary venous congestion, and the cardiac output all bore an inverse relationship to the size of the orifice. The matter may be summed up by stating that the degree of stenosis was the fundamental factor which determined the severity of the disease, and pulmonary vasoconstriction was the most important physiological reaction which modified its course and behaviour; auricular fibrillation and embolism were in the nature of accidents.

Post-operative Course

Shock from the operation, intrathoracic haemorrhage, pleural effusion, collapse of the lung, and left chest pain, having no bearing on the present thesis and being purely surgical matters, are not discussed.

Post-operative Auricular Fibrillation. Auricular fibrillation occurred post-operatively in 24% of the surgical cases, usually during the first week. It tended to last about ten days in those cases in which normal rhythm was resumed spontaneously, but if left to nature it was often permanent. At first we attempted to prevent the rhythm change by means of quinidine, but this failed; it was found much better to prepare the patient with digitalis, so that the ventricular rate was controlled when auricular fibrillation developed. We also learned that it was a mistake to try to restore normal rhythm too soon, the reversion being more easily accomplished towards the end of the second week. Since it is now believed that only fresh clots are responsible for embolism, anticoagulants are begun on the seventh day, so that no clot is likely to form in the left atrium during the five days before quinidine is given. Normal rhythm was restored in this manner and without embolic complications in 95% of the cases in which quinidine was used (Table XXII). Post-operative auricular fibrillation was left alone when the surgeon had found clots in

TABLE XXII

	Incidence (%)		Functional Results (%)			
	Total	In Each Group	Excellent	Good	Fair	Poor
Normal rhythm throughout	31.3		56	33	9	2
Post-op. A. Fib.	24					
Spontaneous reversion		21	100	0	0	0
Quinidine		39	40	55	0	5
Quinidine failed		3	100	0	0	0
Permanent A.F., no quinidine		17	50			50

Died	6.6		12	37	33	

the left atrium, or when valvotomy was not technically satisfactory. Quinidine was also given to a limited number of patients whose auricular fibrillation had been present before the operation if conditions for restoring normal rhythm seemed favourable. The results in this small group were far less satisfactory, however; for normal rhythm was restored in only half of them, and of these two-fifths relapsed.

Fever and Left Chest Pain.—Recurrent attacks of fever, usually associated with pain in the left chest, lasting about one week and with intervals up to a month, occurred in 10%. For a long time the cause of these attacks was by no means clear. The course of each was uninfluenced by antibiotics and salicylates, and it was soon realized that both fever and pain abated just as quickly when no special treatment was given. No rheumatic manifestations accompanied the fever. Reference of pain to the left neck and flank, occasional pericardial friction or effusion, and certain electrocardiographic changes suggested pericarditis, and it is now believed that this is the usual explanation. The attacks closely resembled those seen in association with pericardial foreign body (Wood, 1950). No serious consequences have ever been observed, and in the end they have always subsided permanently.

Psychosis.—Confusional psychiatric states, usually with delusions, during the immediate post-operative course occurred in 5% of cases. The disturbance was always temporary, however, and normal mental function was restored within a matter of weeks. There was no evidence of cerebral embolism in these cases, but the exact mechanism is unknown.

Results

Results were assessed in terms of function and were excellent in 30%, good in 40%, fair in 15%, poor in 9%, and fatal in 6%. Excellent meant that effort intolerance became normal or improved by three grades. For example, the result was classed as excellent if a patient who was totally incapacitated before the operation had only slight effort intolerance three months afterwards. A good result meant that effort intolerance improved by two grades and a fair result by one grade. Good results were also characterized by abolition of paroxysmal dyspnoea, orthopnoea, haemoptysis, angina pectoris, peripheral embolism, and serious winter bronchitis in all cases.

The chief causes of indifferent or bad results were inadequate splitting of the commissures or mitral incompetence (either pre-operative or as a direct consequence of the valvotomy). The chief surgical complication which sometimes spoiled an otherwise good result was systemic embolism.

During the three-year period under review 5% of the cases have re-stenosed, including 3 out of the first 20. Since mitral stenosis takes from three to fifteen years to develop after active rheumatic valvulitis, a similar time interval must elapse before the true incidence of re-stenosis is known.

SUMMARY

All cases of mitral valve disease may be grouped according to the anatomical lesion or the physiological state; in certain circumstances the former is more useful, in others the latter. In practice, a combination of the two has been found best. In respect of anatomy one is concerned whether mitral stenosis or mitral incompetence is dominant and with the degree of obstruction or leak; also with the presence and degree of associated aortic valve disease or tricuspid stenosis. Physiologically, the most important factor is the pulmonary vascular resistance. In the present series the cases have been grouped according to the anatomical lesion and its severity when the resistance was normal or borderline; but when the resistance was high or extreme the cases were grouped separately and subdivided into those with dominant stenosis and those with dominant incompetence, for the degree of valve damage was never trivial or mild in these cases. The incidence of each group and subgroup is set out in Table XXIII.

1. Pure Mitral Stenosis (35%)

The clinical features of pure mitral stenosis may now be described as follows.

The patient is usually a woman in the mid-thirties. The chief symptom is breathlessness rapidly progressing to paroxysmal cardiac dyspnoea, orthopnoea, and sometimes death from acute pulmonary oedema. Blood-spitting is frequently associated with congestive attacks, and these are often complicated by winter bronchitis. Pulmonary apoplexy may be an early symptom. Pregnancy aggravates the symptoms and usually causes some permanent deterioration.

On examination she looks well, and although the hands may be cold there is little peripheral cyanosis and the mitral facies is commonly absent. The peripheral pulse is small and firm, the jugular venous pressure and pulse are normal. The left ventricle cannot be felt at the apex of the heart; there is only a slight lift, if any, over the right ventricle in the left parasternal line, and none over the pulmonary artery. In the mildest cases a presystolic murmur and an accentuated first heart sound are the only auscultatory signs, but an opening snap soon develops. In better-developed cases which are still free from symptoms all the classical auscultatory signs are invariably present. At the apex of the heart these consist of a presystolic murmur, a loud slapping first sound, no systolic murmur, a soft aortic second sound, a loud opening snap, no third heart sound, and a long mitral diastolic murmur of moderate intensity, often accompanied by a thrill. The tap imparted to the palpating hand represents the first heart sound. At the base the second heart sound is normally split, and the second or pulmonary element is only slightly if at all accentuated. There is no pulmonary incompetence. In the third left space it is often possible to hear the pulmonary component of the

second sound separating out on inspiration, and the opening snap increasing in intensity during expiration.

The electrocardiogram shows a normal P wave in trivial cases and a P mitrale in better-developed cases, certainly in all those requiring valvotomy. The QRS-T complexes are normal.

X-ray films show a small aorta, a normal or only slightly dilated pulmonary artery, slight or sometimes moderate dilatation of the left atrium, normal ventricles and right atrium, and a varying degree of pulmonary venous congestion, according to the severity of the case, being absent in mild cases and gross in the most severe. Haemosiderosis may be present in cases giving a history of pulmonary apoplexy. No calcification can be seen in the mitral valve, or if present it is only slight. The cardiothoracic ratio is under 50%.

On cardiac catheterization the right atrial pressure and wave form are normal. The right ventricular diastolic pressure is normal. The mean pulmonary artery pressure is commonly 10 to 15 mm. Hg above the left atrial pressure, which is normal in trivial cases, still under 10 in mild cases, and between 15 and 30 in the great majority requiring valvotomy. On exertion the left atrial pressure rises considerably, sometimes well above 35 mm. Hg, and the pulmonary artery pressure rises passively. Whether or not pulmonary vasoconstriction develops during an attack of pulmonary oedema is still uncertain. Such a reflex would certainly be expected as a result of the anoxia and would be a physiological life-saving event. The arterial oxygen saturation is normal unless there is pulmonary oedema. The arteriovenous oxygen difference is well below 50 ml. per litre in mild cases and commonly between 50 and 60 in those requiring valvotomy. The cardiac output is normal or only slightly reduced at rest; it rises normally in mild cases, but is strictly limited in the more severe; nevertheless, it is by no means fixed. The pulmonary vascular resistance is normal or near normal. At operation in cases severe enough to warrant it, the left atrium is usually free from clot, there is no calcium in the mitral valve and there is no mitral incompetence. The mitral orifice commonly measures 10 by 5 mm., but may be a little tighter (8 by 4 mm.) or even extreme (5 by 3 mm.); it is occasionally less stenosed, but is never more than 15 by 5 mm. as estimated by R. C. Brock (1952). Necropsy figures are usually higher. The cusps themselves are usually mobile, but the margins of the orifice may be fibrous and tough.

Mitral valvotomy is advised in all cases of pure stenosis with grade 2B to grade 4 effort intolerance, the results of a technically successful operation being excellent. Premature valvotomy should be avoided in view of the operative risks and the chance of re-stenosis (probably greater than at present envisaged).

2. Mitral Stenosis with Trivial Incompetence (6.6%)

This small group differs in no way from that just described except for the presence of a slight-to-moderate mitral systolic murmur, and a small regurgitant jet appreciated at operation.

3. Mitral Stenosis with Serious Incompetence (12.3%)

The patient is as likely to be a man as a woman. The symptoms are similar to those described for group 1, but pulmonary apoplexy is more likely to have occurred. The physical signs are very different. The peripheral pulse is small, but slightly water-hammer in quality. Auricular fibrillation is highly probable. The cardiac impulse is left ventricular in type and hyperdynamic. On auscultation there is no presystolic murmur even in those with normal rhythm, the first heart sound is soft, normal, or only slightly accentuated, there is a loud mitral systolic murmur usually associated with a thrill, no opening snap, a loud third heart sound, and a mitral diastolic murmur of moderate intensity and duration. The electrocardiogram usually shows left ventricular preponderance. The x-ray appearances are char-

acterized by considerable or gross dilatation of the left atrium, enlargement of the left ventricle, and conspicuous calcification of the mitral valve; haemosiderosis may be seen in cases giving a past history of pulmonary apoplexy. The cardio-thoracic ratio is usually much increased owing to the dilated left heart.

The physiological findings are similar to those of pure stenosis except that the left atrial pressure tends to swing more and the arterial tracing may show systolic collapse.

At operation a powerful regurgitant jet can nearly always be felt. The valve is heavily calcified and disorganized, and usually measures about 15 to 20 by 5 to 10 mm. If it is sufficiently stenosed to encourage the surgeon to undertake simple valvotomy the degree of incompetence usually increases, and, although the patient is occasionally improved, he is usually no better off. Partial valvotomy may be more rewarding than a radical bilateral split. Combined stenosis and incompetence really requires a repair operation, but the techniques employed to date are none too satisfactory, and the results are indifferent. At the time of writing, therefore, it is wise to defer such cases, if not too advanced, in the belief that surgical techniques will continue to improve. If life is already threatened, however, conservative or partial valvotomy may be the best solution.

4. Pure Mitral Incompetence (15.6%)

The patient is usually a man. The symptoms are similar to those of pure mitral stenosis except that the downhill course is more rapid once breathlessness has developed. There is often, however, a longer latent interval which may compensate for the more rapid course. On examination the physical signs are similar to those of the combined lesion described in group 3, except that the mitral diastolic murmur is very short or absent altogether, and the gap between the systolic murmur and the third sound may be partly closed. The electrocardiographic and x-ray appearances are also similar to those in the combined lesion, but occasionally the left ventricle dominates the whole picture in a manner never seen when stenosis is present. Conspicuous systolic expansion of the left atrium, particularly in the antero-posterior view, is a valuable sign of organic mitral incompetence. The physiological findings are similar to those of the combined lesion, and in some the swing of the v wave in the left atrial pressure pulse is gross.

A repair operation is required. This may be undertaken at the present time if it is too dangerous to wait (Logan and Turner, 1952), but should be deferred in the majority of cases until the surgical technique is more satisfactory.

5. Mitral Valve Disease Complicated by a High Pulmonary Vascular Resistance (12.6%)

In this group the symptoms are much the same as in simple stenosis, the degree of pulmonary vasoconstriction being insufficient to prevent the development of high pulmonary venous pressures, but in some of the cases the symptoms of pulmonary venous congestion are damped. In a sense it is a transitional group between those with relatively normal resistances and those in the extreme grade.

There is more obvious peripheral cyanosis and the mitral facies may be present. The peripheral pulse is very small, and the jugular venous pressure may be a little raised; in some cases there is frank congestive heart failure or functional tricuspid incompetence, which are not seen in cases of stenosis with normal resistance. The left ventricle cannot be felt at the apex of the heart unless there is marked mitral incompetence as well; but there is nearly always a strong lift over the right ventricle. The auscultatory signs may be slightly damped, but as a rule are scarcely changed, except that the pulmonary element of the second sound is clearly accentuated. The electrocardiogram shows right ventricular preponderance, but the P wave is still mitrale in type. X-ray films show enlargement of the pulmonary artery and right side of the heart in addition to the appearances already described in the other groups.

Cardiac catheterization reveals a higher mean pulmonary artery pressure and a pressure gradient between 20 and 30 mm. Hg; the cardiac output tends to be lower and more fixed, the arterio-venous difference between 60 and 70 ml. per litre, and the pulmonary vascular resistance between 6 and 10 units. At operation the pulmonary artery is seen to be bulging and tense and the right-sided enlargement is confirmed. After technically successful valvotomy there is nothing to prevent an excellent result, and the pulmonary resistance is expected to return to normal.

6. Mitral Stenosis Complicated by an Extreme Pulmonary Vascular Resistance (7.6%)

It is very unusual for gross resistance to develop in cases of mitral incompetence or combined stenosis and incompetence. The patient is more likely to be a woman than in any other group. Although there is still breathlessness on exertion, and even slight orthopnoea in some cases, paroxysmal cardiac dyspnoea and pulmonary oedema do not occur and breathlessness is overshadowed by fatigue and oedema; ascites and angina pectoris are relatively common. Symptoms from pulmonary venous congestion are replaced by those related to a low cardiac output. It is this group, above all, that develops functional tricuspid incompetence and congestive heart failure. Haemoptysis due to pulmonary infarction occurs late in the course; indeed, death from pulmonary embolism secondary to phlebotrombosis in the legs is a constant danger.

The patient has either a conspicuous mitral facies and intense peripheral vasoconstriction, or, rarely, the palmar flush and vasodilatation of hepatic dysfunction. The peripheral pulse is exceptionally small. The jugular venous pressure is usually raised and the venous pulse may show a giant a wave in cases with normal rhythm. The left ventricle is always palpable, but the heaving thrust over the right ventricle may extend as far across as the anterior axillary line. There may be pulsation over the pulmonary artery, but it is uncommon. The auscultatory signs are thoroughly damped. A presystolic murmur, if present, is difficult to hear. The first heart sound, however, is still accentuated. A loud systolic murmur may sometimes be heard at the apex of the heart, but it is tricuspid in origin and can be heard equally well at the left sternal edge. The opening snap may be inaudible, but in such cases may sometimes be demonstrated by means of phonocardiography. There may be a right ventricular third heart sound, which in association with the systolic murmur already mentioned may encourage a mistaken diagnosis of mitral incompetence. The mitral diastolic murmur may be abolished altogether or it may be heard only very occasionally and then only with great difficulty. In other cases the auscultatory signs of mitral stenosis are still obvious, but they are never florid. At the left sternal edge in addition to the tricuspid systolic murmur there may be a loud pulmonary systolic click synchronous with the opening of the pulmonary valve, as described by Leatham (1954). At the base the pulmonary component of the second sound is short, sharp, high-pitched, and loud, but may be difficult to separate from the aortic element even on inspiration. When there is pulmonary incompetence, which is common, the pulmonary second sound loses its characteristic quality.

The electrocardiogram shows either a P pulmonale or a combination of this and the P mitrale. There is usually gross right ventricular preponderance, high-voltage R waves and inverted T waves extending across from V₁ to V₃ or V₄, and no Q waves can be seen in V₆ for the right ventricle usually forms the apex beat.

X-ray films reveal a very small aortic knuckle, considerable or gross dilatation of the pulmonary artery, and marked enlargement of the right ventricle and atrium. The left atrium may not be obviously dilated in the antero-posterior view, but can usually be distinguished in the first oblique position. Pulmonary venous congestion may be absent altogether, the pulmonary vascular markings being chiefly arterial proximally, and very light distally, as described by

Goodwin *et al.* (1952). The cardio-thoracic ratio is much increased owing to the right-sided enlargement.

The physiological findings are characterized by a prominent a wave in the right atrial tracing when there is normal rhythm, a raised right atrial and right ventricular end diastolic pressure, a pulmonary artery pressure in the region of 100/50 mm. Hg or above, a pulmonary pressure gradient well over 30 mm. Hg, and only an average rise in left atrial pressure. The arterial oxygen saturation is a little reduced in about one-third of the cases, the arteriovenous oxygen difference very high, and the cardiac output low and fixed. The pulmonary vascular resistance is between 10 and 30 units.

After a technically successful valvotomy the right ventricle may remain in difficulties for many weeks or months, and convalescence must be slow. There is good reason to believe, however, that the resistance falls gradually over the months and the whole situation may be very much improved a year afterwards.

7. Associated Aortic Valve Disease (5.6%)

When this is trivial it does not alter any of the clinical syndromes described. When it is severe it dominates the picture and need not be considered here. The cases which make up the group under discussion are those in which it is often difficult to decide whether the aortic or the mitral lesion is the more important.

The symptomatology and course are like that of mitral valve disease. The physical signs are thoroughly complicated, particularly when there is both aortic and mitral stenosis and incompetence, which is as likely as not. The mitral lesion tends to damp the signs of the aortic. When the pulmonary vascular resistance is raised in addition, the confusion is even greater and it becomes almost impossible to know which lesion is mainly responsible for the physiological changes in the circulation. It must suffice here to say that if aortic valve disease is not obviously the chief lesion, either it is of no importance or mitral disease is more advanced than suspected.

When aortic valvotomy or aortic valve repair can be more successfully undertaken these cases will have to be worked out with greater precision. At the moment the results of mitral valvotomy and attempted aortic valvotomy are indifferent, although sometimes good enough to have made the operation worth while.

8. Tricuspid Stenosis (3.3%)

Just as mitral stenosis damps the features of aortic valve disease, so does tricuspid stenosis damp those of mitral valve disease. These cases present with clinical features resembling those of the extreme pulmonary hypertensive group, but on examination, although the giant a is present in the neck, there is no lift over the right ventricle and no accentuation of the pulmonary second sound; similarly, the electrocardiogram reveals a tall P pulmonale, but little right ventricular preponderance, and radiologically, although the right side of the heart is distended, the pulmonary artery is not. Careful auscultation usually reveals separate tricuspid murmurs which are louder during inspiration. The diagnosis is made with certainty by demonstrating a pressure gradient of several mm. Hg across the tricuspid valve during diastole.

When tricuspid stenosis is severe mitral valvotomy cannot be recommended. But in relatively mild cases, in which the symptoms are due to mitral stenosis, the operation has been very successful. Tricuspid valvotomy is in its infancy.

Conclusion

Three hundred cases of mitral valve disease have been studied in detail. It is hoped that the facts revealed may be of some value to those interested in this fascinating subject.

I would like to thank Dr. J. B. Lowe, Dr. Maurice Clarke, Dr. J. Gardiner, Dr. R. G. Epps, and Dr. R. V. Gibson, who in turn have been my senior registrars at the Brompton Hospital,

for their unstinted help; numerous registrars at the National Heart Hospital who carried out some of the cardiac catheterizations; and the cardiologists technicians at the Institute of Cardiology and at the Brompton Hospital, particularly Mr. Brabrook-Norman, Miss P. Hogg, Mrs. Milne, and Miss Anderson, for their technical help. It goes without saying that the whole work would have been impossible without the lead, initiative, and skill of the thoracic surgeons at the Brompton Hospital, particularly Mr. R. C. Brock.

HORMONE TREATMENT OF DISSEMINATED BREAST CANCER

BY

RONALD W. RAVEN, O.B.E., F.R.C.S.

Surgeon, Westminster (Gordon) Hospital; Surgeon, the Royal Cancer Hospital

In the endeavour to control malignant disease, clinical and experimental work is being carried out to find substances which will inactivate cancer or reverse the cancerous changes back to normal. There is evidence that by alterations brought about in the hormonal status of the body by various methods the cancerous process in certain patients can be checked, thus enabling them to live on for a number of years in excellent health. By this means a form of treatment is being developed which may enable us to attain our object, and ultimately it seems likely that hormone therapy will play an important part in those cancers which are hormonal-dependent. At present new methods are required for biological assays of hormones to provide us with scientific measurements of the changes which are brought about by various stages of cancer and the effects of hormonal treatment. We could thus measure the hormonal balance of the body and abnormal amounts of particular hormones, and determine the constitution of abnormal hormones which may be present. Treatment to-day is largely empirical, based upon clinical observations, and further advances will be made in our search for the truth when the laboratory comes to our aid in this way.

The presence of disseminated breast cancer creates a serious situation for the patient and a difficult problem for the surgeon. Until recent years the prospect was gloomy, but now a little gleam of light is showing. A number of workers have demonstrated that some of these patients are sensitive to variations of their sex

hormones; for regression in the disease has occurred with oophorectomy, adrenalectomy, and the administration of either androgens or oestrogens. This important therapeutic progress is not reviewed here; the object of this paper is to record the effects in a group of patients and especially to call attention to those patients who are living in excellent health more than four years later. The case record of the first patient has already been published (Raven, 1950); her subsequent history is now reported.

Case 1

A married woman aged 50 was seen on April 13, 1948, with disseminated carcinoma of the left breast. She stated that the various lumps became bigger just before her menstrual periods. A carcinoma 3.5 cm. in diameter was present in the upper inner quadrant of the left breast, with enlarged cervical and left axillary lymph nodes, the latter being fixed. Numerous skin deposits were present in the region of the left shoulder, left arm, chest wall, and right loin. A nodular lump 3.4 by 2.2 cm. was present in the right pre-auricular region. Histological examination of a cervical lymph node and a skin nodule showed spheroidal-cell carcinoma.

I performed a bilateral oophorectomy on July 7, 1948. The disease gradually disappeared, and on February 22, 1949, I found no evidence of cancer. The 17-ketosteroids in the urine were normal in January, 1950. In January, 1951, I excised a group of enlarged right axillary lymph nodes. Histological examination showed nodes replaced by sheets and cords of closely packed anaplastic polyhedral carcinoma cells. On January 8, 1952, an enlarged right supraclavicular lymph node and two small skin nodules in the posterior aspect of the chest were found; the patient was given methyltestosterone, 50 mg. daily, and these lumps regressed. The testosterone was withdrawn on July 28, 1953. Radiological examination of the chest and cervical, dorsal, and lumbar parts of the spine and pelvis was always negative for metastases. On December 22 I found a cyst 4 cm. in diameter in the left breast, and there was no clinical evidence of cancer anywhere. The patient is well, lives a normal life, and I think she looks younger than before, with colour in her cheeks; she volunteered the information that the latter was new for her, as she was always pale before the treatment. The amount of hair on her face has now decreased markedly, but her voice remains at a lower pitch than normal.

Case 2

A married woman aged 42, without children, noticed a lump in the right breast in November, 1946. This was removed elsewhere in February, 1948, and histological examination showed a carcinoma. A week later I performed a right radical mastectomy. In May, 1949, radiological examination showed metastases in the ribs, pelvic bones, right femur, and probably in the neck of the left femur. Palliative high-voltage x-irradiation was given to relieve the pain they were causing, and she was also given methyltestosterone, 50 mg. daily, until September, 1950. There was marked reduction in the pain in the right hip and improvement in the pain in her back. In March, 1951, she looked and felt very well; hot flushes occurred after the testosterone was withdrawn. Flexion was slightly limited at the right hip, otherwise movements in both hips were full. Testosterone therapy was recommenced and the dose increased to 75 mg. daily by April, 1952; it was withdrawn in May, 1952. At this time palliative x-irradiation was given to the right hip. In June, 1952, pain occurred in the right shoulder and there was radiological evidence of a metastasis in the upper part of the shaft of the right humerus; palliative x-irradiation was given to this region.

On October 20, 1953, methyltestosterone, 25 mg. daily, was given because radiological examination of the pelvic bones showed that the affected areas were bigger and an increase had occurred in the area of rarefaction in the right

humerus. I examined the patient on December 22 and found her in excellent health and living a normal life; there was no evidence of soft-tissue metastases; the radiological appearances of the osseous metastases persist. There is very little hair on the face; her voice has a lower pitch than normal.

Case 3

A married woman aged 60, with one child, noticed a lump in the left breast in November, 1951, and in February, 1952, a left radical mastectomy was performed elsewhere for a carcinoma, and followed by a course of high-voltage x-irradiation.

She was brought to hospital by ambulance on December 16, 1952. On examination she looked ill, cyanosed, and dyspnoeic. There were no clinical signs of local recurrence; metastases in the chest were suspected. Radiological examination of the chest showed some elevation of the left diaphragm, the trachea was displaced to the left, and there were enlarged hilar shadows on both sides and an opacity in the left upper zone of the lung which resembled lymphogenous spread of carcinoma. The patient was treated with testosterone phenylpropionate, 50 mg. twice weekly. Examination on March 24, 1953, showed that she had improved and was gaining weight. The testosterone injections were increased to 100 mg. twice a week. On June 23, the improvement was maintained; her voice was lower in pitch, and the testosterone injections were decreased to 50 mg. twice weekly. On November 24 the patient stated that she felt well; the testosterone injections were continued, and thyroid extract, $\frac{1}{2}$ gr. (32 mg.) twice daily, was prescribed. A radiological examination of the chest showed that the opacity in the left mid-zone was more clearly defined. When examined on December 22 she looked well, no dyspnoea or cough was present, her general condition was good, and there was no evidence of soft-tissue metastases.

Case 4

A married woman aged 56 first attended hospital on August 14, 1941, with a rodent ulcer involving the external canthus of the right eye, which was treated with low-voltage x-irradiation. On October 21, 1952, she complained of a lump in the left breast, and on examination it was found that the nipple was retracted and a carcinoma was present in the upper and inner quadrant, attached to the skin and deep fascia. The left axillary nodes were palpable. Radiological examination showed metastases in several right lower ribs, in the bodies of the eleventh and twelfth dorsal and the lumbar vertebrae, and also in the neck of the left femur. Injections of testosterone phenylpropionate, 50 mg. weekly, were given for four months. In March, 1953, she complained of pain in the lumbar spine; the injections of testosterone were stopped and ethinyl oestradiol, 0.05 mg., was given twice daily. In May a palliative course of high-voltage x-irradiation to the lumbar spine was given and the ethinyl oestradiol was continued.

On October 13 the patient was examined; she had no pain in her back and only a small area of residual thickening remained in the left breast; no lymph nodes were palpable in the left axilla. Radiological examination showed extensive osseous metastases in the spine, pelvis, and neck of the left femur. A follow-up letter dated December 18 stated that her condition remained the same.

Case 5

A married woman aged 49, with two children, attended hospital in August, 1953, with multiple skin nodules of carcinoma; the first of these had appeared six months previously. Thirteen years ago a hysterectomy for a fibroid uterus and excision of the right ovary for a cystadenoma had been performed elsewhere. In 1947 a left radical mastectomy was performed elsewhere for a carcinoma of the breast, proved by microscopical examination, and in 1952 a right radical mastectomy was done elsewhere for a car-

cinoma of the breast, proved by microscopical examination. A course of x-irradiation was given after each operation.

On examination irradiation changes were seen in the left supraclavicular region; there were multiple skin nodules over a wide area, including the right chest wall, left hypochondrium, left iliac fossa, and the right arm. Radiological examination of the dorsal spine showed no evidence of metastases. Injections of testosterone phenylpropionate, 50 mg. twice weekly, were given. Examination on October 27, 1953, showed considerable regression in the skin nodules.

Case 6

A married woman aged 80, without children, attended hospital in April, 1949, with a lump in the left breast which had been present for nine years. It had been increasing in size slowly and had bled during the past two months. Three months after the lump appeared in the breast another lump developed in the left axilla. On examination an ulcerating carcinoma 7.5 by 6 cm. occupied the inner half of the left breast attached to the chest wall, and the nipple was destroyed. A hard lymph node 1.5 cm. in diameter was present in the left axilla attached to the skin. Radiological examination of the chest showed no metastases. A course of high-voltage x-irradiation was given to the left breast, left axilla, and left supraclavicular regions. On September 16, 1952, the ulcerating carcinoma and axillary lymph node was still present and the patient was treated with stilboestrol (5 mg., thrice daily) until November 20, when vaginal bleeding occurred and the stilboestrol was withdrawn. By December 20 the ulcerating carcinoma had almost healed. On October 13, 1953, it was seen that the lesion had regressed considerably, was dry and practically healed, and no abnormality was present in the left axilla. From April 21 she has had ethinyl oestradiol, 0.05 mg. twice daily. On January 12, 1954, the lesion was flat and healed.

A summary of results in the above cases is given in the accompanying Table.

Results of Hormone Treatment in Disseminated Breast Cancer

Case	Variety of Disease	Treatment	Survival Period after First Treatment Given	Survival Period after Start of Hormone Treatment
1	Carcinoma breast; cervical and bilateral axillary lymph node metastases; multiple skin nodules	Oophorectomy; excision right axillary lymph node. Methyltestosterone	5½ years	5½ years
2	Carcinoma breast; multiple osseous metastases	Radical mastectomy. H.V.T. (palliative). Methyltestosterone	6 "	4½ "
3	Carcinoma breast; pulmonary metastases	Radical mastectomy. Post-op. H.V.T. Testosterone phenylpropionate	2 "	1 year
4	Carcinoma breast; multiple osseous metastases	Testosterone phenylpropionate. Ethinyl oestradiol. H.V.T. (palliative)	1½ "	1½ years
5	Carcinoma breasts rt. and lt.; multiple skin nodules	Radical mastectomy rt. and lt. Post-op. H.V.T. Testosterone phenylpropionate	7 "	2 months
6	Ulcerating carcinoma breast; axillary metastases	H.V.T. Stilboestrol	4½ "	1½ years

Discussion

Each patient received benefit from hormone therapy with androgens or oestrogens, and Cases 1 and 2 are of special interest because they are in excellent health 5½ and 4½ years respectively later. In the first patient there is no evidence of carcinoma; in the second there is radiological evidence of bone metastases, but this is not adversely affecting the

patient's health. The voices of both patients are lower in pitch, but there is no other evidence of masculinization. The amount of hair on the face in Case 1 has diminished considerably and she has a much more youthful appearance than before the oophorectomy. The other patients will be followed up for a longer period to assess the results. If patients are enabled to live on in comfort for several years in spite of persistent cancer the value of this treatment will be established, and it is likely that some method will be found to counteract any unpleasant side-effects which may occur.

Since Loeser (1940) suggested testosterone therapy for advanced breast carcinoma several reports have described the effects in soft and osseous tissue dissemination. Additional information is now required on survival periods after this treatment is begun. More than 50 years have gone since Beatson (1896, 1902) wrote of the beneficial effect of oophorectomy in some of these patients, and it has received sporadic attention to the present time. This operation is also being performed in the younger pre-menopausal group of patients after radical mastectomy, and it is necessary to evaluate the end-results after the lapse of an adequate follow-up period.

Regarding the dosage of testosterone, I usually give a big dose during the first course of treatment, which in one patient has extended for 18 months. A careful check is kept on the patient's general condition, including examinations of the blood urea and serum calcium. An important observation is the improvement which occurs after the cessation of hormone treatment, and it is suggested that these interruptions play an important part. When they have obtained the maximum benefit from oophorectomy and androgen therapy there are certain patients with severe pain from osseous metastases who may be helped further by adrenalectomy. The selection of patients for this final form of treatment must be done carefully, and at present it seems that the number suitable for it is small.

Summary

The results of hormone therapy in a group of patients with disseminated breast cancer are described and attention is called to two patients who are in excellent health 5½ and 4½ years later.

The Minister of Health is to be asked to receive a deputation from the London County Council on the question of the extension of chiropody services provided by the Council under the National Health Service. In the county of London facilities are provided at the rate of 1.38 chiropodist sessions per 10,000 population, but there is no provision in the City of London and in 13 other metropolitan boroughs. The Health Committee of the Council states that the inadequate and unbalanced service is due to the diversity of the arrangements taken over in 1948. They regard chiropody as essentially a preventive service, which could do much to prevent the ill-health resulting from foot trouble, and urge that an extension of the service is a logical development of the functions of the local health authority under the N.H.S. Act. The approval of the Minister was sought for a long-term scheme of extension of the service as a whole by 34%, and a short-term scheme for an immediate extension of the service in those boroughs without any service at all at present. All the clinics would be in existing or projected health service premises. The Minister replied that while appreciating the Council's concern in the matter he did not feel able to approve either of the schemes. Accordingly he is to be asked to receive a deputation.

ACUTE POST-OPERATIVE LARYNGEAL OBSTRUCTION

BY

J. B. PRENDIVILLE, F.R.C.S.I.

Senior Surgical Registrar

AND

H. G. MIDDLETON, F.F.A.R.C.S., M.R.C.S.
L.R.C.P., D.A.

Consultant Anaesthetist

Plastic Surgery Centre, St. Lawrence Hospital, Chelmsford

Though large series of post-anaesthetic conditions have been reported from time to time, we have found little reference to lesions of the upper respiratory tract. Obstructions of various bronchi by mucus plugs giving rise to segmental and sometimes massive collapse of the lung are well known, but the more serious obstruction at the larynx is notably absent from the literature. Four cases of this grave complication occurring after grafting operations in children are presented.

Case 1

A girl aged 3 years was admitted to the burns unit with a history of having fallen into boiling water six weeks previously. Her general condition was poor and she had obviously lost weight. On examination an extensive granulating area involving her abdomen, back, and both lower limbs was found.

On the afternoon of the third day a grafting operation was performed under general anaesthesia induced with cyclopropane and oxygen and maintained with methyl *n*-propyl ether ("neothyl") and oxygen. A No. 1 "flexometallic" endotracheal tube was passed without difficulty and the operation was uneventful, though the defect was not fully grafted owing to its extent.

Shortly before midnight on the same night very slight stridor was noted, but was not regarded as significant. Next morning the stridor was more pronounced and was accompanied by a moist cough, but there was no other evidence of laryngeal obstruction. Treatment consisted of steam tent, postural drainage, and systemic penicillin. At midday she vomited after a bout of coughing and the larynx went into spasm, but this subsided on careful toilet of the pharynx by suction. Some time after this episode her breathing became more laboured and there was indrawing of the suprasternal notch. This became more pronounced during bouts of coughing in her effort to clear the air passages of a tenacious sputum. At 4.45 p.m. an acute airway obstruction developed, followed by cyanosis, coma, and convulsions. The latter was localized to the right side of the face and the left side of the body.

An emergency tracheotomy was performed and aspiration of the air passage carried out, with considerable improvement in her colour. On cutting down the dressings on her abdomen to ensure unrestricted respirations an acute dilatation of the stomach was uncovered. This was thought to be due to sucking air into the oesophagus during the airway obstruction, and was deflated with a stomach tube.

Her general condition was still very poor and severe convulsions continued. An intravenous drip was set up and the convulsions were controlled with gallamine triethiodide ("flaxedil"). An initial dosage of 12.5 mg. of gallamine followed by 7.5 mg. within a few minutes sufficed to control this attack. A dosage of 2.5 mg. half-hourly was maintained, but convulsions recurred eight hours later. These subsided only after the administration of 50 mg. of gallamine in divided doses, and 12.5 mg. was given on any

further evidence of twitching. From then on a steady recovery was maintained and a pyrexia of 102° F. (38.9° C.) subsided in a few days.

The tracheotomy tube was removed on the sixth day and grafting was subsequently completed. Her second operation, which was carried out without endotracheal anaesthesia, was uneventful.

Case 2

A girl aged 3 years was admitted with deep burns of the left side of the chest, abdomen, and left arm, which were sustained when her clothes caught fire. She was in good general condition.

Two weeks after admission a grafting operation was done. General anaesthesia was induced with cyclopropane and maintained with neothyl, nitrous oxide, and oxygen. A No. 1 flexometallic endotracheal tube was passed without difficulty. Operation was uneventful and the grafting completed. In the immediate post-operative period she was described as being "chesty," but there was no evidence of any airway obstruction.

Six hours later a mild degree of stridor was noted, and during the night it increased. It continued during the first post-operative day, and was accompanied by very moist chest sounds. Bouts of heavy coughing were productive of a very little tenacious sputum and caused a severe stridor and indrawing of the suprasternal notch. Temperature rose to 103° F. (39.4° C.), pulse 122, and respirations 35.

Treatment consisted of steam tent, postural drainage, and systemic penicillin, with careful observation. Under this regime her breathing became less laboured and the cough more productive. The temperature began to subside on the second day and the stridor had settled by the fourth day. She has made an uneventful recovery, and subsequent examination of the larynx has revealed no abnormality.

Case 3

A girl aged 6 years was admitted with a history of flame burns which occurred during an attack of epilepsy six weeks previously. Her general condition was reasonably good.

Grafting operations were carried out on the sixth and twentieth days after admission. Anaesthesia for these was induced and maintained with nitrous oxide and oxygen and trichlorethylene, and rubber endotracheal tubes were introduced without any difficulty. Six hours after the second operation some stridor was noted, and thought to be due to oedema of the larynx. The usual routine of steam tent and penicillin treatment was adopted, but the stridor showed no signs of subsiding. Twelve hours later she developed an acute respiratory obstruction with deep cyanosis, and an emergency tracheotomy had to be performed with toilet of the air passages by suction catheter. Very moist sounds, especially at both bases, were heard in the chest, and bronchopneumonia was diagnosed.

Twenty-four hours after tracheotomy the tube slipped out of the trachea and into the tissues of the neck, giving rise to surgical emphysema and a left pneumothorax. The tube was reintroduced and the chest aspirated by underwater suction.

Her general condition remained poor for some days, but a final recovery was made. Subsequent chest x-ray films showed a resolving pneumothorax and patchy areas of lung collapse.

Case 4

A child aged 4 years was admitted two years after a flame-burn accident for correction of scar contractures and grafting of the defects. Operation was carried out under nitrous oxide and oxygen and ether anaesthesia, and a rubber endotracheal tube was introduced without any difficulty. Operation was uneventful.

Twenty-four hours later she was very chesty and had some stridor and pyrexia. Treatment with steam tent and systemic penicillin was carried out. For a time she seemed to settle down on this regime, though there were occasional

bouts of distress with expectoration of a thick mucous material. On the fourth day, however, she developed severe respiratory embarrassment with deep cyanosis and coma. An emergency tracheotomy was then performed, followed by the usual routine of careful aspiration and the maintenance of a clear airway. A pyrexia of 100 to 101° F. (37.8 to 38.3° C.) subsided in a few days and her general condition was very much better. The tracheotomy tube was removed five days later.

Discussion

Four cases have been described of an acute post-operative condition of the air passages of such severity as to cause a respiratory obstruction, and it is the purpose of this discussion to consider certain factors which may have given rise to this grave disaster.

All four patients were female children undergoing grafting operations as the result of burns, and all were carried out under endotracheal anaesthesia. No difficulty was experienced in the intubation of any of these cases, and this was carried out by a different specialist anaesthetist in each instance, in two different hospitals, and the operations performed by three different surgeons. Flexometallic tubes were used in Cases 1 and 2 and rubber tubes in Cases 3 and 4.

Grafting operations in children may require many changes in position for the removal of dressings, cleansing, grafting, and redressing. During these procedures the head may undergo many alterations in position in relation to the body, and this may cause the endotracheal tube to rub and produce friction on the lining walls of the airway. When intubation is used in children great care should be taken to avoid this form of trauma.

Cinchocaine ("nupercaine") ointment 10% was used as a lubricant for the tube in all cases. Systemic intoxication due to cinchocaine is well known, but adverse local effects have not been reported to our knowledge.

A search through the literature has revealed very little on the subject of acute post-operative airway obstructions of this nature. Gittins (1942) included allergy and trauma as aetiological factors in acute non-specific laryngeal obstruction, and yet we cannot find reports of this following the use of the large variety of endotracheal tubes and their various lubricants. Emery (1952) suggests that abacterial agents, by interfering with the growth of bacteria, may upset the liquefaction of sputum and thus give rise to a thick tenacious glue-like material which cannot easily be expectorated, and which is found obstructing the already narrowed airway. It is evident that the post-anaesthetic condition we have observed is, in fact, a form of laryngo-tracheo-bronchitis (Briggs and Heseltine, 1952) which has followed the irritation of endotracheal anaesthesia, and the use of antibiotics may well have aggravated the course of the lesion. It is also suggested that pre-operative atropine may be a factor in the production of thick viscid mucus.

Treatment is a very controversial question, and requires clear thinking in this alarming emergency. In a mild case such as Case 3, steam tent, postural drainage, and penicillin may be sufficient to allow the condition to subside, but careful observation must be kept for worsening of symptoms. If the airway becomes so obstructed by narrowing and tenacious secretions that there is indrawing of the suprasternal notch, cyanosis, or acute restlessness, then there is no doubt that other means of relief must be resorted to. Reintubation and tracheo-bronchial suction may be a life-saving measure, and if easily performed will allow an immediate tracheotomy to be carried out as a set procedure. Continued intubation is entirely illogical in that the added trauma must further offend the already inflamed airway and may produce chronic arytenoid oedema with subglottic swelling and ulceration. Early low tracheotomy with careful and frequent suction toilet of the air passages is the treatment of choice. "We always preach early tracheotomy, but practically always do it late; dangerously late" (Chevalier Jackson, 1921a, 1921b).

Careful aftercare is as important as the tracheotomy in maintaining a clear airway, and this must be the whole-time job of a nurse who is trained in performing suction toilet and in care of the tube.

Summary

Acute laryngeal obstruction occurring as a post-operative condition is described in four cases. Its aetiology and treatment are discussed. It is considered that, though there may be no difficulty on intubation, the trauma of an endotracheal tube is an aetiological factor and that cinchocaine used as a lubricant may be contributory. In the treatment of a severe case tracheotomy is preferred to reintubation.

We acknowledge with thanks the co-operation and helpful criticisms of Mr. Emlyn Lewis, consultant plastic surgeon to the Welsh Regional Hospital Board, and Mr. A. H. R. Champion and Mr. A. McDowell, consultant plastic surgeons to the Manchester Regional Hospital Board, under whose care these patients were admitted.

[We wish to mention that since this paper was written Dr. J. R. Rook has published an article in which three similar cases are cited (*Lancet*, 1953, 1, 1214).]

INDIFFERENCE TO PAIN IN LOW-GRADE MENTAL DEFECTIVES

BY

T. A. COUSTON, M.B., Ch.B.

Registrar in Mental Deficiency, Baldovan Institution, by Dundee

In the normal course of acute conditions, whether surgical or medical, the symptom of pain is an important factor in diagnosis. In mental defectives, however, this important symptom does not always present. Seven cases are listed below, all occurring in one unit over a period of six months.

Case Reports

Case 1.—A male mental defective (imbecile grade), aged 14, confined to bed, had a series of severe epileptic fits. On recovery he was somewhat confused and irritable. Next day the irritability persisted and he showed some resistance to being moved about at meal-times. Temperatures, pulse, and respirations remained normal. On examination he showed some resentment on movement of the lower limbs, particularly the left, and unnatural mobility was present at the left hip. He could sit up, however, and turn himself in bed. On being referred for x-ray examination a fracture of the neck of the left femur was found.

Case 2.—A male mental defective of low feeble-minded grade, aged 42, suddenly collapsed. He was pale, the skin cold and clammy, the pulse rapid and weak, and the respiratory movements were curtailed. Marked upper abdominal rigidity, but little complaint of pain except on deep palpation. A perforated duodenal ulcer was suspected, and he was admitted to hospital, where a large duodenal diverticulum with ulceration at its base was found.

Case 3.—A male mongol of imbecile grade, aged 24, had an attack of what appeared to be catarrhal jaundice. Recovery initially was uneventful, but his condition rapidly deteriorated with gross liver enlargement and lower

abdominal rigidity. Temperature, pulse, and respirations were normal. He continued to eat normally and did not complain of pain. His condition rapidly became worse in spite of continued apparent "well-being," and he was admitted to hospital, where he died two days later. Post-mortem examination revealed a tuberculous enteritis.

Case 4.—A female mental defective of idiot grade, aged 12, suddenly vomited clear fluid for no apparent reason, and a short time afterwards passed approximately 1½ pints (1,750 ml.) of dark-red offensive-smelling partially clotted blood per rectum. There was marked abdominal rigidity, and she was deeply shocked but maintained a completely detached and uninterested view of her condition, no mention being made of pain, and no signs of pain were noted. She was admitted to hospital, where a diagnosis of Meckel's diverticulum was made.

Case 5.—A male mentally defective macrocephalic, aged 14 (imbecile grade), fell during a grand mal attack and received a severe lacerated wound of the forehead. He showed no evidence of pain, and the wound was cleansed and sutured without administration of an anaesthetic. His attitude throughout the procedure was one of detached annoyance.

Case 6.—A male mental defective of imbecile grade (congenital word deafness), aged 14, suddenly developed a gross swelling of the left testicle. This swelling attained a size of approximately 3 by 2 in. (7.5 by 5 cm.) but did not appear to inconvenience him in any way. It was decided to admit him to hospital, where a biopsy could be carried out to determine the cause of the swelling. A torsion of the left testicle was found.

Case 7.—A female mental defective of imbecile grade, aged 40, was noticed to have a severe herpes zoster affecting the left fifth and sixth thoracic dermatomes. There was no complaint of discomfort, far less of pain. On the condition clearing she presented no symptoms of post-herpetic pain.

Discussion

These seven cases all show absence of pain where pain would normally be expected. Even allowing for individual variation to painful stimuli it is difficult to understand the absence of pain in these cases.

The only similar examples of indifference to pain as exemplified in this series occur in the condition known as congenital universal indifference to pain or asymbolia for pain. This rare condition is generally diagnosed in childhood, when a child is noticed to have a stoical indifference to episodes causing bodily injury. Several cases have been noted during the past few years, and so far no anatomical basis has been found to explain the condition. There appear to be no post-mortem reports in the literature on the examination of brain tissue from any cases. The outstanding feature in this condition is that the patient can name correctly any painful stimulus applied, but at the same time shows no obvious sign of pain and makes no effort to withdraw from the stimulus. It will be seen that in this condition there is no analgesia or thermæsthesia. So far there are no reports of mental deficiency associated with this condition.

It will be appreciated that the interpretation of painful stimuli presents a major neurological problem. In this series the problem lies in fixing the level at which the normal reaction to a painful stimulus takes place.

A lesion producing indifference to pain probably appears to interrupt the frontothalamic projection fibres.

It has already been determined that lesions involving the thalamus may affect the sensations of pain and sensibility. The thalamic syndrome of Dejerine and Roussy is produced, being characterized by spontaneous pain and hyperreaction to disagreeable stimuli such as heat and cold.

If the lesion occurs in the associated cortical or sub-cortical areas the opposite side of the body is then affected. Position sense is lost and two-point discrimination becomes

faulty—astereognosis. Tactile discrimination and weight sense are lost. Crude sense of pain touch and thermal sensitivity are retained, but the degree of recognition may become inconstant. This is the condition of cortical anaesthesia. In discussing lesions affecting the frontothalamic projection fibres the thalamus itself must be considered.

The thalamic nuclei may be divided into three main groups: the cortical relay nuclei, association nuclei, and nuclei with subcortical connexions. None of these nuclei receive ascending fibres. It seems that the area under discussion involves either the association nuclei (dorsomedial, lateral, and pulvinar) or their associated connecting fibres. These nuclei are connected to the following cortical areas: dorsomedial, areas 9, 10, and 12 (Brodmann); lateral, areas 5 and 7; pulvinar, areas 18 and 22.

In the modern technique of frontal leucotomy of the partial combined intervention type (leucopectomy) the object of the operation is the severance of three main groups of fibres passing from the frontal cortex to the thalamus. These groups are: (1) from cortical areas 9, 10, and 45 (Brodmann); (2) from cortical areas 11, 12, 13; (3) from cortical areas 24 and 32.

A recent application of leucotomy has been the relief of intractable pain, generally in terminal neoplastic conditions where normal drugs have become useless and the object of operation is to make the closing stages of life pain-free for the unfortunate patient.

Such an operation does not sever any known pain pathways, but the end-result is that the division of the frontothalamic projection fibres completely alters the patient's reaction to pain. It now appears quite certain that the sensation of pain is in no way altered or abolished, but that the patient ceases to worry about the pain and thus relief is obtained.

It will now be seen that this state closely resembles that found in congenital universal indifference to pain.

It therefore appears that the frontothalamic projection fibres involved in the interpretation of pain and the imposition of pain on consciousness derive from cortical areas 9, 10, and 12, and pass into the dorsomedial nucleus of the thalamus. It can be presumed from anatomical and embryological evidence that connexions exist between the thalamus and that integration of interpretation from left and right cortical areas will occur.

In low-grade mental defectives the psychological, intellectual, and personality states in many cases can be compared to the changes found after leucotomy in mental patients. This may point to defective development either in frontal cortical areas or in the fronto-thalamic projection fibres. If this is the case, this hypothesis gives an explanation for the indifference to pain found in low-grade mental defectives accompanying acute surgical and medical conditions.

Summary

Seven cases of surgical and medical conditions occurring in low-grade mentally defective patients are reported. In the normal patient these conditions are associated with pain of severe degree. In these mentally defective patients there was a marked indifference to pain, although some discomfort was felt in a few cases.

An explanation has been advanced for this indifference to pain on the theory of frontothalamic projection fibres associated with cortical areas 9, 10, and 12 being defectively developed or in defective development of these cortical areas themselves.

A comparison has been drawn between the condition of congenital universal indifference to pain and the cases in the above series.

INTRAVENOUS ERGOMETRINE AND THE UNDIAGNOSED SECOND TWIN

BY

J. K. RUSSELL, M.B., Ch.B., M.R.C.O.G.
Lecturer in Obstetrics and GynaecologyD. TACCHI, M.B., B.S., D.Obst.R.C.O.G.

ANNE L. M. GRAHAM, M.B., Ch.B., D.Obst.R.C.O.G.
Registrar

(From the Department of Obstetrics and Gynaecology, University of Durham, and the Princess Mary Maternity Hospital, Newcastle-upon-Tyne)

Our purpose in writing this paper is to draw attention to a complication associated with the use of intravenous ergometrine in the control of the third stage of labour. During the past two years, on four occasions in the Princess Mary Maternity Hospital, an undiagnosed second twin has been discovered after the administration of intravenous ergometrine; three of the cases occurred within the space of a fortnight, and this brought the problem to our notice.

Case Reports

Case 1.—The patient, a gravida-3 aged 39, was admitted to hospital as an emergency case of ante-partum haemorrhage four weeks before term. Three hours after admission she delivered spontaneously a live male child weighing 4 lb. 10½ oz. (2.1 kg.). Intravenous ergometrine, 0.5 mg., was given with the birth of the anterior shoulder, but as soon as the child was born it was realized that a twin pregnancy was present. The second twin was presenting as a vertex, and within a few minutes a female child weighing 3 lb. 15½ oz. (1.8 kg.) was delivered spontaneously. The placenta was expressed quite easily after the delivery of the second baby. The twins were in good condition at birth and made satisfactory progress.

Case 2.—The patient, a gravida-2 aged 24, was booked for hospital delivery, and was admitted in premature labour at 30 weeks. The uterus was noted to be slightly larger than for the gestation period, but a twin pregnancy was not suspected. Twenty-five minutes after admission an outlet forceps delivery was performed under local analgesia; the baby, a male, weighed 3 lb. 6 oz. (1.5 kg.). Intravenous ergometrine, 0.5 mg., was given with the delivery of the anterior shoulder. A twin pregnancy was diagnosed as soon as this child had been delivered. A vaginal examination showed the presentation to be a footling, and the membranes were ruptured by the operator. Strong uterine contractions began at once, but no progress was made, and after an interval of 8 to 10 minutes a general anaesthetic was started. Vaginal examination revealed a constriction ring in the lower part of the uterus. The anaesthesia was deepened, and with some difficulty a breech extraction was carried out. The child, a male, weighed 3 lb. 10 oz. (1.6 kg.) and was limp and blue at birth; respirations were never satisfactorily established, and the infant died at 55 minutes. A post-mortem examination was not obtained, but the cause of death was presumed to be anoxia and possibly traumatic cerebral damage. The first twin made satisfactory progress.

Case 3.—This patient, a gravida-3 aged 25, was booked for delivery in hospital and was admitted in labour two weeks before term. After a labour lasting three hours she delivered spontaneously a male child weighing 6 lb. 14 oz. (3.1 kg.). Ergometrine, 0.5 mg. was given intravenously with the delivery of the anterior shoulder, but only with the delivery of this child was a twin pregnancy diagnosed. Vaginal examination showed that the second twin was

presenting by the breech. The membranes were not ruptured on this occasion, and the operator, with his hand, kept the presenting part high in the pelvis until a general anaesthetic had been administered. The membranes were then ruptured and a breech extraction was easily performed 25 minutes after the delivery of the first child. The second twin, a male, weighed 6 lb. 2 oz. (2.8 kg.). The placenta had to be removed manually. Both babies made satisfactory progress.

Case 4.—The patient, a gravida-4 aged 36, was admitted to hospital as an emergency case four weeks before term. After a labour lasting two and a half hours a male child weighing 3 lb. 7 oz. (1.56 kg.) was born. Intravenous ergometrine, 0.5 mg., was given with the birth of the anterior shoulder; a twin pregnancy was diagnosed as soon as this child had been delivered. Vaginal examination showed the second twin to be presenting as a vertex, and the operator kept the presenting part high in the pelvis whilst a general anaesthetic was administered. The membranes were then ruptured and a male child weighing 3 lb. 12 oz. (1.7 kg.) was delivered by forceps; the placenta was expressed quite easily. The first child made satisfactory progress, but the second suffered from repeated cyanotic attacks for several days; the appearance of the second twin strongly suggested mongolism, but this diagnosis has yet to be established.

Discussion

There is convincing evidence that intravenous ergometrine, provided it is given with the crowning of the foetal head or birth of the anterior shoulder, will reduce the risk of post-partum haemorrhage and shorten the duration of the third stage of labour (Martin and Dumoulin, 1953). Certain drawbacks to its use have been noted. Grimes *et al.* (1948) and Priver *et al.* (1949) have reported side-effects such as nausea, headaches, and vomiting, while Martin and Dumoulin noted a significant increase in the incidence of manual removal of the placenta. For the past two years, in our hospital, intravenous ergometrine has been used widely but not routinely in the control of the third stage of labour. During this time there have been 74 cases of twin pregnancy, and nine of these have been undiagnosed. Four out of the nine patients were given intravenous ergometrine as the first baby was being delivered, and details of these cases have been given. One of the eight babies born to these women died, and, although we cannot be sure, we suspect that the death was at least in part caused by the strong uterine contractions which followed the administration of ergometrine; this drug is known to cause tonic contraction of the uterus and is therefore liable to interfere with placental circulation and so lead to foetal anoxia. As a result of the difficulty experienced in the delivery of the second twin in Case 2, we made a point, in the later cases, of not rupturing the second sac of membranes until we were in a position to carry out immediate delivery of the second twin. By conserving the sac of membranes there is less likelihood of the uterus contracting firmly down on the second twin.

So far we have been fortunate in that none of the undiagnosed second twins has been lying transversely. Were this to happen, then the operator might well be faced with a difficult intrauterine manipulation where the uterus had contracted down firmly on the foetus. There might then be a risk to mother as well as to child.

A number of authors have now reported the use of intravenous ergometrine in large series of cases, but, so far as we are aware, no one has acknowledged the complication to which we draw attention in this paper. In our experience the hazard is a real one and must be taken into account when an assessment is made of the advantages and disadvantages of the use of intravenous ergometrine in the control of the third stage of labour.

Summary

Attention is drawn to the complication of the undiagnosed second twin when intravenous ergometrine has

been given in the control of the third stage of labour. This complication occurred four times in two years at the Princess Mary Maternity Hospital, and one baby died. Details of the four cases are given.

It is suggested that when this complication occurs every effort should be made to avoid rupture of the second sac of membranes until the patient is under an anaesthetic and immediate delivery of the second twin can be undertaken. With an intact sac of membranes there is less likelihood of the uterus contracting down on the second twin and interfering with placental circulation.

We are indebted to Professor Harvey Evers for permission to publish details of cases which were under his care.

RENAL CLEARANCE OF CREATININE AND UREA IN THE WEST AFRICAN

BY

R. A. KENNEY, Ph.D., B.Sc.

Colonial Medical Research Committee's Laboratory for Hot Climate Physiological Research, Oshodi, Lagos, Nigeria

We have previously reported from this laboratory the low levels of plasma urea (Phillips and Kenney, 1952) and the low output of urea following the ingestion of 30 g. of this substance (Kenney, 1953) encountered in the West African subject. The clearance data reported in this paper were obtained in order to provide a further standard of comparison with the European subject. Precise investigation of the renal partial functions, glomerular filtration rate, and the rate of renal plasma flow (Kenney, 1954) had demonstrated the identity of these values in the African and European subjects.

Methods

Ten African subjects were used. All were familiar with the procedure of venepuncture and were trained to empty their bladders completely and spontaneously at frequent fixed intervals. The subjects were typical members of the local labour force, in regular employment and enjoying a good standard of nutrition by African reckoning—that is, a diet containing about 70 g. of protein a day, about one-third of which was meat.

The subjects reported to the laboratory at 8 a.m., after their normal morning meal, and rested in bed for a period of two hours. During this time their water intake was adjusted so as to provide a low urine flow of less than 1 ml. a minute at the start of the experimental period. At the end of this time the bladder was emptied and urine collection started. Urine samples were obtained every 15 minutes for a period of 90 minutes. During this time two or three blood samples were taken by venepuncture with the minimum of stasis. The blood was stored in a heparinized vessel and the plasma separated off by centrifugation for subsequent analysis. During the period of urine collection water was given by mouth in volumes sufficient to raise the urine flow from its original low level to about 5 to 6 ml. a minute. In this way a series of urine samples were obtained over the wide range of urine flows.

Urine and plasma samples were analysed for creatinine and urea by the following methods.

Urea.—The method of Karr (1924) was applied to both urine and tungstate filtrates of plasma in appropriate dilution. The final colorimetric estimation was carried out in a Coleman junior spectrophotometer set at a wavelength of 5,000 Å.

Creatinine.—Diluted urine samples and tungstate filtrates of plasma were treated by an alkaline picrate method (W. S. S. Ladell, 1951, personal communication), the final estimation being carried out in the Coleman junior spectrophotometer set at a wavelength of 5,200 Å.

Results

From the values for plasma concentration, urine concentration, and urine flow were calculated the clearance values for the two substances by the usual formula. The results obtained are set out in the Table, together with the mean values and the standard deviations of the observations. The table also records the mean values obtained on a group of European subjects examined under the same conditions. The values for urea clearance have been divided into two groups—those obtained at urine flows less than 2 ml. a minute and those obtained at higher rates of flow. In both cases the true clearance value is recorded; the empirical standardization of the values obtained at low flows has not been employed.

Urea and Creatinine Clearance Values

Subject	Creatinine Clearance ml./min.	Urea Plasma Concentration mg./100 ml.	Urea Clearance ml./min. flows 2 ml./min.	Urea Clearance ml./min. flows 2 ml./min.	Urea Clearance/Creatinine Clearance
Os	121	15.0	44	52	0.43

Co	85	10.2	42	21	0.41
Pa	168	10.7	35	46	0.15
Ma	102	11.9	35	31	0.43
Ge	129	16.7	34	54	0.22
La	141	18.8	60	46	0.44
An	120	19.6	63	46	0.44
Mean	127	13.9	45	42	0.345
s.d.	23	3.4	16	11	
European values:					
Mean	122	26.7	70	54	0.48
s.d.	12	4.7	8	9	

Discussion

The value obtained for the creatinine clearance is in very good agreement with the values commonly observed in the European subject. It appears that creatinine is as adequate a method of determining the rate of glomerular filtration rate as is the more popular inulin or mannitol clearance, and if this be accepted the glomerular filtration rate in these subjects agrees well with the "world average" for this function quoted by Smith (1951). The creatinine clearance was completely unaffected by the rate of urine flow.

It will be observed that the values of urea clearance are nearly identical whether observed at high or low rates of urine flow. The African subject, therefore, fails to show the "augmentation" phenomenon which is characteristic of urea excretion in the European subject (this is supported by the values recorded in the table).

The absolute values of the urea clearance are low, being only about two-thirds of the normal standard. The average ratio of urea clearance to glomerular filtration rate at random urine flows in 37 normal subjects observed by Raaschou (1948) was 0.65 (range 0.458–0.776). Shannon and Smith (1935) obtained a value of 0.64 (range 0.59–0.67), and Blegen, Haugen, and Aas (1949) reported a mean value of 0.59. The ratio observed in this laboratory for the European subject lies at the lower extreme of the range reported by the Danish workers. This may, however, merely be a reflection of a preponderance of low rates of urine flow in the present European data. In the African

subject, even at high rates of urine flow, the clearance value is less than that observed at flows below the augmentation limit in the European subject.

It is well known that the level of dietary protein affects the rate of urea elimination, and for this reason the comparison of African with European data may not be valid. The European subjects investigated had a daily protein intake of about 100 g. (half of which was of animal origin) compared with an intake of 70 g. for the African (about one-third of which was meat). The plasma concentration of urea will, however, be conditioned by the same factor, and, since it is the clearance value which is here being considered, the effect of the lower elimination may be to some extent compensated. Although Jolliffe and Smith (1931) and Shannon, Jolliffe, and Smith (1932) have demonstrated a fall in urea clearance on low-protein diets, this fall has been accompanied by a fall in the filtration rate; in the present series there was no indication of reduced filtration rate.

The possibility that there is a real difference between the mode of urea elimination in the African and the European is the subject for further investigation, with particular reference to the secretory phase of urea elimination which has been demonstrated in the European subject (Barclay, Cooke, and Kenney 1947; Kenney *et al.*, 1950).

FAT UTILIZATION IN ADULTS ON A DIET OF COWS' MILK

BY

R. HECKER, M.B., M.R.A.C.P., D.T.M.&H.

AND

W. H. H. ANDREWS, D.M., D.T.M.&H.

(From the School of Tropical Medicine, Liverpool)

Although extensive investigations into the absorption and excretion of fat in infants, both breast-fed and on cows' milk, have been carried out by Holt *et al.* (1919a, 1919b, 1919c), we have found no reference to fat absorption by adults on a milk diet. During the course of another experiment we were required to live on a diet of cows' milk for one month, and below we record our fat absorption and excretion taken over three days of the fourth week.

The fat content of a milk diet is much higher than that of a normal mixed diet. Wollaeger *et al.* (1946) found that on normal mixed diets the amount of fat ingested by adults may be increased to 208 g. a day without gross change in the percentage absorbed, an average of 9% only of the ingested fat being excreted. Annegers *et al.* (1948) studied the effect of varying quantities of fat added to a mixed diet, and found that, within normal limits, neither the quantity nor the type of ingested fat influenced the amount of excreted fat in any individual subject. A normal fat

absorption on a milk diet is therefore to be expected. On the other hand, Holt *et al.* (1919a, 1919b) found that normal infants fed on cows' milk passed more than twice as much fat as infants who were breast-fed, and that the average utilization of dietary fat was 88.6% for cows' milk and 95.8% for breast milk. They also found that the percentage of the total fat excreted as soap was much higher in infants taking cows' milk. We therefore believe that our results are worth recording.

Methods.—The collection of faeces was carried out between carmine markers over a period of three days. The diet consisted of nothing but pasteurized cows' milk, and the intake was kept constant before and during the period of collection of faeces. Five millilitre samples of milk from all bottles drunk were collected, and the fat content of the mixed samples was estimated. The faeces were collected in screw-capped glass jars containing a small amount of formalin, and were dried over a water-bath, ground, and mixed carefully. The estimations of soap, neutral fat, and free fatty acids were carried out in duplicate, using Soxhlet apparatus by the method described by Harrison (1947).

The results are shown in Table I.

TABLE I

	W.H.H.A.	R.H.
Daily milk intake	12 pints	10 pints
Fat content of milk	3.3 g.% (w/v)	3.3 g.% (w/v)
Daily fat intake	225 g.	187.5 g.
Weight of dried faeces (3 days)	147 g.	131 g.
Total fat in dried faeces	28.6%	26.4%
Percentage fat as (1) Soaps	74.5%	72%
(2) Free fatty acids	13.5%	14%
(3) Neutral fat	12%	14%
Total daily weight of excreted fat	14 g.	11.5 g.
Fat intake absorbed	93.8%	93.9%
Total body weight. Gain or loss over one month period on milk in brackets	195 lb. (+5)	155 lb. (nil)
Daily calorie intake approximately	4,450	3,700

Discussion

Although a diet of cows' milk becomes monotonous no difficulty was experienced in continuing it for a period of one month. At times we observed minor degrees of flatulence, but general health was apparently unaffected. One of us, in fact, played competitive tennis throughout the whole period and even travelled to London for the Coronation, having to sit all day in Hyde Park drinking milk. The motions seemed to be increased in bulk, rather constipated, and of uniform consistency and colour (pale) throughout. The calorie intake was obviously adequate, and one of us (W.H.H.A.) gained 5 lb. in weight over a total period of one month on milk.

The most striking feature of the results is that fat utilization is 94% (Table II), a figure well within the usually accepted, roughly defined normal range for adults, in which the amount of fat in the stool should not exceed 10% of the ingested fat. The other feature of interest is the high percentage of the total fat excreted which appears as soap. This bears a close relation to the figures which Holt *et al.* obtained for infants fed on cows' milk. The percentage of

TABLE II

	Total Fat in Dried Faeces	Percentage as Soap	Percentage as Free Fatty Acid	Percentage as Neutral Fat	Utilization of Fat Intake
W.H.H.A.	28.6%	74.5%	13.5%	12%	94%
R.H.	26.4%	72%	14%	14%	94%
Average for normal breast-fed infants (Holt <i>et al.</i>)	34.5%	43.1%	36.7%	20.2%	95.8%
Average for infants fed on cows' milk (Holt <i>et al.</i>)	34.1%	60.5%	18.6%	12.1%	88.6%
Average for children on milk with bread and cereal (Holt <i>et al.</i>)	30.7%	60.9%	25.1%	14.0%	90.6%
Average for normal adults on a mixed diet containing 208 g. fat (Wollaeger <i>et al.</i>)	33.7%	—	—	—	96%

total fat in the dried faeces is just above that which is usually regarded as being within normal limits for a mixed diet of average fat content, but below the figure obtained by Wollaeger *et al.* on a mixed diet containing 208 g. of fat.

Conclusions

An investigation was made into the fat absorption and excretion in adults on a milk diet.

It was found that adults living on a high fat diet consisting of cows' milk absorb a normal proportion of their fat intake.

As in infants on cows' milk and normal children on a milk diet, a considerable proportion of the excreted fat is in the form of soap.

A milk diet for one month has no adverse influence on health.

The work of one of us (R.H.) was carried out during the tenure of a John Holt Research Fellowship and with the aid of a grant from the Royal Australasian College of Physicians. The milk fat estimations were kindly carried out by Mr. N. Heron, of the City Analyst's Department, Liverpool, and the faecal fat estimations by Mrs. E. Smith, of the Department of Tropical Medicine, Liverpool School of Tropical Medicine.

Medical Memoranda

Intestinal Polyposis associated with Pigmentation of the Oral Mucosa

This syndrome was described by Peutz (1921) and again by Jeghers (1944), who later collected a further 22 cases from the world's literature. Of the 30 patients so far reported few proved cases have been described in the British Isles.

In view of the apparent rarity of the condition, which may yet prove to be more common than is at present supposed, two further cases are considered worth recording. The first patient, in whom the polyposis is confined to the small intestine, is exceptional in that he has been admitted to hospital on eight occasions with an intussusception and has undergone five operations for this complication. In the second patient the polyposis occurred predominantly in the large intestine, and radical surgery was possible.

CASE 1

A man aged 28 attended in March, 1948, with symptoms of recurrent partial intestinal obstruction. In 1943, when in the Forces, he had been operated on for intussusception. His son, aged 8, has pigmented lips but as yet no symptoms. He was a dark, tall, thin man with typical pigmentation of the lips and buccal mucosa. Barium enema revealed a chronic ileo-colic intussusception.

At laparotomy on March 15 chronic jejuno-jejunal, ileo-ileal, and ileo-colic intussusceptions were found. All three were reduced. Nine large polyps were present at intervals throughout the small intestine. No resection was carried out. He was subsequently readmitted in six attacks of acute intestinal obstruction.

At laparotomy on May 5 an ileo-colic intussusception was partially reduced. A few inches of ileum and the contained polyp required resection. Pathological examination showed a benign adenomatous polyp.

MAY 15, 1954

At laparotomy on May 30, 1949, an ileo-ileal intussusception was reduced; no resection. On April 20, 1950, laparotomy revealed an irreducible ileo-ileal intussusception; 12 in. (30 cm.) of ileum was resected.

In November, 1950, and January and July, 1951, he was admitted with intestinal obstruction and intussusceptions were palpated, but spontaneous reduction occurred shortly after admission. He often suffers from both mild and severe attacks of colic, but so far has required no further admission to hospital.

CASE 2

A boy aged 12 attended in February, 1951, with a rectal polyp. He had had an operation for intussusception in 1939. There was no relevant family history. He was a tall, thin child with typical pigmentation of the lips and oral mucosa. A polyp was removed from the rectum. Barium enema and sigmoidoscopy revealed no further polyps at that time. A second polyp was removed in July 1951, and in May, 1952, examination revealed a third rectal polyp and mass in the ascending colon.

An exploratory laparotomy on July 9, 1952, revealed a polyp in the jejunum, 12 in. (30 cm.) from the duodeno-jejunal flexure, a polypoid mass in the caecum, a polyp in the appendix, a polypoid mass in the descending colon, where a chronic intussusception was present, and a polyp in the sigmoid colon; the mucosa of the terminal ileum was nodular, but no true polyps were present. Resection of 6 in. (15 cm.) of upper jejunum and total colectomy, anastomosing the lower ileum to the rectum, were carried out. The pathological report stated "benign adenomatous polyps."

Post-operative progress was complicated in October, 1952, by intestinal obstruction due to adhesions, which were divided. No further polyps have developed in the 4 in. (10 cm.) of rectum remaining.

I wish to thank Mr. Ridley Thomas and Mr. Norman Townsley for permission to publish the histories of these patients, who are under their care, and for their help and advice.

Intestinal Polyposis associated with Pigmentation and Intussusception in Triplets

Hunter and Wilson (1953) define two types of true adenomatous polyps of the small intestine: (1) those associated with pigmentation of the lips and buccal mucosa and with familial tendencies; and (2) those not associated with pigmentation and no obvious hereditary factor.

In view of the rarity of this condition the following cases of type 1 occurring in triplets are considered worthy of note. All three presented initially with abdominal colic and all showed marked pigmentation of the lips and buccal mucosa, including the gums; all were of tall, thin complexion and had dark hair.

CASE 1

The patient was first seen on November 17, 1944, when aged 8. For three years, on and off, she had complained of colicky abdominal pain associated with diarrhoea and vomiting. Marked circumoral and buccal pigmentation was noted along with a patchy brown pigmentation of the abdominal wall. A tentative diagnosis of Addison's disease was made, and she was admitted for further investigation. Full blood examination showed only very slight anisocytosis; blood sodium 307 mg. per 100 ml.; and blood potassium 24 mg. per 100 ml. X-ray examination showed no supracolic calcification and the Kepler water test was normal.

A diagnosis of mild Addison's disease was made, and she was discharged on January 15, 1945.

She was readmitted on February 10 with symptoms of acute intestinal obstruction. At laparotomy (A. L. L.) 4 feet (122 cm.) of gangrenous ileum was seen and was thought to be due to volvulus. Resection with end-to-end anastomosis was performed. Some calcified tuberculous glands in the mesentery were included in the resection. She was seen again on April 9, complaining of intermittent abdominal pain, but full x-ray examination showed no abnormality.

On March 10, 1953, she was readmitted with very severe abdominal pain and symptoms of intestinal obstruction. Examination revealed a large sausage-shaped swelling in the lower and right abdomen. A diagnosis of small-bowel obstruction was made and laparotomy was performed (W. P. C.). An ileo-ileal intussusception extending through the ileo-caecal valve was found. Reduction was impossible, and a right hemicolectomy was performed. A large, simple adenomatous polyp was found to have initiated the intussusception. Convalescence was uneventful, and since discharge she has been seen several times and has remained perfectly well.

CASE 2

This sister was first seen on April 22, 1948, when aged 12, with symptoms of acute small-bowel obstruction. Circumoral and buccal pigmentation was noted. Laparotomy (A. L. L.) revealed an ileo-ileal intussusception 4 in. (10 cm.) in length. This was reduced and an intestinal polyp $\frac{1}{2}$ in. (1.9 cm.) in diameter was palpated through the bowel wall. The polyp was excised and the bowel sutured transversely. Histological examination showed inflammation of an adenomatous polyp. She was readmitted on May 26, complaining of left lower abdominal pain, but sigmoidoscopy and barium examination revealed no abnormality.

On March 28, 1949, she was again admitted with severe lower left abdominal pain associated with vomiting. At laparotomy a colo-colic intussusception of the sigmoid loop was demonstrated. This was easily reduced, and was found to be initiated by a polyp palpable through the bowel wall. Several other polyps were palpable further up the large bowel as far as the transverse colon. A Paul-Mikulicz resection of the sigmoid colon containing the intussuscepting polyp was performed. The double-barrel colostomy was later successfully closed.

CASE 3

This girl is the only one of the triplets who has not required laparotomy. Nevertheless she was seen on April 9, 1951, aged 15, complaining of colicky abdominal pain. At examination she, too, had marked circumoral and buccal pigmentation. In view of her sisters' history full barium x-ray examination and sigmoidoscopy were performed, but no evidence of polyposis could be demonstrated.

COMMENT

The association of circumoral and buccal pigmentation with polyposis of the small intestine and intussusception, though rare, is by now a well-recognized syndrome. The familial tendency of the condition is well demonstrated in these triplets, but no history of similar pigmentation or intussusception could be elicited from the parents or other members of the family.

Hutchinson (1896) first described pigmentation of the lips and buccal cavity in twins, and Parkes Weber (1919) recorded that one had died of intussusception. Jeghers (1944) and Jeghers *et al.* (1949) described the syndrome more fully and recorded 10 further cases. Tanner (1951) added a further case, and Wolff (1952) reviewed the literature and recorded a case of his own. Kaplan and Feuchtwanger (1953) and Kitchin (1953) added three further cases. Hunter and Wilson (1953) recorded yet another case of adenomatous polyp of the small intestine associated with pigmentation and intussusception, and suggested a classification of intestinal polyps. So far as can be ascertained 31 cases have been recorded.

A GUIDE TO THE LANGUAGE OF MEDICINE

CHARLES SINGER.

CLINICAL CYTOLOGY

More than 20 years have passed since Dudgeon and his co-workers published the first of several papers on the use of the cytological method in the diagnosis of tumours and in the systematic examination of sputa for malignant cells. Exfoliative cytology was subsequently employed by Papanicolaou and his colleagues in the U.S.A. in the examination of the vaginal smear, and has since been adopted for the diagnosis of malignancy in other pathological fluids such as urine, prostatic secretion, and pleural effusions. In the United States the cytological diagnosis of cancer is almost universally regarded as reliable and scientific. British pathologists, however, remain unconvinced and are for the most part unwilling to submit this technique to a fair and rigorous trial. The appearance of this volume is most opportune, for it has the unusual advantage in books on this subject of treating the subject in a commendably broad and comprehensive manner. Two valuable chapters, devoted to general cytology, contain detailed descriptions of the morphological appearances of normal cells and of the many alterations of structure which accompany general pathological processes, including the various types and

J. BAMFORTH.

In this sort of book, as usual, one finds that in most of the case histories there has been a fairly abnormal environment.

The reader is left wondering what psychotherapy would be applied should the therapist be faced with the problem of the child of normal parents who was nevertheless finding life difficult. In the end an illustrative case history is given, and an examination of this shows two interesting facts. It would appear that no analysis is done, in the sense of the interpretation of the unconscious, as it becomes ready for interpretation in the transference neurosis samples. On the other hand, toleration and unexpressed understanding enable the child to find therapeutic gain through a regression in the relationship to the therapist, and to make subsequent progress in emotional development on a firmer basis. The value of regression is not, however, specifically pointed out in the discussion.

We find here valuable intuitive clinical work put forward, but without the psychological formulations which give the work a firm basis. Certainly in certain cases it is better to allow a child to regress and to make new progression, rather than to do the alternative of interpreting without understanding the need for regression. On the other hand, it is very important for psychology that the regressive techniques should be developed by those who are able and can show that they are able to do ordinary psycho-analytic work.

ELECTROCARDIOGRAPHY

Études Electrocardiographiques. By Jean Laham. Tome 1. (Pp. 285. No price given.) Paris: Librairie Maloine. 1954.

In the first volume of this work on electrocardiographic studies the author discusses myocardial infarction, coronary insufficiency, and pericarditis. Unfortunately, as so often with French books, there is no index, so it is difficult to find what one wants. Discussing infarction, the author claims that in 95% of recent cases characteristic cardiograms can be found, and that the size of an infarct as shown by the cardiogram has a bearing on prognosis; such information as this is easy to find. But there are a number of serious disadvantages to this sort of book. Certainly only the most hard-bitten cardiologist will try to read it, for there is not a single illustration, and the effort of mentally visualizing the curves, the technical description of which appears in the text, is by no means small, even to the initiated.

There are many abbreviations, where capitals stand for words—not easy again for the foreigner to translate. The references are profuse; sometimes ten or twelve lines of them, all in small capitals with the dates in brackets; this makes the text almost unreadable. How much better it would be to collect them all in appropriate herds and refer to them in the text by little numbers. The style is intensely tabular, broken up into short didactic paragraphs, numbered and classified into many headings and subheadings. This seems to be the fashion in some of the French medical publications of to-day. Gone is the elegant fluency of the older writers. Tiring to the eye also are the many statistics, whole series of percentages, and so forth, which may or may not mean much. But if any reader can get over all these difficulties he will find here an enormous amount of information, and the book can well be of great use to the cardiologist for reference, to be taken in very small doses. After all this electrocardiography one might easily forget all about the patient.

TERENCE EAST.

OBSTETRIC STATISTICS

Das Geburtshilfliche Gutachten im Vaterschaftsprozess. By Professor Kurt Podleschka. (Pp. 237; 64 illustrations. M. 33.) Stuttgart: Georg Thieme. 1954.

German scientific literature is replete with compendial monographs which, while contributing little or nothing in the way of original thought or research, emerge mainly as extremely well presented reviews of all the available knowledge to date on their particular subject. The present work, the cumbersome title of which may be translated as "obstetrical aids in the assessment of paternity claims," is

characteristic of the genus. The author discusses the problem of disputed paternity from a strictly statistical viewpoint, marshalling the relevant facts with enviable precision and efficiency. He thoroughly dissects the vexed questions of time of conception, date of ovulation, duration of pregnancy, and post-maturity, and reduces them to tabular or graphic form, and he leaves the reader with the impression that the determination of these distressing legal claims is merely a matter of turning up and quoting the appropriate authority. The matter is in practice by no means so simple, for natural variation in these factors is so great that the average court will accept a width of application sometimes amounting to discrepancy. The medical witness, however, will find the concentration into one handy volume of all the scientific data concerning a difficult subject of value in replying to precise legal questioning, and the book should be in the possession of those likely to be so involved.

BROADMOOR

Broadmoor: A History of Criminal Lunacy and Its Problems. By Ralph Partridge. (Pp. 278; illustrated. 21s.) London: Chatto and Windus. 1953.

"On May 15, 1800, a man named James Hadfield was arrested after firing a pistol at King George III in the Royal Box at Drury Lane Theatre. The bullet narrowly missed its mark, as the King happened to be bowing his head at the time to the audience." At his trial it was revealed that the prisoner thought he was acting on the direct instructions of God, who had commanded him to save the world by sacrificing his own life. Suicide being too wicked, he hoped to be executed, but his wish to be hanged, drawn, and quartered was not to be gratified. Within a month of his trial the Criminal Lunatics Act of 1800 was passed, under which persons acquitted on grounds of insanity or found insane on arraignment could be ordered to be detained "until His Majesty's Pleasure be known."

So begins Mr. Partridge's fascinating story. After discussions in the first chapters on insanity from the legal and the medical point of view, Chapter III begins the history of Broadmoor from its founding in 1856 down to a full account of its organization at the present day. The history of the institution is to a large extent a history of its successive medical superintendents, with their varying inclinations to liberalism or rigour. At the beginning, as the author remarks, greater reliance was placed on the science of engineering than on the science of medicine; if one could not try to cure the patients, one could try to keep them inside. Nevertheless, escapes were quite frequent in the earlier days, and have continued on rare occasions until now. The commonest means of leaving the hospital—as it became in 1941—had, up to that date, been by transfer to other mental institutions and by death. However, it is noteworthy that about a quarter of the patients admitted either have been discharged recovered or have recovered and been sent back to prison. One must hope that the next 5,000 patients dealt with will show a considerable improvement on these figures.

Some of the improvements made in the organization during the superintendency of Dr. Hopwood, who retired in 1952, are of interest. He succeeded in introducing parole, despite the misgivings not only of authorities but even of his own staff; needless to say, the parole system has amply justified itself. Doors within the hospital also began to be flung open, so that trusted patients could pass freely from one part to another. Social occasions were begun, at which the sexes were allowed to mix: women number about a quarter of the total, which must be a higher figure than in sane prisoners. Other amenities have been added, bowling greens, away matches for the cricket team, and the famous dramatic society of patients, "The Broadmoorists." It was owing to Hopwood that Broadmoor came to be recognized as a mental hospital, that turnkeys passed away and even attendants became nurses, that patients wear sports coats and flannel trousers and clean-shaven faces. The era of wise humanitarianism had done its best.

HORMONE TREATMENT OF BREAST CANCER

In 1829 Astley Cooper¹ suggested that a functional relationship existed between the ovary and the mammary gland. It was soon recognized that this relationship might be of major importance in the genesis of breast cancer, but it was not until 1896 that oophorectomy was first advocated and performed by Beatson² as a means of treating this disease. The operation fell into disuse partly because complete regression of tumour growth was rarely obtained.

Much of our present-day knowledge of breast cancer is based on animal experiments. The carcinogenic potency of the ovaries was first demonstrated in mice by Loeb³ and his co-workers in 1919, who found that removal of both ovaries from young mice of various strains with a high susceptibility to cancer considerably reduced, though it did not entirely prevent, the incidence of mammary cancer. Then Murray⁴ in 1928 found that mammary cancer could be produced in castrated male mice of a highly susceptible strain by grafting into them the ovaries of their sister litter mates. But it was not until Lacassagne⁵ announced in 1932 the results of his classic experiment that the relationship between the ovarian factor and breast cancer became firmly established. By repeated administration of oestrogen Lacassagne was able to induce mammary carcinoma in male mice which normally never develop it. This was a very important discovery, not only because oestrogens proved to be the first substances originating in the body which could cause cancer, but also because oestrogens came to be used in the hormonal treatment of certain types of neoplasia which arise in organs under endocrine control.

The next important advance was made by Murray,⁶ who discovered that in certain of their

biological activities oestrogens and androgens are antagonistic to each other. He found that when male and female mice of a high cancer strain are joined in parabiosis the female partners, which normally develop mammary carcinoma, failed to do so under these experimental conditions. Since then Lacassagne and others have shown that hormonal antagonism, while preventing spontaneous breast cancer in mice, has considerably less influence on growths which are already established and in which malignancy has appeared.

In the clinical field Loeser⁷ was one of the first to use testosterone therapy on advanced breast carcinoma in women. Later Adair and Herrmann⁸ reported regression of breast cancer with bone metastases following large doses of testosterone propionate, and Mr. R. W. Raven in an article at page 1124 of this issue of the *Journal* describes several cases of breast cancer with metastases which he treated with methyl-testosterone. In two instances the survival periods after treatment was begun were six and seven years. Other clinicians, relying on the depression of pituitary function and hence inhibition of ovarian secretions, have used massive doses of oestrogen for the treatment of breast cancer. Haddow and his co-workers⁹ in Britain and Nathanson¹⁰ in the U.S.A. have obtained partial regression of advanced breast carcinoma in women with this form of therapy. More recently Stoll and Ellis¹¹ have published interesting clinical data on the treatment by oestrogens of pulmonary metastases from breast cancer. In the treated group 31% of cases survived over 12 months, as compared with 7.5% in the untreated group. In the treated group 26% showed regression of pulmonary lesions, whereas in the untreated group there was no regression at all.

Since the time of Beatson many workers have re-introduced bilateral ovariectomy for the treatment of mammary cancer, while others have preferred irradiation with x rays as a substitute for ovariectomy. The reports of both these forms of treatment are in many instances conflicting. A notable case is now reported by Mr. Raven in which ovariectomy was performed on a woman with breast carcinoma accompanied by cervical and axillary lymph node metastases. The operation was done five and a half years ago, and the patient to-day shows no clinical evidence of cancer and leads a normal life.

Recent work in endocrinology has demonstrated conclusively that the ovaries are largely but not entirely responsible for the induction of breast cancer because of their share in the production of oestrogen. But it must be remembered that under certain conditions the ovaries are capable of secreting andro-

gens, the Sertoli cells of the testis secrete oestrogens, and the adrenal cortex elaborates both oestrogens and androgens. It has become clear, for instance, that cancer in the male breast can now be attributed with some confidence to the secretion of oestrogens by the testis. New light has recently been shed on the hormonal genesis of breast cancer in mice by Muhlbock¹² in Amsterdam. He has discovered that frequent implantations of fresh hypophyses induce mammary neoplasia in the absence of both the milk factor and extraneous oestrogen. This finding is important because it suggests that a pituitary gonadotrophin plays a part in the development of this disease.

There are many encouraging examples by which the growth of a neoplasm arising in a gland under endocrine influence can be temporarily held in check over considerable periods by administration of hormones, but reports of complete recovery from the disease are rare. Reactivation of the tumours almost invariably occurs, and it would seem that, in many instances when a hormone imbalance is created after surgical removal of an endocrine gland or by administration of a hormone, a compensatory mechanism develops in which the anterior pituitary gland stimulates other endocrine organs to make up for the deflection caused by a particular form of treatment.

The work of Huggins strongly suggests that this happens. He has frequently observed that breast cancer in either the male or the female at first shows a favourable response to gonadectomy, but that recurrence of the growth occurs later. Working on the assumption that elaboration of steroid hormones from the adrenal cortex was responsible for the renewed growth of these tumours, he obtained a further regression after bilateral adrenalectomy and the administration of cortisone acetate. Thus he contends¹³ that breast cancers may be either ovary- or adrenal-dependent. Occasionally in women they are entirely dependent on the ovary for sustained growth, and this probably accounts for the occasional success which follows treatment by ovariectomy alone. As most breast tumours appear to be adrenal-dependent, Ling-Yuan Dao and Huggins¹⁴ recommend ovariectomy to be carried out before adrenalectomy or both operations simultaneously, since they found it impossible to determine by distinctive morphological characters whether a breast cancer will prove to be adrenal-dependent or not. Pearson *et al.*,¹⁵ using calcium excretion as a measure of the growth rate of mammary tumours with bone metastases, prefer to classify mammary cancer in relation to oestrogen rather than with the organs producing it. One type depends on oestrogen for maintenance of growth and the other

type does not depend on oestrogen. Patients with non-oestrogen-dependent tumours fail to respond to ovariectomy and probably also are not helped by adrenalectomy. It is claimed that cortisone induces remission in non-oestrogen-dependent mammary cancer, but this work is too recent to allow a forecast yet on whether improvement can be maintained over long periods.

Endocrine therapy is one of the most interesting and promising fields in cancer research, but until more is known of steroid metabolism it will be impossible to improve much on the sort of result which is being obtained at the present time. We do not know why some patients respond favourably, neither do we know why so many growths prove ultimately to be refractory.

MITRAL STENOSIS

The value of mitral valvotomy for the relief of mitral stenosis is now well established, and the operation is being carried out in many centres in this country and abroad with excellent results in the majority of cases. The success of the operation depends to a large extent on the selection of suitable cases, and this has led to intensive study of the clinical, radiological, and haemodynamic changes in mitral stenosis in the hope of increasing the accuracy of diagnosis. For this reason Dr. Paul Wood's paper on mitral stenosis, published in this and last week's issues, is timely, particularly as he shows that, by applying the results of methods of investigation which can be carried out only in special centres, an accurate clinical diagnosis of the nature and effects of the mitral valve lesion can be made. In the patient with pure mitral stenosis, with steadily and often rapidly progressing disability, the clinical picture is clear cut: there is a right ventricular lift on the left of the sternum, the mitral first sound and the opening snap are loud, there is no third heart sound, and the mitral diastolic murmur is long. A major difficulty in the pre-operative study of patients with mitral stenosis has always been the assessment of the degree of mitral incompetence which may be present, since if this is significant the results of surgical treatment are poor. Serious mitral incompetence will be recognized if Dr. Wood's criteria are followed. The small water-hammer pulse, the hyperdynamic left ventricular apical thrust with electrocardiographic evidence of left ventricular

hypertrophy, the soft mitral first sound followed by a systolic murmur, the presence of a third heart sound and the absence of the opening snap, and the radiological appearances of dense calcification of the mitral valve, are all definite signs of mitral incompetence and therefore indicate that operation should be avoided.

Most investigators agree on the general pattern of the haemodynamic changes in mitral stenosis, although they differ in their interpretation of the significance of these changes. The cardiac output in severe mitral stenosis is low at rest, and on exercise often fails to increase and may sometimes fall, the additional oxygen necessary during muscular activity being obtained by increasing the oxygen extraction from the blood. With slight or moderate valve-narrowing the resting pulmonary capillary pressure is normal or slightly increased, and the pulmonary-artery-pulmonary-capillary pressure gradient is unchanged, so that there is passive pulmonary hypertension. With more severe stenosis, either calculated by the Gorlin formula¹ or estimated at mitral valvotomy, the resting pulmonary capillary pressure is raised to about 30 mm. Hg, this being approximately the same as the plasma osmotic pressure. With this marked narrowing of the mitral valve orifice the pulmonary artery pressure rises sometimes to the level of the systemic pressure, the pulmonary-artery-pulmonary-capillary pressure gradient is greatly increased, and the pulmonary arteriolar resistance, calculated by the Poiseuille equation, is correspondingly raised.²

The cause of this increased pulmonary resistance, which raises the pulmonary artery pressure and adds to the work of the right ventricle, is probably active vasoconstriction rather than the structural changes in the vessels described by Parker and Weiss,³ since there is no correlation between the calculated resistance and the appearance of the pulmonary vessels studied by lung biopsy at operation.⁴ Dexter and his colleagues⁵ introduced the concept that the raised pulmonary arteriolar resistance protected the pulmonary capillaries against sudden increases in pressure—possibly resulting from sudden changes in cardiac output—which could cause pulmonary oedema. It has also been suggested that the raised resistance is responsible for the low cardiac output, either directly or indirectly by increasing the pressure gradient across the mitral valve.

Dr. Wood attaches particular importance to the pulmonary arteriolar resistance in relation to the production of both symptoms and signs of mitral stenosis and supports Dexter's view that a high resistance protects the patient against pulmonary

oedema. Other investigators, however, have questioned the conception of "protective pulmonary hypertension,"^{6,7} and the measurement of pulmonary resistance itself has been criticized, either because of the difficulties in making accurately the measurements necessary for its calculation⁸ or because of doubt about the validity of the Poiseuille formula in the presence of turbulence at the mitral valves and varying rates of blood flow.⁹ The pulmonary capillary pressure often rises on exercise to 50 or 60 mm. Hg, which is well above the plasma osmotic pressure level, and these patients may develop pulmonary oedema. The pulmonary arteriolar resistance, whether initially high or low, is unchanged on exercise despite the increase in pulmonary capillary pressure, and in these circumstances no protection of the pulmonary capillaries has occurred.⁶ It seems that only under resting conditions may the high resistance help to maintain the capillary pressure at a safe level, and this protective mechanism may break down under conditions of stress. The effect of tachycardia in raising the pulmonary capillary pressure may well be the cause of pulmonary oedema in some patients. Tachycardia, whatever its cause, shortens the diastolic ventricular filling period, and a raised left auricular pressure is necessary to increase the pressure gradient across the mitral valve and to maintain the cardiac output.¹⁰

Rheumatism is one of the commonest causes of heart disease in this country, and if Dr. Wood's estimation of the number of cases of mitral stenosis is correct it is clear that a large number of mitral valvotomies will need to be carried out annually. His series is composed largely of more seriously incapacitated patients, and it should not be forgotten that the disease is not necessarily progressive and that only a minority of those with little or no cardiac enlargement ever develop serious symptoms.¹¹ A healthy myocardium may be able to sustain for long periods the additional work imposed by the mechanical obstruction at the mitral valve. The operative mortality of 6%, and the 10% incidence of embolism at operation, should discourage operation in symptomless patients or in those with only minimal disability.

REMUNERATION OF CONSULTANTS AND HOSPITAL MEDICAL STAFFS

The discussions on remuneration of consultants and hospital medical staff in the Council last week and the Central Consultants and Specialists Committee a fortnight ago unfortunately only serve to deepen the disquiet many feel about the fate of the Consultant Spens Report and—if that is now in jeopardy—of the

General Practitioner Spens Report, two documents accepted by both Government and medical profession six years ago and deciding factors in persuading a reluctant profession to enter the National Health Service. When Mr. Marquand, as Minister of Health, offered general practitioners £2m. in 1951, they rejected it and determined to press their claim in the terms of the G.P. Spens Report. This was the first overt sign of the Government's—and the Ministry of Health's—wish to undermine the basis on which doctors had agreed to work in the N.H.S. This effort failed. In his able exposition last week in Council of the events that have unfolded since the days of the Negotiating Committee Dr. T. Rowland Hill concluded that the recent agreement was on an "immediate, noncommittal *ad hoc* increase," and that there was no finality in it. He went on to say that the implementation of the Consultant Spens recommendations would be vigorously pursued, and supported the amendment to his report that: "The Council of the Association reaffirms its policy to adhere to the basis of remuneration enunciated in the Spens Reports."

The Staff Side of Whitley Committee "B" believes that "Spens remains the yardstick of consultant remuneration," and no one questions the sincerity of this belief. But do the Government and the Ministry of Health hold the same belief, even without the same fervour? There are, unfortunately, strong grounds for doubting this. Dr. Hill, reading from an agreed minute in last week's Council, referred to the importance attached by the Minister to the Spens Report, and urged that this should be fully reported. The Minister's reply to a question put to him by Sir Russell Brain, as minuted, was as follows:

"The Minister said that the *only point he was now dealing with was the actual level of remuneration. On other matters he agreed fully with the importance attached to the Spens Report*, which must continue to occupy the same place as before in any discussions the Government had with the profession about the consultant and specialist service." (Our italics.)

The Minister of Health is far too experienced a politician to be so naive as this statement makes him out to be. The whole purpose of the Consultant Spens Report was to determine levels of remuneration of consultants and hospital medical staff in a public service. If words mean what they are supposed to mean, the above statement implies explicitly that the Minister no longer attaches much if any importance to levels of remuneration recommended in a report on remuneration. If any doubts remain they are dis-

pelled by the reply, published in this week's *Supplement*, of the Permanent Secretary to the Ministry, Sir John Hawton, to questions put to him by Dr. Angus Macrae, Secretary of the B.M.A. Sir John Hawton states, quite bluntly, that the remuneration of consultants and hospital medical staff is no longer to be determined "by a mere reference back to the contents of Reports which were produced years ago and before there had been any experience of the working of the Service under modern conditions."

The profession is urged to study with the greatest care the words of the Minister and the Ministry's Permanent Secretary, because they were not thrown off carelessly in the heat of a debate, but represent the carefully considered policy of the Government. And if anyone is unaware of their import a careful examination of the recent agreement should show how little regard has been had to the Spens recommendations. We are told that the Management Side—and the Minister—refused to take "betterment" into consideration—one of the twin pillars of the Spens recommendations. When faced with this completely untenable position the Staff Side would have been wise to go back to their constituents for fresh instructions. Having yielded, and in the face of the Minister's and the Ministry's statements referred to, they face their future course with an uncharted map. The actual amount of additional money for consultants and hospital medical staff is in some ways the least significant aspect of the recent agreement between the Staff and Management Sides of Whitley Committee "B": some consultants even hold the view that no claim should have been made. But few can feel happy about the way in which the negotiations have been conducted: secrecy apart, no evidence appears to have been presented on which a proper claim could be pressed. What stands out is that the first time the consultants have sought to have the Spens recommendations implemented—six years after publication of the Report—they have met with a refusal by the Management Side to discuss betterment. In the face of this it is difficult to maintain that "Spens remains the yardstick."

It is possible to interpret the fate of the Consultant Spens Report on the assumption that in relation to the corresponding report on the remuneration of general practitioners it was too generous. This would indeed seem to have been in Sir Russell Brain's mind when he told the Central Consultants and Specialists Committee on April 28 (*Supplement*, May 8) that the new terms for consultants "had restored the balance between the income of the general practitioner and that of the consultant and specialist." And he added: "Moreover, this agreement was not likely

to be thrown over within a short period of years." But if consultants, as has been asserted, intend to press on with their claims, regarding the recent agreement as only interim and noncommittal, this balance will then be upset, and further claims for the general practitioner will presumably be made—a course often described these days as spiral. The danger of all this is that a kind of "pull devil, pull baker" attitude will arise between the two most important sections of the profession. There is more than ever a need for the closest harmony between the two, and for the co-ordination of effort in all aspects of their work. It will be noted that the Council's first amendment to Dr. Hill's report referred to its continued adherence to the Spens Reports—in the plural. The second amendment deplored the secrecy surrounding the recent agreement. Joint consultation on remuneration between consultants and those they represent and general practitioners would seem to be desirable, indeed imperative, if unity of effort and aim is to be maintained in the interests not only of those now working in the N.H.S. but more especially in the interests of future generations. But neither section of the profession should let the guile of the politician wheedle them out of the standard of living promised by the two Reports drawn up on the basis of carefully ascertained statistics by responsible committees presided over by Sir Will Spens.

THE FUTURE OF NEUROLOGY

In an interim report¹ which has just been issued the Committee on Neurology of the Royal College of Physicians advises the avoidance of a rigid plan for training neurologists, but in general suggests that training should consist of two years' experience of general medicine and surgery followed by five years' hospital work in neurology. As in previous reports,² the committee is opposed to a neurology diploma. The report states that, unlike other specialties, there has been practically no expansion of the neurological services under the National Health Service, and that in many parts of the country a neurological opinion is still not easily available. Indeed, there are only 50 to 60 practising neurologists in England and Wales, more than two-thirds of whom are in the London and the metropolitan regions. Finally, the committee points out that the prospects are so poor that promising graduates are becoming increasingly reluctant to enter a branch of medicine in which this country is still pre-eminent.

This report betrays an unsatisfactory state of affairs, for neurology should be contributing to the developments in many growing fields of research, such as the study of cerebral vascular disease and neurotropic virus diseases, the rehabilitation of the paralysed, and the relief of pain. Perhaps the failure of neurology to

develop with the Health Service is due partly to a certain lack of political sense in the neurological associations, and partly to the fact that the few neurologists in the country are all so busy with purely diagnostic work that there is little time for them to apply their special knowledge to modern therapeutic possibilities. Many of the smaller specialties form what might be called political pressure groups to develop the specialty in all regions, and it is a sad reflection on modern times that neurologists may have to become more politically minded in order to co-ordinate their national effort more closely and to improve their contribution to modern medicine.

British neurologists must always look to the National Hospital, Queen Square, to take the lead in all such matters, and to maintain a close and helpful interest in the work of her disciples in provincial centres.

PREVENTION OF CARIES

The prevention of dental caries rather than the expensive treatment of already diseased teeth is the theme of a memorandum¹ drawn up by the British Dental Association's Child Dental Health Committee. The committee has wisely refrained from abstruse discussions on the theory of dental caries aetiology and has confined itself to known facts of practical significance. The report makes clear the overwhelming evidence that dental caries is associated with the stagnation of food, particularly refined carbohydrates, around the teeth. An increase in the consumption of this type of food is accompanied by a corresponding increase in the incidence of dental caries, and conversely less of it results in less caries. This is well illustrated by the lower dental caries incidence in those countries where sugar and sweets were rationed during the two world wars. It is not only the total consumption of these refined carbohydrates that is significant but also the spreading of it throughout the day. The studies in dental caries recently carried out in Sweden have shown that the greatest damage to the dental structures results from eating sweets and other snacks between meals, while a similar total quantity of this type of food taken at mealtimes is not so detrimental.

It is difficult, in the absence of national economic crises, to alter a nation's eating habits, but much can be done by public education in these matters. There is no doubt that dental caries can be reduced by limiting the consumption of sticky carbohydrates, particularly between meals. If the general public is made aware of this by the combined efforts of the medical, dental, and nursing professions, it should be possible to convince people, particularly parents, that dental decay is largely under the control of the individual.

The report also considers other methods of reducing the incidence of dental caries. Toothbrushing, to be effective, must be carried out immediately after eating, and the method of brushing must be one that removes food debris not only from the exposed surfaces of the teeth but also from the relatively inaccessible areas. The

¹ Interim Report of the Committee on Neurology, 1954, London.
² See *British Medical Journal*, 1945, 2, 292.

¹ *Brit. dent. J.*, 1954, 98, 199-220.

cursory toothbrushing that most people carry out does little to prevent decay, and it is clearly the responsibility of the dental surgeon and the dental hygienist to instruct the public in the correct technique. The practice of rinsing the mouth with water after eating is beneficial and presents fewer social difficulties than might be expected. Water is usually available at the table, and the operation of rinsing can be carried out unobtrusively and the mouthful subsequently swallowed. Chemical treatment of the teeth as a preventive measure has been tried for many years, with disappointing results. Topical application of silver nitrate has been shown to be ineffective. The application of silver nitrate appears to slow down an established carious process, as the committee states, but this procedure does not eliminate the risk of a cavity providing a shelter in which food debris can accumulate, allowing caries-producing micro-organisms to multiply there undisturbed and in time affect the contiguous surface of the adjacent tooth. Topical applications of sodium fluoride may not be as successful as was originally hoped, but the results of the large-scale investigation of the Fluoride Working Party of the Ministry of Education are expected to indicate the value of this measure. Various toothpastes have been manufactured containing what are alleged to be caries-inhibiting constituents, but the committee regards these with considerable reserve and some, such as pastes containing penicillin, with disfavour. Further research on enzymes may result in the introduction of certain anti-enzyme substances into toothpastes or mouthwashes, with favourable results.

Apart from dietary control, the most hopeful means of preventing caries is the introduction of one part per million of sodium fluoride into the public water supply. This practice, widely adopted in the United States since 1945, has been observed to reduce the caries rate. An investigation on these lines is proposed for Britain. Here as elsewhere people living in districts with a natural fluoride content of this concentration in their water have been found to have better teeth than people living where the water is relatively lacking in fluoride.

The problem of caries control at present centres chiefly on education of the public: education in what to eat and when to eat it, and what to avoid eating; education in oral hygiene, education to prevent mothers (or grandmothers) from ruining babies' teeth by giving them rubber dummies dipped in sugar or honey; and education to accept or even demand public health measures designed to reduce their children's caries susceptibility. Parents should be encouraged to take their children for routine dental examination at an early age. Neglected teeth result in apical sepsis and pain, and the improvement in a child's health after the extraction of infected teeth is notable. Premature loss of the deciduous teeth, however, usually has a deleterious effect on the occlusion of the permanent dentition, and mal-occlusion in turn leads to an increased susceptibility to dental caries and predisposition to periodontal diseases. The medical and dental professions can help too by co-operating in devising diets to maintain the general health of the child and ensure not only sound, well-developed teeth but also teeth which are not constantly exposed

to a harmful oral environment. The report should be read by everybody concerned with the health and well-being of children.

ELECTRONIC TRANSLATION

The enormous speed at which electrons travel—or so it seems to humans more accustomed to the London-Brighton road—has tempted scientists in many branches of learning to think of new ways in which these wave-particles can be pressed into service. We have become familiar now with electronic "brains" performing elaborate calculations which in certain respects are far beyond the capacity of human brains, and with the paradox that the human brains must yet devise every move made by their electronic servants. Composing the instructions to be given to the machine can be an intricate operation, and a new profession of programmers to do this is no doubt growing apace. One of the tasks they may in years to come be setting their machines is to translate a scientific paper from one language into another. The need for some such aid to the understanding of medical literature is evident to all but natural linguists. Abstracts from the world's literature offer some help, and in fact *Abstracts of World Medicine*, published monthly by the B.M.A., covers nearly 2,000 journals in over a dozen languages. But if machines could be programmed to turn out comprehensible translations of papers and books in a matter of minutes, or an hour or so, the reader's problems would seem to be much simplified.

Discussing the still formidable obstacles to the design of such machines, Bar-Hillel,¹ of the Massachusetts Institute of Technology, begins by drawing a distinction between the kind of writing seen in novels and that seen in technical papers. What he calls the correlating of certain words in the source language with certain words or phrases in the target language can be complicated if the words to be translated bear such connotations as they often do in works of fiction. The phrase "Came the dawn," for instance, would be easier for a machine to translate correctly in a meteorological than a melodramatic context. Nor are scientific papers often wholly free from the kind of linguistic puzzle that Bar-Hillel himself would present to an electronic translator in the following words: "One method involves adding an additional piece of mechanical equipment of a somewhat more involved nature. . . ." Idioms and synonyms would tax the resources of the machines, or at least of their designers, and at first likely alternative meanings might have to be incorporated in the translation and all but the correct one struck out by a human editor. Even so, as Bar-Hillel points out, sometimes this functionary, whom he calls the post-editor, would be presented with literal renderings of idiomatic phrases to which no amount of shuffling of the translated words will give meaning—despite, too, the post-editor's own programme: "The post-editor will be warned that any preposition might have to be replaced by almost any other preposition. . . ."

Probably a more important task for the post-editor—and one on which Bar-Hillel touches—is to act as what

¹ *American Scientist*, 1954, 42, 248.

we might call a pre-editor. That is to say, he would have to prepare the original paper, by eliminating idioms and so on, so as to present the machine with a verbally unambiguous programme. But as any ordinary editor, neither pre- nor post-, knows, to translate into good English a paper written in bad English is apt to be an almost baffling task even when knowledgeable readers are assumed to be the audience. How much more difficult when the translation is for an unsympathetic electrical circuit. Perhaps the need to write clearly for a human rather than an electronic eye is the more pressing at the moment. At any rate, it seems that some years will elapse before an electronic translator gives any reader the sense of wonder that Keats felt on first looking into Chapman's Homer.

A GREAT RUNNER

Last week at Oxford, Mr. R. G. Bannister, a medical student at St. Mary's Hospital, won the plaudits of the world in being the first athlete to run the mile in under four minutes. His actual time was 3 minutes 59.4 seconds. Since it is only twenty-three years since Jules Ladoumegue was the first to beat 4 minutes 10 seconds, it is natural to ask whether there are any fixed limits to athletic performance and physical endurance. History—including the climbing of Everest last year—suggests that there are not. For many years a record may not be broken, and often it is a round figure which provides the sticking point. But surprisingly, when this point is eventually passed, it is passed by a fair margin. The present discussion of a high jump of 7 ft. will quickly turn to talk of 7 ft. 6 in. once the round figure has been beaten. Only four years ago the weightlifters wondered if a 1,000-lb. total could be reached on the three Olympic lifts. This figure was first exceeded in 1951 by lifts totalling 1,062 lb., and 1,200 lb. is confidently expected soon.

The limits to man's physical performance are imposed by anatomical, physiological, and psychological factors. Many world champions possess certain natural physical advantages, perhaps most noticeably the long limbs and large vital capacities of so many track athletes, and specialized training can improve even natural anatomical advantages. Exercises of endurance induce capillarization of muscle, the number of capillaries being as much as 45% more in trained than in control animals¹; and the haemoglobin content of the muscles of trained dogs is more than twice that in untrained dogs.² It has been said that a gain in endurance may be mainly a problem of improving transport of the blood in the muscles.³ Certainly training has to be regular, intense, and rational, and Bannister's training fulfilled all these conditions. His medical education and research into the physiology of exercise have doubtless influenced the actual technique of his training, which included special strengthening exercises.

Athletes cannot hope to better the performances of their predecessors if training is hindered by inadequate

¹ Petré, T., Sjöstrand, T., and Sylvén, B., *Arbetsfysiologi*, 1936, 9, 376.
² Whipple, G. H., *Amer. J. Physiol.*, 1926, 78, 693.
³ Schneider, E. C., and Karpovich, P. V., *Physiology of Muscular Activity*, 1948, Philadelphia.

facilities or failure to incorporate new and more scientific methods, but psychological factors probably provide, in the form of the challenge and inspiration of new records to be broken, the deciding stimulus which urges men on to ever greater physical endeavour. The effect of intense rivalry on the track is shown by the frequency with which athletes achieve in competition results they have never achieved in training. Athletic records, in fact, are advanced not only by improved training and technique but also by the simple will of man.

WOMEN IN MEDICINE

There are now 7,600 women doctors' names on the *Medical Register*, of whom some 6,000 or more are in active work. This is an impressive number and lends force to the fact that women are now established in medicine and are accepted as a matter of course alike by their male colleagues and the public. Medical women, therefore, might well be excused if they assumed that their major professional difficulties had been overcome. A recent P.E.P. publication,¹ however, and the correspondence in *The Times* which followed, has shown that the path of the married woman graduate to-day wishing to follow her vocation can still be far from smooth: and Dr. Annis Gillie, who last week succeeded another popular figure, Dr. Mary Esslemont, as president of the Medical Women's Federation, thought fit in her presidential address to sound a note of special warning to women medical graduates. None would wish or expect women who have chosen to embark on a professional career to exclude all else from their lives, but marriage continues to remove from the ranks of medical women many who have careers of promise before them, and is likely to go on doing so. A lesser but none the less important effect of early marriage is that it reduces the number of women going on to take higher degrees and thence to a specialty. It is possible for a young woman of determination and character to overcome the impediments to her professional career which marriage entails, but she needs considerable devotion to her work if she is to bear with equanimity the burden of a dual responsibility. Nor is she encouraged to do this by the disheartening cost of paying heavily for her substitute in the home and by the effect of taxation upon a combined income. There is no short answer to these and other particular problems of medical women to-day. Dr. Gillie sees them as a challenge which calls for action by women themselves. A position won must be fortified and held. This is true, but the matter is more than a domestic one and will attract the sympathy of all who would wish to see their women colleagues' contribution to the practice of medicine continue undiminished.

The next session of the General Medical Council will open on Tuesday, May 25, at 2 p.m., when the President, Sir David Campbell, will take the chair and deliver an address.

CLINICAL PATHOLOGY IN GENERAL PRACTICE

INTERPRETATION OF ELECTROLYTE CHANGES IN THE BLOOD

BY

PAUL FOURMAN, M.D., M.R.C.P.

Medical Research Council Department of Experimental Medicine, Cambridge

The general practitioner does not very often have to ask the laboratory for estimations of electrolytes; the results of such tests do come to him, however, in the letters about patients who have left hospital; and he himself may want to follow the electrolyte changes in some of the more chronic diseases he meets. This article sets out to recall the meaning of some of the chemical data that may be encountered and to indicate when the determinations may be useful. The treatment of acute disturbances of water and electrolyte balance was fully discussed by Dr. D. A. K. Black* in another Refresher Course. Disturbances in calcium and phosphorus metabolism, which are not closely related to water balance, are not discussed here.

The Body Fluids

The constituents of the body, other than those of the bones and fat, are held in solution in water. This water accounts for 50-60% of the weight of a man, depending on how fat he may be. One-third of this water is outside the cells in the tissues and in the blood; this is the extracellular fluid (E.C.F.). The remaining water, two-thirds of the total, is intracellular fluid (I.C.F.). The electrolyte content of the two fluids is quite different. In the extracellular fluid, sodium (Na^+) is the main cation; chloride (Cl^-) and bicarbonate (HCO_3^-) are the main anions. In the intracellular fluid of muscle, which accounts for most of the intracellular fluid, potassium (K^+) and magnesium (Mg^{++}) are the main cations; organic compounds of phosphorus are among the main anions. In both extracellular and intracellular fluid protein also acts as an anion, and this may be more important in the intracellular fluid, which contains the greater amount of protein.

The following principles govern the composition of the body fluids. The number of anions equals the number of cations. The reaction, or pH, depends on the concentration of hydrogen ions (H^+), but this concentration is very small compared with the concentrations of the other cations. The total concentrations of ions (cations+anions) largely determines the osmotic pressure of the solution. Changes in the reaction or in the osmotic pressure of the body fluids are usually rapidly compensated; for instance, a loss of base is likely to be accompanied by a loss of acid, and a loss of salt is accompanied by a loss of water.

Only the extracellular fluid can be sampled clinically. This is done when we collect and analyse the plasma or serum of the blood, although these do differ from the extracellular fluid outside the blood vessels in having a higher concentration of protein. Our knowledge of changes in the intracellular fluid is usually only inferred from changes in the serum. The sodium, chloride, bicarbonate, and potassium are the ions commonly measured.

Sampling

Blood is drawn from a vein with a clean, dry, sterile syringe, with a minimum of venous stasis; a wide-bore needle is better than a very fine one. The syringe may be lubricated with liquid paraffin. Instead of a syringe

many prefer a needle with a short length of rubber tubing attached to it through which the blood is allowed to flow. The blood is collected into a centrifuge tube or a screw-capped bottle. If the tube or bottle contains an anticoagulant the blood can be centrifuged and the plasma taken off without delay; this may take up less time than waiting for a clot to form and retract so that the serum separates. Oxalate is a convenient and cheap anticoagulant, but potassium and ammonium oxalates interfere with the determination of potassium and urea. Heparin (2 drops of 1:1,000 solution) does not interfere with these determinations, but it is more expensive. Plasma is needed for the determination of bicarbonate and chloride. Ideally it should be separated from blood which has been collected under a thin layer of liquid paraffin; this is to prevent contact with air and loss of CO_2 by diffusion. Plasma can also be used for determining sodium and potassium, but some laboratories prefer serum separated from blood without an anticoagulant. Serum or plasma for the determination of potassium must be separated as soon as possible because potassium leaves the red cells and gives a falsely high reading in the serum. For the same reason there must also be no haemolysis. The following contribute to haemolysis: traces of water, alcohol, or ether; vigorous expulsion of the blood into the tube, especially through a fine needle; excessive shaking and frothing. Haemolysed blood will not do for measuring the potassium or, incidentally, the phosphate.

The Units of Measurement

Concentrations of electrolytes may be expressed in milligrams per 100 ml. or in milli-equivalents per litre. The latter expression is the more natural, for analytical methods depend upon chemical equivalence, but some laboratories calculate their results in milligrams per cent. For example, they give the sodium and the chloride in the plasma as so many milligrams per 100 ml., and the CO_2 as so many volumes or millilitres per 100 ml. But concentrations of sodium and chloride cannot be exactly compared if they are expressed like this, because a milligram of sodium is not chemically equivalent to a millilitre of CO_2 or to a milligram of chloride. If we wish to make a sum of the anions to compare with the cations, we cannot add milligrams of chloride to millilitres of CO_2 . Many people now prefer to use units based on chemical equivalents. For example, equivalent weights of sodium, chloride, and hydrogen are 23 g., 35.5 g., and 1 g. These are also the atomic weights, in grammes, of these elements. Each one of these weights is 1 unit, which is defined as the weight which will combine with—or displace—1 g. of hydrogen. In hydrochloric acid, 35.5 g. of Cl is combined with 1 g. of H to produce the equivalent weight of HCl—namely, 36.5 g. Similarly, in sodium chloride (NaCl), 23 g. of Na combines with 35.5 g. of Cl to give the equivalent weight of the salt of 58.5 g. The equivalent weight of a substance dissolved in a litre of water makes a normal solution.

The unit usually employed in clinical work is one-thousandth of an equivalent weight, or a milli-equivalent (cf. milligram, millilitre). A milli-equivalent of any substance is the amount contained in 1 ml. of its normal solution. For monovalent elements a milli-equivalent is the atomic weight in milligrams, but the atomic weight of a divalent compound makes two equivalents, so that a milli-equivalent of, say, calcium is the atomic weight in

milligrams divided by 2. In practice, however, only Na, Cl, O_2 , and K are usually measured in milli-equivalents. A milli-equivalent of CO_2 is the molecular weight in milligrams; the volume occupied by this amount under standard conditions of temperature and pressure is 22.4 ml., so divide 22.4 to convert millilitres of CO_2 to milli-equivalents. The figure for CO_2 in milli-equivalents is also the amount of bicarbonate, HCO_3^- , that it can form. Note that:

$$1 \text{ mEq Na}^+ + 1 \text{ mEq Cl}^- = 1 \text{ mEq NaCl} \\ (23 \text{ mg.}) + (35.5 \text{ mg.}) = (58.5 \text{ mg.})$$

The following Table shows the relation between cations and anions in normal plasma.

Base	mEq/litre	Acid	mEq/litre
Na ⁺	142	Cl ⁻	103
K ⁺	5	HCO ₃ ⁻	28
Ca ⁺⁺	5	Protein	16
Mg ⁺⁺	3	Organic acids	5
		HPO ₄ ⁻	2
		SO ₄ ⁻	1
Total 155		Total 155	

Isotonic saline (0.9%) contains 154 mEq per litre of NaCl. Although it is often called, physiologically, "normal saline," it is one-sixth the strength of a normal solution in chemical terms.

Changes in total base are accompanied by changes in total acid. Any major change in total base can only come from a change in Na^+ ; and changes in total acid are largely changes in Cl^- and HCO_3^- . The sum of cations and anions can remain equal in spite of rapid changes in either, because there is an unlimited supply of HCO_3^- from the CO_2 of metabolic processes to make up the balance when required, and any excess is promptly excreted by the lungs as CO_2 . The amount of the bicarbonate depends simply on the excess of cations over the other, fixed, anions.

Normal values in milligrams and volumes per 100 ml. are shown for convenience:

Sodium	325-350 mg.
Chloride (as NaCl)	560-620 mg.
(as Cl)	340-370 mg.
CO_2 combining power	55-75 ml.
Potassium	16-20 mg.

The following discussion assumes, however, that all values are expressed so that their chemical equivalence is obvious—that is, in milli-equivalents.

Changes in Na^+ and Cl^- and the Accompanying Changes in HCO_3^-

In conjunction with the clinical history, the levels of Na^+ and Cl^- in the blood give information on the body stores of these ions. The changes in HCO_3^- (bicarbonate) which depend on these levels are also discussed here. Changes in acid-base balance are then described, followed by the changes in potassium (K), which is primarily an intracellular cation.

The serum sodium concentration can nowadays be estimated quickly and easily if a reliable flame photometer is available. In general, the concentration of sodium in the serum depends on two things at least: the amount of sodium and the amount of water in the extracellular compartment of the body fluids. A gain or loss in the amount of sodium leads at first to a proportionate gain or loss of water, so that a normal concentration of sodium, and hence a normal osmotic pressure, is maintained. It is only with the more severe disturbances that the serum values become abnormal.

Sodium depletion is the commonest electrolyte disturbance. Abnormal losses are usually from the gastro-intestinal tract, by diarrhoea and vomiting, and through the aspiration or the fistulous discharge of intestinal secretions. Abnormal renal losses of sodium occur in rarer conditions like Addison's disease and salt-losing nephritis, in which a low serum sodium is accompanied by the continued loss of sodium in the urine. In addition, low values for the serum sodium are quite often found in patients with oedema or

ascites who have taken a diet low in salt for a long time. Mercurial diuretics, often essential to the treatment, are partly responsible for this complication. They act by increasing the renal excretion of sodium and chloride, and if this does not lead to the desired mobilizing of oedema fluid the concentration of sodium in the body falls. The resulting deficit of sodium may, itself, make the patient ill, and if the serum sodium is low the proper treatment is to restore salt in spite of the risk that oedema may then be aggravated. Occasionally low values for the serum sodium concentration are the result not of a fall in the amount of sodium but of an increase in the amount of water in the extracellular compartment of the body fluids. Low values from dilution with water are observed when the osmotic pressure outside the cells is high compared with that within them; this may happen, for instance, with the hyperglycaemia of diabetes.

A high serum sodium nearly always means a lack of water, and the conscious patient will complain of thirst.

Changes in the plasma chloride are not always the result of abnormal gains or losses of chloride. Usually they depend on the changes in the sodium stores of the body or on changes in the acid-base balance. The plasma chloride may rise if an excess of chloride is given, as in ammonium chloride acidosis, or if the renal excretion of chloride is impaired. It may fall if chloride is lost by vomiting. In general, however, the chloride ion in the plasma is but a partner to the sodium; and the bicarbonate ion a passive make-weight in the anion column. The sum of the chloride and bicarbonate (in milli-equivalents) is a guide to the level of the sodium, which is normally some 15 mEq more than these two together. Organic acids in the plasma account for part of the difference between the values for Na^+ and $\text{Cl}^- + \text{HCO}_3^-$. When, for example, in diabetic ketosis the organic acids accumulate in abnormal amounts, the Cl^- and the HCO_3^- fall and the difference between the determined anions and cations is much increased. The mechanism of the acidosis that accompanies these changes is now considered.

Disturbances in Acid-Base Balance

An explanation of the relation between the CO_2 and the pH of the plasma necessitates a physiological digression. The reaction of the blood is maintained near a pH of 7.4, just on the alkaline side of neutrality. Two types of disturbance may upset it. One is respiratory, the other "metabolic." Both change the plasma CO_2 , but for a given change in the pH they change the plasma CO_2 in opposite directions. This has sometimes led to confusion, but it is easily explained.

The CO_2 in the plasma is mostly that which is combined by base as bicarbonate. A small amount in solution forms the carbonic acid. The reaction, or pH, of the plasma depends on the ratio of the concentration of bicarbonate to carbonic acid:

$$\text{pH} = 6.1 + \log \frac{[\text{NaHCO}_3]}{[\text{H}_2\text{CO}_3]}$$

(The square brackets mean "concentration of.") The bicarbonate is normally 20 times the carbonic acid:

$$\text{pH} = 6.1 + \log 20 = 6.1 + 1.3 = 7.4$$

Now it is clear that the pH may vary because of a change in $[\text{NaHCO}_3]$ or because of a change in $[\text{H}_2\text{CO}_3]$, but the effects of these changes will be opposite. Moreover, changes in the one can be compensated by changes in the other. The amount of H_2CO_3 in the plasma depends on the rate at which the lungs get rid of the CO_2 which the body produces. The amount of NaHCO_3 depends on the amount of sodium ions, Na^+ , not combined with other anions and free to bind bicarbonate.

Respiratory Disturbances

These disturbances depend on changes in the elimination of CO_2 from the lungs and hence on the concentration of carbonic acid in the plasma.

*British Medical Journal, 1950, 1, 893. Ibid., 1951, 2, 1207.

Alkalosis.—This results from the washing out of CO_2 from the blood—for example, in hysterical hyperventilation. The denominator of the fraction $\frac{[\text{NaHCO}_3]}{[\text{H}_2\text{CO}_3]}$ is diminished and the pH rises. To compensate for this the kidneys excrete sodium as bicarbonate and so restore the pH towards normal. The urine is therefore *alkaline*. The total plasma CO_2 is *low*.

Acidosis.—This results from a failure to eliminate CO_2 as may happen in advanced emphysema, in narcotic poisoning, and with laryngeal obstruction. The $[\text{H}_2\text{CO}_3]$ increases and the pH falls. In compensating, the kidneys conserve sodium bicarbonate and the urine is *acid*. The total plasma CO_2 is *high*.

"Metabolic" Disturbances

These disturbances depend on the amount of sodium that is free to combine with bicarbonate in the plasma.

Alkalosis.—This is the result of an increase in NaHCO_3 . An excessive intake of alkali can produce it, but a more usual cause is the loss of Cl^- from the stomach by prolonged vomiting as in pyloric stenosis. An excessive renal loss of Cl^- may be produced by treatment with mercurial diuretics. The resulting fall in plasma Cl^- frees Na^+ to combine with more CO_3 as bicarbonate. The rise in NaHCO_3 , leading to a rise in the pH of the plasma, depresses the respiratory centre and there is a rise in H_2CO_3 —that is, the metabolic alkalosis is so far as possible compensated by a respiratory acidosis. The kidneys excrete bicarbonate, and the urine is *alkaline*, unless there is also a deficit of Na^+ so severe that this compensation cannot take place. The total plasma CO_2 is *high*.

Acidosis.—This is a result of a fall in NaHCO_3 . This happens when acids stronger than carbonic acid accumulate in the blood and displace HCO_3^- from combination with Na^+ . Such acids are produced in diabetic ketosis. When an acidosis is produced therapeutically with NH_4Cl as an adjunct to mercurial therapy, the Cl^- ion accumulates and depresses the level of HCO_3^- . The fall in $[\text{NaHCO}_3]$ may also result from the direct loss of it. This is what happens in the acidosis of chronic diarrhoea. But, however caused, a metabolic acidosis is accompanied by an increased elimination of CO_2 from the lungs because a fall in the pH of the plasma stimulates the respiratory centre. The resulting fall in $[\text{H}_2\text{CO}_3]$ in the plasma compensates for the fall in $[\text{NaHCO}_3]$. The kidneys conserve base and excrete chloride, and the urine is *acid*. The total plasma CO_2 is *low*. In "renal acidosis" the kidneys are unable to excrete acid in the normal way and the urine remains alkaline, while acids accumulate in the body and produce an acidosis, with a low plasma CO_2 . This is an exception to the rule that with an acidosis the urine is acid and with an alkalosis it is alkaline. In general this rule does enable one correctly to interpret the changes in the plasma CO_2 which are opposite for respiratory and metabolic disturbances.

I may summarize by showing in tabular form the meaning of a rise or a fall in the plasma CO_2 .

Plasma CO_2	Reaction of Urine	Abnormality
High	Acid	Respiratory acidosis
	Alkaline	Metabolic alkalosis
Low	Alkaline	Respiratory alkalosis
	Acid*	Metabolic acidosis

* Except in "renal acidosis."

The metabolic disturbances in acid-base balance are more commonly observed than the respiratory; but either type of change compensates the other. For instance, a metabolic acidosis is compensated by over-breathing, which by itself would produce a respiratory alkalosis. The respiratory compensation is an emergency stop-gap: the metabolic disturbance is, in the end, corrected by the renal adjustments, and this requires that the stores and supplies of sodium and water be normal, so that the kidneys may function normally.

Changes in the Serum Potassium

The changes in the composition of the plasma considered up till now have concerned changes in the extracellular compartment of the body fluids. Potassium is the only intracellular ion to be discussed.

It is only in the last six years or so that it has become widely recognized that deficits of potassium at least as large as those of sodium are quite common; they mostly arise, as do the sodium deficits, from gastro-intestinal losses. It is occasionally necessary to follow the level of the serum potassium in renal disease and during treatment with adrenal hormones which produce an increased urinary excretion of potassium. The level of the serum potassium depends on three major factors: (1) the stores of potassium in the body, so that, on the whole, a low serum potassium (less than 3.5 mEq per litre) means that the stores are low; (2) the acid-base balance, for in the presence of an acidosis the serum potassium is often maintained at the normal level in spite of a cellular deficit of the ion; and (3) the function of the kidney; the renal excretion of potassium is not so delicately adjusted to the needs of the body as the excretion of sodium. The excretion may fail in nephritis and in oliguria, although there is an excess of potassium in the body, and the excretion of potassium may persist in the face of a deficit.

The finding of a low level of potassium in the serum means that there is a deficit of the ion, but the extent of the deficit cannot be ascertained, since it falls almost entirely upon the intracellular compartment of the body fluids. Only severe deficits seem to produce any symptoms.

Conclusion

Problems of electrolyte metabolism often obtrude themselves after therapy with artificial fluids, after operations and during acute illnesses. But they may also arise insidiously in more chronic diseases, and, although their recognition may be a signal for the patient to enter hospital, in many instances these disturbances can be prevented from becoming serious by attention to the diet and to the intake of water and of salts. But the diagnosis must precede treatment, and for this some chemical determinations and their proper interpretation may be unavoidable. The subject is a large one and this article has attempted no more than to point the way.

Next article on Clinical Pathology. "Laboratory Control of Chemotherapy," by Professor Robert Knox.

THE MEDICAL CURRICULUM

REPORT OF THE UNDERGRADUATE EDUCATION COMMITTEE OF THE FIRST COUNCIL OF THE COLLEGE OF GENERAL PRACTITIONERS

"The hardest conviction to get into the mind of a beginner is that the education upon which he is engaged is not a college course, not a medical course, but a life course, ending only with death, for which the work of a few years under teachers is but a preparation."

WILLIAM OSLER, *The Student Life*.

The medical curriculum was discussed at the First World Conference on Medical Education organized by the World Medical Association in 1953, at which many original views were expressed and new experiments in medical education described.¹ The British Medical Association has devoted considerable attention to this subject^{2,3}; and the creation of the College of General Practitioners is in some part due to a revived interest in, and growing dissatisfaction with, the undergraduate and postgraduate training of family doctors.⁴ In the

spring of this year, when 15 of the 22 regional faculties of the College in the British Isles had been formed, it was felt that some of these groups of members and associates, through their faculty boards, might usefully survey the medical curriculum in the light of their own professional experience.

Until then many individual opinions had been expressed, but there had been no means of assessing how widely these were held. The object of this survey has been to put forward certain controversial points, and to bring to light opinions about the medical curriculum held by a number of keen general practitioners. It is hoped that the results may stimulate study, both within the College and by the profession as a whole, and that they may contribute something of value to the work of those responsible for the future teaching policy in medical schools.

In the analysis of the replies to a questionnaire prepared by the Council of the College, and in this report, we have tried to examine the curriculum in the light of modern requirements—the need to turn out newly qualified doctors with a sound basic knowledge and broad understanding not only of more than 20 specialties but also of general practice and family doctoring. Every medical student must have a sufficiently broad general education to look at the world from a humanitarian rather than a materialistic point of view. He must be intellectually humble and resilient enough to be able to alter his ideas, because time inevitably changes old beliefs. He must develop a self-discipline in his way of thinking to protect himself from specious advertisements, from unscientific publications, and journalistic enthusiasm. He must be the severest critic of his own work.

These are the basic attributes needed by all medical graduates in whatever branch of the profession they eventually elect to serve. To develop these qualities with economy of time and maximum concentration of effort is, in our view, the purpose of the curriculum. It is no easy target, and to attain it every item in the medical student's training should be scrutinized and ruthlessly discarded if it does not contribute something essential to these ends.

School Education

When young men or women decide that they would like to become doctors, what is the best way in which they should spend their last one or two years at school?

There is a choice between early specialization in scientific subjects—chemistry, physics, botany, zoology—or continuation of a broad general education, including the classical way of thought, until the time of leaving school. This question is at present exercising the university authorities, some of whom already insist that the young student shall have passed the first medical examination before joining them.

In the discussions which have taken place at meetings of some of the regional faculties of the College, or their boards, only a few doctors have favoured early scientific specialization. The great majority preferred the idea of a liberal education for a liberal profession. One faculty quoted Sir Richard Livingstone in his *Education for a World Adrift*: "The knowledge necessary to living must be imparted. People must be taught to use their brains. . . . Knowledge is important, still more so is the power to use it; but most important of all is what a man believes, what he thinks good and bad, whether he has clear values and standards and is prepared to live by them. . . . As Plato said, the noblest of all studies is the study of what man should be and how he should live. . . . If Greek thought and Christianity created the soul of

Western civilization . . . then these are the philosophies for which we are looking, and before his education is completed everyone should have an idea of what they are."

A number of general practitioners were in favour of combining evenly, during the last one or two years at school, a general education with an approach to scientific subjects, but without stretching the latter to the full extent of the syllabus for the first medical examination. Many expressed doubts regarding the necessity of taking chemistry, physics, botany, and zoology to the high level now demanded in the first medical examination; and there was an appreciable feeling that the curriculum could well be shortened in these subjects.

Selection of Medical Students

Are we satisfied with the present method of selection of medical students?

Only one faculty thought that selection now was altogether satisfactory. The others felt that there could be improvement in some way. It is remarkable how great a change has occurred since the 1920's, when almost anyone of reasonable intelligence was welcomed in a medical school. At that time an appreciable number of those who started did not finish the course, because they or their teachers decided that medicine was not for them. It was an automatic method of selection and rejection. Nowadays there are many more applicants than vacancies, so that medical schools have had to adopt some form of selection. This early selection is of great importance; but it is not a simple matter, and we are not satisfied that present methods always admit those candidates who will make the best doctors. Academic achievement in scientific subjects, though important, should not be rated too high at this stage; character, home background, heredity, and school record are probably of equal importance in the long run.

Every study group considered that a wise and experienced general practitioner could usefully assist a dean in the selection of students. Whether or not it is essential for him to be still in active practice is debatable, because this helping in the selection of medical students might be a useful role for men or women who have retired, after a sufficiently long time in general practice, provided that they are not too old. In the selection of all our future doctors, about half of whom will become general practitioners, it seems logical that there should be at least one person on the selection board with first-hand knowledge of the life for which so many of these young people are being chosen.

A Balanced Curriculum

(1) Does the Curriculum Give a Satisfactory Basic Education in All Branches of Medicine?

Each doctor looks back on his own training and treats such a question from his own point of view. Some faculties thought that too much time was spent with the specialties, such as advanced surgery. In the old curriculum it was considered necessary for every medical student, whatever his future, to have a detailed knowledge of anatomy and of the surgery for which this prepared him, so that when he left hospital he would be able to undertake operations which nowadays he would never attempt. Surgery then was taught by general surgeons; nowadays few of these exist, and the student in hospital may have to spend long hours watching complicated, highly specialized techniques which he may never need again.

Some felt that too much time also was spent on the differential diagnosis of obscure conditions, and that there was too little teaching of the simpler variations in health and disease. Nearly all believed that at present the basic curriculum did not, in all schools, include a sufficient insight into general practice. This was discussed in detail last year in the report of this committee on "The Teaching of General Practice by General Practitioners."⁵ The aim of the general medical curriculum is, surely, to produce broad-minded doctors rather than medical scientists or skilled technicians.

(2) Is There a Case for Shortening the Basic Curriculum by Omitting Detailed Studies of Certain Subjects?

If students are to be taught more about the commoner diseases and are to be given more insight into general practice, the curriculum will need pruning. There is much dead wood, and also many overgrown branches, which can well be lopped off the present curriculum. The introduction of the pre-registration year and the two years of national service have made this pruning all the more essential.

One faculty quoted Lord Horder: "The anatomy, the physiology, the chemistry, and the physics of the pre-clinical studies of the medical student should be directed towards the actual examination of the patient. I think we took a step backwards when we put the academic anatomist, physiologist, and chemist in charge of preclinical studies. These men staked out large claims in their respective spheres as though medical students were in training for professorships in these subjects rather than being doctors in embryo. This view led me to plead for spending less time over the intimate structure of the organ of Corti and the theories of colour vision, and more time over . . . simple instruments by which the structure and functions of the normal body are studied. . . . I still meet doctors who have never seen the optic disk clearly, nor the vocal cords at all."

(3) Should More Detailed Attention be Given to Certain Branches of Medicine, and to Common Diseases?

Faculties were unanimous in declaring that this was necessary. Provided the rarer diseases are included to some extent, it should be the hall-mark of a good teacher to illustrate sound medical principles on a disease which is common, as often as possible, rather than on something which is obscure. It is not unusual now to find that the commoner conditions are mentioned only by name and that it is the rarity which is presented for demonstration. The dispensary system of teaching general practice, as at Edinburgh, has given the student a good picture of the commoner diseases.

Dermatology, orthopaedics, psychiatry, allergy, rheumatic disorders, and diseases of the ear, nose, and throat are not always taught as fully as their importance in general practice demands. Paediatrics is not so much a specialty as a grouping together of all branches of medicine and surgery in a particular age group. Family doctors treat many children, and there can be no better training for many branches of medicine, and for general practice in particular, than a spell among children. At the opposite end of life there is the study of the effects of stress and of degeneration on the body and mind. Geriatrics is a subject which has been closely observed by generations of general practitioners; but only recently has it begun to receive in medical schools the attention it deserves.

(4) Should More Attention be Given to the Management of the Individual Patient?

In the Nuffield Trust Survey on General Practice, Dr. Stephen Taylor distinguishes the work of the general practitioner by the one main characteristic of *continuity*. No other doctor has a continuing responsibility for his patient from year to year and from illness to illness, from the cradle to the grave. Any young man who is worth his salt will accept this responsibility as soon as he realizes what is required of him; but it is unlikely that he will appreciate this in hospital, because the patients whom he sees there appear to have been cut off from their family doctors, who rarely enter teaching hospitals. Both general practitioners and consultants are equally to blame for this. Doctors who send their patients to hospital with a scrappy note or a visiting-card advertise themselves as travesties of good family doctors, and are directly responsible for giving both students and their teachers a poor opinion of general practice and the men in it. When we, as general practitioners, write about our patients to consultants we should be on our mettle to show them, and any students whom they may be teaching, that we always take a proud interest

in our patients both as individuals and as medical problems. It must be remembered that a derogatory remark about general practice would probably not be made if it were undeserved.

On the other hand, consultants might do a great deal more in teaching this continuity of care to their students if they knew a little more about it themselves from personal experience. Admittedly it is difficult to teach this continuing responsibility in hospital; but there are several ways in which it can be done. One is practised by a consultant in a London teaching hospital, who uses the domiciliary visit as a teaching experience: he always takes a student with him, and we believe that attendance at such a consultation between the specialist and the general practitioner at the bedside is one of the most useful practical experiences for the student that can be devised. Another is in the writing of letters: the student will sometimes see those from the general practitioner to the hospital, but he rarely hears the advice which is sent back from the consultant to the family doctor, or realizes that the patient's visit to the hospital is but a brief episode in a much longer story. A third method is attendance at health centres or at a general practice teaching unit attached to the medical school, as at Edinburgh. The fourth is attendance of students on general practitioners themselves.

(5) Can More be Done to Teach Students the Relationship Between Family Doctors and Consultants?

Closely bound up with this problem of continuing responsibility is the student's assessment of the relative roles of family doctor and consultant. His experience in hospital may give him the idea that all medical roads lead to the hospital, and that general practitioners are merely signposts to the proper out-patient department. Until he goes out himself, he knows little of the great mass of good medical work done by family doctors without reference to hospital or specialists at all, and is unaware that both patients and general practitioners regard the specialist as someone who, by virtue of a particular training and knowledge, can help the general practitioner to care for his patient.

All doctors are members of a team, and the student must be taught that, for the patient's benefit, the co-ordination of all the different functions of this team is the responsibility of the family doctor. The student should learn from the very start how this can be done; he should not have to find it out slowly for himself later on, rather to his surprise. Probably the best ways for this co-ordination to be taught are for students to meet general practitioners from time to time throughout their clinical studies, both outside hospitals—by attending domiciliary consultations and by visits to general practices, health centres, or dispensaries—and inside hospitals by the presence of general practitioners as lecturers, and as spectators or commentators on teaching rounds. This contact of students with general practitioners will be as valuable to those who remain on in hospitals as specialists as it is to those who go out into the world as family doctors.

(6) Can the Student be Taught to Realize Better the Wide Field Covered by General Practice?

Most of the faculties felt that the student, whatever his future is to be, should be taught to recognize how much of medicine lies within the realm of the general practitioner. When he starts in practice he will then be less bewildered at the wide field he has to cover; and consultants, specialists, and students at hospital will be less mystified by the range of work a general practitioner has of necessity to do himself. The student must learn to appreciate clearly the great volume and variety of service that it is desirable for a family doctor to undertake, and what should be referred to a specialist if there is one within reach. To learn all this will help the student also to discover more easily his own aptitudes and limitations, so that he may decide wisely on his future career.

Conclusions

A questionnaire on the medical curriculum has been discussed by some of the regional faculties and faculty boards of the College. It is hoped that the results will stimulate further study and a continuing review of medical education. In this interim report it is suggested that:

1. The last two years at school should be evenly divided between receiving a broad education and an introduction to the scientific method.
2. The present method of selecting medical students could be improved by co-opting a general practitioner on to each selection board.
3. The medical curriculum requires revision so as to give students a broader introduction to all branches of medicine, including general practice.
4. The present division between preclinical and clinical subjects is too sharp.
5. There is a tendency for too much time to be spent at present on obscure subjects and highly technical procedures, to the exclusion of a study of common disorders.
6. Medical students should be given more insight into medicine as it is practised *outside* hospitals.

Reports of Societies**CHRONIC PYELONEPHRITIS**

On April 27 at the Royal Society of Medicine the Section of Medicine held a discussion on chronic pyelonephritis. The president, Sir HENRY COHEN, was in the chair.

Professor MAX ROSENHEIM said that it was difficult for a clinician to open a discussion on a condition which only a pathologist could clearly define or diagnose. Chronic pyelonephritis was characterized by scarring of the kidneys with corresponding decrease in their size. The changes could be widespread or localized; histologically the scarred areas showed hyaline degeneration of the glomeruli, dilatation of the tubules, and interstitial cellular infiltration. It was now believed that acute pyelonephritis arose as a blood-stream infection; even in the so-called "ascending pyelonephritis" the infection probably often spread to the kidneys through the blood. The invading organisms were most commonly coliform bacilli. Most acute infections could be rapidly cured; in the absence of an underlying abnormality of the renal tract it was doubtful whether a simple urinary infection ever resulted in chronic pyelonephritis. The disease could be unilateral or bilateral; an underlying cause

might or might not be obvious. How often chronic pyelonephritis occurred it was difficult to estimate.

Diagnosis was not always easy, but radiological examination sometimes showed kidneys which were either small or unequal in size. It was often difficult to distinguish the contracted kidney of pyelonephritis from congenital renal aplasia. Clinically, chronic pyelonephritis might present as a case of recurrent urinary infection, raised blood pressure, or of insidious renal failure. Although it was possible for urinary infection to persist for many years without leading to chronic pyelonephritis, it was nevertheless important to cure or control any urinary infection as a safeguard.

A Cause of Hypertension

Chronic pyelonephritis, often bilateral, was a not uncommon cause of malignant hypertension. In many cases of hypertension which had been cured by unilateral nephrectomy the underlying lesion was pyelonephritis. Even though the affected kidney might appear to have useful function, its removal could relieve hypertension. It was not understood why some patients with pyelonephritis developed hypertension while others did not. When renal failure was the presenting feature, pyelonephritis was apt to be confused with chronic nephritis. The absence of hypertension was more suggestive of pyelonephritis, as was a difference in the size of the kidneys. Marked variation in the degree of failure from month to month was also characteristic. In the absence of complicating hypertension, renal failure in chronic pyelonephritis was a slow process and often produced bizarre metabolic disturbances such as the renal bony disorders and the syndromes of sodium or potassium depletion. In the diagnosis of pyelonephritis a history of past or recurrent urinary infection, the recognition of recent severe hypertension, and insidious kidney failure were invaluable guides. Urinary examination was often unhelpful, since the urine might be normal or contain merely a trace of albumin. Pyelonephritis was a disease which could only be diagnosed if its presence was constantly suspected.

Dr. S. J. DE NAVASQUEZ discussed the pathological aspects of pyelonephritis. There was full agreement, he said, on the histological appearances. Microscopically there was replacement fibrosis, often in triangular areas with their apices pointing to the renal pelvis. The renal tubules were atrophic and underwent cystic dilatation. There was a chronic inflammatory exudate, but bacteria were seldom demonstrable. The final stage of contracted granular kidneys was merely the end result of a process which had begun as a simple bacterial infection of the kidney.

Pathogenesis of Pyelonephritis

Experimental methods had solved some of the problems of pyelonephritis where simple anatomical studies had failed. When rabbits were given an intravenous injection of staphylococci, many of them developed renal infection; some rabbits survived the initial infection to succumb later to renal failure. The lesions in such animals resembled those in the human disease. Animal experiments had shown that transient renal infections could give rise to scarring and renal failure. Once the kidneys had become scarred there was, however, a great liability to repeated infection because of the slow blood flow through the granulation tissue. Recurrent infections were usually transient and often passed unnoticed. In the pathogenesis of chronic pyelonephritis it seemed likely that the first stage was a haematogenous renal infection producing acute pyelonephritis. As this disease healed, organization and replacement fibrosis led to intrarenal hydronephrosis. The kidneys were then prone to recurrent attacks of infection, and finally a state of chronic pyelonephritis was produced.

A Difficult Diagnosis in Infancy and Childhood

Dr. J. M. STANSFELD discussed some features of pyelonephritis in childhood. The incidence was difficult to assess, but pyelonephritis was about as common as pyogenic meningitis or intussusception, and, if E.N.T. cases were excluded,

accounted for some 14 of every 1,000 children admitted to hospital. The majority of patients were under the age of 1 year, and at this age the sexes were about equally affected, whereas in older children girls suffered from pyelonephritis much more commonly than boys. In infants the disease was often unrecognized by the family doctor or at welfare clinics. Yet early diagnosis was important if smouldering infections were to be avoided.

The disease was usually overlooked because the clinical features were not well known, because physical signs were sparse, and because pyuria was often difficult to demonstrate. Analysis of the clinical symptoms in a series of cases had shown that gastro-intestinal symptoms, such as anorexia, vomiting, failure to thrive, and constipation, predominated. Symptoms referable to the renal tract were not obvious; rigors and convulsions were rare. Ultimately the diagnosis rested on demonstrating pyuria, and this was sometimes difficult because pyuria was intermittent and modest in amount. Many specimens of urine might need to be examined.

One difficulty had been to establish agreement on how many pus cells could be found in a normal urine. This had been overcome by doing accurate cell counts of urine in a haematological counting chamber. Such cubic-millimetre cell counts had been found a great advantage in revealing pyuria which would otherwise have been overlooked. A cell count of more than 50 pus cells per cubic millimetre in boys and more than 500 per cubic millimetre in girls indicated renal tract disease.

Treatment of chronic pyelonephritis in children was never easy and was a long and hazardous affair. The aim was not merely to sterilize the urine but to eradicate infection from the kidney, and chemotherapy had to be given in full dosage and continued for long enough for this to be achieved.

The Discussion

In the discussion which followed Dr. W. W. PAYNE said he thought there were two distinct groups of children with pyelonephritis. In the first group were placed children with recurrent urinary infections who were completely healthy in the intervals. In the second group the children failed to thrive and often had gastro-intestinal symptoms between the attacks of obvious urinary infection. In this group the histology often showed areas of renal dysplasia; the children had probably started life with some abnormality of the kidneys.

Professor W. C. W. NIXON said that obstetricians in the past had failed to treat urinary infection thoroughly enough, but the tendency nowadays was to treat pyelitis of pregnancy more energetically.

Many other members and visitors took part in the discussion, and it was clear that the current problems of pyelonephritis were attracting the attention of not only physicians but surgeons, pathologists, and radiologists as well.

LOCAL MEDICAL SOCIETIES

Manchester Medical Society

The results of a blind trial of oral cortisone in severe chronic asthma was described to the Section of Medicine by Dr. William Brockbank (with Dr. R. S. Savidge) on April 7. Twenty-four patients were included in the trial, ranging in age from 17 to 70. Thirteen received regular maintenance doses of cortisone and 14 an indistinguishable control. Three who were failures on the control were given cortisone. Of the 13 cortisone cases, six improved greatly in their ability to work and play; four more improved, but mostly subjectively; one was not improved and died eight months after cortisone was discontinued; two died while still taking the drug. In the 14 controls there was no improvement in eight patients and one died. Side-effects were few, increasing weight being the most important. The longest remission after withdrawal of the cortisone was 11 weeks. Most cases tended to relapse within a few days. It was concluded that cortisone could not cure asthma, but

some cases of long-standing chronic asthma could be effectively controlled by moderate doses of oral cortisone, provided the dosage was maintained. But in some undefined types of asthma cortisone treatment was dangerous to life.

In a recent presidential address to the Section of Pathology, Dr. T. Blench spoke on the Law and Medicine. While the Law sought for certainty, Medicine dealt with clinical probabilities. Yet lawyers chided doctors for differing and also for not being willing to differ. Doctors could be sued as a result of their calling, but actions against counsel were banned by statute. Lawyers loved words and documents; but Medicine did not, in contradistinction to Advocacy, lend itself to verbal analysis and verbal agility.

Preparations and Appliances

AN IMPROVED DRIP CONTROL

Dr. G. HERINGTON, consultant anaesthetist, Wanstead Hospital, writes: The increasing use of succinylcholine chloride and other relaxants and anaesthetic agents by intravenous drip calls for a more accurate method of control than the gate clip provided with the standard giving set. The gate clip has two disadvantages: it requires two hands for manipulation, and it is often difficult to adjust the flow rate exactly to the desired level, particularly when a low rate is required. The former difficulty is overcome by clamping the apparatus direct to the upright of the drip stand, while the greater accuracy is obtained by the use of both coarse and fine adjustment controls.

The apparatus illustrated here was designed and made by Mr. E. L. Powell, of Buckhurst Hill, to fulfil the above requirements. The coarse adjustment (A) is provided by

a cam (B) which turns through 180 degrees from a full-open to a full-closed position. The final setting is obtained by a fine-adjustment screw (C) acting on the face of the cam, which affects the compression of the tubing at the pressure pad (D) through a lever (E). A spring is fitted to the pressure pad to ensure that it returns to the full-open position, so that the drip tubing can be readily inserted or removed. A hinged clip (F) is fitted to the back of the apparatus, so that it can be clamped easily to the upright of the stand.

In practice the cam is put to the full-open position, the tube is inserted, and the cam turned to the approximate position required; an accurate setting can then be made by means of the fine-adjustment screw. If desired, a flow rate of as little as one to five drops a minute can readily be obtained.

Correspondence

Preservation of Blood Samples

SIR,—The preservation of blood samples sent by post to the chemical laboratory presents special difficulties. Frequently haemolysis occurs, and is attributed to bacterial infection despite careful collection of the sample. In samples submitted for estimation of blood sugar, fluoride is often added to prevent glycolysis, and recently formaldehyde was recommended for the preservation of samples submitted for determination of the urea content.¹ It has been brought to our attention that formaldehyde may interfere with the estimation of urea by a urease-Nessler method, and this we have confirmed. However, samples for haemoglobin estimation have been sent as far as from London to Australia without deterioration when streptomycin and glucose were added as preservative, and we have found that streptomycin does not influence the estimation of urea by the Nessler method of King.² The streptomycin is dissolved in distilled water and added to the containers, which are then dried in a warm oven, stoppered, and kept until required. We have used a concentration of 1 mg. of streptomycin base to 10 ml. blood. Although this preservative has only been tested for haemoglobin and urea estimation, it seems likely that it has a much wider application. This point is under examination here.—We are, etc.,

Undescended Testicles

SIR,—Since no one will question Mr. Denis Browne's skill as an anatomist, diagnostician, or operator, it is obvious that only with great reluctance can I bring myself to comment upon some of the points he makes in his letter (*Journal*, April 24, p. 987). Indeed, bowing to his great experience, I will not attempt to deal with each and every one of them; but there are some on which I fear I do find myself in disagreement.

Like Mr. Browne, I too find the majority of boys referred to me as "cryptorchid" have testicles which can be made to descend into the scrotum—all the way—and are clearly in need of no treatment. Only their parents need reassuring. But there are others in whom I am quite honestly unable to say whether the apparent non-descent is due to ectopia or to retractability. Perhaps Mr. Browne never encounters this uncertainty. My experience, admittedly much inferior to his, has been that the response to gonadotrophin has proved of value in distinguishing the two types. In the course of running a fertility clinic, I see, from time to time, infertile men with histories of cryptorchidism. Some of these have had operative treatment close to or after puberty; others may have had spontaneous descent at the time of puberty. Now, while it is possible that congenital testicular deficiency may have coexisted with the cryptorchidism, it is difficult to reject the view that some at least of these men would have been fertile had testicular descent been achieved—by any means—at an earlier age. Perhaps Mr. Browne never has made a mistake—but has none of the many boys he has considered could safely be left alone let him down, in that spontaneous descent failed to occur before puberty? And if there have in fact been some such mistakes, are these boys now fertile men? Surely this is the crux of the whole matter: unless infallible predictions can be made, some avoidable infertility will result, which, with all due respect, is not likely to come to the knowledge of Mr. Browne.

I will gladly concede Mr. Browne his little joke on the twenty-minute record for descent after hormone injection. By "there and then" I naturally meant within the period of a course of injections of something like 1,000 I.U. of

chorionic gonadotrophin given twice weekly for ten weeks. I have never seen the "serious physical and psychological side effects" mentioned by Professor C. Wells (*Journal*, April 17, p. 932) resulting from such a course of treatment. As for continuing hormone treatment for three or four years, quite obviously no one who has the least idea about the matter would countenance such an absurdity. Rare though worry about non-descent may be, the fact is that some boys and more parents are prone to it. I have, moreover, seen instances where it arose quite early in development. I cannot see why no attempt should be made to deal with it by hormone treatment—if that treatment is likely to succeed.—I am, etc.,

London, N.W.1.

Early Recurrent Acute Intussusception in Children

SIR,—In their interesting article, Mr. David A. Macfarlane and Mr. L. P. Thomas (*Journal*, March 6, p. 559) draw attention to the rare complication of early recurrent acute intussusception in children and report four personal cases. Among 26 proved cases of intussusception admitted to a Danish general surgical hospital in the period 1944–53 we have seen two similar cases.

Case 1.—A male child aged 5 months was admitted to Surgical Department A of Frederiksberg Hospital on January 3, 1947, with a seven hours' history of attacks of abdominal colic, and before admission blood-stained stools had been passed. On examination the child was pale and looked ill, but there was no gross dehydration. Between the colicky attacks a sausage-shaped tumour was felt in the left hypochondrium. A barium enema revealed an ileo-caecal intussusception, and reduction beyond the hepatic flexure was accomplished, but, as a complete reduction was not obtained by this method, laparotomy was decided upon. First operation. Under general anaesthesia the abdomen was opened through a lower right para-rectus incision. A small amount of serous fluid was encountered, and the intussusception in the ascending colon and caecum was reduced without difficulty. Its apex in the ileum was 3 cm. from the ileo-caecal junction, and here the intestinal wall showed cyanosis and oedema. For the first three days after the operation the post-operative course was uneventful, and stools were passed on the second post-operative day.

On the morning of January 6 attacks of abdominal colic started again, and the patient vomited several times. He became worse, with signs of dehydration, and the abdomen was tympanitic; on auscultation metallic bowel sounds were heard. A straight x-ray examination of the abdomen showed a dilated small bowel loop, and a barium enema showed normal filling of the colon, with the barium entering the ileum. Thus no radiological signs of intussusception were found, but signs of obstruction of the lower ileum were present. After the administration of 250 ml. of normal saline his symptoms subsided, and he spent a quiet night. The next morning his condition was again worse, with vomiting and abdominal colic. Laparotomy was decided upon. Second operation. Under general anaesthesia the previous wound was reopened, and moderately distended coils of small bowel presented themselves. About 180 cm. from the ileo-caecal valve an ileo-ileal intussusception was found and reduced. The post-operative course was uneventful, and the child was discharged on January 24, 1947.

Case 2.—A female child aged 6 months was admitted to our department on April 13, 1953, with a history of repeated attacks of vomiting and abdominal pain for the past 24 hours. There had been no bowel action since the previous day. On examination the child was seen to be in a good general condition and showed no signs of dehydration. A sausage-shaped tumour was felt in the right hypochondrium. Rectal examination gave no further information. A barium enema showed an ileo-colic intussusception that could not be reduced, and operation was decided upon. First operation. Under general anaesthesia the abdomen was opened through a lower right paramedian incision. There was a considerable quantity of clear fluid in the peritoneal cavity, and the ileo-colic intussusception was found with its apex 10 cm. up in the ascending colon. Its reduction was easy, and it had originated as an ileo-ileal intussusception 15 cm. from the ileo-caecal valve. Numerous enlarged mesenteric glands were noted. The post-operative course was uneventful, and the child left hospital on April 22, 1953.

The same evening there was again vomiting, and blood-stained mucus was passed. She was again admitted to our department. A lump was felt above and to the left of the umbilicus, but an hour later it had disappeared. The next morning the lump

was again there, and there were attacks of abdominal colic. X-ray examination of the abdomen showed a dilated coil of small bowel, and a barium enema showed normal filling of the colon with no barium entering the ileum. A diagnosis of recurrent small bowel intussusception was made, and laparotomy undertaken. *Second operation.* Under general anaesthesia the abdomen was opened through the previous wound. Distended coils of ileum presented themselves in the wound, and a 20-cm. long ileo-ileal intussusception was found, with collapsed ileum distal to it. The origin of this intussusception was proximal to the previous one, and it was easily reduced. After an uneventful post-operative course the child was discharged on May 5, 1953.

The number of published cases of early recurrent acute intussusception in children given by Macfarlane and Thomas as 81 is thus increased to 83.—I am, etc.,

Copenhagen, F., Denmark

ERIK CHRISTENSEN.

Toxaemia of Pregnancy in Identical Twins

SIR.—Identical twin sisters, aged 24 years, have recently been delivered at two different hospitals within six months of each other by caesarean section, the indications being pre-eclamptic toxæmia not responding to treatment. An almost identical sequence of events took place in the twins, and the salient points are presented in table form below.

	Case 1	Case 2
Blood pressure at first visit to antenatal clinic (12 weeks) ..	154/80	110/60
Blood pressure on admission ..	170/110	170/110
Maturity on admission ..	34 weeks	34 weeks
Oedema on admission ..	Trace	Absent
Proteinuria on admission ..	+	+
Treatment ..	Sedation Caesarean section after 3 days	Sedation Caesarean section after 13 days
Liquor drained at A.R.M. ..	30 oz. (0.8 l.)	30 oz. (0.8 l.)
Blood pressure at operation ..	152/114	165/110
Birth weight and sex at operation	5 lb. 6 oz. (2.4 kg.) male (live)	5 lb. 14 oz. (2.7 kg.) female (live)

Two sisters of these twins, not themselves twins, are under our care, one having recently had an abortion after several pregnancies without toxæmia, the other having had hyperemesis gravidarum but no toxæmia in her first pregnancy. The mother of the twins has hypertension and last year suffered a cerebral haemorrhage.—I am, etc.,

Greenford, Middlesex.

L. A. PIKE.

"Edwardian" Adolescents

SIR.—It is characteristic of many social problems that interest in them is periodic. This is especially true if the problem concerns youth, sex, or crime, and Dr. Margaret Lowenfeld's letter (*Journal*, May 1, p. 1040) touches upon all three. The letter is paralleled by newspaper headlines such as "Girl Attacked by Edwardian Youth Gang." This renewed interest in an old problem has perhaps been precipitated by the recent change from excessively padded, "finger-length," drape suits, startling tie, with thick-soled crepe rubber shoes (called "creepers") to the present Edwardian-like style. Foreign students assure me that an exactly comparable sort of youth exists in many other parts of the world. A book such as F. M. Thrasher's *The Gang* (1927, University of Chicago Press) shows that comparable groups existed in Chicago at least as far back as the 'twenties. As a contribution to a book to be published shortly by Messrs. Butterworth, edited by the late Sir Norwood East, I have outlined the psychology of these youths, who, it would seem, are basically handicapped by strong unadmitted feelings of inferiority. Their exhibitionistic, bombastic, restless ways express their need of reassurance that they can be masculine, tough, command attention, and that they can exist independently from their mothers. They feel easier when banded together with equally handicapped individuals. Their vast majority is content with parading a well-lit street, meeting in "caffs," fighting rival "mobs," and feeling their way towards more mature behaviour. Their dancing, since Dr. Lowenfeld raises the

matter, is of two main sorts; in one the boy progresses monotonously, *back first*—that is, in the girl's position—round and round the floor; the other is the jive in which the boy shuffles *inactively* without moving forward, while the girl performs a highly active series of pirouettes before him.

The family background of these youths commonly shows factors which, acting over the years, have tended to keep the individual in a passive, over-dependent position. Most typical is an imbalance of parental influence; this may mean a possessive mother who holds the family reins and belittles the males of the family, a father who, either because of physical absence or of personal qualities, does not help the boy to cut the apron-strings; the imbalance may be *between* the parents or in the inconsistency of *one* parent. In general the family setting resembles that of homosexuality and the perversions, but differences of degree and perhaps of heredity impel or enable these youths to struggle successfully against that biologically less satisfactory solution to their problem. Seriously antisocial youths, those who actually use their weapons and who assault others, are (in spite of publicity) relatively uncommon. Most of the dangerous types are not of this Edwardian type, but if they do happen to be so then one finds either a coexisting psychiatric condition (perhaps demonstrable by electro-encephalography) or a history of frank hostility from the parents, or domination by a much more pathological companion.

While further investigation into this problem is much needed, I make a plea that these youths should not be regarded as a new phenomenon and that, in this group too, there are more sheep than goats.—I am, etc.,

London, S.E.5.

PETER SCOTT.

Adolescence

SIR.—I note that in your leading article (*Journal*, March 27, p. 748) somebody decries the fact that no one has ever investigated the effect of National Service upon the character of the youth of the country. As I am employed in the psychiatric unit in the Royal Air Force, I am most interested in the project. Perhaps the writer of the leading article could advise me how to embark upon such a study. The easiest manner to decide the beneficial or other effect of National Service would be to compare the work record of young men who have done their National Service with those who are not subject to it, and here the first difficulty of lack of suitable controls becomes apparent. I am most interested in the subject and I would be greatly obliged for any advice as to how such an investigation could be undertaken. I am, etc.,

Halton, Bucks.

P. J. O'CONNOR.

Doctors and Technicians

SIR.—Every doctor should read the letters of A. E. Brown and F. Mather (*Journal*, April 24, p. 983), since they give a clear indication of the direction of medicine. These two technicians are emphatic in their demands for recognition. A. E. Brown states: "The days when the medical laboratory technologist [lab. assistant as he was called in my days] was merely an assistant are long gone—except perhaps in certain university laboratories. The work performed by the technologist nowadays is nearly always done without direction, and the subsequent reports are sent out on his responsibility." While F. Mather states that "the interpretation of findings have passed, or are passing, from the domain of the pathologist to that of the technician. It will be found, particularly in the field of blood transfusion serology, that some of the greatest authorities in the country are not medical men but technologists. . . . It would seem, therefore, to be more justifiable to state that in many respects the technologist has, or should have, equal status to the pathologist." I have heard these claims made by doctors who demanded such assistance, and I know that the claims are not without foundation, for men acquire knowledge and skill worthy of recognition only by doing

the jobs. As Ruskin stated: "There is no furniture of a man's mind which he has a right to exalt in, but that he has hewn and fashioned for himself."

Animal technicians, laboratory technologists, radiographers, photographers, chemists, physicists, therapists, midwives, nurses, dietitians, and a score of others, are being trained to do the work which formerly doctors did for themselves, and as these aids are all provided free in the Welfare State, together with abundant elaborate equipment, the doctor is concomitantly losing his ability to do these things, and, more important still, the ability to assess their value or accuracy, and has to trust to the words and works of others who have not had a basic medical training and do not have the personal responsibility to the patient. Such doctors still seek to be judged for recognition on the works of others by demands for greater elaboration, more ostentatious buildings and furniture, expensive spectacular apparatus, abundant white-coated staff and secretaries. How long can they hope to keep their highly paid, jargon supplying, supervisory posts, when they themselves appear to be losing their power of writing even their signature to reports? Even the Welfare State may think it is paying a great deal for the use of a rubber stamp when all these workers demand equal status to the doctor. The discipline of the pre-N.H.S. days, which forced men to do their own jobs, was good for medicine; but when the demands for the total abolition of private practice are acceded to, and the doctors are left at the mercy of administrators and planners, God help the patients, medicine—yes, and the doctors.—I am, etc.,

Birmingham, 15.

JAMES F. BRILSFORD.

Bovine Tuberculosis

SIR.—May we be permitted to reply to the letter of Drs. R. W. Kind and M. C. Brough (*Journal*, April 17, p. 936) on the subject of bovine tuberculosis? Many parents and a number of schools give children unboiled, specially designated "tuberculin-tested (T.T.) milk" believing it is most unlikely to contain tubercle bacilli. We would repeat our previous statement (*Journal*, March 13, p. 646), that it offers the consumer no guarantee, and we submit the time is long overdue for explaining to the public the true facts about T.T. milk. We do not assume, as Drs. Kind and Brough have implied, that all parents could or always should be persuaded to give boiled milk to children. We appreciate some consider it unnecessary, others too much bother, and that many children will not drink it, but these are not valid reasons for withholding the advice generally. Obviously when milk is universally pasteurized a reasonably good safeguard will be provided for all.

We apologize for having inadvertently used the word "accredited" *per se* in our previous letter. The herd to which we referred was attested tuberculin-tested (the highest Ministry grading). All its members were reported non-reactors in July, 1953. One cow developed a sore on the udder in September, 1953, milking continuing for a further fortnight. The beast was slaughtered in October, found to be heavily infected with tuberculosis, and thereafter all milk was pasteurized. A further two months elapsed before the herd was retested, when eight cows, five being young animals, reacted. To date fourteen children have been notified with clinical tuberculosis which we believe has resulted from drinking unboiled milk from this herd. The figure includes one case of intussusception associated with a tuberculous mesenteric adenitis. Most of the children drank the unboiled T.T. milk at home and at school, but two received it only at school, one of these having always had pasteurized milk and the other boiled T.T. milk in the home. Lest it be thought this incident is the unfortunate exception that proves the rule, may we mention that we know of others. Milk which can bring about these results cannot be described as "representing a reasonable universal level of safety."—We are, etc.,

Marlborough,
Oxford.T. R. MAURICE.
HUGH ELLIS.

Elderly Psychiatric Patients

SIR.—I feel Dr. F. Houston (*Journal*, May 1, p. 1036) misunderstood my letter (*Journal*, April 10, p. 876). My plea was for the abolition of the term "arteriosclerotic dementia" in favour of "post-apoplectic dementia." The large majority of patients who suffer from strokes were not demented prior to the stroke, or are so after they have recovered from the initial effect. In a small number of cases following a second or third stroke there may be intellectual loss and the patient may more easily be provoked to tears. The intellectual level then remains static unless a further stroke occurs.

All the above have presumably suffered from cerebral arteriosclerosis for a number of years, yet the dementia, if it occurs, is related to the apoplexy and not the arterial lesion. The term arteriosclerotic dementia suggests a progressive intellectual loss, and this gives the wrong impression. I am quite sure that necropsy evidence of cerebral infarction does not correlate with arteriosclerotic dementia, as the large majority of cases are not demented. The discrepancy between clinical and pathological lesions has been noted many times, notably by the careful work of Rothschild.^{1,2} I feel Dr. Houston should publish fully his knowledge of deaths following modified E.C.T., as this may be a very serious criticism.—I am, etc.,

A Bung-holder

SIR.—A simple device to prevent ejection of the rubber bung of the giving set during a positive-pressure transfusion can quickly be made as follows.

The band of a standard M.R.C. type bottle-holder is bent, as shown in the photograph, to fit closely round the neck of the transfusion bottle. The "wings" thus formed are secured by artery forceps or drip-regulating screw clips. The hanger loop is bent into an "M" shape so as to press firmly upon the bung when the device is in place.

I am indebted to Male Charge-Nurse J. Atkinson, of the Royal Victoria Infirmary, Newcastle-upon-Tyne, for this suggestion.—I am, etc.,

Newcastle-upon-Tyne, 1.

J. A. G. HORTON.

Injection into Artery

SIR.—It would seem that the warrant for Dr. O. H. Belam's statement made in court and reported in the *British Medical Journal* of March 27 (p. 766) is in fact that so far he has not had the misfortune to inject thiopentone into an artery.

In the letter published on April 10 (p. 875), in which he attempted to mollify his dogmatism, Dr. Belam appears to be equally dogmatic. What does he mean by "an experienced person"? Would a thousand intravenous injections enable one to claim experience? I had certainly performed several times this number before I had the misfortune to inject thiopentone into an artery. I was well aware of this hazard, and had several times inadvertently punctured an

artery and recognized the fact before I had the misfortune to do so without eliciting the usual signs of this mishap. Almost 2 ml. containing 0.1 g. of thiopentone was injected before pain drew attention to my error. This was followed by blanching and then coldness of the affected limb segment. I shall continue to believe that I exercised "reasonable" skill and care and that intra-arterial injection of thiopentone cannot be entirely avoided.—I am, etc.,

Guernsey.

BRIAN WEBBER.

The Winter Vomiting Disease

SIR,—Similar outbreaks of the winter vomiting disease occur in Australia and are known by various names in different localities—"gastric flu," "three-day sickness" (after the bovine complaint), and so on. Winter vomiting is not a very good name here, as the attacks are often in summer, but goldfish spawn in November here as in England, without reference to the season, so perhaps we could call it "February vomiting" or "after Christmas vomiting." The mention by Dr. J. H. Whittles (*Journal*, February 6, p. 333) of infective hepatitis prompts me to remark that the incubation period of our disease is three days, whereas hepatitis is four to six weeks.—I am, etc.,

Wollongong, N.S.W.

M. C. MCKINNON.

Acetone Tests in Diabetic Coma

SIR,—The tests for acetone using 2,4-dinitrophenylhydrazine, described by Drs. Ole Sylvest and René Dybkaer (*Journal*, April 3, p. 816), may be a useful method of detecting acetone in the breath.

In Dr. R. D. Lawrence's clinic we have been using a similar sort of test for some time, in which the patient breathes into Nessler's reagent. If acetone is present a heavy milky white precipitate forms within 20 seconds when there is heavy ketosis, or after 40 to 60 seconds in milder cases. In order to minimize the risk of inhaling this mercury-containing solution, we think it wise to use a simple piece of apparatus made from two boiling tubes in which there is a fluid trap, as shown in the accompanying diagram. The rapidity at which the precipitate forms will of course depend on the volume of air expired, varying with the rate and depth of respiration and the degree of co-operation by the patient. The precipitate is presumably not specific for acetone, being due to a chelation compound with mercury. A high concentration of tobacco smoke also gives a faint white discoloration, but only after several minutes of hard blowing, and alcohol gives a very slight haziness, neither of which are likely to be confusing. With 2,4-dinitrophenylhydrazine a similar cloudiness also forms with tobacco smoke.

We have already carried out both these tests in a few patients, clear positive reactions being obtained in three patients after 35, 70, and 80 seconds with Nessler's reagent, though no visible colour change or crystal formation had occurred after 120, 120, and 300 seconds respectively with 2,4-dinitrophenylhydrazine. For those physicians with a poor sense of smell, tests for acetone in the breath may be of help, but they are far less important than examination of the urine by the old-established methods.—We are, etc.,

London, S.E.5.

K. J. GURLING.
H. R. MILLAR.

Food-poisoning Due to *Cl. welchii*

SIR,—Having been printed in the same issue of the *Journal* as Dr. A. Beck, Dr. A. W. H. Foxell, and Dr. W. C. Turner (March 20, p. 686)—and bearing in mind Professor T. N. A. Jeffcoate's views on public correspondence—I have hesitated to endorse in print the findings of your contributors who reported an outbreak of food-poisoning due to heat-resistant *Cl. welchii*. In the last year I have observed two such outbreaks and intend to publish the reports of these in the *Journal of the Royal Army Medical Corps*. The following data, I think, are consistent with the findings of Drs. Beck, Foxell, and Turner, and I am indebted to the Editor of the *Journal of the Royal Army Medical Corps* for permission to publish them here.

	Day	No. Examined (with Symptoms)	No. Positive for Heat-resistant <i>Cl. welchii</i>
Outbreak 1 (men at risk 138; men with symptoms 48; total number of patients examined 30)	2 15 26 36	30 20 (repeat) 7 3	30 7 3 2
Outbreak 2 (men at risk 300; men with symptoms 25; total number of patients examined 18)	2 4 12	2 2 12	1 2 6

Service conditions facilitate the follow-up of such cases, and, following the second outbreak, investigation of the food-handlers revealed two men who had had no symptoms but who persisted to excrete the organism intermittently for at least four months. One of these men, who was involved in handling meat, appears to have been the source of this outbreak.

The second outbreak was traced as a result of experience gained during the first and consequent reference to the work of Dr. Hobbs *et al.* I am sure that the second outbreak would otherwise have escaped detection, and I agree that a heat-resistant variant of *Cl. welchii* may well be a commonly undetected cause of this type of food-poisoning. I am, etc.,

Newcastle-upon-Tyne.

J. GERALD COLLEE.

REFERENCE

J. Hyg., Lond., 1953, 51, 75.

SIR,—I was interested to read the account of an outbreak of food-poisoning due to *Clostridium welchii* (*Journal*, March 20, p. 686) reported by Drs. A. Beck, A. W. H. Foxell, and W. C. Turner. In one of the schools in the Nashoba Health District, Massachusetts, in May, 1953, we had a similar food-poisoning outbreak with more than 100 children, teachers, and staff upset. In following up the causation it was noted that the only article of diet which was suspect was turkey meat. A specimen of this turkey meat was recovered from the garbage can by the sanitation officer. This was the day after the food had been eaten. This specimen smelt very badly. Cultures of the specimen, however, revealed no staphylococci, no salmonella, but a Gram stain of a direct smear of the meat revealed large Gram-positive rods abundantly throughout the meat. The meat was inoculated into litmus milk in two tubes and a stormy fermentation arose in 24 hours. In thioglycollate broth a cloudy growth with cottony clumps deep in the tube and gas resulted. The organisms also grew on thioglycollate agar, in Brewer plate, with a good growth of white colonies spreading in wet places. A large Gram-positive rod with the morphology of a clostridium was revealed microscopically, but no spores were seen. The biochemical reactions showed acid in lactose, sucrose, dextrose, and maltose. Spores were never seen from the organisms, although the latter were kept in the laboratory for about six weeks on the milk thioglycollate broth and a thioglycollate agar.

The turkeys which were eaten for this school lunch had been brought from a storage freezer in a neighbouring town in the frozen state. However, on the way from the storage refrigerator

unit the carrier truck was allowed to stand out in the open for several hours. The turkeys were then taken to the school and on the following day were prepared for cooking, that is on the afternoon before consumption. During the preparation one of the workers noted that one of the three turkeys had a peculiar red colour—but did not smell bad, nor did she notice any bad smell at all. The turkeys were cooked in the normal manner, and, because they were very hot and it was relatively cool weather, the cook left the turkeys out on the kitchen table at room temperature until the next morning, when the meat was shredded and divided up, a sauce being poured over the shredded meat. No pupil or teacher complained of anything objectionable about the dinner at the time of eating, although practically without exception the children and teachers who partook of the dinner had a sharp turn of diarrhoea, nausea, and general upset within 24 hours, mostly within eight to ten hours of eating the turkey. The normal reports were made to the State Health Department but no conclusions were come to as to the possibility of the toxic properties caused by the clostridium being responsible for the upset. This staff felt, however, that the large anaerobic Gram-positive rod (resembling a clostridium) was in fact responsible for the illness. Later the bacteriologist in the unit, Mrs. Marjorie Dunlap, experimented with turkeys, and she noticed that the turkey meat cooked promptly after defrosting remained sweet and firm for six days although kept at room temperature. Organisms from the turkey which had been recovered from the garbage can were inoculated into this meat and they stayed alive at room temperature but did not cause any particular decomposition. But she felt that possibly decomposition would have occurred if moisture had been added. On the other hand, turkey meat allowed to defrost and kept raw for five days at room temperature was found on examination to have Gram-positive rods in the meat taken from the shoulder or from the skin. These organisms were not seen in the abdominal cavity. It was unfortunate that in this outbreak very few stool specimens were obtained and in those no special organisms were found. In conclusion it was felt that (although not proved) turkey meat properly cooked but carelessly handled was in fact responsible for the outbreak.

In this department it is felt that the advice offered by Drs. Beck, Foxell, and Turner regarding the risk involved in preparing meat dishes prepared the day before their consumption is worth noting, and we in Nashoba have advised our own school systems to make certain that food cooked the day before consumption is properly refrigerated before being used. As a result of this outbreak in one of our schools we have prepared a standard school luncheon series of regulations.—I am, etc.,

Ayer, Massachusetts.

KENNETH I. E. MACLEOD.

Carcinoma and Neuropathy

SIR,—Within recent years much interest has centred upon the association of neurological disorders (polyneuropathy, cerebellar degeneration, etc.) with malignant disease, particularly carcinoma of the lung. In this connexion the report by Dr. P. L. de V. Hart (*Journal*, March 13, p. 606) is of considerable interest. It is, however, important to realize that all cases of proximal muscular weakness developing in patients with malignant disease are not due to a neuropathy. Indeed, an association between dermatomyositis or polymyositis and malignant disease has been recognized for some years, and has been discussed recently by Curtis and his associates.¹ In the case descriptions given by Dr. Hart one looks in vain for any absolutely convincing evidence that his patients were suffering from a neuropathy. The clinical picture which he describes is equally compatible with, if not more suggestive of, polymyositis. The pattern of muscular involvement in both cases was typical of this disease; the first patient had a skin rash and in the second the electromyogram showed that some motor units were "broken up as is seen in neurogenic lesions." Disintegration of motor unit potentials occurs to a much greater extent in primary muscle disease than in a neuropathy.

Dr. Hart refers in an addendum to an account by Dr. R. A. Henson² of eight cases of proximal motor neuropathy in association with carcinoma of the bronchus. At least one of Dr. Henson's patients was believed to be suffering from polymyositis, and from his descriptions, in the absence of pathological evidence, it is impossible to be sure that this was not true of other cases in his series. The remittent

course of several of them makes this a very real possibility. Dr. Henson mentioned that certain of his cases showed fatigability of muscles like that seen in myasthenia gravis, and two showed temporary improvement after prostigmine. In this connexion it is interesting to recall the recent reports of myasthenia in cases of bronchogenic carcinoma.^{3,4} In one of these reports⁵ a battery of diagnostic tests suggested that the patient was suffering from true myasthenia gravis, but in the other two cases the diagnosis was less certain. I have recently observed considerable and sustained improvement in muscular weakness on prostigmine therapy in two cases of polymyositis, though the response was certainly not as good as that seen in true myasthenia gravis.

I make these points in order to stress the fact that many patients with carcinoma who develop proximal muscle wasting and weakness, with involvement of neck and pharyngeal muscles, are suffering from polymyositis and not a neuropathy. The correct diagnosis can generally be made by muscle biopsy. It is a common experience to observe spontaneous remission in cases of polymyositis; the relationship of the improvement which occurred in Dr. Hart's cases to therapy with vitamin B was tenuous in the extreme. To adduce a specific deficiency of pyridoxine or of pantothenic acid or riboflavin as the cause of the patient's muscular weakness is presumptuous on the evidence which is presented to us. To go even further and to propose that the tumour cells compete for these vitamins seems quite unjustified. Much work remains to be done before the pathogenesis of the neurological and muscular disorders complicating malignant disease can be elucidated. The first essential, however, is accurate diagnosis of the lesion or lesions responsible for muscular weakness in each case. Once this has been achieved by biochemical and pathological means it may be possible to make some progress in identifying pathogenic mechanisms.—I am, etc.,

Boston, Mass.

Infectious Mononucleosis

SIR,—Dr. S. Shubert, Captain J. G. Collee and Dr. B. J. Smith's interesting article (*Journal*, March 20, p. 671) offers a good opportunity for re-emphasizing that the haematological picture, and not the agglutination test, is the mainstay of diagnosis in either the epidemic or the "sporadic" form of infectious mononucleosis. This is a fact that requires to be repeated again and again when statements such as "the laboratory let us down" are made, referring to the Paul-Bunnell test.

Regardless of whether one adopts the theory of one causal virus or of different closely related ones, the histological change in the lymphopoietic tissues, and the resulting peripheral blood count, are probably identical in all cases. Tidy,¹ in his remarkable exposé of glandular fever, reviewed the various clinical forms, to which one may add the very rare laryngeal form,² which I have also observed. Both his article and Whitby and Britton's classical textbook³ contain comprehensive information on the value of blood changes and of serological findings in this disease. It has been variously estimated that roughly 10% of cases have a negative Paul-Bunnell test. This figure will undoubtedly be increased by observations of epidemics like the one described by Drs. Shubert, Collee, and Smith.

The differential white blood count appears to be the most constantly positive laboratory test in infectious mononucleosis, even before, or in the absence of, any glandular enlargement, the only exception being the prolonged febrile type of the disease. In this latter form of infectious mononucleosis, the laboratory tests will become diagnostic later on, at the time of the enlargement of the glands.⁴ To be distinguished from infectious mononucleosis is a condition clinically simulating glandular fever with its enlargement of lymph glands, and sometimes recurring at intervals of

several weeks or months. The negative blood findings and negative lymph gland cytology (puncture!) will differentiate this condition of as yet unknown aetiology from infectious mononucleosis.

To summarize, I would like to make the following points: (1) the blood count is the most important test of infectious mononucleosis and is the most likely to reveal the diagnosis at an early stage and during the whole active phase of the disease; (2) the agglutination test (Paul-Bunnell test), if positive, is additional evidence; (3) a negative Paul-Bunnell test does not exclude this diagnosis; (4) a positive Paul-Bunnell test can sometimes be found after convalescence when the blood count might have become normal; and (5) negative haematological findings in the presence of glandular enlargement (especially if repeated) exclude the diagnosis of infectious mononucleosis.

In conclusion, I would like to say that it should be kept in mind that while the Paul-Bunnell test is a purely "technical" test the opinion on the blood film in difficult cases belongs in the domain of the expert.—I am, etc.,

Sheffield.

Pethidine for Pain and Insomnia

SIR,—We have noticed that even the most up-to-date textbooks advocate morphine in cases of pain and insomnia associated with pneumonia. However, it has been our experience that when we have given even small doses of morphine, especially in people over the age of 40, the condition has deteriorated rapidly, with death in a very high percentage of cases.

On the other hand, since we have started using pethidine in similar cases the response has been noticeably better and the death rate has been very low. In our opinion, morphine is contraindicated in all cases of pneumonia, especially nowadays, as we have other drugs to relieve pain and help sleeplessness which are not so depressant on the respiratory centre.—I am, etc.,

R. G. B. WIGODER.
H. JEFFS.

London, S.E.6.

Single Incision for Bilateral Orchidectomy

SIR,—Like Mr. C. J. Cellan-Jones (*Journal*, May 1, p. 1039), my own memories go back to 25 years ago, when I learnt from Mr. Kenneth Walker to approach the testes directly through the scrotum. I have been doing so ever since without any of the complications he describes. So I must admit that, for my part, I took quite seriously Sir Heneage Ogilvie's plea for this approach (*Journal*, April 17, p. 934).—I am, etc.,

London, W.1.

REYNOLD BOYD.

Chronic Vasomotor Rhinitis

SIR,—The two syndromes described by Mr. P. Reading and Mr. K. Malcomson and Dr. D. O'Neill and Mr. K. Malcomson (*Journal*, March 6, pp. 552 and 554) as "non-specific paroxysmal sneezing and rhinorrhoea" and "persistent nasal blockage" respectively are believed by the authors to respond differently to treatment. In the case of the former the symptoms are controlled by antihistamine drugs and sustained improvement follows psychotherapy, whereas the latter requires surgical intervention or zinc ionization. In my experience the two conditions frequently merge and the characteristic symptoms of the two states may alternate in a single individual. I am myself an example of such a "mixed" syndrome, all symptoms being promptly relieved by antazoline hydrochloride, 0.1 g.

The authors might find it of value to investigate how many of their cases had used the "pocket inhaler" in the past. The recent survey carried out by the City Analyst of Birmingham (*Journal*, March 13, p. 616) shows that while some of the inhalers examined were deficient in amphet-

amine others contained an excess of up to 30%. I attribute my own condition to the excessive use of such inhalers to relieve "catarrh," and the amount of amphetamine absorbed in this way was sufficient to cause sleeplessness, abolition of fatigue, and restlessness. A friend of mine in Calcutta, who was incapacitated for days by rhinorrhoea until he took antihistamine drugs, also blames the condition on to the excessive use of inhalers.—I am, etc.,

Udayagiri, India.

D. STEWART McLEARN.

Bacterial Endocarditis Due to *Chromobacterium Prodigiosum*

SIR,—Drs. A. J. Hawe and M. H. Hughes (*Journal*, April 24, p. 968) point out that Wilson and Miles were, in 1946, unable to quote any indubitable report contradicting the view that *Chromobacterium prodigiosum* was non-pathogenic for man. A patient died of septicaemia due to *Bacillus prodigiosus* in 1934 in a London teaching hospital, and the death certificate was lying on the desk of the local registrar of births and deaths when I went in to register the birth of a child. The registrar showed me the certificate (having found out that I was a doctor) and remarked that he had never heard of the condition. I told him that he was probably in the unique position of being the first to register a death from this cause, and I eagerly searched medical journals for some months in the hope that the case would be published. It apparently never was, which is a pity, as it would presumably have been the first of its kind.—I am, etc.,

London, W.1.

J. C. HAWKESLEY.

SIR,—It may be of interest to Drs. A. J. Hawe and M. H. Hughes (*Journal*, April 24, p. 968) to draw their attention to a case of acute fatal septicaemia due to *Chromobacterium prodigiosum* which I published in the *Lancet* in 1935.¹ This was probably the first case of fatal infection with this organism ever published. The point of interest is that it was associated with agranulocytosis, and it seems possible that their case may have had chloramphenicol-induced agranulocytosis and developed endocarditis due to this organism only in the later stages of the illness. I am, etc.,

Guildford.

C. RICKWORD LANE.

Racial and Religious Tolerance

SIR,—It is a sad reflection on the ability of the medical profession to think rationally that out of the fourteen advertisements for assistants in the *Journal* of April 10 seven implied preference for a particular race or religion. What does this imply? Does it imply that each of these doctors believes that a particular race or religion is more likely to supply a compatible colleague, or that it is easier to work with a person of one's own (or possibly not one's own) nation or creed? If this be so, have those concerned bothered to consider if their beliefs are founded on any rational judgment, or merely on emotionally toned prejudice? Do a significantly higher proportion of Scotsmen than Englishmen or Argentinians, for example, make better assistants even to other Scotsmen: do more Catholics than Jews? I have no figures available so am unable to formulate any conclusions lest they be based on prejudice. I think it is true to say that many beliefs of racial superiority or inferiority have been shown not to be founded on fact, and it would be reasonable to suggest that this may be so in this present case.

In any case I feel that a liberal-minded profession should be capable of putting aside emotionally toned judgments and accepting a colleague on his merits as "a good man to work with," irrespective of his race, colour, or creed. It should set an example in this disturbed world, where polls are necessary to decide on the allowable quantity of skin pigment in bus conductors, and abhor the discriminatory techniques so prevalent to-day.—I am, etc.,

Bristol.

C. P. SEAGER.

Obituary

F. L. HOPWOOD, D.Sc.

Professor F. L. Hopwood, who died at Sidmouth, Devon, on May 2, had worked for many years in close association with the medical staff at St. Bartholomew's Hospital, as physicist, as professor of physics, and as vice-dean of the medical college.

Frank Lloyd Hopwood was born in 1884, and was educated at Hawarden Grammar School and at the University College of North Wales, Bangor. He then came to London, where he continued his studies at the Royal College of Science and at University College, taking the London degree of D.Sc. in 1919. Before graduating he worked during the first world war on the improvement of instruments for submarine detection and for underwater signalling, of which he invented a system. He became physicist at St. Bartholomew's Hospital in 1920, and was appointed professor of physics at the medical college there in 1924. He retired in 1949. London University then conferred on him the title of emeritus professor. He was also vice-dean of the medical college from 1939 to 1945.

Hopwood's contribution to radiotherapy was a most important one, for his hospital was one of the most progressive in this field. He published numerous papers in the *British Journal of Radiology*, the *Proceedings of the Royal Society*, and other journals, and he was a member of the Nuclear Physics Committee of the Medical Research Council. For many years also he served the British Empire Cancer Campaign as a member of its grand council and on many of its committees and subcommittees, and latterly as its honorary secretary. He was a past president and Silvanus Thompson Medallist and Memorial Lecturer of the British Institute of Radiology, an honorary member of the Faculty of Radiologists, and from 1925 to 1950 honorary secretary of the British Committee for Radiological Units. At the seventh International Congress of Radiology he was vice-president emeritus, having attended the previous Congress as a British delegate. The University of Cambridge conferred on him the honorary degree of M.A. in 1940, and in the same year he was elected an honorary Fellow of Queens' College, Cambridge.

He married Miss Helen Sproston in 1909, and she survives him. There was one son of the marriage.

We are indebted to Professor A. WORMALL for the following appreciation: Frank Lloyd Hopwood retired in 1949 after 44 years of service happily and fruitfully devoted to the Medical College and Hospital of St. Bartholomew. Even in his retirement, however, there was no cessation of the work he loved so well, and right up to the end he continued to serve Bart's, the British Empire Cancer Campaign, and many other organizations in which he had a special personal interest.

The thousands of medical students who passed through his hands are not likely to forget him as a teacher and, above all, as a man who set a standard of personal and professional integrity which might be equalled but could not be surpassed. Many will for ever be grateful to him for his never-failing kind-heartedness and for the fatherly advice which he so readily gave them when they were in trouble. Those well acquainted with him knew that his opinion and advice were invariably sound, unbiased, and worthy of careful consideration, whatever the topic or the problem under discussion. A committee which had Hopwood as a member was unlikely to take any action which was either unwise or unfair.

Many will remember the prominent part he took in helping to establish the million-volt x-ray unit at Bart's in 1936; others will recall his direct and always helpful interest in the Strangeways Institute at Cambridge, his submarine detection work in the 1914-18 war, or his early fundamental work on ultrasonics. Few people know that it was in his laboratory in 1934 that Szilard and Chalmers carried out the first chemical separation of an artificially produced radioactive isotope. His teaching and administrative duties were heavy, and frequent calls were made on his services for college and university committee meetings. There appeared, therefore, to be little time for him to carry out systematic research. It was characteristic of his real aptitude for research that during his retirement he published several important papers describing investigations which arose from observations he had made when using the kitchen tap and an ordinary household sieve. What an excellent director of a research institute he would have made, for rarely if ever did any researcher consult him without obtaining sound advice; and often he received real inspiration.

As a leader and as a man of wisdom and wide vision Hopwood was outstanding. These attributes received wide recognition when in September, 1939, he became vice-dean of our Medical College, with the task of looking after the preclinical departments during their wartime stay in Cambridge. How splendidly he performed this special duty is well known to his many friends at Bart's, Queens' College, and the Universities of Cambridge and London. I shall remember him particularly as a man of absolute integrity, a staunch colleague, a loyal and generous friend, and a delightful companion for a round of golf or a country walk, or at the lunch table. It was truly a privilege to have known him and to be blessed with his friendship.

J. L. LOVIBOND, T.D., M.D., F.R.C.P.

Dr. J. L. Lovibond, assistant physician at the Westminster Hospital, died suddenly on May 4, his 47th birthday.

John Locke Lovibond was born on May 4, 1907, and was educated at Oundle School, Christ's College, Cambridge, and the Middlesex Hospital, where, after qualification in 1932, he became casualty officer and house-surgeon to Mr. W. Sampson Handley. He then went to the Westminster Hospital as house-physician to the late Dr. Hildred Carill and to Dr. W. E. Lloyd. In 1935 he took the M.R.C.P.

and graduated M.B., B.Chir. at Cambridge, proceeding to the M.D. two years later, the subject of his thesis being hydrothorax in cardiovascular disease. After holding the post of house-physician at the Brompton Hospital, he returned to the Middlesex Hospital to work in the cardiographic department, and later became medical registrar to Dr. Cockayne. In 1938 he was appointed physician to the King George Hospital, Ilford, but had hardly taken up this appointment when war broke out in the following year. As a keen Territorial he was one of the first to leave. He served with the British Expeditionary Force in France, being one of the last to come through Dunkirk, and later in Iraq, Ceylon, and Burma. From officer in charge of a medical division, he became officer commanding the 35th British General Hospital

(Lafayette, Ltd.)

in 1943 and, later, officer commanding the 38th British General Hospital in Burma, holding the rank of colonel. It was while serving in the R.A.M.C. that he was elected F.R.C.P. Towards the end of the war he became consulting physician to the 12th Army, South-east Asia Command. On return to civilian life in December, 1945, he added to his previous appointments by becoming assistant cardiologist at the London Chest Hospital, Victoria Park, and, in 1948, assistant physician to Westminster Hospital.

We are indebted to Dr. F. DUDLEY HART for the following appreciation: "Jock" Lovibond had apparently been in perfect health and on the evening before his death had attended a medical committee meeting, where he showed his usual alertness and vigour. On the following day, although usually scrupulously punctual, he did not turn up for his teaching round at 2 o'clock, and the tragic news was heard a few minutes later. His death came therefore as a sudden and prostrating shock to all of us who had so recently seen his cheerful, alert figure.

Lovibond was a delightful man and his friends were not confined to one profession or school. Although keenly interested in cardiology, he was an excellent all-round general physician with a wide interest in all branches of medicine, as is shown by his varied publications dealing with diseases of the blood, of the colon, of the heart and lungs, and many other subjects. In 1938 he was the first to describe the "profile sign" as an early sign of clubbing of the fingers. Perhaps his most important publication was "Hydrothorax in Heart Failure," published in the *British Heart Journal* in 1941 and written in conjunction with Dr. D. Evan Bedford.

He had wide interests outside medicine. At the Middlesex Hospital he was captain of the first fifteen, and for many years he was a keen horseman, riding in many hunter trials, point-to-points, and following the hounds. He was a keen amateur painter and an able cartoonist, his caricatures adorning the pages of the *Granta* and the walls of the Westminster students' refectory. Some years ago, with a colleague, he built brick by brick his own country cottage. He retained his keen interest in the Army and was attached to the 1st Regiment, Honourable Artillery Company (R.H.A.). Indeed, two days before his death he had been on manoeuvres on Salisbury Plain. As a colleague he was unfailingly kind, co-operative, and cheerful; we never saw him depressed or irritable. The deep sympathy of all his friends and colleagues goes out to his widow and mother in their tragic and sudden loss.

S. SPENCE MEIGHAN, M.B., F.R.F.P.S.

By the sudden death on April 20 of Dr. S. Spence Meighan Glasgow has lost one of her best-known ophthalmologists and the British Medical Association a member who was to have served as a vice-president of the Section of Ophthalmology at the Association's Annual Meeting to be held at Glasgow next July.

Stuart Spence Meighan was born at Glasgow on June 19, 1888, the son of the late Dr. T. Spence Meighan, and was educated there at the High School and at the University, where he graduated M.B., Ch.B., with honours, in 1912, having previously obtained the B.Sc. in 1909. He was elected F.R.F.P.S. in 1920. After qualifying he held resident appointments in Glasgow at the Western Infirmary, the Royal Hospital for Sick Children, and the Eye Infirmary, where his father had been a surgeon. Soon after the outbreak of war in 1914 he entered the R.A.M.C. and served in France with the Highland Field Ambulance in the 51st Division from 1916 until March, 1918, when he was taken prisoner. He was twice mentioned in dispatches.

After the war Dr. Spence Meighan returned to a junior staff post at the Glasgow Eye Infirmary, and soon afterwards became ophthalmic surgeon to Stobhill Hospital, then a Poor Law institution. He was promoted surgeon to the Eye Infirmary in 1926, and in the same year was appointed to the chair of ophthalmology at the Anderson College of Medicine, where he worked until 1943, when ill-health obliged him to resign. Later he became an honorary lecturer in ophthalmology in the University. At Stobhill, and at the Clydebank Eye Dispensary, he did much to extend the ophthalmic services available to the locality.

A member of the council and a vice-president of the Ophthalmological Society of the United Kingdom and a past-president of the Scottish Ophthalmological Club, he was keenly interested in all matters affecting his specialty. He was a member of the British Medical Association's committee on the diagnosis and certification of miners' nystagmus, the report of which was published in 1936. When the National Health Service began he was appointed a member of the Glasgow Northern Hospitals board of management and became chairman of its medical committee, a responsibility for which he was well suited. Dr. Spence Meighan had planned to read a paper before the Section of Ophthalmology at the Annual Meeting in July on trachoma in Glasgow, a subject on which he was an acknowledged expert. He was also particularly interested in the medico-legal problems of ophthalmic practice, and was often called to give evidence in courts of law.

Dr. Spence Meighan will long be remembered for his kindness both to his patients and to his colleagues, and for his readiness to help those who came to him for advice. His innate diffidence could not disguise his sound clinical knowledge and surgical skill. He regarded all his fellow men with an air of benevolence, and his sense of humour found an outlet in mimicry without malice, a gift which his friends enjoyed to the full. He is survived by a widow and two sons.

Dr. HARRISON STANFORD MARTLAND, the American pathologist, died in New York on May 1 at the age of 70. He was born in New York in 1883 and received his medical education at the College of Physicians and Surgeons, Columbia University, where he graduated in 1904. For the next four years he served as pathologist at the Russell Sage Foundation. In 1908 he was appointed city pathologist of Newark, New Jersey, a position which he held for 46 years. He was also chief medical examiner of Essex County. For many years he was professor of forensic medicine at the Postgraduate Medical School of New York University. Martland was a pioneer in the study of diseases due to radioactive substances. In 1925 he investigated the deaths of several girls who had been employed in painting luminous watch-dials and who had developed necrosis of the jaw and severe anaemia. He showed that these deaths were attributable to the habit the girls had of putting a point on the paint-brushes by wetting them on the lips and to the absorption of radioactive material in this way. His papers on this and related subjects were recently republished in book form by the U.S. Atomic Energy Commission, where Martland was employed for a time in designing protective devices against exposure to radioactivity. A proof of the regard in which Martland was held was forthcoming last January, when the thirteen-million dollar municipal hospital under construction at Newark was named the "Harrison S. Martland Medical Center." He was a member of the editorial board of the *American Journal of Surgery* from 1935 to 1946, when he was appointed associate editor.

Medico-Legal

ALLEGATIONS WITHDRAWN

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

An action for negligence against the North-east Metropolitan Regional Hospital Board and Mr. Eric Edmund O'Malley, M.S., F.R.C.S., who had been surgical registrar of the Prince of Wales Hospital, Tottenham, came to an unusual end last week.

The action was brought by Mrs. Storie in respect of the death of her husband, Mr. Lawrence Rodney Storie, a week after an operation for a varicose vein. In 1951 Mr. Storie had been successfully treated by Mr. O'Malley at the Prince of Wales Hospital for varicose ulcers, and doctor and patient had become friends. It was decided to operate for a varicose vein. The operation was performed on February 11, 1952, not by Mr. O'Malley but by the senior house-surgeon, and Mr. Storie was allowed to go home. On February 15 he was examined at hospital by Mr. O'Malley, and again allowed to go home and told to report on February 18. On February 18 he did so, but collapsed and died outside the hospital from a clot of blood 4 in. (10 cm.) long, which was found at necropsy in his heart.

The plaintiff's case was that on February 15 there was already gross sepsis at the site of the operation in the right groin, with enlarged glands which would have been palpable on examination, and that the clot had formed in the ligated vein, been dislodged by the sepsis, and travelled to the heart. It was alleged that Mr. O'Malley had made his examination so carelessly that he had failed to observe the signs of sepsis, and consequently failed to immobilize the patient to reduce the risk of dislodging a clot.

Mr. O'Malley's case was that he made a thorough examination during which he tested for the presence of a blood clot but found no sign of one, and found no sign of sepsis. From his examination he considered that Mr. Storie was going on absolutely as would be expected, and it would have been a bad thing to put him to bed.

The hospital board were joined as defendants on the ground that they were in law vicariously responsible for Mr. O'Malley's alleged negligence. No separate allegation of negligence was made against them.

The action was tried before Mr. Justice Stable and a jury, and at the end of a three-day hearing the jury, after an absence of over an hour, stated that they could not agree upon a verdict, and regretted putting the court to such inconvenience. Mr. Justice Stable, observing that it was not the court but the parties who would suffer, thereupon discharged the jury. On May 6, however, on the application of Mrs. Storie's counsel, the action was withdrawn.

In making the application to Mr. Justice Stable counsel said that, while he had been waiting outside court for the jury's verdict at the hearing, Mrs. Storie had told him that having heard the evidence she was satisfied that there was no ground for complaint against Mr. O'Malley. Mrs. Storie had instructed him so to inform Mr. O'Malley and to repeat it in public so as to clear him so far as she could. The action had not been brought irresponsibly at Mrs. Storie's instance, but on the strength of the medical evidence laid before her which turned out to have been founded on one or more false premises for which she was not to blame.

In allowing the application for the action to be withdrawn Mr. Justice Stable said that in the course of a fairly long legal experience he had not come across an example of such magnanimity as Mrs. Storie had shown in acknowledging that Mr. O'Malley did all and more that a really competent surgeon should have done. Mr. O'Malley emerged from the case with his professional reputation not only not impaired but enhanced. Not only was he a thoroughly competent surgeon, but a most kindly and friendly man.

The Medical Protection Society instructed Messrs. Le Brasseur and Oakley to act for Mr. O'Malley.

The Times, May 7, 1954.

Medical Notes in Parliament

HEALTH SERVICE FINANCE

The Minister of Health, Mr. IAIN MACLEOD, speaking in a House of Commons debate on the Health Service on May 10, ranged over many aspects of the Service from the apportionment of capital expenditure for hospital needs to the cost of drugs and the standard of the general practitioner's surgery. He told the House that the Guillebaud Committee—engaged in a review of the finance of the Service—would begin the preparation of their report towards the end of June.

He commented that for the first time the true gross of the Health Service, at £505m., had exceeded £500m. The conclusion he ultimately reached was that, if one took medical need alone as the criterion, one could justify much greater expenditure—more, indeed, than any Chancellor could sanction or the country could stand. In his judgment the sum provided in the Estimates was enough. This was going to be a difficult year for hospital maintenance, but the sum allocated was £12,500,000 more than the out-turn last year, and that amount should enable them to hold the line, meet major needs, and make some modest advance. The capital outlook was a good deal more encouraging than it had been for some time. In the wider setting of national expenditure he was satisfied this year with the Estimates.

Less for Teaching Hospitals

Mr. Macleod said that he had deliberately allocated less in proportion to the teaching hospitals than to the regional hospital boards, since he felt there was more scope for economy in the teaching hospitals, and that it was right, within the limits of what was available, to be more generous to the regional boards. An analysis of the types of scheme that had been undertaken since the Service began until the end of last year showed that 20% of the money had been spent on ward accommodation, 17% on staff accommodation, 21% on special departments, 6% on out-patient departments; 4% on laundries and kitchens; 19% on engineering services, and 13% on others. It had been the consistent policy of successive Ministers to give high priority to special departments. If central allocations for capital expenditure were to be continued it would take away much of the autonomy and discretion of regional boards in the matter; and if the impression was given that funds would be made available for a particular service it would tend to make the boards think that as the matter was being taken care of centrally they need not bother to finance part of it out of their own budgets.

He had come to be regarded as the apostle of charges for the Health Service, but he was the only one of the four Ministers since its inception who had not introduced a Bill to impose those charges. Before the charges were made the cost of providing dentures had been running at about £2,750,000. It dropped almost at once to less than £1,500,000, and had remained fairly constant at that figure since.

It was immensely difficult to make a comparison between the numbers of prescriptions in different years, because so much depended on the prevalence of sickness. The figures for the first year of the Health Service charges were distorted by the London fog, the East Coast floods, and an influenza epidemic. The prescriptions dispensed now numbered about 213 million, compared with a peak of 225 million. The cost per prescription had turned down from a peak of 49d. to about 47½d. The cost to the Exchequer was £40m., against a peak of £45.5m., and the patients were paying £6.5m. If a Socialist Government should be returned to power he hoped they would think carefully indeed about some of these figures, and reflect that there might well be higher priorities on which to spend money than free laxatives and free vitamin pills.

Delivery dates of artificial limbs had considerably improved, and delays in repairs had also been reduced.

Some Drugs too Dear

Investigations had been made into the cost of basic drugs in four categories—antibiotics, vitamins, hormones, and insulin—and proprietary preparations. During the investigation the prices of penicillin and hormones had been reduced by the manufacturers. In the basic drugs he was conscious of the danger of interfering with valuable research, and also of the importance of the export trade, because there was no question that risks had to be taken by the manufacturers.

Without prejudice to final action the Ministry decided last year to make a number of investigations into the cost of manufacturing certain proprietaries which would seem at first sight to be especially expensive. In categories 2, 3, and 4 there were 6,000 preparations of which they were investigating 91, which accounted for 30% of the total cost of proprietaries to the Health Service and 18% of the total drug bill. In one group investigations were complete. They had not been able to reach agreement with the manufacturers on what they considered a reasonable profit level, and proposed soon to advise doctors that satisfactory price arrangements had not been made and to ask them not to prescribe these preparations.

More Partnerships

In the 12 months ending July, 1953, the number of doctors in partnership increased by more than 1,000, or 3.6%. Of the doctors newly admitted to established partnerships, 555 were known to have been assistants in the practices in which they became partners, which was a welcome development. A substantial proportion of the doctors entering the Service in 1952-3 went into under-doctored urban areas, with the result that the proportion of the urban population in under-doctored areas fell from 60% in October, 1952, to 46% in July, 1953.

Speaking of accommodation and surgeries, he said that as part of a doctor's terms of service he was required to provide proper and sufficient surgery and waiting-room accommodation for his patients. There could be no justification whatever, now that the Danckwerts award had been promulgated, for that not being done up to a reasonable standard. Last October the chairman of the General Medical Services Committee of the B.M.A. drew the attention of all general practitioners to this matter in a letter, and urged the highest possible standard.

On health centres and group practice, he said the report of Sir Henry Cohen's committee was in his hands and would be published soon. People held very different views about the future of the health centres. Another matter which they must seek to develop in the general-practitioner service was that they should have as much help as possible from x-ray and "path" examinations in the hospitals. A good deal of opportunity was being given, and he was certain that it provided a genuine incentive to the keen practitioner. In spite of the difficulties of providing such a direct service, he was told that about half the hospitals with these facilities had made them generally available to the general practitioners.

It was not right that they should look for spectacular changes in the structure of general practice, but they could draw encouragement from the figures he had given and the beginnings of the implementation of the Working Party report. There was great interest in this, and some interesting studies—by Dr. Hadfield,¹ of the B.M.A., and by Dr. Stephen Taylor—helped to encourage that interest. A quotation from Dr. Taylor's book summed up what he had to say about general practitioners and the provision of accommodation: "There is no impossibility about raising the standards of practice of the less good doctors to those of the best, providing that what happens in the best practices is made known to all." That was an accurate reflection of the position.

¹British Medical Journal, September 26, 1953, p. 683.

Opposition's Views

Mr. A. BLENKINSOP (Newcastle-upon-Tyne, East, Lab.), who opened the debate, said that many people had feared that the Guillebaud Committee would be used for the introduction of spot interim recommendations which might have a seriously detrimental effect on the work of the Service. Since then it had become clear that the committee was being given opportunities and time to study the subject carefully and fully. The Opposition welcomed this. They were certain that, the more fully the committee investigated, the more they would be convinced that true economy would demand increased rather than reduced expenditure. (Opposition cheers.)

Recently medical officers of health in speeches at congresses had given a misleading account of the hospital service. One well-known officer had said that no progress had been made since 1948. That was demonstrably false. Great advances had been made, although in some cities, which were particularly fortunate in the past, the same rate of progress had not been maintained as in other areas. It was misleading for men in responsible public positions to attempt to give the impression to the public that because they had lost some contact with hospital development this had meant a complete setback in development generally.

This year the Estimates provided for an increase in the capital allocation to hospitals of 25% over the allocation for last year, but what a miserable total was disguised by the percentage! (Opposition cheers.) It was an increase of only £2m. over the £8m. allocation of last year, and it only brought the allocation nearly back to what it was in the Estimates for 1951-2. It only partly redressed the severe cuts made a year ago, and would in no way meet the needs of the hospital service.

The majority of doctors' practices were good, but a serious proportion were bad. It was a tragedy that those doctors were getting the advantage of payments to which they had no right. Nobody could make him believe that in those shocking practices anything like 38.7% was being spent on expenses. The Service was being swindled and contumely brought on other doctors who maintained a good standard of provision. Premises should be inspected, and some of the worst offenders warned that unless there was some improvement they could no longer be regarded as practising in the Health Service.

Improvements in Hospital Service

Mr. SOMERVILLE HASTINGS (Barking, Lab.) said there had been a great improvement in the hospital service, which had been most marked in the medical treatment in the small ex-Poor-Law hospitals in country districts. The general-practitioner service had provided great benefits for the families of the employed, but there had been complaints. Certain people who were accustomed to "send for the doctor" for almost anything, in the same way that they sent for the plumber or the sweep, had found that they were not getting the same attention—for the very good reason that the practitioners were busy dealing with more important cases. The Minister's action in allocating a percentage of beds in general hospitals for tuberculosis cases had shown the advantage of the unity of control bestowed by the Health Service Act, and the result had been that the waiting-lists had become much smaller. He doubted whether preventive medicine had improved to the same degree as curative medicine, and for that the doctors were largely to blame. He also said that consultants should no longer be paid travelling time and expenses. It encouraged them to dissipate their energies by going to too many hospitals.

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) said that if we had to face an atomic war large stocks of antibiotics, blood, and dried plasma should be available.

General practitioners, he said, should be the first line of attack against disease. More use should be made of them than had been in the past. For them to work in isolation was wrong, particularly in the cities, where group practice

MAY 15, 1954

was the best. There were sufficient general practitioners and consultants if they were properly distributed.

Colonel M. STODDARD-SCOTT (Ripon, Con.) said that the time had come to consider whether the regional hospital boards in England were the best organization for the Health Service. The first form of organization was not necessarily the best, and it should now be decided either to abolish them completely or to reduce their power and influence, at the same time raising the standard of the management committees.

Mr. R. FORT (Clitheroe, Con.) referred to the importance of the general practitioner, and said that this had been brought out by two remarkable publications—the book by Dr. Stephen Taylor and the issue of the *British Medical Journal* last September which included Dr. Hadfield's survey of several hundred general practitioners and the results of his postal inquiry. One difficulty was the increasing specialization which was required, but there was a need for the various branches of the medical profession to work closer together. It was disappointing to find that, according to the article in the *British Medical Journal*, consultants were failing to have general practitioners present at consultations as much as was the case before the Health Service started. It would be well to bring to the notice of specialists how important it was to keep their general practitioner colleagues working side by side with them.

Commander T. GALBRAITH, Under-Secretary, Scottish Office, replying to the debate, said that any practitioners who wished to incur capital expenditure on the provision of premises for group practice were invited to apply for interest-free loans from the £100,000 which had been set aside from the national pool for the development of group practice. Decisions on applications—which were only now coming in—would be taken by a joint committee, one in England and Wales and the other in Scotland, composed of representatives of the general body of practitioners on the one hand and of the appropriate health department on the other. The Government had no rigid preconceived notions on what, for this purpose, constituted group practice, but the committee would endeavour to select those which held out most promise of improving the standard of service which the group of doctors would be able to offer their patients. These loans would be repayable normally over 10 years and the money repaid would become available for further loans. The health centres which had been set up were for experimental purposes, and it would be best to await developments and see how they were serving their purpose. A great deal could be done by group practice and by the doctors themselves.

Hospital Waiting-lists

Dr. BARNET STROSS (Stoke-on-Trent Central, Lab.) asked the Minister of Health whether he had noted the variation in the average waiting time, after inclusion in the waiting-list, for patients who required major surgery for tuberculosis, cancer of lung and bronchus, or bronchiectasis, and what he proposed to shorten the waiting time, particularly in Wales. Mr. IAIN MACLEOD replied on May 6 that the length of waiting time was due primarily to the rapid increase in demand for thoracic surgery and the comparative shortage of thoracic surgeons and trained theatre staff. The number of surgeons had increased by 50% over the past three years, and was likely to increase further, and the annual number of patients dealt with by thoracic surgery departments rose by over 18% in 1953 and had nearly doubled since 1949.

Dr. STROSS said that in Wales the waiting period for tuberculosis before treatment was offered was up to two years, and for bronchiectasis up to five years. Would the Minister increase the number of consultants for this specialty? Mr. MACLEOD said they were doing all they could to iron out the serious discrepancies between the regions. One method was by consultation between senior assistant medical officers to see whether one region could help another. Mr. SOMERVILLE HASTINGS (Barking, Lab.) sug-

gested the concentration of cases in need of chest surgery in a relatively large hospital, so that so much time was not wasted by surgeons travelling from one hospital to another, and better work could be done because of the treatment that trained staff could give. Mr. MACLEOD observed that that was a far-reaching proposal and he would like to consider its implications.

Use of Pay-beds

Mr. SOMERVILLE HASTINGS (Barking, Lab.) asked the Minister of Health on May 6 what percentage of Section V pay-beds were unoccupied in the hospitals under his direction during each of the last three years. Mr. IAIN MACLEOD replied that no figures were available before July, 1952. For the periods July to December, 1952, January to June, 1953, and July to December, 1953, the figures for non-mental hospitals were 34.5, 30.4, and 34.5 respectively. Mr. HASTINGS commented that the figures showed a terrible waste of beds. Large numbers of non-paying patients could use those beds if the Minister would so instruct. Mr. MACLEOD said that he did that last August, and the results of that were not apparent in these figures. He hoped that it would substantially reduce the percentage of non-occupied beds.

Hospital Out-patients

Mr. GEORGE JEGE (Goole, Lab.) asked the Minister of Health whether he had given consideration to the question of reducing waiting time in hospital out-patients' departments, and what action he had taken. Mr. IAIN MACLEOD stated on May 6 that, as he had previously said, he regarded this as a matter which was primarily one for local action by the hospital authorities themselves. He was, however, proposing to ask them to review their present arrangements. He was not convinced that they could do very much by circular; a great deal more could be done by the pressure of public opinion in the different areas. He would consider a suggestion that the Central Health Services Council should be asked to make a survey of the out-patient problem.

Hospital Board Appointments

The MINISTER OF HEALTH was asked on May 6 why he had not reappointed Dr. Stark Murray to the South-West Metropolitan Hospital Board. He replied that in making this and other changes he had followed the example of his predecessors in introducing new members at regular intervals, so as to widen the opportunities for service on the boards.

Mr. H. KING (Southampton, Test, Lab.) said this doctor had been one of the most able and conscientious members of a very good board. It was a bad thing to terminate the appointments of excellent men merely because they had been six years on a board. Above all, could the Minister assure the House that political considerations did not enter this matter, as Dr. Stark Murray was a leading Socialist doctor and his successor was a leading anti-Socialist doctor? Mr. IAIN MACLEOD said that if Mr. King would look at the appointments to this and other boards he would know that there was no foundation for his suggestion.

Colonel M. STODDARD-SCOTT (Ripon, Con.) asked about the appointments of M.P.s to the boards, and the parties to which they belonged. Mr. MACLEOD said the original appointments included six M.P.s, a number subsequently increased to nine, and by a strange coincidence all nine were Socialists.

Dr. EDITH SUMMERSKILL (Fulham West, Lab.) asked whether the Minister knew that this very able doctor was a founder-member of the Socialist Medical Association. Mr. MACLEOD: "I appoint people for medical and not political considerations." Mr. PETER SMITHERS (Winchester, Con.) asked by whom Dr. Stark Murray had been succeeded, and Mr. MACLEOD said it was Mr. Lawrence Abel, one of the finest surgeons in the country.

Tuberculous Immigrants

Mr. KENNETH ROBINSON (St. Pancras North, Lab.) asked the Minister of Health on May 6 if he had any statement

to make concerning the problem of persons from abroad taking up residence in this country while suffering from active tuberculosis. Mr. IAIN MACLEOD stated that the Central Health Services Council had recommended that appropriate action be taken to ensure that those seeking work in this country from abroad should be free from infectious tuberculosis. The Standing Tuberculosis Advisory Committee, on the other hand, had expressed the view that the position did not indicate a serious menace to the health of the country. Special inquiries that had been made suggested that the number of those entering with active tuberculosis was very small indeed.

Mental Nursing Recruitment

Miss PAT HORNSBY-SMITH, Parliamentary Secretary to the Ministry of Health, replying to an adjournment debate on May 3 about the shortage of mental nurses and the action taken to encourage recruiting, told the House of Commons of the improved wages rates that had been recommended after arbitration and were now before the Whitley Council. The Ministry had launched a series of 36 publicity campaigns. It was too early to assess results. The Minister regarded this subject as of top priority, and no effort in aid and encouragement within their power would be spared to get open non-staffed beds and thereafter to provide the staff for new beds.

Scottish Hospital Board.—During the past two years, according to a reply given on May 3 by the Secretary of State for Scotland, 13 persons had ceased to be members of the South-East Scotland Regional Hospital Board and five new appointments had been made. Those who have left the board include Dr. E. A. Cormack (Edinburgh), Dr. A. Simpson (Hawick), and Sir Henry Wade (Edinburgh). The new members include Dr. J. C. G. Mercer (North Berwick), Professor G. H. Percival (Edinburgh), and Dr. G. J. Summers (Edinburgh).

Welfare Milk.—The Minister of Food stated on May 3 that on October 31 a new system of welfare milk based on weekly tokens would be introduced.

Vital Statistics

Occupational Mortality

The deaths in England and Wales in 1950 have been analysed in relation to the 1% sample already tabulated from the 1951 census to provide some preliminary figures on occupational mortality.¹ Only broad groups of occupation are listed; the medical profession is not among them. As a basis of comparison standardized mortality ratios are given in Tables I and II below, extracted from the Registrar-General's tables. These S.M.R. figures are to be compared with the figure of 100 for the total population analysed in each Table, and they illustrate relative, not absolute, differences.

Table I below, concerned with men aged 20-64, shows that there are well-marked gradients upwards in social classes I to V for deaths from chronic rheumatic heart

TABLE I

Causes	Social Class				
	I	II	III	IV	V
Malignant neoplasms, all sites	96	84	105	94	110
Stomach	57	67	100	114	132
Intestines	123	100	105	85	94
Lung, bronchus, trachea	80	79	108	89	116
Chronic rheumatic heart disease	61	87	103	102	114
Arteriosclerotic (coronary) heart disease	150	110	104	79	89
Pneumonia	43	63	97	106	157
Ulcer of stomach	56	81	97	99	144
Ulcer of duodenum	104	78	106	82	126

In Tables I and II figures in italics are based on fewer than 50 deaths, figures in parentheses on fewer than 10 deaths.

¹Registrar-General's Decennial Supplement: England and Wales, 1951. Occupational Mortality, Part I. H.M.S.O. 7s. 6d.

disease, pneumonia, and ulcer of stomach, whereas a reverse gradient is shown for cancer of the intestine and coronary heart disease.

Figures for married women aged 20-64, analysed by the same causes of death and the social class of their husbands, are given in Table II below.

TABLE II

Causes	Social Class				
	I	II	III	IV	V
Malignant neoplasms, all sites	115	90	103	95	107
Stomach	57	72	101	106	138
Intestines	103	100	97	104	106
Lung, bronchus, trachea	120	94	104	96	91
Chronic rheumatic heart disease	63	62	102	118	135
Arteriosclerotic (coronary) heart disease	92	93	101	100	108
Pneumonia	69	75	98	110	138
Ulcer of stomach	(60)	93	96	124	100
Ulcer of duodenum	(100)	68	91	133	131

The infant mortality rate, being the number of deaths in infants aged under 1 year per 1,000 live births, increased through social classes I to V. In 1950 the rate was 17.9 for social class I, 22.5 for II, 28.4 for III, 34.5 for IV, and 41.1 for V; for all classes it was 29.9. The maternal mortality rate also increased by social class, figures for 1950 per 1,000 legitimate live and stillbirths being as follows: 0.77 for social class I, 0.82 for II, 0.80 for III, 0.90 for IV, and 0.93 for V; for all classes it was 0.83.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1945-53 are shown thus ———, the figures for 1954 thus ———.

Except for the curves showing notifications in 1954, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending April 24 (No. 16) and corresponding week 1953.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES In Countries and London	1954					1953				
	Eng. & Wales	Lon.	Scot.	N. Ire.	Eire	Eng. & Wales	Lon.	Scot.	N. Ire.	Eire

Non-respiratory	113	7	31	3				28	7	
Whooping-cough	2,133	63	314	31	25	3,206	237	429	41	149

Infectious Diseases

The largest variations in the returns of infectious diseases in England and Wales during the week ending April 24 were decreases of 208 for dysentery, from 919 to 711, and 205 for scarlet fever, from 994 to 789, and increases of 284 for measles, from 1,912 to 2,196, and 153 for whooping-cough, from 1,980 to 2,133.

Small falls in the incidence of scarlet fever were recorded in every region; the largest decline was 31 in Yorkshire West Riding, from 107 to 76. The largest increases in the number of notifications of measles were 104 in Cheshire, from 87 to 191, 64 in Norfolk, from 308 to 372, and 36 in Yorkshire West Riding, from 185 to 221, and the largest decrease was 30 in Staffordshire, from 215 to 185. 12 cases of diphtheria were notified, being 2 fewer than in the preceding week. The chief feature of the returns of diphtheria was a rise from 2 to 7 in Lancashire, where 4 cases were notified in Liverpool C.B. The largest variations in the trends of whooping-cough were rises of 33 in Sussex, from 45 to 78, 31 in Lancashire, from 190 to 221, and a fall of 35 in Kent, from 161 to 126.

10 cases of acute poliomyelitis were notified. These were 4 fewer for paralytic and 3 fewer for non-paralytic cases than in the preceding week. The only counties with 2 cases were Somerset and Yorkshire West Riding.

For the third consecutive week the number of notifications of dysentery has fallen and the total is now less than half of that of three weeks earlier. The largest centres of infection were Lancashire 138 (Denton U.D. 47, Manchester C.B. 13, Salford C.B. 12, Bolton C.B. 10), London 91 (Islington 26, Lewisham 20), Yorkshire West Riding 81 (Sheffield C.B. 19, Bradford C.B. 16, Dewsbury C.B. 16), Leicestershire 42 (Leicester C.B. 35), Middlesex 37 (Edmonton M.B. 16), Glamorganshire 34 (Llchwyr U.D. 16), Gloucestershire 31 (Bristol C.B. 25), Kent 27, Essex 24, and Warwickshire 20 (Birmingham C.B. 19).

In Scotland the number of notifications of dysentery increased by 78, from 273 to 351. The largest returns were 196 in Glasgow, 65 in Lanark county, 21 in Edinburgh, and 21 in Dundee.

Week Ending May 1

The notifications of infectious diseases in England and Wales during the week included pneumonia 521, scarlet fever 623, whooping-cough 2,233, diphtheria 12, measles 1,970, dysentery 759, acute poliomyelitis 20, paratyphoid fever 3, and typhoid fever 3.

DEATHS in Great Towns	1954					1953				
	Eng. & Wales	Lon.	Scot.	N. Ire.	Eire	Eng. & Wales	Lon.	Scot.	N. Ire.	Eire

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Medical News

Royal College of Physicians of London.—The following were elected Fellows of the College on April 29: M. K. Gray, M.B. (New Zealand), I. G. Davies, M.D. (Leeds), E. T. D. Fletcher, M.D. (London), O. E. J. Murphy, M.B. (Australia), C. L. Stote, M.D. (Shrewsbury), L. G. Bell, M.D. (Canada), H. M. Rennie, M.B. (Australia), R. Whishaw, M.B. (Tasmania), A. C. E. Cole, M.D. (Tanganyika), E. C. Allibone, M.D. (Leeds), H. B. May, M.D. (London), E. M. Darmady, M.D. (Havant), H. A. Dewar, M.D. (Newcastle-upon-Tyne), J. M. Holford, M.B. (Royal Navy), A. P. Dick, M.D. (Cambridge), D. H. G. MacQuaide, M.D. (Northampton), J. Carson, M.B. (Bamford in the Peak), Raymond Greene, D.M. (London), R. J. G. Morrison, M.D. (Royal Army Medical Corps), Georgiana M. Bonser, M.D. (Leeds), C. E. Dent, M.D. (London), J. M. Naish, M.D. (Iron Acton, near Bristol), T. N. Morgan, M.D. (Aberdeen), K. S. MacLean, M.D. (London), J. Lowe, M.D. (London), A. P. Norman, M.D. (London), J. H. Paterson, M.D. (Sidcup), G. MacG. Bull, M.D. (Belfast), L. G. Blair, L.R.C.P. (London), R. Kirk, M.D. (Sudan), D. V. Hubble, M.D. (Derby), A. P. Murphy, M.D., P.R.A.C.P. (Australia), Sir Eric D. Priddle, M.B. (London), H. E. Sigerist, M.D. (Switzerland).

Seventh World Health Assembly.—Dr. M. G. Candau, Director-General of W.H.O., said when he addressed the Assembly on May 3 that the policy of decentralizing W.H.O.'s work had proved to be fully justified. In determining priorities for requests for aid, they took account first of whether the project would raise the general health standards of the country concerned. They had also to be certain that the work would be carried on and completed by the government of the country. Member countries, he said, could depend more and more on W.H.O. for assistance in improving their epidemiological services and their health statistics. They could also rely on W.H.O. to keep them informed of progress made in the scientific aspects of medicine.

Dr. J. N. Togba, of Liberia, has been elected president of the W.H.O. in succession to Dr. M. Khater, of Syria.

Professor G. Macdonald, of the London School of Hygiene and Tropical Medicine, has been awarded the W.H.O.'s Darling foundation prize jointly with Dr. G. R. Coatney, of the U.S.A. The prize consists of a medal and 1,000 Swiss francs.

Board of Registration of Medical Auxiliaries.—The first dinner of the Board was held at Apothecaries' Hall on May 4, with the president, Mr. A. M. A. Moore, in the chair. In proposing the health of the Board Sir Russell Brain, P.R.C.P., said that medical auxiliaries were an integral part of medicine and should not be looked on just as additions to medicine. The existence of the Board showed that the auxiliaries, being part of medicine, shared its ideals and sought to maintain the same high standards of skill, ethics, and professional pride. There must be co-operation not only with the profession, but among themselves. In reply Mr. Moore traced the history and development of the Board. The first move was begun in 1928, when the Representative Body of the B.M.A. resolved that, in view of the risk to the public from the use of electricity and radiation in treatment by untrained and unqualified persons, suitable courses of training should be organized under medical direction, and that those who had satisfactorily followed such a course should be entitled to have their names on an approved scroll. In 1929 the Council of the B.M.A. decided that the only method of carrying out the wishes of the Representative Body was by means of voluntary action, the most satisfactory solution being the institution of a voluntary register. This register came into being in 1930. In 1933 the Representative Body approved the establishment of a register of auxiliary medical services, and in 1936 the Board was incorporated under the presi-

dency of Sir Henry Souttar, the founder members being the B.M.A., the Society of Apothecaries, the Chartered Society of Physiotherapy, and the Society of Radiographers. Subsequently recognition was given to orthoptists, speech therapists, dietitians, and more recently to operating theatre technicians. Recognition was given only after the fullest investigation of the standards of education, training, and examination of the body concerned. The main function of the Board was to publish sectional registers of each of the qualifying bodies registered with it, and it was hoped before long that a comprehensive register would be brought out. One of the main objects of the Board was to promote legislation for the establishment of a statutory register. The Cope Report, which was published in 1951, recommended a degree of statutory registration for medical auxiliaries employed in the N.H.S. and for the registration of others not so employed if they desired it. In 1953 the Minister of Health stated in the House of Commons that there was insufficient agreement on fundamental matters to proceed with statutory registration on the lines proposed by the Cope committees. The Minister had now appointed a working party with a view to evolving a scheme acceptable both to the Minister and to the auxiliaries. Mr. Moore paid a tribute to the many persons who had played an important part in the development of the Board's work. The health of the guests was proposed by Mr. John Hanby, President of the Society of Chiropodists, and responded to in a delightful speech by Sir Heneage Ogilvie.

Availability of Cortisone.—The Board of Trade will issue import licences for cortisone or A.C.T.H. in response to applications made by or on behalf of patients who need these drugs for their personal use. The application must be accompanied by a medical certificate stating the condition from which the patient is suffering and the quantity and form of cortisone or A.C.T.H. required for treatment. The patient should send the medical certificate with a request for form ILB/A (Revised) to the Import Licensing Branch, Romney House, Marsham Street, London, S.W.1.

Rehabilitation Inquiry.—Anyone wishing to give evidence to the Committee of Inquiry on the Rehabilitation of Disabled Persons should submit it as soon as possible, and before June 30, to the joint secretaries of the committee at the Ministry of Labour and National Service, 32, St. James's Square, London, S.W.1.

Drummond Memorial Fellowship.—A fund has now been raised in memory of the late Sir Jack Drummond, and though donations are still coming in the trustees want to appoint a Fellow on October 1. The intention is to award a fellowship to "a young scientist of proved ability to engage in research on nutrition, with special emphasis on human nutrition." Appointment would be for one year at first with a stipend at the rate of £900 per annum. The trustees would consider extending it. The trustees have sent a letter to the heads of departments of appropriate institutions seeking help in the appointment of a Fellow.

The Medical World for April is a special issue devoted to smoking and cancer of the lung, containing a symposium of professional opinion on this subject.

COMING EVENTS

British Association of Sport and Medicine.—The next meeting, a symposium on athletic injuries and their treatment, will be held on May 24 in the Meyerstein Theatre of the Westminster Hospital Medical School, Horseferry Road, London, S.W.1. Details from the honorary secretary, 95, Mount Street, London, W.1.

Sir Howard Florey, F.R.S., will deliver the Croonian Lecture to the Royal Society on May 27 at 4.30 p.m. His subject will be "Mucins and the Protection of the Body."

Friends of Vellore.—A public meeting will be held at Caxton Hall, London, S.W.1, on May 27 at 7.30 p.m. The speakers will be Dr. Hilda M. Lazarus, Sir Samuel Runganathan, and Dr. Howard Somervell. Further information may be obtained from the secretary, Mr. R. Chamberlain, Annandale, North End Road, London, N.W.11.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, May 17

INSTITUTE OF PSYCHIATRY.—5.30 p.m., lecture-demonstration by Dr. E. Stengel.
LONDON UNIVERSITY.—At Guy's Hospital Medical School, 5.30 p.m., first of two lectures by Dr. Bernard B. Brodie (National Heart Institute, Bethesda, U.S.A.): Biochemical and Clinical Implications of Studies in Drug Metabolism.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. N. F. Coghill: Sigmoidoscopy in Medicine.

Tuesday, May 18

ILFORD MEDICAL SOCIETY.—At King George Hospital, Ilford, 8.45 p.m., annual general meeting. Dr. H. N. Rose: Medical Administration.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. L. Forman: Lupus Erythematosus.
SOUTH-WEST LONDON MEDICAL SOCIETY.—At Bellingbroke Hospital, Wandsworth Common, S.W.1, 8.30 p.m., Dr. Paul Wood: The Physician's Approach to Cardiac Surgery.
WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY.—5 p.m., Almroth Wright Lecture by Dr. W. Hayes: Nature of Genetic Recombination in *Bacterium coli*.

Wednesday, May 19

ASSOCIATION OF OPTICAL PRACTITIONERS.—At London School of Economics and Political Science, 8 p.m., 26th Ethics Memorial Lecture by Mr. S. M. Wells, F.S.M.C., D.O.Rth.: Visual Problems of the Older Worker in Industry (Illustrated).
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Histology of Some Skin Conditions in Children.
INSTITUTE OF LARYNGOLOGY AND OTOLARYNGOLOGY.—5.30 p.m., Dr. I. Friedmann: Malignant Granuloma of the Nose.
INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Hammersmith Hospital, 3 p.m., Dr. Mary Barber: Investigation of Sepsis in a Maternity Unit.
LONDON UNIVERSITY.—At Guy's Hospital Medical School, 5.30 p.m., second and last lecture by Dr. Bernard B. Brodie (National Heart Institute, Bethesda, U.S.A.): Biochemical and Clinical Implications of Studies in Drug Metabolism.
MIDDLESEX COUNTY MEDICAL SOCIETY.—At Clare Hall Hospital, 3 p.m., clinical meeting. Papers by Dr. J. S. Crowther: Spontaneous Pneumothorax, Review of 60 Cases; Dr. R. E. D. Harvey-Samuel: Marital Tuberculosis.
OXFORD UNIVERSITY.—At University Museum, 5 p.m., Litchfield Lecture by Professor W. T. Astbury, F.R.S.: Some Observations and Thoughts on the Structure and Mobility of Flagella.
ROYAL EYE HOSPITAL.—5.30 p.m., Mr. L. H. Savin: Ophthalmic Neurology (5).
WILLESDEN GENERAL HOSPITAL MEDICAL SOCIETY.—8.45 p.m., discussion: Medical and Surgical Aspects of Diseases of the Gall-bladder and Liver. Speakers, Dr. R. B. Terry and Mr. F. W. M. Pratt.

Thursday, May 20

● GUY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Carbutt Memorial Lecture by Dr. Michael De Bakey (Baylor, U.S.A.): Surgical Considerations of Diseases of the Aorta.
INSTITUTE OF CARDIOLOGY.—9.30 a.m., Dr. J. H. Wright: Unilateral Renal Hypertension.
LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Medical Society of London, 8.30 p.m., Symposium: Abortion. Speakers, Mr. A. W. Bourne, Mr. L. Courtin, L.I.M., and Dr. H. J. Shorvon.
OXFORD UNIVERSITY.—At Radcliffe Infirmary, 5 p.m., Litchfield Lecture by Mr. C. D. Read: Post-menopausal Haemorrhage.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. J. F. Goodwin: Pulmonary Hypertension.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Arnold Demonstration by Dr. F. Stansfield: Maxillary Air Sinus; 5 p.m., Hunterian Lecture by Professor V. E. Neagus: Comparative Anatomy of the Nose and Paranasal Sinuses.
ROYAL EYE HOSPITAL.—5.45 p.m., Miss J. M. Dollar: Films on Operative Surgery (1).
ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—7.30 p.m., paper to be read by Dr. J. Donald Ball (Uganda): Endomyocardial Fibrosis in Africa (by Drs. A. W. Williams, J. N. P. Davies, and J. D. Ball). A discussion will follow.
ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Professor Lawson Wilkins (Baltimore, U.S.A.): Diagnosis and Treatment of the Adrenogenital Syndrome.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., neurology demonstration by Dr. J. H. Paterson.

Friday, May 21

FACULTY OF RADIOLOGISTS.—At Royal College of Surgeons of England, 2 p.m., general meeting. Group Captain D. A. Wilson, A.F.C.: Radiological Experiences of the Atomic Explosion at Woomera. A cine-film will follow. 3.15 p.m., Skinner Lecture by Dr. F. Baclesse (Paris): Radiotherapy in Cancer of the Breast.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. R. T. Brain: Skin Diseases in Children.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. D. A. K. Black: Disturbed Electrolyte Metabolism in Pyloric Stenosis.
● ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS.—5 p.m., William Blair-Bell Memorial Lecture by Dr. Ian Donald: Anteclastis Neonatorum.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Webb-Johnson Lecture by Professor H. F. Humphreys: Value of the Teeth as Evidence—Scientific, Clinical, and Forensic.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor G. W. Pickering: Obstetric/Gynaecological Conference.

Saturday, May 22

INSTITUTE OF ORTHOPAEDICS.—At 234, Great Portland Street, W., 10 a.m., clinical demonstration by Mr. P. H. Newman: Clinical Aspects of Lumbar Instability and its Complications.
LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—2.45 p.m., visit to Royal Horticultural Society Gardens at Wisley.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Vision for the Navy

Q.—What visual standards are required of entrants to the Royal Navy? I am sometimes asked this by the parents of boys who are considering a career in that Service.

A.—The visual standards for entry into the Royal Navy vary according to the branch of the Service. Acute form-vision in both eyes without glasses is required for those employed on look-out duties. Other branches accept men with moderate defects of form-vision which can be corrected by glasses, the wearing of which is permitted in some branches. In addition, colour perception must be within certain standards, and examination of the refraction and ocular muscle balance is required for certain categories. Broadly speaking, a candidate would be acceptable for some type of Naval Service, in so far as form-vision is concerned, if his unaided vision in each eye is not less than 6/60 and can be corrected with glasses to 6/12:6/12 or alternatively to 6/6:6/24.

Doctors who are consulted by prospective candidates for entry into the Royal Navy are advised to communicate with the Medical Department of the Navy, Queen Anne's Mansions, St. James's Park, London, S.W.1, indicating which particular branch of the Navy the candidate wishes to enter. Exact details of the visual standard required for the branch in question will then be provided.

Risks of Late Child-bearing

Q.—A couple have married rather late in life. The husband is 45, the wife a nullipara of 42. They are anxious to have a child. How grave are the dangers to the mother at this age? Ought I to advise them against child-bearing?

A.—Provided that the woman's general health is good, that the blood pressure and urine are normal, and that lesions of the pelvic organs—for example, fibroids—are excluded, child-bearing at the age of 42 or later does not carry any great risk. There is a slightly increased chance of hyperemesis, abortion, toxæmia of pregnancy, placenta praevia, faulty uterine action in labour, foetal malposition, soft tissue dystocia, and stillbirth, but the dangers tend to be exaggerated, and many women having their first baby at a comparatively late age have a surprisingly smooth pregnancy and labour. In a case such as this, where the deferment of pregnancy is the result of lack of opportunity rather than of infertility, the occurrence of conception would itself be evidence of good reproductive function, and would augur well for the pregnancy and labour. Even if complications do arise they can nowadays usually be easily treated or circumvented if the delivery is conducted in a well-equipped hospital—which it should be.

Another aspect to be considered is the increased risk of foetal malformation which is present in women more than 40 years of age. This applies mainly, if not entirely, to mongolism, and, again, the chance is not so great that it should deter a couple who are anxious for a family.

Yellow Fever Vaccine for Children

Q.—What modification of dosage is required for children receiving yellow fever vaccine? Is a reaction to the vaccine likely?

A.—Children of all ages receive the same dosage of yellow fever vaccine as adults. Neither local nor general reactions occur in the vast majority of cases.

perimental animals. This implies that, even if diseases are caused by an excess of such hormones, the corticoid concentration in the blood and urine may have returned to normal by the time the patient consults a physician (Green, 1953). It remains to be demonstrated, however, that natural adrenal hormones, secreted during stress, could also exert such delayed pathogenic actions.

(5) Some investigators consider it paradoxical to assume that the same factor, stress, can both inhibit and produce disease manifestations (Rosenberg, Woodbury, and Sayers, 1952).

We have now devised an experimental model on which these points can be tested by quantitatively measurable objective indicators. To permit generalizations a simple pathogen was used which produces such fundamental disease manifestations as inflammation and necrosis—that is, lesions commonly encountered in clinical medicine. As outlined below, the basic elements of this model are: the “pathogen” or topical stressor (the principal immediate cause of disease), the direct effect of the topical stressor (the local disease manifestations, such as inflammation and necrosis), the systemic stressor (which influences the local disease manifestations), and the adrenals (upon which the actions of the systemic stressor could depend) (Selye, 1954).

The purpose of this communication is to report upon three series of animal experiments, performed with a technique of this type.

Materials and Techniques

Experimental Animals and Their Maintenance

In all these investigations we used female Sprague-Dawley rats, weighing 120–150 g. at the beginning of the experiment. They were fed on “Purina Fox Chow,” and, since some of them were adrenalectomized, for uniformity's sake all received 1% NaCl as drinking fluid.

Topical Stress

The “granuloma-pouch” technique, which has been described in detail elsewhere (Selye, 1953a, 1953b), was used to produce and assess topical stress. In essence, the test is performed by injecting 25 ml. of air under the shaved dorsal skin of the rat, this being immediately followed by the injection of some irritant, the “local pathogen,” into the regularly shaped, ellipsoid connective-tissue chamber thus formed. In the present experimental series various dilutions of croton oil (in corn oil) have been used as examples of mild and severe local stressors, respectively.

The resulting amount of a haemorrhagic inflammatory exudate can be assessed approximately, day by day, by transillumination of the pouch with an electric flashlight; it can subsequently be measured accurately by withdrawing the fluid into a graduated syringe. This serves as an indicator of inflammation.

If the granuloma is weak, and the croton-oil solution comparatively strong, then the skin which covers the granuloma pouch undergoes manifest discoloration and necrosis. This serves as an indicator of local tissue death. As will be seen below, usually there is an inverse relationship between the intensity of inflammation and of necrosis.

Systemic Stress

In the first experiment, systemic stress was produced by fasting on the third, fourth, sixth, and seventh days after the granuloma pouches were prepared. However, the animals were allowed drinking fluid *ad libitum* at all times.

In the second and third experiments, forced restraint of the animals' free movements was used as a systemic stressor. The advantage of this procedure is that it does not necessitate the introduction into the body of any foreign materials or the infliction of traumatic tissue injuries. In principle, this technique (also described in more detail elsewhere—Selye, 1954) consists in temporarily restraining free loco-

motion by fastening the animal to a wooden board with adhesive tape. Since the procedure is irritating and provokes a certain amount of struggling, the condition of the rat is not unlike that occasioned by physical and mental fatigue in man.

Earlier experiments had shown that inflammation in the granuloma-pouch can most readily be inhibited by corticoids or systemic stress during a “critical period,” at about the third and fourth days in the development of a granuloma pouch (Selye, 1953c, 1954). Hence we applied the stress of forced restraint between the 72nd and the 96th hour of the experiment, both in the second and in the third experimental series. It should be added that, although during immobilization the animals received no food, many earlier control experiments had shown that a single day of fasting has no measurable effect upon the development of the granuloma pouch.

Assessment of the Adrenal Factor

All adrenalectomies were performed through the lumbar approach—in the first experiment 24 hours before, in the second and third experiments on, the day the granuloma pouch was prepared.

Some form of corticoid therapy was given in all three experimental series. In the first experiment, in which all animals were adrenalectomized, the rats of Groups I and II received cortisone acetate, those of Groups III and IV desoxycorticosterone acetate (D.C.A.), in the form of aqueous microcrystal suspensions, as distributed by Merck and Co., Inc. Both steroids were administered subcutaneously, twice a day, at the dose of 500 gamma in 0.2 ml. of suspending agent, between the 48th and the 168th hour of the experiment—that is, during the “critical period.”

In the second and third experiments, only some of the rats (Groups III and IV) were adrenalectomized, and hence in need of corticoid substitution therapy. Yet for uniformity's sake all animals were given 1 mg. of cortisol acetate microcrystals subcutaneously in 0.2 ml. of suspending agent twice daily. Unlike in the first experiment, this slowly absorbable cortisol ester was given throughout the period of observation (instead of the rapidly absorbed cortisone acetate during the “critical period”), to ensure a more constant blood-corticoid level. Numerous preliminary tests had shown that at this threshold level both corticoids increase the systemic resistance of adrenalectomized rats sufficiently to permit survival under considerable stress, and yet in themselves they do not greatly alter such reactions to local stress as exudation or tissue necrosis in the granuloma-pouch test.

Experimental Observations

First Experiment: The Effect of Fasting Upon the Topical Actions of Croton Oil in Adrenalectomized Rats Maintained with Cortisone or D.C.A.

This experiment was performed in order to establish whether the well-known anti-inflammatory effect of starvation is due exclusively to a stimulation of antiphlogistic corticoid (A-C) production by the adrenals, or whether it can also manifest itself in adrenalectomized animals if they receive maintenance therapy with such a corticoid.

Four groups, each consisting of ten adrenalectomized rats, were treated as outlined in Table I. The amount of exudate was measured, after aspiration into a graduated syringe, on the tenth day following the preparation of the granuloma pouch. In the table the mean volume of exudate is given with the standard error.

TABLE I.—Effect of Fasting Upon Exudation Due to Croton Oil in Adrenalectomized Rats (Maintained with Cortisone and D.C.A. Respectively)

Group	Treatment	Exudate (ml.)
I	Cortisone	5.5 ± 0.5
II	Cortisone and fasting	0.5 ± 0.16
III	D.C.A.	7.7 ± 0.36
IV	D.C.A. and fasting	5.5 ± 0.34

It will be noted that, in itself, the small dose of cortisone given to these animals failed to suppress exudation (Group I). Yet it caused almost complete inhibition of inflammatory fluid formation in the fasted animals (Group II). On the other hand, the rats maintained with D.C.A. developed considerable amounts of exudate, whether they were otherwise untreated (Group III) or exposed to starvation (Group IV).

It may be concluded that, although fasting has little or no effect upon exudation in adrenalectomized animals maintained with D.C.A., it considerably augments the antiphlogistic effect of cortisone. This augmentation is manifest in the absence of adrenal tissue—that is, under conditions when the stress of starvation could not act by stimulating the production of endogenous corticoids.

Second Experiment: The Effect of Restraint (Neuromuscular Stress) Upon the Topical Actions of Croton Oil in Intact and in Adrenalectomized Rats

The second experiment was performed on two groups of ten intact and two groups of ten adrenalectomized rats. Their treatment is summarized in Table II. A compar-

TABLE II.—Effect of Systemic Stress (Immobilization), in Intact and in Adrenalectomized Rats, Upon Topical Actions of Croton Oil

Day	Group I	Group II	Group III	Group IV
1	0.5% Croton oil	0.5% Croton oil	Adrenalectomy 0.5% Croton oil	Adrenalectomy 0.5% Croton oil
4	Exudate: ++	Exudate: 0	Exudate: ++	Exudate: ++
7	Exudate: ++	Exudate: 0	Exudate: ++	Exudate: ++
8	Exudate: ++	Exudate: 0	Exudate: ++	Exudate: ++
15	Necrosis: 10%	Necrosis: 100%	Necrosis: 10%	Necrosis: 90%

tively dilute croton-oil solution was introduced into the cavity of each granuloma pouch at the beginning of the experiment. On the fourth day one of the intact and one of the adrenalectomized groups were exposed to the neuro-muscular stress, occasioned by forced immobilization (as outlined in the introductory section of this paper). On the 15th day the exudate content of the pouches was measured after aspiration into a graduated syringe, and the mean value so obtained is shown in the Table.

Perusal of Table II indicates that a large amount of exudate was formed in the non-stressed intact (Group I) and adrenalectomized (Group III) rats, while no trace of exudate could be demonstrated in the intact stressed animals (Group II). In the adrenalectomized stressed rats (Group IV), exudation was reduced by about 50% as compared with the adrenalectomized non-stressed controls.

Evidently, under these circumstances, stress proved to be a very effective antiphlogistic factor in intact animals. In the adrenalectomized rats the inhibitory effect of stress was still very obvious, but not as marked as in intact rats. This was so despite the fact that threshold amounts of cortisol were administered to all groups. Previous experiments had shown that, in adrenalectomized rats maintained with D.C.A. (which has no antiphlogistic properties), systemic stress of this kind causes virtually no inhibition of inflammation (Selye, 1954); hence it was postulated that two factors may be involved in this effect: (1) an increased discharge of endogenous antiphlogistic corticoids (which can occur only in the intact stressed rats); and (2) a peripheral synergism between the corticoids so liberated and some non-adrenal-mediated effect of stress.

It was then decided to perform a third experiment, with a still more dilute croton-oil solution, to see whether its exudate-forming action could be completely inhibited by systemic stress even in adrenalectomized rats if they are maintained on threshold doses of cortisol. At the same time, in this last experiment we wanted to test the resistance of the granuloma-pouch wall to the necrotizing action of more concentrated croton oil, given at a time when the non-stressed rats had already developed a strong granulomatous barrier. Such an experimental arrangement would permit the assessment of the functional value of

granuloma tissue as a barrier against the production of necrosis in adjacent tissues (in this case the skin).

Third Experiment: The Effect of Restraint (Neuromuscular Stress), in Intact and in Adrenalectomized Rats, Upon the Topical Actions of Weak and Strong Croton-oil Solutions Respectively

In this experiment we used two groups of ten intact and two groups of 20 adrenalectomized rats. They were treated as outlined in Table III. A weak croton-oil solution was introduced into the cavity of each granuloma pouch on the first day of the experiment. Then one of the intact and one of the adrenalectomized groups was exposed to the stress of immobilization during the “critical period.” The degree of inflammation was first estimated on the seventh day by transillumination of the pouches. Subsequently, on the eighth day, a strong (normally necrotizing) croton-oil solution was injected into the pouch cavity, and the incidence of skin necrosis was noted on the 15th day.

TABLE III.—Effect of Systemic Stress (Immobilization), in Intact and in Adrenalectomized Rats, Upon Topical Actions of Weak and Strong Croton-oil Solutions Respectively

Day	Group I	Group II	Group III	Group IV
1	0.25% croton oil	0.25% croton oil	Adrenalectomy 0.25% croton oil	Adrenalectomy 0.25% croton oil
4	Exudate: ++	Exudate: 0	Exudate: ++	Exudate: ++
7	Exudate: ++	Exudate: 0	Exudate: ++	Exudate: ++
8	Exudate: ++	Exudate: 0	Exudate: ++	Exudate: ++
15	Necrosis: 10%	Necrosis: 100%	Necrosis: 10%	Necrosis: 90%

It will be noted that, under these conditions, stress prevented inflammatory exudate formation not only in intact rats (Group II), but also in those adrenalectomized and maintained with comparatively small doses of cortisol (Groups II and IV). On the other hand, large amounts of exudate had formed both in the intact (Group I) and in the adrenalectomized (Group III) non-stressed rats, although they received the same amount of cortisol as the others. Thus the findings on the seventh day confirmed the observations of the first and second experimental series, under slightly modified circumstances.

Interestingly, the subsequent injection of strong croton oil caused necrosis of the skin in all the intact stressed (Group II) and in 90% of the adrenalectomized stressed (Group IV) rats, while all but 10% of the intact (Group I) and of the adrenalectomized (Group III) non-stressed rats resisted this necrotizing action of the strong topical irritant.

It may be concluded that, here, the same stressor, which protected against the local disease-manifestations (exudation) usually produced by a weak topical irritant, actually sensitized the tissues to the more severe damage (necrosis) normally elicited by higher concentrations of the same local pathogen. It is also evident that a transitory exposure to systemic stress on the fourth day considerably altered tissue-reactivity to local irritants introduced into the pouch, either before or after this time.

Discussion

Let us now consider the information which these experiments have furnished concerning the much-debated points enumerated in the introduction.

The first experiment gives objective evidence in support of what I have called the “antiphlogistic-corticoid-conditioning effect (A-CC)” (Selye, 1953b; Selye and Horava, 1953). Adrenalectomized rats maintained with small doses of cortisone are still capable of responding to topical injury by intense inflammatory exudation. If these animals are exposed to the stress of fasting they lose this ability. Here starvation obviously could not have acted by increasing endogenous corticoid secretion, since the rats had no adrenals, yet the animals, by the withdrawal of food, were conditioned for the antiphlogistic effect of exogenous antiphlogistic corticoids.

On the other hand, under similar circumstances, adrenalectomized animals maintained with D.C.A. (a steroid

devoid of antiphlogistic properties) retained their ability to produce inflammatory exudate even during prolonged starvation. Hence the inhibition of inflammation by food withdrawal cannot be the unconditional direct effect of inanition as such.

The adrenalectomized rats of the second and third experimental series showed that this antiphlogistic conditioning potency is not a specific characteristic of starvation, because it can be duplicated by an entirely different kind of stressor—namely, the neuromuscular exhaustion resulting from forced immobilization. These same animals also demonstrate that cortisone is not the only antiphlogistic hormone whose activity can thus be augmented by stress, since they were maintained on cortisol.*

The probable mechanism of these responses to systemic and topical stress is illustrated by the accompanying schematic drawing.

Another point illustrated by the second and third experiments is that tissue reactivity to topical damage can be altered not only during, but even several days after, exposure to a transitory period of systemic stress. The delayed susceptibility (predisposition for necrosis) or refractoriness (resistance to inflammation) to disease, which is thus produced by stress, depends upon endogenous corticoids, since it is not seen in the absence of the adrenals unless suitable substitution therapy is given.

Finally, the third experiment demonstrates that the same factor, stress, can both inhibit and facilitate the production of local disease manifestations, since it inhibits the phenomena of inflammation and aggravates those of necrosis.

These observations also help to understand the mechanism through which the biological reactions of systemic and local stress are integrated. The so-called “local adaptation syndrome” (L.A.S.), the characteristic triphasic adaptive response to topical injury, comprises both necrosis and

*It should be mentioned in this connexion that, in additional unpublished experiments, adrenalectomized rats were maintained on threshold doses of cortisone and injected with lyophilized thymic, lymphatic, and splenic tissue, or subjected to complete ligation of their main bile duct. These animals likewise showed complete inhibition of exudate formation in the granuloma-pouch test. Here, again, the inhibition could not have been due to the direct unconditional effect of the extracts or of biliary retention, since it was not manifest in adrenalectomized rats maintained with threshold doses of D.C.A. A variety of purified A.C.T.H. preparations (including “corticotropin-B,” kindly furnished by Merck and Co., Inc.) also proved highly effective in augmenting the antiphlogistic effect of cortisone in adrenalectomized animals. The question arises whether the various “A-CC agents” act through different mechanisms or through the intermediary of their ability to stimulate the A.C.T.H.-production of the animals’ pituitary. This point is now under investigation.

inflammation. It has been demonstrated and discussed at some length by several participants of the International Symposium on the Mechanism of Inflammation (Jasmin and Robert, 1953). The experiments reported in this paper furnish additional evidence in support of the view expressed at that Convention, that a close relationship exists between the general adaptation syndrome, as a systemic manifestation of stress, and the local adaptation syndrome, as its topical counterpart. In particular, local stress can cause systemic stress, and the latter can, in turn, greatly modify the course of the former. Indeed, various combinations of these two responses represent integral parts of many among the common maladies of man.

Our experimental model is directly concerned only with the role of the adrenals in determining the production of inflammation and tissue necrosis by a topical irritant, during systemic stress. However, inflammation, necrosis, topical irritants, and systemic stress are fundamental elements of most, if not all, maladies. Actually, there is no evidence to prove that any tissue damage (no matter where and no matter by what agent it be produced) would fail to be similarly regulated through the adrenals during the systemic stress of disease.

Summary

Using the granuloma-pouch technique, it was shown that, depending upon circumstances, systemic stress can either inhibit or aggravate the topical damage caused by exposure of a limited tissue area to a pathogen—for example, a chemical irritant, such as croton oil.

The antiphlogistic effect of stress is not merely due to increased secretion of cortisol-like hormones, since it is also observed in adrenalectomized animals maintained on (in themselves inactive) threshold doses of injected cortisol.

The aggravation of topical tissue injury by systemic stress also depends only in part upon endogenously produced adrenal hormones; it is abolished by complete adrenalectomy, but not if suitable substitution therapy with antiphlogistic corticoids (cortisone, cortisol) is given.

Both these effects of systemic stress upon topical tissue reactions can be delayed, becoming manifest only after the systemic stressor has ceased to act.

The interrelation between systemic and local manifestations of disease in general are discussed in the light of these findings.

This work was supported (in part) by the Medical Research and Development Board, Office of the Surgeon General, Department of the Army, Contract No. DA-49-007-Md 186, and by a Consolidated Grant from the National Research Council of Canada.

EXPERIENCES WITH A.C.T.H. AND CORTISONE

A NOTE ON LONG-TERM THERAPY

BY

EDWARD H. McGEHEE, M.D.

McCrae Fellow from the Pennsylvania Hospital,
Department of Medicine, Guy's Hospital

AND

KENNETH MacLEAN, M.D., M.R.C.P.

Assistant Physician to Guy's Hospital
From the Department of Medicine, Guy's Hospital

A.C.T.H. and cortisone have now assumed a most important place in the treatment of a number of diseases for which we could previously do little. The prognosis of the generalized collagen diseases, certain severe skin diseases, particularly pemphigus and acute exfoliative conditions, and several eye disorders has been improved at least from black to grey. To achieve success, however, treatment must usually be continued for indefinite periods, and with the limited supplies so far available this has presented a most difficult problem. Our results in the long-term steroid therapy of these patients at Guy's Hospital are briefly presented.

The first supplies, received in December, 1950, were only sufficient to treat five patients simultaneously. It was therefore essential that a central authority should arbitrate between the requests received from the various members of the hospital staff so that the best use might be made of the amount available. The department of medicine was asked to assume this duty. As soon as a request is received the patient is visited by a member of the department and the dose and method of administration are suggested according to the needs of the case and the current level of supply. While receiving treatment the patient is visited at least once a week, and further therapy is decided in consultation with the member of the staff in charge of the case. Clinical responsibility for the patient remains entirely with the consultant under whose care he had been admitted, and the consultant's wishes regarding dosage are followed as closely as the level of supply allows. If it is impossible to meet a request the circumstances are discussed personally with the consultant concerned.

At first it was decided that patients should receive a set course of approximately three weeks, during which time they were in hospital and under constant observation. Treatment consisted of cortisone, 100 mg. daily by intramuscular injection, or of A.C.T.H., by four intramuscular injections to a total daily dose of about 60 mg. Second courses were given only in exceptional circumstances. It soon became apparent that these drugs were life-saving in certain cases, that bigger initial doses were often necessary, and that maintenance therapy would have to be arranged. Thus a greater proportion of the slowly increasing supplies had to be allotted to long-term cases which required treatment after discharge from hospital.

In mid-1951, following the results of the clinical trial reported by Renold *et al.* (1951), we began to administer A.C.T.H. by the slow intravenous drip method. We found this most satisfactory, an adequate response usually being produced with a daily dose of 20 mg. or less. Thus our supply of A.C.T.H. was enough to treat

three or four times as many patients as when it was given intramuscularly in divided doses. Late in 1951 we received the first supply of oral cortisone tablets, and at the beginning of 1953 A.C.T.H. gel became available. These new preparations were used mainly for maintenance therapy.

Method

Our present practice is to treat patients receiving these drugs for the first time according to one of the following schemes: (1) 20 to 40 mg. of A.C.T.H. daily by intravenous drip for a minimum of eight and occasionally up to sixteen hours (McIntosh and Holmes, 1951); (2) 20 to 40 mg. of A.C.T.H. gel daily, given in a single intramuscular dose; (3) 100 to 200 mg. of oral cortisone daily in four divided doses; (4) 100 to 150 mg. of cortisone intramuscularly in a single daily dose. When it becomes apparent that the disease has been controlled—usually after seven to fourteen days—the daily dose of cortisone is reduced, or the A.C.T.H. is administered on alternate days.

Initially all patients had a chart showing output and intake of fluid, and eosinophil chamber counts were performed thrice weekly. Estimations of the serum sodium and potassium, the urinary 17-ketosteroid excretion, and the erythrocyte sedimentation rate were carried out weekly. We soon found that such detailed laboratory control was unnecessary, and our practice now is to do an initial serum sodium and potassium estimation, which is repeated only if intensive therapy is continued for more than two weeks or if the patient's clinical condition warrants. If the drugs are being given daily we restrict fluid intake to about 50 to 60 oz. (1.4 to 1.7 litres) in apyrexial patients. No added salt is allowed. The patient is weighed every second day and his blood pressure is recorded daily. Drinks with a high potassium content, such as Horlick's or “ovaltine,” are given, or capsules of potassium chloride to a total of 4 g. daily may be taken.

The diagnoses of 185 patients treated between December, 1950, and June, 1953, are given in Table I.

TABLE I

Endocrine Disorders	General Medical Disorders

With the exception of those suffering from endocrinological disorders, all received intensive therapy as inpatients in the first instance. The response of these patients accorded well with that to be expected from a study of the literature, which has been well summarized by Thorn *et al.* (1953). We do not propose, therefore, to analyse these results further, but the complications encountered seem worthy of mention. Three patients on A.C.T.H. had gastro-intestinal perforations (one ulcerative colitis, one polyarteritis, and one unsuspected peptic ulcer in a patient receiving treatment for rheumatoid arthritis). Two of these patients died, and we wish to emphasize the way in which A.C.T.H. or cortisone may mask the classical early symptoms of an abdominal emergency. Three patients developed acute psychosis necessitating removal to a psychiatric unit; two of these gave a history of previous mental illness. Two patients (one nephritic, one terminal polyarteritis nodosa) died in uraemia, but death seemed inevitable before steroid treatment. One patient with polyarteritis nodosa developed

steroid diabetes. Further reference is made to this case. Minor complications included abscess at an injection site (four cases), A.C.T.H. sensitivity (one case), hypokalaemia with asthenia (one case), and occasional mild depression. Purulent bronchitis, sinusitis, and minor hand infections seemed to occur much more often than in the rest of the hospital population, and called for immediate antibiotic treatment. Special complications developing during long-term maintenance therapy are discussed under the appropriate sections.

Maintenance Therapy

Table II gives a list of 44 patients whose condition appeared to merit long-term out-patient therapy.

TABLE II

Note.—Discrepancies between the members in this group and those in Table I are due to numerous factors—death, distance from hospital, continued care under private physician, etc.

Endocrine Disorders

The patients in the endocrinological group have been maintained on oral cortisone under the supervision of Dr. P. M. F. Bishop and have been seen regularly at the endocrinological out-patient department.

Since October, 1952, the patients with Addison's disease have been maintained on 12.5 mg. of cortisone by mouth daily and periodic D.C.A. implants. In addition to the daily dose of cortisone, each patient is supplied with an emergency ration of 100 mg. of cortisone and 3 g. of oxytetracycline ("terramycin") which is for immediate consumption in case of sudden appearance of untoward signs—severe infection of any kind, vomiting, fever. Patients are instructed to report to hospital as soon as possible for further care on these occasions. So far the general health of these patients has been better than when they were maintained on D.C.A. implants alone. Their cases will be reported in full at a later date.

Four patients with hypopituitarism have been given cortisone as daily maintenance treatment, with good response to 12.5 mg. a day in two. A poor result has been obtained in the other two; one of these failed to respond to as much as 50 mg. a day.

The single case of congenital adrenal hyperplasia has responded well to daily doses of 25 mg. of cortisone as reported by Wilkins *et al.* (1951). Her 17-ketosteroid output has decreased and there was commencing breast development.

Non-endocrine Conditions

The remaining cases have been followed at a regularly scheduled out-patient session. This permits regular examination and laboratory follow-up when necessary. Patients who are on treatment are seen weekly or fortnightly; others slightly less often.

Maintenance therapy, in order of frequency of use, has consisted of: (a) 20–35 mg. of A.C.T.H. administered intravenously over an eight-hour period twice or three times weekly. (b) Combinations of one or two intravenous infusions as above and one or two intramuscular injections of 20 mg. of A.C.T.H. gel, so that patients received the equivalent of two or three days' prolonged adrenal cortical stimulation. (c) Combinations of intravenous A.C.T.H.

drips two or three times a week and 50–100 mg. of cortisone, in divided oral doses, on one, two, or three of the off days. (d) Oral cortisone tablets in divided doses.

Our findings are in line with those of Thorn and others in that 20–40 mg. of A.C.T.H. gel is as effective as an eight- to ten-hour drip of 20–40 mg. of lyophilized A.C.T.H. Only small supplies of gel were available during the period of this review.

If intravenous therapy is ordered, the patients arrive about 9 a.m., weigh, urinate, and then sit in comfortable armchairs to receive the drip, which usually finishes between 5 and 6 p.m. This is more convenient for reading, eating, and chatting with fellow "drips," and makes it possible to bring these patients into a busy hospital ward without overcrowding or disrupting the usual order of business. No patient has registered dissatisfaction at the use of armchairs; in fact, most of them have expressed a definite preference for the chair versus the bed.

During this long-term out-patient therapy we have used the clinical laboratory rather sparingly, not attempting any extensive metabolic follow-up. Serum sodium and potassium levels have been carried out weekly or fortnightly. Occasional blood counts, urinalyses, blood sugars, chest films, sedimentation rates, serum protein determinations, etc., have been performed as necessary. Antibiotics (particularly depot penicillin or oxytetracycline tablets) have been prescribed freely whenever there has been evidence of infection. Potassium chloride has been taken by all long-term patients in 3- or 4-g. amounts depending upon their serum levels. The decision to terminate steroid treatment has been reached arbitrarily in discussions with the original consultant. Criteria have varied with the different diseases, but, in general, the key point has been that the patient's condition must have been static for four to eight weeks. Treatment was restarted at the first conclusive evidence of relapse, and has usually produced a response adequate enough to obviate admission to hospital.

Results

Polyarteritis Nodosa

Three patients were referred to the follow-up clinic; reports on them are given below.

Case A.—A woman of 35 was desperately ill when cortisone therapy was begun. She had been asthmatic for some years and was admitted in congestive heart failure with pulmonary infection and intense bronchospasm. There was a scaly rash on forehead and cheeks, her urine contained albumin and red cells, and there was a 25% blood eosinophilia. One month earlier she had had an acute pneumonic episode which had responded to penicillin. Intramuscular cortisone (100 mg. twice on the first day and subsequently once daily) was given together with chloramphenicol. Improvement was rapid, although the oedema persisted in spite of mersalyl injections. Cortisone was stopped after three weeks in order to produce a diuresis. She relapsed almost at once and developed a mononeuritis multiplex. Cortisone was reinstituted, and the daily dose was then gradually reduced to 37 mg. orally; she then again began to go downhill and was given intravenous A.C.T.H. therapy. She has had continuous steroid therapy for 16 months and is at present well and able to perform the normal duties of a housewife. She is subject to occasional asthmatic attacks and still has a mild tachycardia. She continues to receive A.C.T.H., 20 mg. either as gel or by intravenous drip on three days a week and 100 mg. of oral cortisone at week-ends. Any attempt to reduce this dosage is almost immediately followed by a recrudescence of her disease.

Case B.—A man of 52 had a history of a pyrexial illness with marked loss of weight for eight months. He had had a haemoptysis, and serial x-ray films showed patchy transient consolidations in various parts of the lung fields. There were raised purpuric plaques over the hands and legs. He was hypertensive, and the urine contained albumin and casts. Occasional specimens showed glycosuria, but glucose-tolerance tests before and during steroid therapy were normal. Intravenous A.C.T.H. (20–30 mg. daily) was started, and after six weeks this was reduced to 10 mg. three times a week, with 25 mg. of oral cortisone on other days. Within three weeks he developed severe conjunctivitis, and purpura returned on the legs. Increasing the intravenous dose of A.C.T.H. to 25 mg., and then to

40 mg., two or three times a week did not prevent a slow deterioration, and he was readmitted for a month's intensive therapy with daily A.C.T.H. (20–25 mg. by intravenous drip or as gel). He improved greatly and after a further month in hospital, during which he received similar treatment on alternate days, he was discharged in complete remission. He has had out-patient A.C.T.H. treatment three times a week since and also continuous cortisone (100 mg. daily) but his purpura has again returned and the sedimentation rate, normal on discharge, has risen to 74 mm. in one hour (Westergren). He has, however, had little constitutional disturbance. Improved supplies of gel have enabled us to give him A.C.T.H. daily as an out-patient and he is again improving. Ten months after steroid therapy was started it was certain that neither 100 mg. of cortisone daily nor 20 mg. of A.C.T.H. three times a week (by intravenous drip or gel) would keep his disease fully controlled. This case has already been reported in full (Baker, 1953).

No spontaneous remission has therefore been produced in either Case 1 or Case 2 over sixteen and ten months respectively.

Case C.—A man of 45 had had a pyrexial illness for three months with polyarteritis, hypertension, and mild renal involvement. He then developed a patchy peripheral neuritis and his blood showed a mild eosinophilia. He was treated with intravenous A.C.T.H., 20–30 mg. daily, for two weeks and then on alternate days for a similar period. He made a complete recovery apart from slight residual paraesthesia and has been followed for a further five months without any sign of relapse.

Special Complication.—During the four weeks the third patient received A.C.T.H. he developed diabetes. This is said to be rare (Jenkins, 1953). Glycosuria had been found on several occasions before treatment, and two glucose-tolerance tests showed curves of the "lag" type. During treatment he lost 5 lb. (2.3 kg.) in weight in spite of obvious clinical improvement. All specimens of urine showed a brick-red reduction of Benedict's solution at this time. A third glucose-tolerance test, a week after treatment had finished, showed a severe diabetic response, but a further test a week later was almost normal. No glycosuria has been found at out-patient attendances since. At no time did he receive insulin. Results of the glucose-tolerance tests are shown in Table III.

A.C.T.H. therapy was given from February 5 to March 6.

Disseminated Lupus Erythematosus

Two patients in whom the diagnosis has been confirmed by the demonstration of L.E. cells have been followed.

Case D.—A girl of 19 was admitted in May, 1951, severely ill with high pyrexia, polyarthritides, and the typical butterfly rash. She had had two previous acute episodes—the first in 1947, when she was in hospital for eight months with joint involvement and pericardial and pleural effusions, and the second in 1949, polyarthritides being the predominant symptom. She received intramuscular A.C.T.H. (50–80 mg. daily in four divided injections) for three weeks in June, 1951, but this was only partially successful in limiting the disease. Five weeks later a second course was started, the total daily dose being increased to 150 mg. At first she responded well, but in the third week an injection abscess caused her temperature to rise again. A.C.T.H. was stopped after 24 days and treatment by surgical incision and antibiotics was started. She improved steadily after this, and was discharged in September feeling well, although she still had a low-grade pyrexia and a high E.S.R.

A satisfactory remission continued for nine months, when high fever, anaemia, and arthritis returned and she was readmitted again severely ill. A.C.T.H. intravenous drips (45 mg. reduced gradually to 20 mg.) were given daily for three weeks and then oral cortisone, 75 mg. a day, was substituted. Her response to the A.C.T.H. had been excellent, but she lost ground during the

six weeks she received oral cortisone, low-grade pyrexia and joint swelling returning. A.C.T.H. drips twice a week (50 mg.) were started, with cortisone, 25 mg., on the other days. This completely controlled her symptoms and she was discharged on out-patient treatment. The cortisone was omitted after two more months, and she received two intravenous A.C.T.H. drips (25–40 mg.) a week with a third injection of A.C.T.H. gel (20 mg.) on an intermediate day. On this regime she has felt better than at any time since 1947 and is completely afebrile. The E.S.R., however, remains moderately raised. Steroid therapy was stopped at the beginning of July, 1953, and she remained completely well, although there has been a further increase in the E.S.R. (from 40 to 77 mm. in one hour). It is of interest that in February, 1953, while in remission on maintenance steroid therapy, she developed vertigo. Without alteration of treatment the vertigo disappeared in three weeks, while the nystagmus has persisted in diminishing intensity since. Electroencephalograms were performed during the vertiginous period and for four months afterwards. The former showed long periods of slow and fast activity, with spikes and waves on overbreathing and photic stimulation which were interpreted by Dr. D. A. Pond as being somewhat similar to those seen in epilepsy. Epileptiform seizures are now well recognized in disseminated lupus erythematosus (Sedgwick and Von Hagen, 1948; Russell *et al.*, 1951). The latter tracing was regarded as approximately normal. This patient noticed some menstrual irregularity during her prolonged course of maintenance therapy.

Case E.—A woman of 35 had had several previous attacks of joint swellings associated with lesions of the fingers originally diagnosed as chilblains. These occurred when she was 13, 21, 23, 27, and 34 years of age. They seemed to respond to gold therapy, and she was well in between the attacks. Six months before her admission to Guy's in May, 1951, she experienced severe generalized joint involvement and the rash appeared on the arms and face for the first time. She rapidly became very ill, with a high pyrexia. Intramuscular A.C.T.H. therapy (50–100 mg. in four divided doses) was given daily for four weeks and then it was changed to a daily dose of 100 mg. of intramuscular cortisone for a further three weeks. A complete remission was produced, although a low-grade pyrexia returned two weeks after stopping treatment. For the next 18 months she remained in partial remission, but her skin never completely cleared and she had bouts of low-grade pyrexia and joint involvement. In the spring of 1953 she began to relapse rapidly and was readmitted. She received A.C.T.H. gel daily for one week, followed by a similar dose on alternate days for a fortnight. Complete remission occurred, and she was discharged on out-patient treatment at the end of May. For two months she received cortisone (75–100 mg. orally) daily for two weeks each month. She lives too far away to make drip therapy practicable. She is moderately well, but relapses during the weeks off treatment.

While the spontaneous remissions and exacerbations in these two patients make it difficult to assess the value of maintenance therapy, it seems that their disease has reached a stage when steady deterioration is to be expected in the absence of steroid therapy, and that they will be able to lead active lives only if this is continued indefinitely. It has certainly proved dramatic in combating the acute stages of the disease.

Subacute Collagen Disease

A woman of 47 was admitted in November, 1952, with pyrexia, polyarthritides, and pericarditis of one week's duration. There was no previous history of rheumatic fever. The E.S.R. was 130 mm. in one hour, the blood showed an eosinopenia and the serum albumin was reduced. She had no rash, however, and marrow study failed to reveal Hargreaves cells. The diagnosis is still uncertain. Salicylates produced no improvement, but she rapidly responded to a daily intramuscular injection of cortisone (100 mg.). This was gradually reduced until after six weeks she was receiving 25 mg. orally when she relapsed. Intravenous A.C.T.H. produced immediate response, and she was discharged to out-patient treatment on three drips a week, which was later changed to cortisone, 75 mg. orally daily. She was so well that after five months all steroid therapy was stopped. Within a week the E.S.R. had risen from 15 to 84 mm. in one hour, and a few days later symptoms of pericarditis returned. These immediately disappeared when drip A.C.T.H. therapy was restarted, and she was then well and about to return to out-patient maintenance treatment. It appears that she will require continuous treatment for an indefinite period.

Scleroderma

We found A.C.T.H. or cortisone of little value in the far-advanced cases with visceral involvement and marked contractures, so that in such patients no attempt at prolonged maintenance therapy was made. Five patients with early to moderate sclerodermatous changes have been followed up for from five to fourteen months. Each has obtained a good response to intensive courses of A.C.T.H. but have relapsed between courses, slipping further downhill with each relapse. Three have now received continuous out-patient treatment with A.C.T.H. for three, two, and two months, with encouraging results. Another has improved on oral cortisone intermittently for six months. The fifth patient, who lived too far away for regular maintenance treatment has benefited from frequent periods in hospital for monthly courses of treatment during the past year.

Scleroderma in its early stages would appear to demand the highest priority for A.C.T.H. or cortisone, and it seems likely that a programme of almost continuous treatment will be necessary. It is now our practice to give each new case an intensive course of A.C.T.H. therapy (20-30 mg. daily by drip or gel) for one month and then decide whether the improvement seen makes long-term treatment worth while.

Rheumatoid Arthritis

The shortage of supplies has enabled us to undertake long-term treatment on only one patient with rheumatoid arthritis, and no conclusions can be drawn from this single case.

Pemphigus

Of the nine patients with pemphigus who received steroid therapy, six were subsequently referred for long-term treatment. Details of these cases are given in Table IV.

(Cases 3 and 4) occurred while the patients were receiving 50 mg. of oral cortisone a day. These patients have at all times responded to A.C.T.H. gel or intravenous drip, a daily dose of 20 mg. usually being adequate, although it has been necessary to give as much as 40 mg. for the first few days. Once the disease has been brought under control no relapse has occurred while the patients have been receiving three injections of 20 mg. of A.C.T.H. a week either as gel or by intravenous drip.

If cortisone is to be used in the treatment of pemphigus, therefore, a daily dose of 300 or 400 mg. may be necessary, and we consider that A.C.T.H., given either as gel or an intravenous drip, is the most economical method of treatment.

The longest remission so far obtained without treatment is nine months (Case 1), while two patients (Cases 2 and 6) are still well six and three months after the cessation of steroid treatment.

Special Complications.—As might be expected when treatment with high doses has to be continued for long periods, two of these patients developed many "Cushingoid" features, but these regressed slowly when treatment was interrupted.

Exfoliative Psoriasis

Two cases which had been treated with most of the widely used remedies were thought severe enough to warrant steroid therapy. Both responded remarkably to daily intravenous A.C.T.H. over periods of three to six weeks. After that, one was just barely maintained for two and a half months with a few skin plaques on three prolonged drips a week; when treatment was stopped he relapsed completely in three weeks, and required another intensive course for two weeks before reaching a point where out-patient main-

TABLE IV

Case No.	Sex	Age	Diagnosis	Condition before Treatment	Months since Initial Therapy	Longest Remission (Months)	Condition on July 31, 1953
1	F	53	<i>P. vulgaris</i>	Generalized pemphigus of mouth and body. Dangerously ill	25	9	On treatment. Very well. Occasional oral blisters
2	F	61	" "	Oral blisters; conjunctivitis. General condition fair	21	6	No treatment. Very well. Occasional oral blisters
3	F	55	" "	Oral blisters. General condition fair	18	3	On treatment. Well and working. Occasional blisters
4	F	52	" <i>ollicus</i>	Generalized pemphigus; heart failure. Dangerously ill	12	4	Well but lesions relapsing on face (retreated 10.8.53)
5	F	75	" <i>vegetans</i>	Oral blisters; crops starting on body. Moderately ill	9	0	On treatment. Vegetans lesions still present on face. Constitutionally well
6	F	69	" "	Generalized pemphigus; vegetans lesions on neck. Dangerously ill	8	3*	Very well. Occasional blister. No treatment

* Remission continuing.

Three of these six were critically ill when treatment was started, while the remainder, although having less constitutional disturbance, had extensive oral lesions which seriously affected nutrition. Skin lesions were present in all cases. They have been followed up for periods varying from eight to twenty-five months, and five of the six are leading full active lives with no more disability than an occasional blister. The sixth (Case 5) developed crusted "vegetans" lesions over most of the face which harboured *Staph. aureus* infection. These have so far resisted all attempts at steroid and antibiotic therapy. She is, however, constitutionally well, and new blister formation has been prevented. Since without steroid therapy all these patients would almost certainly be dead, pemphigus is obviously an absolute indication for prolonged treatment with A.C.T.H. or cortisone.

Two cases (1 and 4) were initially controlled by daily intramuscular doses of 200-300 mg. of cortisone for three days followed by 100 mg. Case 2, however, showed no improvement on 100 mg. of intramuscular cortisone daily for ten days, while a relapse of Case 3 failed to respond to 200 mg. of cortisone daily. Furthermore, two relapses

tenance was again feasible. As two more months of high doses of A.C.T.H. three times weekly plus cortisone tablets at the week-end failed to prevent slow deterioration, all steroid therapy was abandoned for a trial period.

The other patient was admitted with widespread psoriasis and pneumonia. Treatment with antibiotics preceded the use of A.C.T.H. by about a week. Response was excellent while in the ward, but out-patient maintenance was hampered by her requirement of large quantities of A.C.T.H. and by irregular attendance due to personal affairs. Eventually her steroid treatment was discontinued.

Complications.—After receiving pig A.C.T.H. for a period of three and a half months, the first patient with psoriasis began to suffer with widespread angioneurotic oedema following and/or during intravenous administration. This was the only drug he was receiving at the time. Skin tests were negative. Treatment was stopped until ox A.C.T.H. could be obtained; during his two months' treatment with this he encountered no difficulty. From our experience with these two patients we do not consider that steroid therapy is indicated in the long-term treatment of exfoliative psoriasis, although it may be of great value in tiding over

the acute exacerbations which occur from time to time. These patients required greater quantities of A.C.T.H. to suppress their disease adequately and continuously than did any other group treated. The maintenance dose of cortisone required was never determined, but it seems certain that it exceeded 100 mg. a day.

Chronic Non-granulomatous Uveitis

These cases usually are well controlled for long periods on small (25 mg.) daily doses of cortisone by mouth. All four patients have responded to steroids administered in various methods, including cortisone by subconjunctival instillation or drops. Relapses, occurring while patients were receiving local applications, have responded to systematic administration. An occasional seven- to ten-day period of intensive A.C.T.H. therapy has been followed by relatively long symptom-free periods. One patient was maintained completely symptom-free for three and a half months with two A.C.T.H. drips a week. Following cessation of treatment she went two months before misty vision and ocular discomfort returned. She then responded to small doses of oral cortisone.

Choroiditis, Non-specific

Two patients have been given intensive courses of A.C.T.H. and a two-months follow-up on out-patient steroid treatment. Most of the improvement took place during the first three weeks of treatment. There has been no evidence of relapse in five months since treatment was stopped in one; after three months the other patient noted some return of visual symptoms which responded to oral cortisone (25-50 mg. daily).

Discussion

The continued satisfactory response to A.C.T.H. and/or cortisone two or three times a week of these patients with disseminated lupus erythematosus, polyarteritis, scleroderma, choroiditis, and chronic non-granulomatous uveitis deserves emphasis. Similarly, in accordance with Lever's (1953) findings, five of our patients with pemphigus have shown excellent response to prolonged therapy; when relapse has occurred two weeks to nine months after cessation of steroid treatment, reinstitution of treatment has quickly produced regression of lesions. The least satisfactory results have been achieved in the two patients with exfoliative psoriasis who required larger doses of drug more frequently. This was mentioned by Lever (1951). In addition, each of these patients had some associated emotional factors which have been found to be so important in severe psoriasis.

This method of out-patient management offers several worthy features: maintenance of the patient's self-confidence, outside contacts, and home life; continued, rather close, observation by the physician; a tendency to lessen the prolonged stimulatory effects (Ingle, 1950; Gordon *et al.*, 1951) of A.C.T.H. and A.C.T.H. gel (Frazier, 1953) and the adrenal hypoplasia resulting from prolonged cortisone administration (Forsham *et al.*, 1950; Sprague *et al.*, 1950); and it diminishes the cost of the drugs per patient and makes more hospital beds available.

The outstanding lament sounded repeatedly in articles describing the remarkable results obtained with A.C.T.H. and cortisone in diseases of the type mentioned here is their temporary nature, due to the cost of the drug used, the accumulating untoward side-effects, and problems of administration in the case of A.C.T.H. Intermittent dosage as used by Lever and described above seems to be a partial answer to these difficulties and seems worthy of general trial. Russell *et al.* (1951) mentioned intermittent treatment with lyophilized A.C.T.H. intramuscularly on a follow-up basis in some of their patients with disseminated lupus. However, they did not elaborate on the details of treatment or their results. Slow intravenous drip therapy can be offered to out-patients effectively on an intermittent

schedule with little inconvenience to any of the parties concerned—patients, ward nurses, or physicians. A.C.T.H. gel has likewise been used satisfactorily on intermittent-dosage schedule in amounts equivalent to that (lyophilized) used for one intravenous drip. The advantages of a single intramuscular injection which can be given by the patient's own doctor are obvious. Recently the supplies of gel have increased substantially, and it seems that this will be the ideal method for continuous steroid therapy. Patients need attend hospital only for assessment and regulation of dosage at weekly or biweekly intervals, so that many will be enabled to return to work, which was impossible while the necessity for regular intravenous drip therapy continued.

Summary

A brief review of cortisone and A.C.T.H. therapy at Guy's Hospital from December, 1950, to July, 1953, is presented. In the early stages, set courses, generally of three weeks' duration, were given, the various dosage schemes of which are described. The diagnoses of the 185 patients who received treatment are tabulated.

Complications encountered included three cases of gastro-intestinal perforation with two deaths, three psychotic episodes, and one case of steroid diabetes. Four abscesses occurred at an injection site.

It soon became apparent that maintenance therapy was going to be essential in many cases, and the long-term treatment of 44 patients is discussed. Eighteen of these were suffering from Addison's disease or pituitary dysfunction, and these were supervised at the endocrine clinic by Dr. P. M. F. Bishop. The remaining 26 cases were diagnosed as follows: polyarteritis nodosa (3); disseminated lupus erythematosus (2); subacute collagen disease (1); scleroderma (5); rheumatoid arthritis (1); pemphigus (6); exfoliative psoriasis (2); eye conditions (6). The manner in which these patients were treated as out-patients and their subsequent progress are described in detail. The results obtained proved highly satisfactory. Many patients entered a phase of remission enabling treatment to be stopped, at any rate for a time. The two patients with exfoliative psoriasis responded poorly, although the acute phase of the condition was greatly helped temporarily.

The manner in which limited supplies of A.C.T.H. may be conserved by the use of slow intravenous drip therapy is stressed.

We should like to thank the physicians under whose care the patients were admitted for the help and co-operation we received from them. In particular we should like to thank Dr. E. J. Moynahan under whose care four of the pemphigus cases were admitted. He proposes to publish these in greater detail at a later date.

NYSTAGMUS IN OTHERWISE NORMAL COAL-MINERS

BY

R. C. BROWNE, D.M., M.R.C.P.

AND

I. FLORA BECK, A.M.I.A.

(From the Nuffield Department of Industrial Health,
King's College, Newcastle-upon-Tyne, University of
Durham)

For years the popular opinion of coal-miners' nystagmus has been that it is a psychological disease and that the men are hysterical, anxious, obsessional, pathologically truculent, or, indeed, doubtfully genuine (Culpin, 1932). Moreover, Halliday (1948) has implied that the disease is "psychosocial." On the other hand, a previous study (Browne *et al.*, 1950) suggested that miners who develop the disease are very much like those who do not. In the first comparison the men were certified in 1942, and in the second, which is described in this paper, in 1950, so that any reproducibility of the main results after a period of eight years and in different groups of men may lend some weight to the original conclusions.

The problem in this disease is to apportion the cause between the physical conditions of the miner's work and the psychological and social setting of his life.

The Method

Fifty consecutive cases from County Durham were studied. In each case a certificate of disablement for the disease had been granted by the same certifying medical practitioner. They were matched with 50 normal men who were the controls, and who were chosen from the same 29 different collieries at which the men with nystagmus had been working when they were certified. These collieries were visited, and the names were selected at random from their office records to match, by age (so far as possible to the nearest decade) and occupation, the men with nystagmus who had worked there. All but three of the controls attended for examination; one of them developed nystagmus after his name had been selected, and the other two refused to come. One had "never been able to pull himself together" since his son was killed seven years before, and the mere thought of attending hospital upset him. The other was a man with a suspicious turn of mind who could not understand the method of selection.

A special clinic was instituted for this work, where the men were seen throughout by the same clinician, who took their medical and occupational histories and made a simple physical examination. They were also seen by an almoner, who inquired into their social background.

Results of Medical Study

Table 1 shows the number of miners in each decade and also the mean ages of the two groups. This was 52 years 8 months for the men with nystagmus, and 51 years 2

TABLE I.—*Number of Miners in Each Decade and Mean Ages of the Two Groups*

Age	No. of Miners	
	Nystagmus	Control
25-34 years	1	0
35-44 " " " "	9	12

65-74 " " " "	5	3
Mean age	52 8/12	51 2/12

months for the control group. The usual age of onset given in the literature is 45, and it therefore seems that the age of onset is tending to rise.

The previous illnesses of the two groups were almost identical (Table II). The term "nervous illness" includes psychological as well as neurological conditions, but only

TABLE II.—*Previous Illnesses*

two more of the men with nystagmus than of the controls complained of them. The pattern of complaints for digestive diseases, peptic ulcer separately, and skin disease is also about the same in both groups of men. However, the pulse rate (Table III) of the men with nystagmus tends

TABLE III. Summary of the Physical Findings

Average	Nystagmus	Control	Statistical Significance P
Pulse rate	79	71	< 0.005
Respiration rate	19	18	0.04
Blood pressure:			
Systolic (mm. Hg)	147	136	0.04
Diastolic (mm. Hg)	87	80	0.01
Height	66 in. (168 cm.)	67 in. (170 cm.)	
Weight	146 lb. (66.2 kg.)	150 lb. (68 kg.)	

to be a little higher than that of the controls, and the same tendency is shown by the respiration rate and the blood pressure. These are unlikely to be chance findings, but the values, even for the men with nystagmus, can hardly be regarded as abnormal. The heights and weights of the two groups are, however, much the same.

Results of Occupational Study

The number of years the two groups of men spent in various kinds of mining occupation is given in Table IV. It shows that the men who broke down with nystagmus had, on the whole, graduated to face-work earlier than had the controls. They had also served in the responsible position of deputy (or underground foreman) to a greater extent than the others. In the decade 15 to 24 the nystagmus men spent 3.3 years on face-work, but the controls only 2.2, and the next two decades show a similar trend. For the job of deputy in the decade 35 to 44 the men with nystagmus spent 0.7 year and the controls 0.5, and the figures for the next two decades (0.8, 0.7; 0.3, 0.1) are similar. Fewer absolute man-years were worked by the control group, but this is largely because there are three fewer men in it.

The type of lamp used by the two classes of men was not appreciably different (Table V), since both spent about 60% of their working lives in oil light, about 27% in hand electric, about 6% in a naked light, and about 6% with the modern type of electric lamp which fits on to the protective hat.

From the time of Snell (1892) it has always been thought that nystagmus was found more often among men who worked in low seams. It is not easy to find figures to support this, but it is indeed a reasonable supposition on clinical grounds, because oscillations of the eyes are elicited most easily either when a man is stooping or when he is looking up—both of which he has to do when the roof is not high enough for him to stand up straight, or low enough to force him to be on his face, side, or back. Table VI shows the heights in which the men worked.

TABLE VI.—*Heights in Which the Men Worked*

Height of Seam	Nystagmus		Control	
	Years		Years	
	No.	%	No.	%
Under 3 ft. (91 cm.)	257	22.8	337	31.8
3 ft.—4 ft. 11 in. (91–150 cm.)	519	46.0	332	31.3
Over 5 ft. (152 cm.)	352	31.2	391	36.9
Total	1,128	100.0	1,060	100.0

The nystagmus group spent about 15% more time in seams of 3 ft. to 4 ft. 11 in. (91 to 150 cm.), and consequently the less of its time in seams higher or lower than this. The odds against this connexion between nystagmus and working in this seam height being due to chance are less than one in a thousand ($\chi^2 = 37.0$. $P < 0.001$). There is therefore statistical support for Snell's original idea that nystagmus is found more often among the men who work in low seams. However, it is not the lowest seams that do the damage, but those of intermediate height, which cause the men to bend forward and look up at the same time.

Results of Social Study

Results of Social Study

Fourteen of the men with nystagmus and 17 of the controls were born and bred in the village in which they were living. Twenty-eight in each group came from elsewhere in County Durham, and only eight with nystagmus and two controls came from outside it, while all the men started their working lives within the area of the Durham coalfield (Table VII).

TABLE VII.—*Number of Men by Birthplace, Father's Job, and Their Own Preference for Work*

	Birthplace			Father's Job			Own Job Preference		
	Present Village	Other Village Same County	Elsewhere	Coal-miner	Other	Unknown	Coal-mining	Indifferent	Other
Nystagmus Control	14 17	28 28	8 2	41 42	8 4	1 1	21 15	19 20	10 12

Seven men with nystagmus and six controls had their early home life upset by the death of one or both parents, and one in each group had an acutely disturbed childhood deprived of normal parental care. But only one man in

each group spoke of childhood as an unhappy period; the man with nystagmus had finally run away to live with a sister; the control said that "drink was his father's downfall." All the other men in both groups appeared to have had normal home backgrounds. Varying degrees of poverty had been endured, but even when it had been "scrub and go" it did not seem to have blighted the home. Many of these men had gone short of clothes as children, but they had seldom gone short of food.

Most of them had taken it for granted that they would go into the pits as soon as they left school. Even those who had the offer of different work often chose the pits in order to remain with their schoolmates, and a few went into mining in spite of strong opposition from their parents. The range of youthful ambitions among those who would have preferred some other work was much the same in both groups. None seemed to have been strenuously opposed to the idea of mining.

Two of the men with nystagmus were under 20 when they married, and one was over 35. Five of them were single. Seventeen of the controls were under 24 when they married, 4 were over 35, and 2 were single, which represents only an insignificant difference between the two groups (Table VIII).

TABLE VIII.—*Number of Men by Age at Marriage and Type of House*

	Age at Marriage (Years)							Housing		
	— 20	21 — 24	25 — 29	30 — 34	35 +	Single	Unknown	Colliery	Council	Other Rented
Nystagmus... ..	2	21	15	6	1	5	0	19	19	7
Control	0	17	18	5	4	2	1	20	16	6

After marriage, most of them moved into a house of their own after a few months spent in rooms or with in-laws, and a waiting period of longer than a year was uncommon. Three in each group had to wait over five years before they could set up as a separate household, and one control had lived apart from his wife for six years until a house became available.

Two men with nystagmus and two controls were widowers. Two other men with nystagmus and one control had lost their first wives and married again later in life. One of the widowers with nystagmus had remarried, but had lost his second wife as well. One man with nystagmus and three controls mentioned other serious domestic tragedies. What was probably by far the heaviest emotional load had been carried by one of the controls whose wife had never fully recovered from a mental illness following the loss of her baby. One man with nystagmus whose wife "suffered with her nerves" may have had a rather difficult home background, and one other had a wife who was diabetic and probably had low social standards as well. There was no indication of severe matrimonial difficulties except in the case of one control who was separated from his wife.

Five men with nystagmus and two controls remained unmarried. One in each group lived in lodgings. The single man with nystagmus had been in the same lodgings for over 40 years. The control had changed lodgings twice in the past 27 years. One man with nystagmus was living by himself in his own bungalow. The other single men lived with relatives.

The homes were not visited, but only two men with nystagmus and one control said that their houses were in poor condition and overcrowded. There were no complaints from any of the others.

The men were asked what they liked doing in their spare time, and Table IX shows what they put first in their spontaneous answer, as well as the other activities which they

TABLE IX.—Leisure Activities

	Nystagmus		Control

Club and pub	3	4	5	7
Pictures	2	3	—	4
Reading	—	2	1	1
Doing nothing	4	—	8	—

mentioned. Twenty-one men with nystagmus and 19 controls liked gardening, though some of the nystagmus group had been forced to give it up because it meant stooping. Twenty-one in each group enjoyed watching football or other sports. These were the most popular spare-time occupations, but a variety of others, both active and passive, were mentioned. One man in each group spent most of his leisure time on trade union work. Twelve men with nystagmus and ten controls had three or more separate spare-time activities apiece. At the other end of the scale, nine men with nystagmus and twelve controls had scarcely any outside interests at all.

Two men with nystagmus and three controls seemed well below the average in intelligence. At the upper end of the scale there were some highly intelligent men in both groups, but the gradation to these from the rank and file was in small stages, and the differences could not fairly be judged subjectively. The general impression was that there was not much to choose between the two groups.

One man in each group combined high intelligence with an unusually strong and stable personality and an active interest in outside affairs. Among the other memorable characters was a man with nystagmus who summed himself up by saying that "the three best things in life are singing, dancing, and rearing flowers." One of the elderly controls, an original and enterprising man, was keen to discuss the history of wood-carving in various countries.

Two in each group were excitable and voluble men who seemed a good deal less stable than the rest. Four men with nystagmus and two controls were very negative in temperament, backward in social contacts, and lacking in drive. These include the two men who had spent most of their childhood in institutions; they both seemed also of limited intelligence and both had remained unmarried. Another of the single men with nystagmus is included here, and a married control whose wife managed all his affairs for him. But in both groups the majority of men were solid ordinary miners with no outstanding characteristics.

Discussion

To select a group of conditions with well-marked but relatively inexplicable signs and symptoms, and to call them

psychosomatic—as has happened in the case of coal-miners' nystagmus—is apt to have a number of results which are not always beneficial to the patients. Research into the physical aspects and prevention of the disease are impeded. Sooner or later it gets around among the people suffering from it that they are "neurotic" or "no good," and the same attitude is apt to infect both their employers and their doctors, with the result that once they are labelled or certified they are apt to drift without adequate medical management. The past history of coal-miners' nystagmus illustrates all these points. The pulse and respiration rates and blood pressures of men with this disease are higher than normal, and the reason for this is not immediately obvious. The previous study (Browne *et al.*, 1950) showed that five years after removal from the conditions which caused the disease their systolic blood pressures were normal, but their diastolic pressures were still significantly higher than those of the controls. On the other hand, as workmen and as family men they are not worse but, if anything, rather better than other coal-miners. Both investigations suggest that men who eventually contract the disease are, until this, rather better workmen than the others. This tends to support an opinion among mine managers that the disease attacks the more conscientious men. They live in the same sort of homes as other miners and have the same sort of interests. There is, however, a connexion between working in seams of intermediate height and the onset of the disease in susceptible men which appears to be unlikely to be due to chance.

It may perhaps be objected that the number of men seen is too small or the methods used are too coarse to display any differences between the groups. But if the test of life itself, so far as it can be simply measured, fails to reveal a difference between two groups of 50 men, they are surely, for practical purposes, identical. Workers (Ohm, 1916; Riesen, 1950; Browne, 1951) widely separated by both time and space have shown that nystagmus can be produced in animals, whose visual apparatus is analogous to that of man, by simply keeping them in the dark, and that they recover when replaced in the light. This finding, together with the repeated demonstration that men with and without nystagmus are alike in other respects, suggests the conclusion that the cause of the disease is somatic rather than psychological.

Summary

Fifty consecutive men with coal-miners' nystagmus, who were given certificates of disablement by the same certifying medical practitioner, are compared with 47 randomly chosen miners without the disease, matched in respect of age, detailed job, and colliery.

The medical histories, heights, and weights of the two groups were similar, but the men with nystagmus had slightly higher pulse and respiration rates and blood pressures. The nystagmus group did not suffer more psychological disease than the controls.

The men with nystagmus climbed their professional ladder a little more quickly and spent slightly more time at higher positions. They spent the same times in the different kinds of mine lighting, but had worked more in seams of medium height.

The men with nystagmus marry at the same ages, live in the same types of house, and have the same work preference and interests outside work as do men without the disease.

The results of this study confirm those of one made of men certified with the disease eight years before, and, when related to the experimental production of the condition, lend no support to the opinion that coal-miners' nystagmus is primarily a psychological rather than a somatic condition.

There is a relation between the development of the disease in susceptible men and working in coal seams of intermediate height—3 ft. to 4 ft. 11 in. (91 to 150 cm.).

Acknowledgments are due to the National Coal Board for an expenses grant, to the National Union of Mineworkers for help in the organization of the work, and especially to the miners who acted as the control group, many of whom made long journeys to come for examination.

TREATMENT OF PERNICIOUS ANAEMIA WITH ORAL VITAMIN B₁₂ WITHOUT KNOWN SOURCE OF INTRINSIC FACTOR

BY

J. N. M. CHALMERS, M.D., M.R.C.P., D.P.H.

AND

ZAIDA M. HALL, B.M., M.R.C.P.

(From the Haematology Department, St. George's Hospital and Medical School)

Several groups of workers have investigated the effect of orally administered vitamin B₁₂ in the megaloblastic anaemias. The majority of the reports have come from America, and include those by Berk *et al.* (1948), Spies *et al.* (1949), Hall (1950), Meyer *et al.* (1950), Conley *et al.* (1951, 1952), Glass *et al.* (1952, 1953), and Unglaub *et al.* (1954). British publications are those of Ungley (1950, 1951-2), and Girdwood (1953).

It appears from these reports that single oral doses of vitamin B₁₂ of less than 1,000 µg. have, in general, little effect, and that, while repeated daily doses of 50-100 µg. may cause some haematological response, the degree and length of improvement have been very variable. In some instances no responses were obtained. Spies and his colleagues concluded that a daily oral dose some 30 to 60 times that of a single intramuscular injection is necessary to obtain similar effect.

Ungley (1950) first showed that a single massive oral dose of 3,000 µg. of vitamin B₁₂ without any intrinsic factor was therapeutically effective in cases of pernicious anaemia

in relapse, and this was confirmed by Conley *et al.* (1951) and Chalmers *et al.* (1951). The haemopoietic effect of smaller doses of oral vitamin B₁₂ has been shown to be enhanced by giving it with normal gastric juice and other sources of intrinsic factor (see Ungley, 1950; Glass and Boyd, 1953; Latner *et al.*, 1953). Haematological responses have also been reported in cases of pernicious anaemia treated with oral aureomycin (Lichtman *et al.*, 1950), and oral and parenteral penicillin were found to be effective in the megaloblastic anaemias described by Foy *et al.* (1952). If the intrinsic factor present in normal gastric juice acts by protecting vitamin B₁₂ from utilization by intestinal bacteria, as was indirectly suggested by the work of Ternberg and Eakin (1949), these antibiotics may have increased absorption of the vitamin by alteration of the bacterial flora. Ungley (1950) tried to prove this by introducing vitamin B₁₂ into a washed portion and a partially sterilized portion of the intestines of patients with pernicious anaemia in relapse, but no responses were obtained.

In Ungley's investigations the patients were given oral doses of vitamin B₁₂ when fasting, and this condition was strictly observed in the following experiments, in which oral vitamin B₁₂, in amounts ranging from 9,000 µg. in a single dose to repeated daily doses of 50 µg., was administered without known source of intrinsic factor to cases of megaloblastic anaemia in relapse.

Material and Methods

Twelve of the patients studied were suffering from pernicious anaemia in relapse, with typical blood values, megaloblastic marrows, and histamine-fast achlorhydria. Three others had undergone gastrectomy, but resembled cases of pernicious anaemia in other respects, including their ultimate complete response to treatment with vitamin B₁₂. No free hydrochloric acid was found when test meals were attempted on these patients, and there were no symptoms or signs of steatorrhoea. Fat-balance studies were not made. Oral vitamin B₁₂ was given after different periods of observation to ensure that there was a maintained fall in pre-treatment blood-count values; Case 11, who was known to have suffered from pernicious anaemia previously and to have responded to parenteral liver extract, did not want treatment restarted "until it was necessary," and provided for us a prolonged period of control observation.

When in hospital, the patients were placed on a diet from which offal was excluded, with restriction of eggs, meat, milk, and cheese. Patients receiving single amounts of oral vitamin B₁₂ were given the dose when fasting at 9 a.m., and no food or drink was permitted for four hours afterwards. When daily doses were employed it was found convenient to give the vitamin at midnight, no food or drink being taken between the hours of 6 p.m. and 6 a.m.

Technical methods were the same as described previously (Chalmers, 1951), except that a photoelectric colorimeter with Thompson's grey standard, calibrated so that a recording of 100% was equivalent to 14.8 g. Hb per 100 ml., was used throughout.

Results

Effect of Large Single Doses of Oral Vitamin B₁₂

Haematological responses of Cases 1 to 7 are shown in Table I. Single doses of oral vitamin B₁₂ in saline given to the fasting patients resulted in prompt haematological improvement in six of them when the dose administered was 2,000 µg. or more. Sharp reticulocyte peaks on the fifth or sixth day compared well with the results obtained by us with single intramuscular doses of 20–100 µg. of the vitamin. With the exception of Cases 4 and 7, all satisfied the formula of Della Vida and Dyke (1942) in their average weekly red-cell gain.

While Case 4 almost reached this arbitrary standard, Case 7 showed only a slight increase in red cells and reticulocytes after an oral dose of 1,000 µg., and subsequently had a secondary reticulocyte response of 26.5% after a single intramuscular

FIG. 2.—Case 11. Results of treatment with oral vitamin B₁₂ alone over a period of 18 months.

injection of 200 µg. vitamin B₁₂ given on the tenth day of the experiment.

FIG. 1.—Case 11. Initial response following oral vitamin B₁₂ therapy.

Effect of Smaller Daily Doses of Oral Vitamin B₁₂
At the suggestion of Dr. W. F. J. Cuthbertson two patients suffering from pernicious anaemia in relapse were treated with oral vitamin B₁₂ in daily doses of 50 µg. combined with 0.2 g. of the surface agent polyoxyethylene sorbitan monolaurate ("tween twenty"), to see if this substance could act as an aid to absorption of the vitamin. No food or drink was taken for six hours before or after the dose was given, and the experiment was continued for 14 days. Significant clinical and haematological improvement occurred in both cases (Table II, Cases 8 and 9). Reticulocyte responses usually of a prolonged or "plateau" type were observed, the maximum levels being on the ninth and tenth days after the starting of treatment. The marrows became essentially normoblastic by the eleventh day.

Control experiments were then carried out on five further cases of pernicious anaemia in relapse, giving 50 µg. of oral vitamin B₁₂ without the surface agent for 14 days under the same test conditions. Equally good clinical and haematological improvement was obtained.

In one patient (Case 15) the same dose of the vitamin taken immediately after the midday meal showed much less clinical effect, although a small increase in red cells, reticulocytes, and packed cell volume occurred, together with some increase of normoblasts in the marrow.

Though facilities did not exist for following up most of the cases, it was possible to arrange for Case 11, who

had already accommodated us with a very adequate control period before treatment, to be maintained on doses of 50 µg. of oral vitamin B₁₂. Details of this case, showing haematological values for over a period of two and a half years, are shown in Figs. 1 and 2. She had a primary response that satisfied Della Vida's formula and has kept in haematological remission for 18 months, during which time she has received no other treatment than 50 µg. of oral vitamin B₁₂ taken every night before retiring.

Discussion

The experiments show that, under the conditions of the clinical trials described, oral vitamin B₁₂ without added source of intrinsic factor is haemopoietically active when given either in large single doses of 2,000 µg. or more or in repeated daily doses of 50 µg. The results of the experiments in which the vitamin was given in saline do not suggest that tween twenty increased absorption of the vitamin to any significant extent. The uniformly good results obtained with oral daily doses of 50 µg. could be related to the strict precautions taken to ensure that the patients took the dose when fasting and had no food for six hours afterwards.

There are several possible reasons for this. (1) In the fasting state there is greater opportunity for the vitamin to come into contact with the intestinal mucosa than when it is mixed with food. Close contact between the intestinal mucosa and vitamin B₁₂ in adequate concentration may be the necessary condition for the absorption of the vitamin without intrinsic factor. Castle and his colleagues have now suggested that the role of intrinsic factor is merely to increase assimilation of vitamin B₁₂, and that its effect may be on the intestinal wall rather than directly on the vitamin (see Berk *et al.*, 1948; Wallerstein *et al.*, 1953). (2) Vitamin B₁₂ may be destroyed by digestive secretions unless protected by intrinsic factor (Hall, 1950) and, if so, the small amount of secretions in the fasting state may not destroy all of the 50 µg. dose. (3) If intrinsic factor prevents utilization of vitamin B₁₂ by bacteria, some temporary alteration in bacterial flora when the patient is fasting may allow the vitamin to be absorbed.

Another possible reason for the responses obtained could be that the patients with histamine-fast achlorhydria were still secreting a small amount of intrinsic factor. It has been suggested that lack of intrinsic factor is not absolute in all cases of pernicious anaemia (Goldhamer, 1936; Campbell *et al.*, 1949), and, while it might seem unlikely that we would encounter this condition in a series of consecutive cases, the possibility cannot be excluded. To prove that the fasting state was important in allowing absorption of the vitamin, it would be necessary to use each patient as his own "control," giving the vitamin first with food and, later, in similar dosage when fasting. It was unfortunately not possible to carry out such studies on the present series of cases or to draw conclusions when smaller doses were given under the same conditions.

While the reason is not yet understood, it would seem that oral vitamin B₁₂—now accepted as "extrinsic factor"—can cause haematological response in cases of pernicious anaemia in the absence of any known source of intrinsic factor. We do not advocate this method of oral therapy for routine management of cases of pernicious anaemia, but our results demonstrate again that extraneous sources of intrinsic factor are not essential for utilization of vitamin B₁₂ and that oral therapy with the vitamin alone may be most effective when given to fasting patients.

Summary

Cases of megaloblastic anaemia in relapse given single oral doses of 2,000–9,000 µg. of vitamin B₁₂ showed initial haematological responses similar to those obtained by a single intramuscular injection of 20–100 µg. of the vitamin.

Daily doses of 50 µg. of oral vitamin B₁₂ taken when fasting caused significant haematological responses in cases of pernicious anaemia in relapse. A less satisfactory response was obtained when the same dose was taken with food.

The surface agent "tween twenty" did not appear to be of value in aiding absorption of vitamin B₁₂.

A case of pernicious anaemia in relapse has been initially treated and maintained in remission for over 18 months on a dose of 50 µg. of oral vitamin B₁₂ taken daily on retiring at night.

While intramuscular preparations are preferable and more convenient for routine management, it is concluded that, without intrinsic factor, oral vitamin B₁₂ can be utilized when taken fasting by patients suffering from pernicious anaemia and that clinical and haematological remission can be obtained with oral vitamin B₁₂ alone.

Thanks are due to the Research Fund of St. George's Hospital for a grant given to one of us (Z. M. H.); to the physicians of the hospital for clinical facilities; to Mr. H. K. Rogers and Mr. S. Louland for technical assistance; and to Glaxo Laboratories Ltd., Greenford, for supplies of vitamin B₁₂.

Pharmaceutical exports declined slightly in 1953 to £30.7m. from £31.7m. in 1952. According to the *Annual Report for 1953-4* of the Association of British Pharmaceutical Industry the main reasons were the fall in world prices and the export of bulk instead of finished goods. The principal market was India, which took £3m. worth; British West Africa and Australia came next with over £2m. Exports to the Union of South Africa, New Zealand, Malaya, Hong Kong, and Eire each exceeded £1m. Difficulties were experienced in trade with Pakistan and Egypt. In 1952 Pakistan was Britain's second best customer with £2m., but, owing to the reduction in her own exports, imports of drugs were curtailed and fell to £823,000. Exports to Brazil, formerly about £500,000, almost entirely disappeared. Countries poorly developed industrially are beginning to manufacture drugs or at least finish the later stages. Consequently material is being exported in bulk for local finishing and profits are lower. The Chinese government is said to be embarking on a manufacturing programme which will make it independent of all outside supplies of drugs.

DIAGNOSIS OF ACUTE PORPHYRIA

BY

ERIC G. SAINT, M.D., M.R.A.C.P.

D. CURNOW, Ph.D.

R. PATON, M.B., B.S.

AND

JOHN B. STOKES, M.B., B.S.

(From the Clinical Research Unit and the Department of Biochemistry, Royal Perth Hospital, Western Australia)

Although the pattern of symptomatology in acute intermittent porphyria is recognizable with ease in retrospect or in frankly paralytic cases, it is well known that striking simulation of abdominal or neuropsychiatric disease may deceive the practitioner with no personal experience of the condition.

The disease may be described as uncommon but not rare. In Australia it is possible to arrive at an approximate estimation of its incidence. Ten cases have already been reported (Derrick, 1946, two cases; Hetzel, 1949, two cases; Saint *et al.*, 1952, six cases). Fifteen new cases were diagnosed in one year (1952-3) in Western Australia, South Australia, Victoria, and part of New South Wales, giving an approximate "standardized" incidence of 1.5 per 100,000 in adult females. Other mild cases undoubtedly pass unrecognized; but the incidence is low enough to preclude the majority of family doctors and many general physicians attending a case in the course of their professional life. Since there is evidence that the indiscriminate use of some drugs, notably barbiturates and sulphonamides, may materially worsen prognosis, it is felt that attention should be paid to early clinical recognition. Three further cases of acute porphyria are presented from this point of view.

In each case diagnosis was eventually established by the identification of porphobilinogen in the urine by means of the modified Ehrlich reaction of Watson and Schwartz (1941). Total uroporphyrin and so-called "uroporphyrin III" in 24-hour urine specimens was estimated quantitatively by methods described by Sveinsson *et al.* (1949). Urinary coproporphyrin was estimated by the method of Schwartz *et al.* (1951), using Soret absorption and corrections described by Rimington and Sveinsson (1950). The three cases were investigated in the Royal Perth Hospital between December, 1952, and May, 1953.

Case 1

Classical Acute Porphyria with Pain, Psychosis, and Neuropathy, with Death from Respiratory Paralysis

A 27-year-old married woman of Scots ancestry complained quite suddenly, in November, 1952, of nondescript pains in the legs and back, and was treated by her family doctor for "influenza." Sulphonamides and barbiturates were freely prescribed. After several weeks improvement had not occurred. She became extremely depressed and was admitted to a mental hospital, where a short course of electric convulsion treatment was given without material benefit: in fact, her condition worsened, and she was admitted to the Royal Perth Hospital in January, 1953, complaining of generalized abdominal pain of great intensity, constipation, and weakness of all limbs. For several weeks she had been vomiting intermittently, and it was clear that her nutritional status had greatly deteriorated.

Examination revealed a dehydrated woman, weeping and grimacing in consequence of severe pain, and greatly con-

fused with respect to time and space. Her temperature was 99.4° F. (37.4° C.); pulse 140; blood pressure 110/90 mm. Hg. No abnormality was detected in the heart or lungs; the abdomen, despite some pain, was lax and not tender. The cranial nerves were normal. There was profound weakness of all the muscle groups of both arms and legs and the trunk. Diaphragmatic movements appeared impaired (confirmed fluoroscopically). Her confusional state prevented a full examination of sensory function—at least, pain sensibility did not seem impaired. Loss of deep reflexes was patchy: the biceps, knee, and ankle-jerks could not be elicited on either side, but supinator and triceps jerks were present. Plantar reflexes were flexor. Freshly collected urine was a deep burgundy colour, darkening on standing in light.

For a day or two she appeared to improve, taking food and drinks by mouth satisfactorily. Pain was controlled with pethidine. In view of her inability to cough, penicillin and streptomycin were given to prevent respiratory infection. Five days after admission she became more confused than ever. Weakness of intercostal muscles appeared suddenly, and she was transferred to a Both respirator, in which she was fed by means of an intragastric drip. However, both temperature and pulse rose, weakness and confusion increased, and she died two days after the initiation of artificial respiration, seven days after admission to hospital, and two months after the onset of her illness.

The only abnormal finding from a variety of biochemical investigations was a fasting blood urea of 56 mg. per 100 ml. The Watson and Schwartz test on fresh urine was strongly positive.

Porphyrin Excretion.—Quantitative studies on urinary porphyrins are shown in Table I.

TABLE I.—Quantitative Studies on Urinary Porphyrin Excretion in Case 1. Significant Worsening of Symptoms Occurred on D+5 and D+6. Death Occurred on D+7

Day after Admission	Total vol. of Urine (ml.)	Total Uroporphyrin Excreted (mg./24 hrs.)	"Uroporphyrin III" Excreted		Total Coproporphyrin Excreted (mg./24 hrs.)
			Total (mg./24 hrs.)	% of Total Uroporphyrin	
+1	500	13.7	11.5	84	0.368
+5	475	9.7	8.7	90	0.667
+6	785	25.2	20.2	84	2.375

Necropsy.—Marked congestive changes were seen in both lungs. No macroscopic abnormality was seen in the adrenals, kidneys, spleen, alimentary tract, brain, or spinal cord. The liver showed on its surface, and on section, numerous irregularly distributed foci of yellow discoloration of inconstant shape, measuring up to 5 mm. in diameter. Microscopically, moderate patchy fat infiltration was seen. Microscopical sections of the myocardium showed marked disintegration of muscle fibres with loss of nuclei and striation. Patchy demyelination was seen in peripheral nerves.

Familial Studies.—There was no evidence of consanguinity in the marriages of the parents or grandparents of the patient. Urine from the majority of her close relatives—both parents, four siblings, and four children—was examined both qualitatively for porphobilinogen and quantitatively for uroporphyrin, with negative results.

Comment.—Although the significance of the tetrad of pain, polyneuritis, psychosis, and port-wine urine was apparent late in the course of her illness, it is not difficult to see how the vague onset must have seemed like an influenza illness to her family doctor, and how the association of depression with ill-localized pain later suggested hysteria. During this phase large doses of sulphonamides and barbiturates were administered empirically, and E.C.T. given; it is reasonable to suppose that they did not aid recovery.

Case 2

Acute Porphyria in an Elderly Patient with Associated Hypertension and Diabetes Mellitus

A 61-year-old married Scotswoman was admitted to the surgical wards in December, 1952, with severe epigastric pain. At 23 she had a caesarean section, and in 1944 spent a week in hospital with acute vomiting, dyspnoea, and signs of pulmonary oedema, attributed to hypertensive and coronary heart disease. For ten years she was known to have moderate hypertension (200/100) and mild diabetes well controlled by diet.

The abdominal pain was of sudden onset. It was accompanied by vomiting, was unremitting, and was felt in the upper abdomen, radiating to the back. She had not been taking drugs.

She was extremely obese. Her temperature was 98.4° F. (36.9° C.), pulse 130, blood pressure 200/130 mm. Hg. The heart was not apparently enlarged. There were no abnormal signs in the central nervous system. Some tenderness was noted in the upper left abdominal quadrant. The urine was straw-coloured; sugar and acetone were not detected at first examination.

During the ensuing week she continued to complain of abdominal pain. The urge to explore was resisted in the face of a lax abdomen, a normal plain x-ray film of the abdomen, a normal cholecystogram, and normal urinary findings. At least 4 gr. (0.26 g.) of phenobarbitone was given daily, along with pethidine.

When a specimen of urine was noticed to be of a reddish colour the Watson and Schwartz test was found to be positive. Thereafter she became confused and occasionally delirious. During the next two weeks her condition rapidly deteriorated: her limbs became paralysed; she had difficulty in swallowing, necessitating intragastric feeding; she developed a right facial paresis and paralysis of the limbs; all deep reflexes were absent; she became incontinent of both urine and faeces; her diastolic blood pressure remained persistently high (130-140 mm. Hg). Only a minimal degree of narrowing of vessels was seen in the optic fundi.

She died in a coma three and a half weeks after admission. Of the many investigations, significant positive findings included a fasting blood urea of 72 mg. per 100 ml., and a fasting blood sugar of 172 mg. per 100 ml. Electrocardiographic tracings showed a pattern of left ventricular strain.

Porphyrin Excretion.—Only one specimen was examined quantitatively. It fluoresced strongly in ultra-violet light. The total porphyrin content of native urine was 10.3 mg. per litre (of which 0.4 mg. per litre was ether-soluble—coproporphyrin); after heating with N/2 HCl this increased to 21.9 mg. per litre.

Necropsy.—Congestion and signs of early bronchopneumonia were present in both lungs. The heart was not enlarged and the coronary vessels showed minimal atherosclerotic changes. The pancreas was atrophic and contained areas of recent necrosis. Fat infiltration was present in the liver. Macroscopically and microscopically the kidneys appeared to be normal.

Comment.—Manifestations of porphyria begin as a rule in the third or fourth decade of life; the late onset in this patient is worthy of comment. The 64-year-old patient of Kench *et al.* (1953) is possibly the oldest on record, but symptoms were mild in their case and had been present for many years. The localization of abdominal pain was highly suggestive of pancreatitis. This was confirmed at necropsy by the appearances of recent focal necrosis in the pancreas. The association of long-standing hypertension with porphyria inevitably gives rise to speculation. Macleod and Grant (1953) describe a case with attacks of left ventricular failure: at necropsy chronic pyelonephritis was present. Our patient probably had "essential" hypertension, which by the usual clinical and pathological

criteria seems to have been relatively benign. It is not inconceivable that the attack of pulmonary oedema she is said to have had in 1944 was due to sudden rise in blood pressure, beyond an elevated baseline, due to an episode of porphyria.

Case 3

Mild Acute Porphyria with Evidence of Pancreatitis

A 27-year-old woman of Scots ancestry was admitted in April, 1953, with a short history of generalized pain and vomiting. Six months previously she had had a similar illness diagnosed as "influenza"—but, unlike a virus infection, muscle pain had persisted three weeks. On the present occasion she complained of occipital headache, pain in the back and legs, and nausea. The urine was noted to be "dark": her family doctor was inclined to diagnose subicteric infectious hepatitis, which was endemic in the neighbourhood.

Although she looked ill the only abnormal sign was an unexplained tachycardia of 130 a minute. The liver was not enlarged and the abdomen was lax. Her blood pressure was 130/72 mm. Hg. There were no abnormal signs in the central nervous system. The urine was amber-coloured.

For a week after admission her chief complaint was of pain in the epigastrium radiating to the back, with intermittent vomiting. The Watson and Schwartz test proved to be positive. The site and radiation of pain suggested pancreatitis, which was confirmed by the finding of raised levels of serum amylase (see Table II). She was discharged, free of pain, three weeks after admission.

TABLE II.—Quantitative Studies on Porphyrin Excretion in Case 3. Related to Severity of Abdominal Pain and Serial Estimations of Serum Amylase

Day after Admission	Vol. of Urine 24 hours (ml.)	Total Uroporphyrin mg./24 hr.	Uroporphyrin III		Abdominal and Back Pain	Serum Amylase (units) (N=70-200)
			mg./24 hr.	% of Total Uroporphyrin		
+7	—	—	—	—	±	20
+8	—	—	—	—	++	—
+9	—	—	—	—	+++	228
+10	—	—	—	—	++	—
+11	990	5.76	4.30	75	—	—
+12	—	—	—	—	±	—
+13	—	—	—	—	—	359
+14	—	—	—	—	—	—
+15	910	3.39	2.95	87	—	384
+17	1,410	6.60	5.80	88	—	—
+18 & 19	1,530	2.26	2.00	87	—	—
+20 & 21	3,020	2.67	2.12	79	—	—
+22	880	1.65	1.20	73	—	285
+23	2,010	2.83	2.42	85	—	50
+25	—	—	—	—	—	—

The majority of investigations were negative, apart from the bromsulphthalein test, which showed 12% retention of dye at 30 minutes; other tests of liver function were normal.

Porphyrin Excretion.—Porphobilinogen was present in all specimens examined. The daily output of total uroporphyrin varied between 1.65 and 6.60 mg., between 73 and 88% being present as uroporphyrin III (see Table II).

Comment.—This was a comparatively mild episode, probably only the second the patient had ever had. As in Case 1, the initial diffuseness of pain led to a provisional diagnosis of virus infection. Happily, sulphonamides and barbiturates were not prescribed. As in Case 2, the site of pain was compatible with a clinical diagnosis of pancreatitis, proved biochemically.

Discussion

These case records indicate how vague and misleading are the early symptoms of acute porphyria. The simulation of abdominal emergencies (Case 2) is well known; but pain may not always be confined to the abdomen (Cases 1 and 3)—"virus infection," "rheumatism," "fibrositis," and "hysteria" were the diagnostic dustbins into

which our patients had been relegated at an early stage in their illness. Too great a reliance cannot be placed on the colour of the patient's urine; early in the course of the illness of Case 3 the urine was of normal appearance. In diagnosis the Watson and Schwartz test for porphobilinogen is an extremely simple and valuable one which can be performed in any side-room; moreover, it is wholly reliable (Hammond and Welcker, 1948). It is possible that the more widespread use of this diagnostic test might bring to light many more mild cases of porphyria.

This question of early diagnosis and the diagnosis of mild cases is of more than purely academic interest. At present the disease defies comprehension, and treatment is for the most part supportive, attention being paid to nutrition, prevention of respiratory complications, and the control of pain. The supervention of profound and widespread paresis should not engender complete despair: Saint *et al.* (1952) described a case with paralysis of the diaphragm and intercostal muscles in which full recovery occurred after two weeks in a respirator. If we can do patients little positive good, there is certainly evidence that we can do positive harm. The unfavourable influence of sulphonamides and barbiturates on the natural history of the disease has been recorded too often to be ignored. Unfortunately the very symptoms with which the disease is announced—pain and psychotic behaviour—are those which often call for the empirical use of these drugs. The answer to the problem must lie in awareness of the diagnosis.

Like the understanding of the underlying metabolic anomaly, the origin of symptoms in porphyria remains obscure. There is much to support the contention of Denny-Brown and Sciarra (1945) that many of its manifestations are explicable on the basis of spasm of smooth muscle, particularly of the circular muscle of small arteries. The diffuse pathological changes seen in the central nervous system and elsewhere are highly suggestive of focal ischaemia. In this respect the variety of systemic manifestations—renal (hypertension), abdominal, neurological, myocardial—calls to mind that other disease of focal ischaemia, *periarteritis nodosa*. To the long list of organs involved in porphyria the pancreas must now be added, for the clinical, biochemical, and pathological evidence of mild pancreatitis in Cases 2 and 3 was wholly convincing. It is interesting in this connexion to note that pancreatic involvement sufficient to cause abnormality in the sugar-tolerance curve in *periarteritis nodosa* has been recorded by Middleton and McCarter (1935) and by Baker (1953).

Summary and Conclusions

A survey of the reported cases of acute porphyria in Australia indicates an approximate incidence of 1.5 per 100,000 females over the age of 15 years.

Three cases with classical biochemical findings are described in which the earliest symptoms bore little relation to the "classical" picture of the disease.

In two cases pain was entirely peripheral in distribution, and was attributed to mild infective illness. The unfolding of neuropsychiatric symptoms and signs followed the administration of barbiturates.

In two cases the abdominal pain was due to pancreatitis, proved biochemically and at necropsy.

The importance of early recognition is stressed so that the harmful influences of sulphonamides, barbiturates, electric convulsion therapy, and unnecessary surgery may be avoided. The more widespread use of the simple Watson and Schwartz test in the diagnosis of obscure abdominal and peripheral pain, hysteria, unexplained depressive states, and neuropathy is urged.

We are grateful to Dr. J. Ord Poynton, of the Institute of Veterinary Science, Adelaide, Mr. Ian Parsons, of the Department of Biochemistry, University of Melbourne, and Dr. C. R. B.

Blackburn, of the Royal Prince Alfred Hospital, Sydney, for information regarding the incidence of porphyria in Australia; and to Drs. Ian Thorburn and John Calder and Mr. N. Robinson for permission to quote the cases under their care.

ACUTE PANCREATIC NECROSIS AS A CAUSE OF SUDDEN DEATH

BY

G. WILLIAMS, M.B., Ch.B.

Demonstrator, Department of Pathology, King's College, University of Durham

Acute pancreatic necrosis has long been recognized as an acute and frequently fatal abdominal catastrophe, but it does not usually figure as a cause of sudden death. Roberts *et al.* (1950), however, mentioned the possibility, and Gaskell (1942) described 10 cases of sudden death from this condition.

During the past two years five cases have been encountered in the course of post-mortem examinations carried out at the Royal Victoria Infirmary, Newcastle-upon-Tyne, all of them investigated at the request of H.M. Coroner. In the following account a short summary of the clinical history of each case is given together with descriptions limited to the state of the pancreas and adjacent organs and any other positive findings.

Case Histories

Case 1.—A public works contractor aged 48 (weight 112 kg.), an obese subject enjoying good health, was suddenly seized with acute abdominal pain. He became breathless at work, collapsed, and died instantly. A month previously he had suffered an attack of "food poisoning," with subsequent recovery. **Post-mortem Examination:**—The pancreas (weight 200 g.) was soft and swollen, and the cut surface showed diffuse areas of haemorrhage with a limited amount of fat necrosis. Histology confirmed a severe necrosis of the pancreas with abundant haemorrhage. Stomach and duodenum contained a recent meal; the mucosal surface appeared congested. The liver showed severe fatty change. The lungs were congested and very oedematous.

Case 2.—A brewer's cooper aged 62, well nourished and of good physique (weight 70 kg.), who normally enjoyed good health, suddenly complained of abdominal pain whilst at work. His colleagues saw him collapse. He lost consciousness and died instantly. **Post-mortem Examination:**—The pancreas (weight 160 g.) was dark plum-coloured and flecked with yellowish necrotic material. Histology showed a haemorrhagic necrosis of pancreatic tissue with limited fat necrosis. The stomach, duodenum, gall-bladder, and bile ducts appeared normal. The lungs were severely congested and oedematous.

Case 3.—An obese elderly woman aged 73 (weight 65 kg.), living at home, had been under the care of her doctor for several years on account of thrombophlebitis in her right leg. She developed symptoms suggesting pulmonary embolus a few weeks before death, but subsequently recovered. On September 10, 1952, she got out of bed at 10 a.m., suddenly collapsed, and died. **Post-mortem Examination:**—The pancreas (weight 140 g.) was swollen, soft, and oedematous, with numerous subcapsular haemorrhages. On section one major haemorrhage was seen in the head of the pancreas with numerous smaller ones throughout the gland. There was a minimum amount of fat out the gland. Histology showed a complete necrosis of the parenchyma with perivascular haemorrhages. The stomach and duodenum contained a recently ingested meal. The gall-bladder contained numerous pigment stones, but the mucosa was normal in appearance. The bile ducts were healthy. The splenic vein contained a recent ante-mortem thrombus. The main pulmonary arteries contained ante-mortem thrombi, which were firmly adherent to the vessel walls and were shown histologically to be in varying stages of organization. There was moderate atheroma of the coronary arteries but no recent thrombus. Two large simple cortical cysts were present in the left kidney. There was an extensive organized thrombus in the right femoral vein.

Case 4.—A well-nourished woman aged 69 (weight 58 kg.), living at home, had been in failing health for some months. She complained of sudden pain in the chest and brought up a small quantity of blood. The pain subsided, but the following morning she had a further severe attack of upper abdominal pain, collapsed, and died before her doctor arrived. **Post-mortem Examination:**—The entire pancreas (weight 145 g.) was found to be swollen and congested. Sectioning showed an extensive haemorrhagic necrosis of the head of the pancreas with smaller haemorrhages throughout the gland. Histology confirmed extensive necrosis of glandular tissue with diffuse haemorrhage and slight fat necrosis. The stomach contained altered blood and mucus, with congestion of the mucosa and scattered submucosal haemorrhages. The duodenum was moderately congested. The gall-bladder and bile ducts appeared healthy. The lungs showed oedema.

Case 5.—A general labourer aged 28, well developed and in good nutrition (weight 68 kg.), had been in normal health. On November 11, 1951, he ate a good lunch and shortly afterwards ran some distance and boarded a bus. On reaching his seat he was seen to slump forward, and by the time help arrived he was dead. He had been treated at the age of 16 for meningitis. In 1945 he had been wounded in the leg while serving with H.M. Forces in Germany. **Post-mortem Examination** showed a haemorrhagic necrosis of the head of the pancreas, which was confirmed histologically. The stomach contained a large quantity of recently ingested food; the mucosal surface was healthy. The duodenum was congested. The gall-bladder and bile ducts were healthy.

One further case deserves mention. A man aged 65, who had been in previous good health, was found by the police unconscious in his bedroom. In hospital he revived slightly with nikethamide, but relapsed into coma and died the following day. Subsequent necropsy revealed an acute haemorrhagic pancreatitis, which was confirmed by histological examination. In view of the delay between discovery and death, this case cannot be accepted as one of sudden death, but nevertheless it bears certain similarities to the series being described.

Comment.—The main necropsy findings in all cases were acute haemorrhagic pancreatitis with necrosis of the parenchyma. Fat necrosis was present in variable amounts but was not a prominent feature. The susceptibility of the pancreas to post-mortem autolysis was borne in mind in assessing the lesions, but in all cases the cellular activity and haemorrhagic infiltration indicated a genuine necrotic process. Sudden death was common to all cases. In Case 4

the history suggested two separate attacks, the second one being instantly fatal. In Case 3 the issue was obscured by a concurrent pulmonary embolism, but it was felt that the extent of the pancreatic lesions together with considerable organization of the majority of the pulmonary thrombi warranted the pancreatic condition being cited as the cause of death. In none of the cases was there evidence of coronary arterial thrombosis.

Discussion

The aetiology of this condition remains obscure. Certain authors regard the lesion as the result of auto-digestion by activated pancreatic enzymes, resulting from acinar rupture taking place at the height of enzyme secretion. The fact that the lesion may occur in the wake of a recently ingested meal would tend to support this idea. Lium and Maddock (1948) reinforce this interpretation by animal experiments in which they produced pancreatic necrosis in starving rats by ligating the ducts and then stimulating the gland by artificial means. The most extensive inflammatory changes followed ligation of the ducts at the height of digestion, approximately two hours after the animal had eaten. Paxton and Payne (1948) stressed the role of alcoholism as an aetiological agent. In two of the cases described above there was a history of alcoholic tendencies.

The possibility of the lesion being primarily the result of vascular disease must also be considered. In two of the above cases ante-mortem thrombi were located in pancreatic arterioles not immediately related to necrotic tissue. This would tend to suggest that in the more acute forms of the disease there may well be a primary arteriolar thrombotic process giving rise to acute haemorrhagic infarction of the pancreas, with subsequent liberation and activation of gland enzymes. At any rate, the arteriolar lesions probably succeed in promoting extension of the lesion if not in initiating it, and may well be a main factor in rendering this type of pancreatic necrosis an irreversible and frequently fatal disease.

Summary

Acute pancreatic necrosis can cause sudden death. Five such cases are described. The aetiology of the condition is briefly discussed.

Attention is drawn to the significance of arterial thrombosis as a factor in the pathogenesis of the disease.

I wish to thank Professor J. B. Duguid for his helpful criticism and advice.

The need for a home where severely handicapped children can stay for short periods during holidays and family crises has so impressed the Invalid Children's Aid Association that it has turned over its John Horniman Home at Worthing to this purpose. The home, which is in the charge of a married couple with nursing and domestic assistance, can take 24 children (boys 7 to 13 and girls 7 to 15 years, inclusive). Physiotherapy is available at the local hospital. The maximum length of stay is eight weeks, and the fee £5 10s. a week. Children with the following disabilities are considered suitable: spina bifida, poliomyelitis, congenital deformities, haemophilia, muscular dystrophy, cerebral palsy (I.Q. not below 65), fragilitas ossium, congenital or quiescent rheumatic heart disease. Children are not accepted who have been ascertained as mentally defective, or who suffer from epilepsy, pulmonary tuberculosis, or blindness. Application forms for admission and further details may be obtained from Miss Rattenbury, 4, Palace Gate, London, W.8.

BACK TO BILLROTH I

A COMPARISON OF RESULTS OF BILLROTH I
AND II OPERATIONS

BY

G. E. MOLONEY, M.B., F.R.C.Sed., M.R.C.P.

Assistant Surgeon, the Radcliffe Infirmary and the Churchill
Hospital, Oxford

More than a million people in these islands are denied the pleasure of the table for weeks or months or years at a time owing to peptic ulcer. The most frequent sufferer is the breadwinner of the family, and as the pit of his stomach grows heavy his purse grows light, his face long, and his temper short, until in time the whole family comes to feel the strain of father's ulcer. This miserable "pre-gastrectomy syndrome" can be exchanged for a life of domestic and epicurean bliss, up to the levels permitted by political expediency, for most of these medical sufferers by well-planned, old-established, and adequately performed surgery. This happy "post-gastrectomy syndrome," which can be at times for the "ninety and nine," is too often forgotten in the quest of the unfortunate "one."

Much attention has been given to features arising after gastrectomy and labelled "post-gastrectomy syndrome," as if they were a customary expectation following partial gastrectomy. Perhaps a better description of what is implied would be "post-Polya-gastrectomy syndrome."

A great volume of work has been published on the late results of gastrectomy for benign ulcer, and, as fresh complications after the Polya procedure have been brought to light, loops have been passed for a time from right to left then back again, made antecolic then retrocolic, made long then short, then long again. "Valves" also have had an equally unsettled existence. In the past decade attempts were made to clarify these issues by accurate measurement of long-term results, "dumping" was born, and later came the after-birth of "early and late syndromes." Most of the analyses have been on the results of some modification of the Billroth II operation, whether it be the Polya or a "valve" with a disputed, unpronounceable title. This state of affairs is largely due to the Polya operation having been made fashionable, partly because of the comparative ease with which it can be performed, and partly by the untested faith of those early zealots who first gave it to us. There have been few reports on post-operative studies of series of Billroth I gastrectomies, and still fewer on a comparison of results of the various methods.

Capper and Butler (1951), in assessing 102 patients treated by the Billroth I method, compared these with several groups of about the same number treated by varieties of the Polya-type gastrectomy, and they found no patients with early post-gastrectomy syndrome in the Billroth I group as against 12-15% in each Polya-type group.

Wells and Brewer (1948) say they found no dumping in 363 cases, mostly of the Polya type, but Wells and Welbourn (1951), in what is mostly an excellent review, claim enough experience to be able to write about it. They state that the Billroth I operation is technically difficult in duodenal ulcer and that ulcers are apt to recur. They referred to Wells and Brewer (1948) for

evidence, but Wells and Brewer claim only 24 patients treated by the Billroth I technique. Further, they say it is likely that their deductions are false, as in most of the examples of the Billroth I operation which they quote the resection of the stomach was inadequate. There is no sound evidence here.

On the other hand, Schoemaker (1947), in 129 patients with peptic ulcer (40 gastric and 89 duodenal), used his own modification of Billroth I in 111 patients without any instances of dumping in the follow-up.

Custer, Butt, and Waugh (1946), at the Mayo Clinic, say that they did not find dumping in the cases treated by the Schoemaker modification of the Billroth I, but they had a high incidence of dumping in those who had undergone the posterior Polya anastomosis. They say it follows gastric resection of the latter type in 5-12% of cases and is apt to be permanent.

In a comparison of results there is no sound evidence against the Billroth I procedure, but there is some solid evidence for it. There is much sound evidence against the Polya types of anastomosis.

Mortality

My personal experience of Billroth I and Polya operations for benign ulcer to the end of 1952 is: Billroth I, 193 operations (gastric 93, duodenal 100); Polya, 89 operations (gastric 16, duodenal 73). The proportion of Polya operations is much higher than I would now advise or find necessary. The mortality of these operations is as follows:

Billroth I Series (193).—(a) Elective operations (162)—1 died. Post-mortem examination: a wasted man of 69 explored on the suspicion of carcinoma and dying of bronchopneumonia. (b) Emergency operations for bleeding (31)—3 died. Post-mortem examination: (i) coronary thrombosis; (ii) massive pulmonary embolism; (iii) leakage of suture line.

Polya Series (89).—(a) Elective operations (82)—3 died. Post-mortem examination: (i) a man of 73 operated on for pyloric stenosis died of bilateral suprarenal haemorrhage; (ii) a man of 45 operated on for duodenal ulcer died of inhalation pneumonia; (iii) a man of 57 operated on for duodenal ulcer died from leakage at the duodenal stump. (b) Emergency operations (7)—1 died. Post-mortem examination: a woman of 57 operated on for a huge duodenal ulcer with uncontrolled bleeding died from rupture of a posterior perigastric abscess with no good evidence of leakage.

The mortality for all elective operations was 4 deaths in 244 resections, and for all emergency operations for acute bleeding 4 deaths in 38 resections.

The safety of the Billroth I operation has been questioned at times on the grounds of a high incidence of leakage at the so-called "danger angle," where the reconstituted lesser curve meets the gastro-duodenal suture line. In this series there was no evidence of leakage in 162 elective operations, and in 31 emergency operations the only instance occurred in a woman of 84 with acute haematemesis who developed the signs of a leak on the sixth day after operation following removal of the aspiration tube on the fifth day. The post-mortem examination showed poor healing reaction and a leakage at the danger angle. Fluid had accumulated in the stomach and the resulting drag had caused the sutures to cut through the tissues in the absence of support by natural healing. The debilitated 84-year-old patient often heals poorly.

On this evidence it would be fair to say that the results of the Billroth I operation from the surgical aspect of the resection and anastomosis are almost devoid of mortality.

In the Polya series there was one instance of leakage at the Achilles heel, the duodenal stump. This operation is equally safe in accustomed hands, as shown by Hosford (1949), who had 1 death in 200 elective operations, com-

pared with 1 death in 162 elective operations by Billroth I technique in my series. So there is no evidence of any significant difference in the relative safety of either operation when properly performed, and the relative merits must be judged by the degree of sequelae.

Morbidity

It was my impression that the patients on whom I had performed a Billroth I gastrectomy were not showing the dumping syndrome, nor were a proportion wasting as were some of those patients who had had a Polya gastrectomy. It was to confirm this impression that this analysis was made.

The patients in this study total 154, and were those on whom I had performed a partial gastrectomy for benign ulcer in the public ward of the Radcliffe Infirmary or the Churchill Hospital before the end of 1951. Private operations and those done elsewhere were not included, nor were patients on whom vagotomy was added to partial gastrectomy. The review was 94% complete. The interviews were made in the out-patient department by my medical colleague, Dr. E. M. Buzzard, and by myself. Both the type of ulcer and of operation were unknown to Dr. Buzzard, and many I could not recall. All results were assessed and tabulated before examining the case notes for the nature of the ulcer and of the operation. The analysis was done under the headings of weight, various symptomatic complaints, and assessment of the result, which was made independently by both of us; and, further, I asked every patient to give his frank opinion of what he thought about the result of the operation. These broad assessments have been classified individually. We have not drawn a distinction between the effects that came on early or late after meals, a simple tally being made of all the symptoms. The worst picture has been painted, as all symptoms have been totalled whether recorded by one or both of us. For ease of reading the discussion of symptoms is done under each separate heading.

General Features

Total patients examined—154 (19 female, 135 male). Ages—the usual large group between 40 and 60 years, 9 below 30, 8 over 70, and 4 over 80.

Varieties of ulcer—62 gastric, 86 duodenal, and 5 stomal, 1 in which no ulcer was found at operation. Multiple ulcers were found in 10% of patients, the more severe ulcer being the one used for subsequent classification.

Operations—Billroth I, 98 (49 for gastric and 49 for duodenal ulcer); Polya, 56 (13 for gastric, 37 for duodenal, and 5 for stomal ulcer).

BI=Billroth I. P=Polya.

Weights were assessed as nearly as possible by taking the patient's opinion of the usual weight, and weight a year pre-operative and immediately pre-operative. These were all checked so far as possible against information taken from notes. An assessment was made from these data of the likely normal weight in the past year or two, and the weight found at interview was compared with it. A return of weight to normal following a loss during operative treatment was not accepted as a gain in weight for the present purpose,

nor was it regarded as a loss when there was reduction of fatty tissue after operation in a patient made overweight by a recent milky diet. Gains or losses up to 6 lb. were classed as "same," 7 to 13 lb. were classed as + or -7 lb., 14 to 20 lb. were + or -14 lb. A fair amount of latitude must be allowed in consideration of weight owing to difference of clothes and the slight seasonal alterations, and it was thought that one must allow 6 lb. for such changes.

It will be seen from Table I that in the Polya series quite a high proportion of patients showed a weight loss. The Billroth I series shows only nine patients with a loss of 7 lb., which is not a very significant loss when such factors as clothes, seasonal changes, and change of work are concerned.

The Billroth I series shows only a 1% loss of 7 lb. or more, whereas the Polya series shows a 20% loss of 7 lb. or more.

Others have noticed this weight loss with the Polya type. Muir (1949) showed that of 86 patients submitted to Polya gastrectomy and examined at intervals of six months to six years after operation, over 40% had lost 7 lb. or more and over 20% had lost over 14 lb. or more. Only 10% of patients had gained weight. This led Muir to comment, "Further investigation of this important abnormality in gastrectomized patients is obviously required." Among my cases 16% of the Polya series, in contrast to 22% of the Billroth I series, showed a gain in weight. Ward-McQuaid (1949) showed that of 49 patients operated on by Mr. Elliot Smith, 24 (50%) were 7 lb or more below normal weight one to two and a half years after the Polya operation, 15 (32%) had lost 14 lb. or more, and only 4 had gained weight.

These findings support the general impression I had formed when seeing patients after operation, that the Billroth I series had not lost weight to the degree seen in the Polya series. The loss or gain of weight is not obviously associated with any functional upset, but it is often a nuisance or an embarrassment to patients, who complain of being too thin or having to buy new suits of clothes. The maintenance of weight in the Billroth I series may be due to better mixing of food, bile, and pancreatic juices as the food passes into the duodenum, and the loss in the Polya series may be due to imperfect mixing, with perhaps a loss of bile from bilious vomiting, which is often a feature in the Polya-type case. But those who have lost weight after a Polya-type operation are not always those who have bilious vomiting. The maintenance of weight in the Billroth-I-type case is not in this series due to inadequate resection of the stomach, as is shown by the large number of Billroth-I-type patients with a reduced capacity for food in the first two years (Table IV). This finding of maintenance of weight in Billroth-I-type patients has not been brought to light before to my knowledge, and will need investigation in series by other surgeons before it can be adequately substantiated.

Symptomatic Complaints

Flatulence is a difficult symptom to assess from a patient, and must depend partly on how much air he swallows. There is no evidence in Table II of any essential difference between the Billroth I and the Polya series.

TABLE II.—Flatulence

	Billroth I				Polya			
	No.	+	++	+++	No.	+	++	+++
Gastric	49	4	1	0	13	2	0	0
Duodenal	49	2	2	0	43	2	7	1
Total	98	6	3	0	56	4	7	1

Analysis of these symptoms in years after operation: Billroth I, 0-2 years, 4 (74); 2+ years, 5 (24). Polya, 0-2 years, 2 (10); 2+ years, 10 (46).

Regurgitation of bile occurred in the Billroth I cases in the early post-operative period, but not in those operated on two or more years before. In the Polya series, however,

the proportion is high in those operated on two or more years before (Table III). The demonstration of this feature is not new, the tendency for the patient with the Polya type of operation to bring up bile even years after operation has been well shown in various papers. There has been much talk of "afferent loops."

TABLE III.—Regurgitation of Bile

	Billroth I				Polya			
	No.	+	++	+++	No.	+	++	+++
Gastric	49	3	—	—	13	—	—	—
Duodenal	49	2	1	—	43	3	—	—
Total	98	5	1	—	56	3	—	—

Analysis of these symptoms in years after operation: Billroth I, 0-2 years, 6 (74); 2+ years, 0 (24). Polya, 0-2 years, 1 (10); 2+ years, 10 (46).

All complaints of a reduced capacity to take food or liquids, especially with the main meal, are included in Table IV. These tend to lessen in the Billroth I series, but nearly half of those in the Polya series show real difficulty with food and liquids after two years.

TABLE IV.—Reduced Capacity

	Billroth I				Polya			
	No.	+	++	+++	No.	+	++	+++
Gastric	49	16	—	—	13	3	1	—
Duodenal	49	12	2	—	43	9	3	2
Total	98	28	2	—	56	12	4	2

Analysis of these symptoms in years after operation: Billroth I, 0-2 years, 25 (74); 2+ years, 5 (24). Polya, 0-2 years, 2 (10); 2+ years, 16 (46).

Table V shows a clear preponderance of persistent trouble with the Polya series and an entire absence of symptoms with the Billroth I patients after two years.

TABLE V.—Puddings Produce Unpleasant Symptoms

	Billroth I				Polya			
	No.	+	++	+++	No.	+	++	+++
Gastric	49	2	—	—	13	3	—	—

Table VI reveals nothing significant except a low incidence of sweating.

TABLE VI.—Sweating

	Billroth I				Polya			
	No.	+	++	+++	No.	+	++	+++
Gastric	49	1	—	—	13	1	—	—
Duodenal	49	1	—	—	43	1	—	—
Total	98	2	—	—	56	2	—	—

Analysis of these symptoms in years after operation: Billroth I, 0-2 years, 2 (74); 2+ years, 0 (24). Polya, 0-2 years, 0 (10); 2+ years, 2 (46).

Table VII suggests a remission of dizziness and sleepiness in the Billroth I series, but a strong persistence and high incidence in the Polya series.

There were two instances of anaemia, both in women who had had Billroth I operations for gastric ulcer. There was one instance of stomatitis and glossitis, in a man who had had a Polya operation for duodenal ulcer. The comparison of patients with gastric and duodenal ulcers shows no significant difference in either series.

TABLE VII.—Dizziness and Sleepiness

	Billroth I				Polya			
	No.	+	++	+++	No.	+	++	+++
Gastric	49	2	—	—	13	3	—	—
Duodenal	49	2	—	—	43	6	—	—
Total	98	4	—	—	56	9	—	—

Analysis of these symptoms in years after operation: Billroth I, 0-2 years, 4 (74); 2+ years, 0 (24). Polya, 0-2 years, 2 (10); 2+ years, 9 (46).

The Billroth I series had mild effects from a small stomach for a variable time, but after one to two years most patients develop a satisfactory capacity with few, if any, side-effects. The Polya series, on the other hand, show a proportion with persistence of bile regurgitation, unpleasant symptoms with puddings, reduced capacity for food and liquids, and dizziness and sleepiness after meals.

Perhaps there were not the same troubles when protein was plentiful, and a beefsteak with Yorkshire pudding in the afferent loop may not have been as productive of rising bile or sleepiness as is Yorkshire pudding without the beefsteak. But as we cannot forecast certain dietary problems it would seem best to let the jejunum keep the natural 12 in. (30 cm.) or so from the stomach as often as is possible.

Personal Assessment of Results

An assessment was made separately by Dr. E. M. Buzzard, myself, and the patients (Table VIII). The results were grouped into six categories—excellent, very good, good, improved, not improved, and recurrent ulceration.

Personal judgments vary, but it will be seen that the physician and the surgeon largely agree in essentials. It will also be seen that the "customer" was the most satisfied of all, and the contrast between his reckoning and ours shows that in many cases in which we see some defect the patient thinks nothing of it in his happiness at being able to eat when and what he likes, and at having no subsequent pain. With the exclusion of two patients with recurrent ulcers there was only one patient in the Billroth I group (98 patients) who classed herself as "improved," and none considered they were "not improved." In the Polya group (56 patients), three patients classified themselves as "improved," and two as "not improved."

Recurrent Ulceration

There were two patients with recurrent ulceration in the Billroth I series, both being after operations for gastric ulcer. One came on 51 months and the other 22 months after the original operation. Both these patients have been reoperated on, the procedure being excision of the ulcer, further reduction in the size of the stomach, vagotomy, and then reconstitution by Billroth I anastomosis. The second operations were done less than a year ago and the patients have had no further digestive upsets. There was one recurrent ulcer following a Polya operation for a duodenal ulcer.

Much has been written of the recurrence rate following the Polya operation, but the literature is surprisingly quiet on the recurrence rate for the Billroth I operation. The only reliable statistics are those of Schoemaker (1947), who reviewed 94 patients, all at an interval of more than three years after operation, and found two instances of recurrent ulceration. This compares with my recurrence rate of 2%. There is certainly no real evidence to show that the Billroth I operation is more productive of recurrent ulceration than is the Polya operation.

It would be a pity if in zeal to produce no instance of recurrent ulceration the philosophy of the late Hedley Visick (1948) was generally adopted. He claimed that by removing the greater part of the stomach, more than three-quarters, and anastomosing the jejunum to the remnant, he found no subsequent recurrent ulceration. With the whole stomach removed it would also be likely that there would be no recurrent ulceration, but after the very radical type of operation which Visick recommended one must expect to see in high numbers such sequelae as bilious vomiting, reduced capacity for food, weight loss, and other unpleasant features. It is better, I submit, to treat 100 cases by less radical measures, such as the Billroth I operation, and to secure a good functional result for 98. If two should later prove themselves by re-ulceration to be the black sheep, only those need be given a near-total clipping of the offending organ to be rid of pain at the price of possible unpleasant sequelae.

Discussion

The main inference from these results is that the Billroth I operation should be used wherever possible for the surgical treatment of gastric and duodenal ulcers. There is a strong swing back to the Billroth I operation for treating gastric ulcer, but, owing to what may be unhappiness in the dissection of the difficult duodenal ulcer, the Polya operation is so often considered to be more suitable for dealing with a duodenal ulcer, and the devil take the post-operative consequences.

I find that most duodenal ulcers can be dissected out with patience and care, though it is not advisable if they are far distal in the second part of the duodenum near the opening

of the bile duct. I use the Billroth I operation for duodenal ulcers as often as I can, as I believe there is a better post-operative result. One must expect a proportion of difficult dissections, but once the duodenum is freed beyond the ulcer it is well to remember that if there is enough to close there is enough to anastomose, and one might as well do a Billroth I. In the past two years I performed the Billroth I operation for 50 gastric ulcers and 78 duodenal ulcers, while the Polya operation was done for 3 patients only, all with distal duodenal ulcers.

In the past 18 months I have been endeavouring to overcome the reduced capacity, especially for the main meal, owing to the small stomach remnant. This is seen in the early months after the operation, but greatly improves later. Men under 50 are usually more vigorous, needing a bigger food intake, and in these I have been leaving nearly half the stomach, adding vagotomy in those with duodenal ulcer. This is not done in order to achieve an anastomosis, for high resection with gastro-duodenal anastomosis can be achieved after resection of a duodenal ulcer. My theory is that a Billroth I procedure gives more than the equivalent of a pyloroplasty, for it means a fresh start without the ulcer. The removal of the lower half of the stomach takes away that great stimulator of gastric juice, the mucosa of the pyloric antrum, and the vagotomy reduces the secretory capacity of the remaining mucosa; thus humoral and nervous mechanisms of secretion are both eliminated. As half the stomach is removed the incomplete emptying found with vagotomy alone is unlikely to occur. So much for the theory. In practice it has been working well, judging by impressions, but the results have not yet been subjected to time or detailed analysis, nor have the numbers been sufficient. This must therefore remain an interim investigation.

Summary

The results of a series of 154 operations for varieties of peptic ulcer by Billroth-I-type and Polya-type techniques are contrasted.

The main findings are that the patients after a Billroth I gastrectomy do not lose weight in an abnormal way like some of those who have had a Polya gastrectomy.

After Billroth-I-type gastrectomy patients showed few distressing symptoms after meals, and such unpleasant features as there were tended to wear off with the passage of time, in contrast to a persistence of those following Polya-type gastrectomies.

The incidence of recurrent ulcer is the same in both series (2%), and it is claimed that there is no real evidence of a difference in recurrence rate between the two methods.

A plea is made for avoiding too radical resection of the stomach, which may eliminate recurrent ulcer but cause unpleasant post-operative sequelae.

Mention is made of a method on trial for improving the reduced stomach capacity found at times in the early months after operation.

I thank Dr. E. M. Buzzard for giving so much time and effort as an independent judge in this assessment.

INFANTILE ECZEMA TREATED WITH ORAL CORTISONE A CLINICAL REPORT

BY

BETHEL SOLOMONS, *jun.*, M.D., F.R.C.P.I.*Dermatologist to Dr. Stevens' and the Royal City of
Dublin Hospitals*

The dramatic but unfortunately temporary improvement which occurs in infantile eczema when cortisone is administered has already been reported by Glaser *et al.* (1951). The purpose of the present trial was to observe the clinical transformation which they found.

Some cases urgently call for temporary improvement because of the severity of the skin lesions and the distressingly poor general condition of the infant. For these, short courses of cortisone may be considered, but, bearing in mind the potential dangers of the drug and the relative harmlessness of infantile eczema, it should be administered only to carefully chosen cases.

All the 15 cases in this series were severe and, except for the two with hay-fever, had had a good deal of treatment. The routine management of the condition, which was carried out before it was thought necessary to administer cortisone, consisted in a carefully taken history, general examination, skin-testing, local and general forms of treatment, as well as a period in hospital. Each patient was also regularly weighed, and regular eosinophil counts and routine blood pressure estimations were made. There were 10 males and 5 females. Five were between 6 and 12 months old; two were between 1 and 2 years, and seven were between 2 and 3 years.

The most difficult point to arrive at in these cases was to determine upon a dose unlikely to produce toxic effects, and it was thought wisest not to exceed 75 mg. a day. This was adhered to except in three cases, in which 87.5 mg. daily was given for a short time. No other treatment was given, except when weeping lesions were present and local applications were essential.

In the following three groups of cases only observations referable to the clinical response of the eczema have been noted. The first group describes a number of infants whose response to cortisone was slow, unconvincing, and not maintained. In none of these was an exacerbation seen after treatment. The third case produced toxic symptoms.

Group 1

Case 1.—A 7-months-old boy had had weeping lesions on the face and flexures of the elbows for four months. His mother and sister had asthma. On June 3, 1952, 50 mg. of cortisone daily was started. As there was little change two weeks later, 75 mg. was given daily. A slight improvement resulted, and after six weeks, although the lesions were drier, cortisone was gradually discontinued. When she was seen two months later exudative lesions were again present.

Case 2.—A boy aged 8 months had had eczema of the face, flexures, and trunk for the previous three months. From April 2, 1952, he was given 75 mg. of cortisone a day. There was no improvement after fourteen days, and the dose was increased to 87.5 mg. daily. After another fortnight the condition was much the same, and the drug was gradually discontinued.

Case 3.—A 2-year-old boy had suffered from eczema of the face, neck, and flexures of arms and legs for twenty

months. There was a lot of crusting and scaling. He had a moderate degree of ichthyosis. From March 12, 1952, he was given 75 mg. of cortisone daily. A month later the skin was much improved, but, alarmingly enough, there was a rounding of the face, with increase of the scalp and eyebrow hair. He gained 2½ lb. (1.1 kg.) in seven days. The cortisone was discontinued within a week. The eczema relapsed within ten days. At the end of a month his weight was the same. By the beginning of August his face was normal, and the excess hair had markedly diminished.

Case 4.—A boy aged 2 had had severe atopic dermatitis of the face, flexures of elbows, and forearms for eighteen months. His father had eczema and asthma. On January 6, 1953, 75 mg. of cortisone daily was started. At the end of a week he was much better, and the dose was reduced to 50 mg. daily. Three days later exuding lesions were again present. The dose was raised to 75 mg. daily, but as this did not control the rash, at the end of a week it was increased to 87.5 mg. daily. After 16 days with no improvement the drug was gradually discontinued.

Case 5.—A 3-year-old girl had had severe generalized atopic dermatitis since the age of 18 months; her arms and legs were very excoriated, and itching had been extreme. Her mother has severe asthma. From November 7, 1952, the patient was given 75 mg. of cortisone daily. A fortnight later the itching had diminished, but the rash had not quite cleared from the legs. The dose was dropped to 62.5 mg. daily, but within five days the skin condition was worse. Again 75 mg. daily was administered, but, as it produced scarcely any improvement after a fortnight, 87.5 mg. daily was given for 14 days. Little improvement occurred, and the drug was gradually discontinued.

Case 6.—A 3-year-old girl had had severe chronic atopic dermatitis of the arms and legs, and slightly on the cheeks, for one year, with a flare-up causing oozing lesions. She was allergic to all types of fish, and had had severe attacks of angioneurotic oedema involving the face, mainly lips and tongue. She was given 75 mg. of cortisone daily from August 24, 1952. A week later there was little change, and the dose was increased to 87.5 mg. daily. Three weeks later the condition was much the same, so cortisone was gradually withdrawn. Her skin condition is now much the same as when first seen.

Group 2

These cases illustrate a moderately good response to cortisone. Exudation was abolished for considerable periods, and itching was always remarkably reduced.

Case 7.—A 10-months-old girl had had a severe dermatitis of the face, flexures of arms, and backs of knees for three months. From April 8, 1952, 50 mg. of cortisone was given daily. Within a week all the lesions were dry, and five days later the dose was cut to 37.5 mg. daily. On May 10 there was a sudden flare-up of the facial lesions, but a return to 50 mg. daily rapidly improved it. This dose was maintained for eight weeks. It was gradually reduced to 25 mg. daily and stopped on August 2. During the past 10 months she has had two mild recurrences, relieved by local treatment.

Case 8.—A girl aged 15 months had had moderately severe atopic dermatitis involving the cheeks, backs of forearms, legs, and thighs for four months. From May 28, 1952, she was given 75 mg. of cortisone daily. Ten days later there was a great improvement and the dose was cut to 50 mg. a day. Two weeks later she got worse and moist lesions appeared. The skin responded well again to 75 mg. daily, and 14 days later it was reduced to 62.5 mg. During the next three months the dose varied between this and 37.5 mg. daily. It was discontinued at the end of October. When seen in April, 1953, there was some redness and scaling, but there had been no exudation, and itching was negligible.

Case 9.—A boy aged 2½ had had diffuse papular lesions on the trunk, limbs, and face for ten months. His sister had had eczema as an infant. On September 4, 1952, 75 mg. of cortisone daily was started. Ten days later

owing to marked response, it was reduced to 62.5 mg. and a week later it was possible to cut it to 50 mg. daily. At the middle of October the dose was further reduced to 37.5 mg. daily and, as no new lesions appeared, a month later cortisone was gradually discontinued. When last seen in May, 1953, there had been no fresh acute attacks. There was a little redness of the flexures of the arms, and occasional papules appeared on the trunk.

Case 10.—An 11-months-old girl had had itchy papular lesions of the face, neck, and interscapular regions for five months. Her scalp was covered with a good deal of greasy scales. On November 6, 1952, 50 mg. daily of cortisone was started. In ten days there was considerable improvement of the facial and interscapular lesions. The scalp also improved, but never to the degree of the other areas. At the beginning of January, 1953, there were no lesions below the scalp, and the cortisone, which had been maintained at the original dose, was gradually discontinued. When last seen in April, 1953, nothing abnormal was noticed except slight scaling on the scalp.

Case 11.—A 15-months-old boy had a sudden exacerbation of eczema, from which he had suffered since the age of 10 months. Weeping lesions developed on the cheeks, arms, and forearms. The attack may have been due to wool, to which he was extremely allergic. From October 6, 1952, cortisone was given in doses of 50 mg. daily. By the end of a week the lesions were dry, and ten days later the dose was cut to 37.5 mg. daily. A month later only redness and a few papular lesions were present in the original areas, and cortisone was discontinued. Up to May, 1953, there had been no further acute attacks, although the rash was more pronounced and itchy.

Case 12.—A 2-year-old boy had had a diffuse papular rash involving the face, arms, trunk, and backs of knees for seven months. From March 22, 1952, 75 mg. of cortisone was given daily. Ten days later, as he was much improved, the dose was reduced to 50 mg. The rash began to recur within a week. He was again given 75 mg. daily, and this was maintained for six weeks. It was very gradually reduced to 25 mg. daily over a period of seven weeks, and successfully discontinued in July. In March, 1953, he developed weeping lesions for the first time, and 75 mg. daily for a month was necessary to dry them up. Gradual withdrawal over a period of six weeks resulted in no relapse, and when seen in May there was a slight papular rash involving the cheeks and the backs of the knees.

Group 3

This group showed a very satisfying response, reacting rapidly to cortisone, without return of symptoms.

Case 13.—A boy aged 9 months had had dry papular lesions on the face, scalp, shoulders, and flexures of elbows, and slightly on the wrists, for two months. On June 11, 1952, cortisone, 50 mg. daily, was started. A week later the rash had cleared except for very slight scaling and redness of the face. Up to September it was kept in good control by 37.5 mg. or 25 mg. daily. It was slowly discontinued in October, and there had been no exacerbation up to March, 1953.

Case 14.—An orphan boy aged 2½ had a papular and scaly dermatitis of the face, arms, legs, feet, and interscapular and lumbosacral areas, associated with hay-fever. It was his second attack, the first one having occurred a year before. On May 7, 1952, cortisone, 50 mg. daily, was started. Ten days later he was practically well. By the middle of June, as pollination was over and the signs of eczema were limited to slightly scaly areas on the back of the left leg, cortisone was gradually discontinued. There was no recurrence up to January, 1953, soon after which he went to America.

Case 15.—A girl aged 3 had a severe diffuse papular dermatitis associated with severe hay-fever. It was her first attack of eczema. On May 10, 1953, cortisone, 75 mg. daily, was started. There was an immediate improvement in the hay-fever and skin lesions. Five days later the dose

was reduced to 50 mg. daily. A week later the rash had disappeared except for residual erythema. She was maintained on 37.5 mg. daily until the middle of June, when the drug was discontinued. A month later there had been no recurrence of the rash.

Comment

Owing to the dangers already mentioned, there seems to be little justification at present for administering cortisone to infants with eczema, unless the lesions are severe, the infant's general health is definitely deteriorating, and scratching has become a ceaseless habit. Then cortisone is often of great value for temporary improvement. Sometimes there is a temptation to give it in moderate cases when there is pressure from anxious parents, but it is better to explain to them that the benefits of cortisone in infantile eczema are only temporary, and indicate that exacerbations may occur after withdrawal of the drug.

One of Lever's (1951) contentions regarding the disadvantages of cortisone in atopic dermatitis is that the rebound of the disease after discontinuation of the drug is worse than in most of the other diseases. My patients, however, did not have this experience following treatment, although lesions assumed their former character in many. Unfortunately, toxic effects give no warning of their appearance. The 2-year-old boy (Case 3) developed excessive growth of hair four weeks after a relatively low dosage of cortisone. Other patients who had larger doses had no toxic symptoms. One of the infants in Glaser's (1952) series developed transient hypertension.

Generally speaking, when the patient responds to cortisone it should not be continued for a protracted period. But in very exceptional cases Baer and Leider (1951) consider it warranted so long as a maintenance dose of 25 mg. is used. Glaser (1952) has also done this when asthma was a feature of the case, and W. R. F. Collis (1953, personal communication) reports a case of infantile eczema, complicated by asthma, which has been treated with A.C.T.H. and cortisone for one year without ill effects and with much benefit. Glaser (1952) suggests that in long-term therapy alternation between courses of A.C.T.H., which causes hypertrophy of the adrenal glands, and cortisone, which causes atrophy, should be used to maintain a reasonable balance.

The euphoria which is usually so pronounced in adults taking this drug is also obviously present in infants. Also, their appetite increases and sleep is prolonged, and all these features are usually evident within two or three days of taking cortisone. When the eczema responds to cortisone the effect is so dramatic and satisfying that the underlying complex, and perhaps allergic, nature of the condition is frequently forgotten. It often requires a little reflection on the part of the administrator to realize that, unfortunately, the treatment is symptomatic only.

As will be seen from the description of these cases, there were few results which could be classified as good. Two cases which responded well were associated with severe hay-fever, and Reicher *et al.* (1952) have already shown that the latter condition frequently benefits from the judicious use of cortisone. In most of the other cases, all of which had severe skin lesions, the temporary benefits these unfortunate infants obtained appeared to justify the administration of short courses of cortisone.

The question yet to be answered is: What will be the effects produced by this early administration of cortisone as the infants grow? On account of immediate and unknown late risks, therefore, it is felt at the moment that until every other form of treatment has been tried, and except for the severe distressing generalized cases, cortisone should be withheld in infantile eczema.

Summary

Fifteen cases of infantile eczema were treated with oral cortisone. Temporary benefit usually resulted.

One case showed toxic effects by growing an excess of hair on the face.

Infections which are easily masked by cortisone should be carefully watched for.

Medical Memorandum

Use of Methyl *N*-Propyl Ether as an Anaesthetic for Children

The use of methyl *n*-propyl ether in anaesthesia dates from its inclusion in a series of ethers investigated by Krantz *et al.* (1946). The physical and chemical properties are not dissimilar to those of diethyl ether, of which it is an isomer, and similar precautions against explosion risk must be observed. Its safety margin is close to that of diethyl ether, the arbitrary standard (Krantz *et al.*, 1947), and it is excreted from the body without having undergone metabolism. The chemical formulae of the two substances are:

In the present series of 378 cases in which methyl *n*-propyl ether was used as a maintenance agent all the patients were subjected to plastic surgical procedures, and the group selected for study includes ages from birth to the fifth birthday, distributed as follows: 1st year, 108; 2nd year, 87; 3rd year, 71; 4th year, 50; 5th year, 62.

By the age of 3 most of the surgery for hare-lip and cleft-palate has been completed, and the liability to burns and trauma causes the increase in surgery in the fifth year and subsequently. The duration of administration of anaesthesia varied from 10 minutes to 180 minutes, the average being 76 minutes. With the exception of eight cases, administration was carried out by means of an intratracheal tube, using the method described by Picken (1950), the vaporizing agent being oxygen or a 2:2/3 oxygen and nitrous oxide mixture at a flow rate of 4 to 5 litres a minute.

In this series 209 patients were operated upon for repair of hare-lip and/or cleft-palate, among them an Abbé repair of primary hare-lip at 5 months, in which the administration lasted 145 minutes; 80 underwent excision and/or grafting of burns; and the remaining 89 were submitted to a large variety of procedures, including a repair of spina bifida lasting 105 minutes, eleven hours after birth, and a colostomy at 26 hours.

Premedication.—Atropine alone, 1/200 to 1/100 gr. (0.3 to 0.6 mg.), was used in the smallest children. Pentobarbitone sodium ("nembutal") at the rate of 0.7 gr. per stone (7 mg per kg.) body weight, with atropine, was given orally to some; morphine sulphate, 1/40 gr. per stone (0.25 mg. per kg.), with atropine was given to others; while a few of the older children received papaveretum and scopolamine. All these drugs, with the exception of pentobarbitone, were given by the intramuscular route.

Induction.—Cyclopropane and oxygen 50:50 was used as the inducing agent in 200 cases, and ethyl chloride followed by methyl *n*-propyl ether on the open mask in most of the other 178. In a very few cases induction and maintenance were carried out with methyl *n*-propyl ether alone. Cyclopropane is preferred by one of us (H. G. M.) because it gives a very rapid induction, free from coughing or excitement. Its vapour density (21) is greater than that of air (14.3), and most of the children were anaesthetized without

the use of a mask by "pouring" the gas from a tube concealed within the hand. Intubation was carried out, using either the Magill or the Macintosh laryngoscope, as soon as the jaw was relaxed. Induction with ethyl chloride and methyl *n*-propyl ether appeared to be more rapid than induction under similar circumstances with ethyl chloride and diethyl ether. The relatively non-irritating vapour of methyl *n*-propyl ether causes less coughing and breath-holding and allows induction to proceed more smoothly.

Course.—After intubation anaesthesia was maintained with either pure oxygen or a mixture of nitrous oxide and oxygen as a vaporizing agent for the methyl *n*-propyl ether. The vapour is carried by pressure tubing to a Cardiff connector attached to the end of the intratracheal tube so that there is no resistance to breathing in the circuit. Because this ether is relatively non-irritating we have found that anaesthesia may be deepened very rapidly when required, and therefore a very light plane may be maintained when relaxation is not needed. The respiratory rate is not apparently increased to the same extent by methyl *n*-propyl ether as by diethyl ether, nor is there any apparent increase in capillary oozing in the presence of an unimpaired airway. We have observed no cardiac irregularities in the series. The response of the pupil to methyl *n*-propyl ether shows a time lag when compared with the sequence for diethyl ether (Guedel, 1937), and consciousness may be reached during withdrawal of anaesthesia from depth before the pupil contracts (Shane, 1947). Recovery from anaesthesia is rapid, and the cough reflex is quickly restored. Excitement and struggling are very uncommon. It has been found possible to begin feeds in all cases very soon after withdrawal of anaesthesia, thus minimizing nutritional loss. In the concentrations used there have been no complaints of headaches or disagreeable feelings in the surgical teams (Fisher and Whitacre, 1947).

Sequelae.—We have found no significant alteration in the incidence of post-operative nausea and vomiting when compared with diethyl ether. No vomiting persisted beyond the first post-operative 24 hours. The type of surgery undertaken in this series has necessitated the acceptance for operation of a higher than normal proportion of patients with chest infections. It is our impression that complications are few, since coughing is restored rapidly and co-operation in physiotherapy soon follows. There were no deaths immediately or remotely attributable to the anaesthesia.

We are indebted to Mr. Emyln Lewis, consultant plastic surgeon to the United Cardiff Hospitals and the Welsh Regional Hospital Board, under whose care these patients were admitted, for his co-operation.

The United States Food and Drug Administration has directed that drug products containing more than 5% of oil of wintergreen must bear on their labels a warning that they should be kept out of reach of children, and that use contrary to directions may be dangerous. The methyl salicylate in the oil of wintergreen attracts young children by its smell, and a considerable number of deaths have occurred in the U.S.A., as in Britain, from young children drinking such preparations as liniments containing oil of wintergreen. Parents are not often aware of how dangerous these preparations are to children.

STRESSES AND STRAINS

Stress and Disease. By Professor Harold G. Wolff, M.D. (Pp. 199; 38 figures. 40s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1953.

Psychosomatic disorders are in the forefront of medical attention at the present time, but they are difficult to investigate by the methods of inductive science. It is therefore valuable to have a general statement of the views of Wolff, who has been remarkably successful in devising objective methods for their study. Wolff uses "stress" in a slightly different sense from Selye, and more correctly in terms of mechanics. Stress is the internal or resisting force brought into action by the external force or load; the result is called strain or deformation. Wolff has been particularly concerned with the detection and measurement of these strains as revealed by disturbed function of organs, circulatory changes, contraction of smooth muscle, and similar effects in man. Selye has written more about the common and non-specific effects of illness seen in experimental animals, whose relevance to human disease has not yet been completely demonstrated.

Wolff gives a fascinating account of the experimentally observed effects of stress in man. He shows that much of the human equipment has to do with meeting emergencies and overcoming crises, and that in certain circumstances the responses may be qualitatively as well as quantitatively inappropriate and may result in disease. When he goes further and says that the social impact of man on man may be as seriously traumatic as the assaults of 'micro-organisms or physical forces, some of us will find it difficult to follow him. The actual proof that social or emotional upsets can produce peptic ulcers, ulcerative colitis, or exophthalmic goitre still seems to be lacking. Certainly these disorders have not been produced experimentally—as hysterical paralysis or anxiety neurosis has been so produced.

If it is argued that these diseases are multifactorial in aetiology, then surely the approach to them should be statistical and not anecdotal. The English reader will not find the interpretation of symptoms in terms of organ jargon convincing, particularly in American patients who appear to be well read in *Life*, *Time*, and the *Reader's Digest*, and anxious to volunteer what the doctor expects them to say. The epidemiological approach is likewise marred by special pleading. For example, on page 111 we are told that there was a striking rise in hyperthyroidism in Norway, Denmark, and Holland in the recent war, but not in neutral Sweden; and we are not told that there was no rise in England. Nor are we told that there was a striking fall in thrombosis and embolism in Norway during the war, though on page 89 we are told that one of the important effects of painful experiences or periods of alarm and anxiety is an increased clotting proclivity.

In conclusion, then, this monograph is most stimulating as a record of experimental work, but less convincing when the author is theorizing from his data. Indeed, one can say about Wolff what he himself says about Selye, that his generalizations, "important though they may be in illuminating aspects of many reactions to stress, cannot be construed as a universal formulation."

L. J. WITTS.

PHILOSOPHY OF VISION

Introduction to Physiological Optics. By Armin von Tschermak-Seysenegg. Translated by Paul Boeder, Ph.D. (Pp. 299; 111 figures. 75s.) Oxford: Blackwell Scientific Publications. Springfield, Illinois: Charles C. Thomas. 1952.

The American Committee on Optics and Visual Physiology, a joint committee of the American Ophthalmological

Society, the Academy of Ophthalmology and Otolaryngology, and the American Medical Association, has done a service by translating the second edition of Tschermak-Seysenegg's book into English. The German original appeared in 1941, but the book is still fresh and valuable. It breathes the spirit of the school of physiology of Prague, where the author occupied the chair in succession to the great Ewald Hering, one of the few whose experimental and philosophical work will always exert an influence on the interpretation of visual sensations and perceptions so long as these subjects are studied.

Tschermak's great contribution to our understanding of the physiology of the visual process was his insistence on the relationship between objective and subjective phenomena. His philosophy implied the reality of a physical sphere independent of the observer and a subjective sphere, equally real and equally susceptible of analysis, not identical with but related to observable physical phenomena. The reader will not find details of the optical, photochemical, or neurological groundwork of visual sensations in this book, but rather an interpretation of this dual philosophy of visual perceptions as applied to the light sense, the colour sense, and our appreciation of space. The original German text was by no means easy reading; nor, indeed, is this translation; but few could have conveyed the sense of the author in more readable and fluent English than the translator, Dr. Paul Boeder, of the Harvard Medical School.

STEWART DUKE-ELDER.

INDIAN SOCIAL MEDICINE

Medicine and Our Social Welfare. By Praphulla C. Dutta, O.B.E., M.B., D.G.O., F.R.C.S. Foreword by Professor F. A. E. Crew, M.D., F.R.C.P., F.R.S., and Introduction by Rajkumari Amrit Kaur, Minister for Health, India. (Pp. 185. 6s.) Calcutta: Thacker Spink and Co. 1953.

Professor Crew is right when he says that India is beset by a multitude of problems, and this book offers to the statesman both a challenge and loyal co-operation. One influential statesman, the Minister for Health, agrees with the author that the giants are ignorance, poverty, and disease, against whom must be brought environmental hygiene, health education, and housing—which is true of Britain also, but the needs are much more urgent in India.

In this book a short chapter on the history of medicine is interesting and salutary—salutary in that medical practice in some of the earlier civilizations is discussed from what to British readers is an unusual viewpoint, philosophic as well as geographic. Under the heading of socio-economics, the relationship in India between poverty on the one hand and morbidity and mortality on the other is starkly revealed. Here, as elsewhere, bad housing presents an appalling problem, but the basis of all the distress in India is clearly poverty and the other problems are essentially sequelae. The average income per head in dollars in India is given as 34; in the U.S.A. it is 554; in the United Kingdom it is 468.

There are at least two possible remedies—an increase of income and a reduction in the number of heads. The author is in favour of both, and in relation to fertility he discusses continence, the safe period, home-made contraceptives, sterilization, and contraceptive paraphernalia invented by Europeans and Americans for the destruction of the human race. The author, much burdened by the distress of the people and so much in earnest in his efforts to help, would increase his services to India if he would advise the first two methods only of family planning.

This little book produces a sense of grief—a sorrow that there should be so many millions of people in the world who are deprived of a minimum of the basic necessities to which in accordance with natural justice they are entitled. For that reason, I hope the book will be widely read, with consequent enlightenment and stimulation of conscience.

C. METCALFE BROWN.

THE TUBERCLE BACILLUS

The Metabolism of the Tubercle Bacillus. By William F. Drea, D.M.D., and Anatole Andrejew, I.C. With a foreword by Professor E. R. Long, M.D., Ph.D., Sc.D. (Pp. 448; 24 illustrations. 90s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1953.

This book is intended for the research worker in the field of tuberculosis and is compiled by two authors, one of whom is associated with tuberculosis research in the United States of America and the other in France. The present volume brings up to date *The Chemistry of Tuberculosis* published by Wells and Long in 1932 and *L'Infection Bacillaire et la Tuberculose* published by Calmette in 1936. In five chapters the authors review all the recent work on the metabolism of the tubercle bacillus, such as the organic and inorganic requirements of the tubercle bacillus for its growth *in vitro*, the modern methods and the principles of the depth culture of the bacillus, the respiratory requirements of the organism, both *in vitro* and *in vivo*, the enzymes associated with the bacillus and the products of metabolism of the organism. The most informative chapter is that on the enzymes, and the reading of this leaves one in little doubt how complex the whole problem of attacking the tubercle bacillus through its enzyme system must be. The work has been carefully compiled and reports the knowledge gained from about 750 recent publications on the subject. A list of these is given in the bibliography. The book requires intensive study to be appreciated, and its value would have been enhanced if the authors, who are authorities on the subject, had stated more frequently their own opinion on many of the papers under review.

JOHN W. S. BLACKLOCK.

PROBLEMS OF THE NEUROSES

Problems in the Field of Neurosis and Psychotherapy. By Professor H. C. Rümke. (Pp. 74. 15s.) Oxford: Blackwell Scientific Publications. 1953.

Professor Rümke attaches great value to Hughlings Jackson's principle and considers that its importance in psychiatry—especially in the understanding of the neuroses—has been overlooked. Jackson says, "The symptomatology of nervous diseases is a double condition: there is a negative and there is a positive element in every case." Disease produces negative mental symptoms due to the disturbance of integrative activity. What we observe in psychopathological states—namely, the positive element—is normal psychic life going on under the conditions brought about by the dropping-out of some function. Psychogenesis, Rümke believes, has been given too much significance, because psychiatrists, concentrating on the positive, have neglected the negative element. Only in a few cases is a psychogenic condition aetiological. A neurosis is not only a clinical condition but a syndrome made possible by entirely different circumstances. The neuro-physiological and neuro-anatomical studies of psychiatric disease have too often been neglected. Often unchangeable qualities in the personality are present, and it is here that psychotherapy finds its limitations. Nevertheless, Rümke considers psychotherapy to be indispensable. He admits that we must rely on clinical experience and acumen to realize the psychogenic factors and to separate them from the non-psychogenic. Psychiatric "sects" have been a source of weakness in the development of effective psychotherapy. There have been too many enthusiasts who feel that in one system or another lies the final answer to the problems of neurosis and psychotherapy. The personality of the patient must be assessed, and here he follows the teaching of Klages on the structure of the personality. The sections devoted to the personality of the psychotherapist are thoughtful and salutary. We must rid ourselves of the illusion that any psychotherapist who has had a training analysis is *ipso facto* an efficient psychotherapist.

This slim volume contains five lectures given to experienced psychiatrists with special reference to the organization of psychiatry in Denmark. Unfortunately the lecture form

has been maintained and the material is somewhat condensed and at times irritatingly dogmatic. Nevertheless this contribution is stimulating and will repay careful reading.

E. A. BENNET.

A GOOD DOCTOR

The Good Doctor, and other selections from the Essays and Addresses of William de Berniere MacNider. With tributes by Chancellor Robert B. House, Dr. William M. Coppridge, and Victor S. Bryant. Edited by William W. McLendon and Shirley Graves Cochrane. (Pp. 179. 40s.) North Carolina: University Press. London: Geoffrey Cumberlege. 1953.

William MacNider, the subject of this memoir, was born in 1881 in Chapel Hill, and he died there in 1951. One of his Negro fellow-citizens declared that he was "the best pneumonia doctor that's ever been on Chapel Hill." He was not only a horse-and-buggy doctor but he was also professor of pharmacology in the University of North Carolina. The long list of his scientific papers at the end of this finely produced book demonstrates the importance of his research work. His colleagues and his students write here eloquently of his enthusiasm, his devotion, and his goodness. "This little city of Chapel Hill has become indeed the Capital of the Southern Mind" we are told, and in no one was this better exemplified than in Dr. MacNider. He was a character if not a card: he would say to his pharmacology class, "It is spring; and this weekend forget pharmacology, send some red roses to your girl, go to church, and worship God." He came early under the influence of Osler, and the essays in this book are in the Oslerian tradition, but they have none of Osler's genius. In 1937 he addressed the medical school of the University of Tennessee on "The Biologically Minded Physician." This is a fine subject and we turned to the essay with eager expectancy. Two extracts will indicate its quality. "The great advance made in the understanding of heart diseases did not come from an elaborately mechanized laboratory but from and through the mind of a country doctor in Scotland carrying on his inquisitiveness on human beings living under thatched roofs in districts remote from medical centers." Can this be Burnley? "Money is refuse which comes as a by-product of thoughtful living in which happiness develops through a loss of the individual in thought and reason." One does not need to be a Stephen Potter to see that the example of William Osler encourages a turgid and unreasoning sententiousness in more ordinary physicians. Dr. MacNider was a great and good man in his place and in his generation; this expensive memoir has no more than a local and topical value.

D. V. HUBBLE.

Each year medical workers coin new words to describe their discoveries and express their hypotheses. So long as medicine is on the march this is inevitable—at least to some extent. True, some of the new terms are unnecessary, and some misbegotten, but there remains a useful modicum without which we could not well manage. This alone would be enough to justify the existence and regular revision of the several excellent medical dictionaries on the market. But, in addition medical nomenclature is so adorned—and muddled—by a wealth of synonyms, many eponymous, that it is hardly possible to read the briefest medical paper without recourse to a dictionary. *Stedman's Medical Dictionary* is one of the best available, and Messrs. Baillière, Tindall and Cox, Ltd., have recently brought out a revised edition (the eighteenth). It has been edited by Dr. Norman Burke Taylor, professor of medical history and literature in the University of Western Ontario, Canada, in collaboration with Lieutenant-Colonel Allen Ellsworth Taylor, classical editor. The printing was done in the United States, and the style and spelling are American. Besides the main body of the book, comprising 1,536 pages of double-column entries, there are an introductory chapter on medical etymology and some useful appendices (weights and measures, comparative temperature tables, anatomical nomenclature, etc.). This edition contains several thousand new entries and over 500 new illustrations. Although the great majority of the terms are medical, there are also words from dentistry, chemistry, botany, biology, and veterinary and electrical science. Brief medical biographies are given and eponymous terms are described. The dictionary is strongly bound, and is about the size of *Gray's Anatomy*. It costs 63s.

REACTIONS TO STRESS

When an animal is injured, develops an infection, is exposed to x rays or to cold, or is subjected to almost any circumstances not ordinarily encountered in its day-to-day existence, a series of bodily reactions take place which allow the animal to withstand and adapt itself to the insult. Professor Hans Selye, in Montreal, has carried out extensive and ingenious investigations in an attempt to elucidate the mechanisms by which this adaptation is achieved.^{1,2} Out of this work have grown his conception of the general adaptation syndrome and his belief that certain pathological conditions in man and animals—the so-called diseases of adaptation—are caused by some abnormality in this process of adaptation. Some of Selye's ideas are hard to accept, and his terminology does not make the understanding of them easier. Other investigators³ have not always been able to reproduce his experimental findings, and the interpretation and significance of the results, particularly when applied to man, are not clear.

When an animal is exposed for a long time to a particular noxious stimulus it adapts itself, and a series of bodily changes may occur, such as a fall in body temperature and blood pressure, involution of lymphatic tissue, lymphopenia, a polymorphonuclear leucocytosis, adrenal hyperplasia, and diminished resistance to other non-specific stimuli. The sum of these non-specific bodily reactions constitutes the general adaptation syndrome, and Selye believes that the adrenal cortex plays an essential part in causing the anatomical and biochemical changes found in the syndrome. Certainly adrenalectomized animals and patients with untreated Addison's disease are unable to survive minor traumata which would not cause any apparent disturbance in a normal subject. Other investigators^{4,5} have contended that the adrenals

play only a permissive role, that the presence of adrenocortical steroids is required for the changes found in the adaptation syndrome to take place but that they are not themselves the cause of the changes.

Selye observed that rats, when exposed to cold, forced exercise, or formalin, developed hypertension, transient arthritis and pathological lesions akin to nephrosclerosis, periarteritis nodosa, and Aschoff bodies, particularly if the animals were previously conditioned by unilateral nephrectomy and a high-salt diet. He postulated that, because these pathological lesions developed during the process of adaptation to a variety of different stimuli, they might be causally related to overactivity or abnormal activity of the adrenal glands. Support for this hypothesis was obtained by observing that the lesions could be potentiated with deoxycortone (D.O.C.) and prevented or attenuated with corticotrophin or cortisone. Selye suggested that for unknown reasons adrenal secretory activity sometimes becomes abnormal during adaptation to prolonged stress, that the balance is disturbed between the amounts secreted of mineralocorticoid inflammation-stimulating hormones (such as D.O.C.) and of glucocorticoid anti-inflammatory hormones (such as cortisone and cortisol), and that in consequence the diseases of adaptation develop.

These hypotheses have been criticized on many grounds.⁶ There is no satisfactory evidence that non-specific stressors will cause adaptation diseases in laboratory animals under naturally occurring conditions. It is doubtful whether the experimentally induced pathological lesions in rats, previously conditioned by removal of one kidney and fed on a high-salt diet, are the same as those occurring in the human connective-tissue diseases. While certain forms of stress, such as surgical trauma, undoubtedly cause increased adrenal activity, it has not been proved that all types of stress cause such a response.^{7,8} Until recently there was little evidence that a specific mineralocorticoid, especially potent in controlling electrolyte metabolism, was elaborated in man, but this objection must be overruled since the isolation of aldosterone (11,21-dihydroxy-3,20-diketo-4-pregnene-18-al), formerly called electrocortin.^{9,10} Preliminary reports^{11,12} on this substance suggest that it has glycogen-depositing and eosinopenic, in addition to sodium-retaining, properties, but it remains to be seen what are its physiological effects and whether there is any disturbance in the relationship between the amounts of this compound and of cortisol secreted before or after the onset of the so-called diseases of adaptation. There is little evidence to support the suggestion that non-specific therapy is beneficial in

rheumatoid arthritis, for example, by increasing the secretion of glucocorticoids.¹³ Although in a carefully conducted study Caughey and McCoy¹⁴ have reported that D.O.C. aggravated the arthralgia in a patient with pre-existing rheumatoid arthritis who subsequently developed Addison's disease (they did not, to quote Selye,¹⁵ "produce arthritis with D.O.C. at will"), Perera and Ragan¹⁶ failed in a similar case to aggravate the arthritis with D.O.C., and other workers¹⁷⁻¹⁹ have not found that D.O.C. exacerbates the symptoms of rheumatoid arthritis or counteracts the beneficial effects of cortisone.

The communication from Selye published in our opening pages this week is related to the observation that the inflammatory response to a locally applied irritant is much reduced when the experimental animal is exposed to stress. It has been previously supposed, but not proved, that the reduction in the inflammatory response is related to increased circulation of adrenocortical hormones, since it is well known that cortisone and cortisol diminish the intensity of an inflammatory reaction. In the present experiments croton oil was used as a local irritant to produce an inflammatory reaction, and starvation and forced immobilization to produce the general stress. The effects of the presence or absence of the adrenal glands and of the administration of glucocorticoids or D.O.C. were observed. Under the conditions of the experiment a general stress decreased the local inflammation. This decrease was greatest in animals with intact adrenal glands but occurred to a less extent in adrenalectomized animals maintained on small doses of cortisone or cortisol and not in animals maintained on D.O.C. Thus Selye postulates that the anti-inflammatory effect of general stress is mediated by two factors—an increased discharge of endogenous glucocorticoids and a peripheral synergism between the corticoids so liberated and some other effect not mediated through the adrenal glands. He also found that further application of the local irritant caused a greater degree of necrosis in those animals that were subjected to stress and previously had shown the least inflammatory reaction. Selye uses this as evidence that local tissue reactions can be modified by stress applied several days earlier.

What deductions about human reactions may be drawn from these experiments is uncertain. It remains to be shown how much starvation or forced immobilization activates the pituitary-adrenal system, and what is the nature of the non-adrenal factor which reduces the inflammatory reaction and increases the tendency to necrosis. Critics may question whether the condition of an immobilized rat "is not unlike that occasioned by physical and mental fatigue in

man." When all has been said, Selye's technical brilliance as an animal experimenter, and his imaginative boldness in theory, continue to act as a provocative stimulus to other workers.

OCCUPATIONAL MORTALITY

The late Professor M. Greenwood¹ described the Registrar-General's decennial studies of occupational mortality in England and Wales as "the most valuable single instrument of socio-medical research our national armoury contains," and many will wish to study the latest contribution in this series, a preliminary analysis of deaths in 1950 related to the 1951 Census 1% sample tables. This publication² is the more welcome in that it is twenty years since the previous occupational mortality analysis was undertaken, when deaths in 1930-2 were related to the 1931 Census, and many changes have taken place since then in our national life and in medical science and practice, changes that could have the effect of rendering some of these earlier findings out of date. In due course this report will be followed by a much more detailed one covering the five years 1949-53.

Since 1851 the Registrar-General has taken the deaths registered in or about each census year and has related them to the numbers of people enumerated in various occupations at the census; and since 1911 the occupations have been grouped into a number of so-called social classes. Eight classes were distinguished in 1911, but since 1921 there have been five—I (professional occupations), II (intermediate), III (skilled), IV (partly skilled), and V (unskilled occupations). This social classification is purely an occupational one, and takes no regard of personal circumstances, income, education, and so on except in so far as these are reflected by the individual's occupation. As only one year's deaths have been tabulated for this latest report and as the population estimates are based only on a 1% preliminary sample, most of the mortality rates that are given are for the social classes; little attempt has been made to calculate rates for individual occupations, though a few are shown for one or two large groups such as miners, transport workers, and clerical workers. Mortality indices for various diseases are given separately for men aged 15-64 and aged 65 and over, and for married women classified by their husbands' occupations.³

Though it will probably be advisable to await the detailed five-year tables before drawing too many conclusions from this interim report, comparison of

¹ *Some British Pioneers of Social Medicine*, 1948, London.

some of the 1950 results with those for 1931 makes an interesting and profitable study. In the 1931 analysis, as in the one before it, the standardized mortality ratio (S.M.R.) of men aged 15-64 increased steadily from social class I, where it was 90, to social class V, where it was 111. The same kind of difference has persisted between these two classes in 1950, with S.M.R.s of 97 and 118, but the indices for the three intermediate classes have lost their uniform gradient. In 1950 the lowest index of all was given by social class II (86) and the second lowest by social class IV (94). This reorientation of the social class mortality gradient has not arisen, it is believed, from random fluctuations in the data, but the report suggests the advisability of awaiting confirmation from the full 1949-53 analysis before speculating unduly about the reasons for the change.

Among causes of death that, as in 1931, showed a steep gradient of increasing mortality from professional to unskilled occupations were bronchitis (S.M.R. increasing from 33 in social class I to 172 in social class V), pneumonia (43 rising to 157), gastric ulcer (56 to 144), cancer of stomach (57 to 132), myocardial degeneration (67 to 137), and respiratory tuberculosis (64 to 149—but only 62 in social class II). Once again coronary disease displayed the opposite tendency, with highest mortality among professional men and the lowest among unskilled workers. In 1931 the range of S.M.R.s was from 237 to 67, and though the disparity was less in 1950 (namely, 150 to 89) it is still a striking feature of this disease. One odd finding, however, was that the gradient for coronary disease in married women was in the opposite direction to men, a new development since 1931. With so much interest centring upon cancer of lung these days it is worth observing that the social-class mortality gradient among men was indefinite in 1921 and 1931; and the new figures do not help much. S.M.R.s were lowest in social classes I and II (80 and 79) and highest in social classes III and V (108 and 116), the index for social class IV being 89. There was evidence, as in 1931, of higher mortality from leukaemia in professional than in unskilled occupations and of a similar, though less certain, gradient for appendicitis.

An analysis of infant mortality and of stillbirths by social class confirms what has been suspected for some time, that despite the enormous reduction in mortality that has been achieved during recent decades the characteristic social class differences have remained relatively unchanged. Total infant mortality has remained more than twice as high among the children of parents in unskilled occupations as among the children of those in professional occu-

pations—rather less than twice as high for stillbirths and deaths under 4 weeks of age, but four times as high for infants dying between 4 weeks and 1 year. If social advance during the course of this century has been responsible, as most believe, for much of the recent improvement in infant mortality, it is clear that all sections of the community have shared in these advances and that the social factors that influence infant mortality are as widely dispersed as they were thirty years ago.

At a recent meeting of the Epidemiology Section of the Royal Society of Medicine Dr. W. P. D. Logan discussed the development of occupational mortality studies and gave a preview of the 1950 results. He summarized the value of these studies as a means not for detecting specific occupational risks but for providing background data for epidemiological research and for widening our understanding of the aetiology of disease. Like its predecessors, the latest report provides ample material for this purpose.

FITNESS, FERTILITY, AND BLOOD GROUP

The human blood groups are remarkable in that they show how several alternative, not uncommon, genetic factors may occupy a particular place on a chromosome and yet their relative frequencies remain remarkably constant so far as can be judged. In England the proportions of the three genetic factors or groups of factors responsible for the A, B, and O antigens were estimated by Dobson and Ikin⁴ to be 32, 6, and 62% respectively. Most other populations have appreciable amounts of each of these three antigens, though the proportions differ from country to country. If any one of these genetic factors contributed even some slight extra element of fitness to their possessors, we should have expected this factor to be common and the others to be rare. It is natural then to look for mechanisms which could produce a stable balance between the different groups.

One possibility, as Fisher⁵ indicated in a general discussion of problems of this kind, is that the heterozygotes (for example, those who are AB, AO, and BO) have some extra element of fitness over individuals who are homozygous (those who are AA, BB, and OO). To take an extreme theoretical possibility merely by way of illustration, if those who are AA and OO were unable to reproduce, while those who were AO were fertile, random mating would always give a population one-quarter AA, one-quarter OO, and one-half AO. Another possibility is that the genetic factor for one antigen may have

an advantage under one set of circumstances, say town-life or life in the valleys, while that for another has the advantage in country-life or life in the hills. Constant migration between town and country or hill and valley would prevent either antigen from finally ousting the other.

Several workers in consequence have been searching for such balancing selective advantages of one or other of the blood groups. Perhaps the best-established finding hitherto is that by Aird, Bentall, and Roberts³ that there is a definite excess of group A among patients with carcinoma of the stomach. The selective effect of this would be small. More striking, though perhaps needing confirmation, is Struther's⁴ finding that in a Glasgow hospital there were an excess of A children among those dying under the age of 2 years and that this was confined to those in whom, macroscopically at least, bronchopneumonia was present at necropsy.

Another approach is that begun by Hirsfeld and Zborowski.⁵ They noted that in some series where both parents and child had been grouped there were relatively fewer A offspring from the mating of O mothers with A fathers than in the mating of O fathers with A mothers. Hirsfeld,⁶ however, was unable to confirm this in his later work. Waterhouse and Hogben⁷ retested the hypothesis on a mixed collection of series published up to 1944, selecting only those series which they considered were reliable. They found a highly significant shortage of A children from the mating of O mothers with A fathers and that this deficit increased with increasing birth order. This work may be criticized on the grounds that the series were not homogeneous and because of possible unconscious bias in selection. No one has tested the hypothesis on a single large personal series where the groups of children and both parents are known, but Boorman⁸ in a large series from one hospital found no deficit of A children of O mothers compared to O children of O mothers. On the other hand, support for the idea of progressive loss of A children of O mothers has come from Kirk and Stenhouse's⁹ observation that in an Australian hospital O women had significantly more pregnancies before the age of 25 and after the age of 35, though A women had more children between 25 and 35 and also a slightly higher overall fertility. They suggested that O women might be basically the more fertile, but that some of them became sterile from A-O incompatibility.

The most recent contribution on these lines is an ingenious analysis by Allan¹⁰ of Waterhouse and Hogben's collected series. He shows that in these series it is not compatibility of mating that appears important but rather that each sex has its own order of fertility according to blood group. For example, men who are group A have relatively few children not only when married to an O woman but also when married to women of any other group. Disregarding the marriages where both parents have the same group, he finds that the order of fertility for mothers is A, O, AB, B, and for fathers is precisely the reverse, B, AB, O, A. It is not clear that these differences in fertility according to sex could by themselves produce a balanced polymorphism, but combined with differences in survival rate

they might well do so. Allan¹¹ has in fact found some indication of such differences in the relative ages of blood donors of groups O, A, and B in earlier wartime series from south-west England and from Ulster. For men the order of increasing age (and so perhaps of increasing fitness) was B, A, O, while for women the order was the reverse, O, A, B. These tendencies run counter to the differences in fertility. All this work so far has thrown up intriguing hypotheses rather than definite facts. New series are required on which the hypotheses can be further tested—not only series of families but series of children according to age and sex, and series of patients with many different diseases.

THE APOCRINE GLANDS

According to the recently published researches of Shelley, Hurley, and Nichols¹ the characteristic smell emanating from the human adult is due to bacterial decomposition of the secretion of the apocrine glands. These glands, which do not become active until puberty, are normally to be found only in the axillae, around the nipples, and within the genital and perineal area. They are situated in the deepest part of the dermis or in the subcutaneous tissues, and consist in a single coiled tube from which a duct passes to convey the secretion to the surface of the skin. The duct commonly empties into hair follicles. Secretion of the apocrine glands is stimulated by adrenaline and the result is a viscid, white, milky fluid. Hurley and Shelley² have provided considerable evidence that this is the only secretion produced by the apocrine glands. Other workers have at times suggested that these glands may also produce a clear watery fluid, but according to Hurley and Shelley the latter is always the product of adjacent eccrine glands of ordinary sweat-gland type. The function of the apocrine glands is not precisely known, but it is suggested that they have the property of attracting the opposite sex. It is certainly difficult to believe that any vestigial structure would show such active function as the apocrine glands.

Shelley, Hurley, and Nichols have now demonstrated that when apocrine fluid is secreted it is entirely without smell; if it remains sterile or if antiseptic is added no odour develops, but if the ordinary bacterial inhabitants of the axilla are allowed to contaminate the sweat the characteristic odour develops within a few hours. In these experiments it was found virtually impossible to sterilize the skin of the axillae, and the presence of hair makes this even more difficult. The development of axillary odour can be considerably delayed if the area is shaved and treated with an antiseptic such as hexachlorophene, and these authors found that if the axilla is shaved and washed axillary odour fails to develop within 24 hours in nine out of ten subjects. The same authors have examined the effect of deodorants; they conclude that deodorants make no notable difference to

¹ Arch. Derm. Syph. (Chicago), 1953, 68, 430.

² Brit. J. Derm., 1954, 66, 43.

³ Ibid., 1952, 64, 116.

⁴ Brit. J. plast. Surg., 1953, 6, 231.

the amount of apocrine secretion, but they were able to show that aluminium chloride has an antibacterial effect in addition to a property of neutralizing in some way those products of bacterial decomposition which actually cause the smell.

The apocrine glands do not commonly give trouble. The rare disorder known as Fox-Fordyce disease consists in an itching papular eruption which usually appears on all those areas where apocrine glands are present. It is believed to be due to blockage or inflammation of the ducts of these glands, but nothing is known of its nature. Occasionally the glands become infected, and this leads to painful boils. The axillary fat is liable to be infected, with the production of chronic sinuses which may undermine the skin for some distance around. It is usually the axillae which are affected, but in more severe cases the groins and perineum may be involved as well, and an extensive area may become undermined by fistulous tracks. In milder cases conservative local treatment is all that is necessary and it is probably better if the temptation to incise the abscess is resisted. In more resistant cases this treatment is not enough, but hormonal therapy, which has sometimes been tried, seems to be ineffective. Long courses of antibiotics given systemically do not often accomplish a great deal.

The unhappy plight of these patients has led surgeons to attempt more drastic measures. Goldsmith showed at the Royal Society of Medicine a patient who had been treated by Naunton Morgan.³ On several occasions deep abscesses and sinuses had been opened on to the surface and packed so that they were made to heal by granulation from the bottom. Healing is slow and results in considerable scarring, but eventually the infection seems to be overcome.

Wynn Williams⁴ now records the results in his cases of excising the entire area of skin together with subcutaneous tissue and grafting. Only the axillae required treatment and the results were entirely satisfactory. On the perineum this might not be so. This procedure may at first seem rather drastic, but the apparently hopeless plight of the patient who is seriously affected no doubt justifies the operation.

THE CAMBRIDGE MEDICAL SCHOOL

The Cambridge Medical School occupies a distinctive position in the medical services of East Anglia, and it is fitting that the headquarters of the school should now occupy new, though still temporary, premises in the grounds of Addenbrooke's Hospital. As Sir Lionel Whitby, the Regius Professor of Physic, writes in his latest annual report,¹ the new premises, which include haematological and chemical laboratories, will afford further opportunities for the closer integration of the teaching and research staffs of the university departments with the staff of the United Cambridge Hospitals. The school of postgraduate teaching and clinical research comprises the departments of medicine, experi-

¹ Cambridge University Reporter, 1954, 84, 841.

mental medicine, radiotherapeutics, and human ecology; and the pathological and biochemical services of the United Cambridge Hospitals are provided by university teachers under the direction of the professors of pathology and biochemistry. Undergraduates cannot, as yet, complete the full clinical course at Cambridge, but a limited number can work for a time as medical clerks, surgical dressers, or obstetrical clerks. During the long vacation there is a course in elementary clinical methods, which helps to bridge the gap between the pre-clinical and clinical periods of the curriculum. One of the most popular features of postgraduate training at Cambridge are the one-day symposia on subjects of particular interest to general practitioners. These are held on Saturdays at monthly intervals, and the total attendance at the ten symposia during 1952-3 was 290.

Under arrangements made with the Ministry of Health many general practitioners are able to attend the postgraduate courses and symposia without fee. Clinico-pathological conferences, also held once a month, afford useful opportunity for local general practitioners to meet the staffs of the hospitals and of the medical school. In these and other ways the several departments of the university medical school are being used to help clinicians with the day-to-day problems of clinical practice.

MEDICINE IN INDIA

In its campaigns for educational and hospital reform in India, for improved public health measures, and for the suppression of quackery and other abuses, the monthly periodical the *Antiseptic* holds a prominent place of honour in that great subcontinent. It was started fifty years ago by two remarkable men—Dr. T. M. Nair, its first editor, and Dr. U. Rama Rau, who succeeded to the editorship on the early death of Dr. Nair. By a family succession unique in scientific journalism Dr. Rau's son, Dr. U. Krishna Rau, followed him as editor, and his son, Dr. U. Vasudeva Rau, has now taken over in turn, his father remaining proprietor. A special issue of the journal to mark its golden jubilee has now appeared, and we join with many other well-wishers in offering our congratulations to those responsible for producing this vigorous publication. It is only natural that on some occasions during these fifty years of campaigning to improve both the standards and the working conditions of the medical profession in India the *Antiseptic*, and those who thought like it, should have had differences of opinion with British Government representatives. But a retrospect shows that men of good will in the two nations were not seriously divided over these issues, which may be seen now rather as the struggles of humane idealists against the traditional conservatism among the people of the country and the caution habitual to governing bodies. With Sir Arcot Mudaliar, who contributes a foreword to the golden jubilee number, many will hope that the *Antiseptic* "will continue its great mission."

CLINICAL PATHOLOGY IN GENERAL PRACTICE

LABORATORY CONTROL OF CHEMOTHERAPY

BY

ROBERT KNOX, M.D., F.R.C.P.

Professor of Bacteriology, Guy's Hospital Medical School

In the past few years our ability to deal with most bacterial infections has been transformed by the discovery of a series of powerful antibacterial drugs. But knowledge of the correct use of these drugs has not advanced so fast, and there is a danger that, through misuse, many of them may lose their effectiveness or even do harm. The practitioner, knowing that laboratory results are often too late to be of immediate use in urgent cases, tends not to consult the laboratory in those cases in which it can be really useful. The laboratory worker often lacks the experience or imagination to understand the practitioner's difficulties and is apt to criticize him for using drugs blindly without laboratory tests. Yet if these drugs are to be used wisely and safely there is urgent need for clinician and laboratory worker to share their ideas and experience.

Chemotherapy for our present purpose may be defined as "the treatment of infections by specific drugs"—specific both because ideally they are drugs which attack the infecting organism without harming the tissues of the patient and because many of them selectively attack some micro-organisms and not others. In both these ways they differ from antiseptics, though it is not always easy to draw the dividing line. The chemotherapeutic substances in use at the present time fall into two main groups: (1) substances of known constitution prepared by the chemist, such as the sulphonamides, *para*-aminosalicylic acid, isoniazid, etc.; (2) substances which may be of known or unknown chemical composition synthesized by living organisms—the class of antibiotics such as penicillin, streptomycin, chloramphenicol, aureomycin, oxytetracycline ("terramycin"), polymyxin, and erythromycin. The distinction can, of course, be artificial, since chloramphenicol when synthesized by the micro-organism *Streptomyces venezuelae* is classed as an "antibiotic" but it becomes a "drug" or chemotherapeutic substance when made by the chemist.

The laboratory can take part in the control of chemotherapy in the following ways: (1) by identifying the causal organism by direct microscopy and culture; (2) by determining its sensitivity to drugs and reporting the development of drug resistance; (3) by finding out whether adequate concentrations of drugs are being attained at the site of infection or in the circulation; and (4) by preventing or detecting undesirable side-effects.

In this article only bacterial infections are considered, and infections due to protozoa, fungi, and viruses are excluded.

Identification of the Causal Organism

The most useful piece of information the bacteriologist can give is to tell the practitioner *before* he starts treatment what the causal organism is. In a certain number of cases an answer can be given within a matter of minutes or at the most an hour or two. It is often possible by direct microscopy to identify beyond all reasonable doubt the *Treponema pallidum* of syphilis in a primary lesion, the gonococcus in a urethral smear, the tubercle bacillus in

a specimen of sputum, the meningococcus or the tubercle bacillus in a specimen of cerebrospinal fluid. We know that syphilis and gonorrhoea usually respond to penicillin, that cerebrospinal fever usually responds to sulphonamides, and that tuberculosis often responds to streptomycin, *para*-aminosalicylic acid, and isoniazid. The mere identification of the causal organism may therefore give a strong indication of the right drug to use—an indication which clinical judgment alone could not always give.

More often it is not possible on direct microscopy to say what the causal organism is, and we must wait for the results of culture. With most of the common pathogenic organisms cultural results should be available in 24 to 48 hours, though complete identification of a pathogenic species takes much longer. In whooping-cough, cultures may take two to five days. In tuberculosis it is often necessary to wait for several weeks even for the results of primary culture. In such cases the choice of drug has to rest on clinical judgment alone, and the practitioner is tempted to ignore the laboratory altogether. But whenever possible he must make efforts first to obtain a specimen for culture and drug-sensitivity tests, even though he may not be able to wait for the results. These may indicate that a change of treatment is necessary long before failure to respond clinically to a wrong drug is obvious. Repeated cultures during treatment may give useful information about the patient's progress.

It is essential that the practitioner should give details of any chemotherapy the patient is known to have had, since high concentrations of drugs in specimens sent to the laboratory may make cultural work valueless unless special precautions are taken—for example, adding *para*-aminobenzoic acid to antagonize sulphonamides or penicillinase to destroy any penicillin in the specimen.

Sensitivity Tests

From what has already been written it is obvious that for different reasons many infections have to be treated without waiting for the results of drug-sensitivity tests. But properly used these can be of great value in guiding treatment.

As soon as the bacteriologist has obtained a pure culture he can test it for its sensitivity to various drugs which are likely to be useful. In many cases tests of drug sensitivity can be performed on primary cultures inoculated direct from the specimen. This may save valuable time, especially with slow-growing organisms.

There are two methods in common use for testing pure cultures for drug sensitivity—diffusion methods and dilution methods.

Diffusion Methods

If diffusion methods are used, the culture is inoculated on to a suitable solid medium such as a blood-agar plate, and solutions of the drug or drugs to be tested are placed in a reservoir from which they can diffuse into the agar. The reservoir is provided in various ways—by cutting holes in the agar and dropping solutions of the drug into the holes, or by placing on the agar porcelain cylinders, blotting-paper disks impregnated with the drugs, or tablets of the drugs. All these methods are in principle the same: there is a race between the molecules of drug diffusing out from the reservoir and the molecules of nutrients in the medium diffusing into the inoculated organisms, whose fate will depend on the relative speed of these two

FIG. 1

FIG. 2

FIG. 3

FIG. 1.—Penicillin-sensitive staphylococcus showing zones of inhibition of growth obtained with paper disks soaked in penicillin solutions of the following strength: 1,000, 100, 10, and 1 unit per ml. (from the top in a clockwise direction) and a control disk with no penicillin in the centre. The culture has grown confluent over the surface of the nutrient medium except in the areas inhibited by the penicillin. FIG. 2.—Penicillin-resistant staphylococcus. Penicillin concentration, etc., as in Fig. 1. Note that even this organism shows a small zone of inhibition around the disk containing the highest concentration of penicillin (=1,000 units per ml.). FIG. 3.—Antibiotic sensitivity of a coliform organism. The antibiotics are (from the top in a clockwise direction), the penicillin (200 units per ml.) and streptomycin, chloramphenicol, aureomycin, and oxytetracycline (200 µg. per ml.). The organism is resistant to penicillin, but sensitive to the other four antibiotics.

processes. Those micro-organisms which are in a position on the plate close to the drug reservoir may be damaged or killed by the drug before they have a chance to start growing; micro-organisms further away from the drug reservoir may have already grown freely before an inhibitory concentration of the drug reaches them—and then, even if the drug goes on diffusing (as it will if the reservoir is big enough or the concentration in the reservoir high enough) it may be too late, for many of the drugs used are not bactericidal, and even those that are bactericidal often kill bacteria only when they are actively growing. The result is that when the culture plate is examined the next day a zone of inhibition appears around the reservoir of any drug with a strong inhibitory action on the growth of the organism under test.

The size of the zone of inhibition ("no growth") depends, other things being equal, on the concentration of drug used in the reservoir and on the sensitivity of the organism to the drug. The size of zone can thus be used in two ways, either for indicating the relative sensitivities of different organisms when standard concentrations of drugs are used in the disks, or for estimating the concentration of drug, for example in body fluids, if a standard organism of known sensitivity to that drug is used. Methods which involve diffusion from a reservoir cannot be used for accurate quantitative work unless they are carefully controlled, but for rough estimation of the sensitivity of an organism to various drugs they are very useful (see Figs. 1, 2, and 3).

When there is great urgency, time can be saved in two ways: (1) By performing sensitivity tests directly on primary material such as pus or sputum whenever this is likely to contain large numbers of organisms. A control plate free from all drugs must always be inoculated as well, for obvious reasons. (2) By looking for zones of inhibition on culture plates a few hours after inoculation. If these are inoculated early in the morning it is often possible to give a preliminary sensitivity report the same day—a point of great practical value. Such reports are almost invariably confirmed when the culture plates are re-examined the next day.

Dilution Methods

If dilution methods are used a series of dilutions of drug in nutrient medium are inoculated with the organism under test and after a suitable period of incubation the presence or absence of growth in the different dilutions is observed. Fig. 4 shows a typical "titration" of this kind. The culture has grown in the control tube of broth and in the tube containing 0.015 unit of penicillin per ml., but not in the tubes containing 0.03 unit per ml. or higher con-

centrations of the drug. The organism is therefore said to be "sensitive" to 0.03 unit but not to 0.015 unit of penicillin per ml. of medium.

Dilution methods may be used either with liquid media or, less frequently, with solid media. But to investigate the sensitivity of only one culture to, say, five drugs—penicillin,

FIG. 4.—Dilution method of testing sensitivity of an organism to penicillin.

streptomycin, chloramphenicol, aureomycin, and oxytetracycline—involves a considerable amount of time, and dilution methods in solid media are not commonly used for routine work.

Dilution methods, like diffusion methods, can be used not only for determining the sensitivity of a culture to a number of drugs but also for estimating the concentration of drug in the serum or other fluid.

Reports of Sensitivity Tests

Different laboratories have different methods of reporting sensitivity tests. If diffusion methods only are used it is enough to report cultures as sensitive or resistant to the various drugs tested. Some laboratories go further and report cultures as "highly," "moderately," or "slightly" sensitive or resistant. When dilution techniques are used, the sensitivity of the organism can be reported with some precision. For example, a strain of *Staphylococcus aureus* might be reported as sensitive to 0.03 unit of penicillin per ml. and to the following concentrations of other drugs—streptomycin 1 µg., aureomycin 0.5 µg., oxytetracycline 0.5 µg., chloramphenicol 2 µg., and erythromycin 0.1 µg. per ml. These figures can be taken as indicating that the organism is about normal in its sensitivity to the commonly used antibiotics. On the other hand, a strain which needed 100 units of penicillin per ml. to inhibit its growth would be regarded as highly resistant to penicillin. There is some difference of opinion concerning the precise form in which laboratory reports on sensitivity tests should be worded.

The most useful laboratory report is one which gives the results of the tests performed, but also gives enough information to tell the clinician which drugs are likely to be useful in practice.

In most cases the results of *in vitro* sensitivity tests are in harmony with clinical experience. But there are many discrepancies, and not all of them are easy to explain. Tests of sensitivity of bacteria to sulphonamides and to aureomycin, in particular, are apt to be unreliable for various technical reasons.

In tuberculosis most methods of culture are slow, and drug-sensitivity tests involving subculture are even slower, so that it may take weeks to report on the drug sensitivity of a strain of tubercle bacillus from a patient's sputum or cerebrospinal fluid. In patients with positive sputum microscopic examination of the sputum can give evidence of the response to a particular drug or combination of drugs much more rapidly than most of the sensitivity tests at present available.

Drug Resistance

Many a drug has shown great promise at first only to prove disappointing later, because of the rapidity with which resistance emerges in bacteria originally sensitive to it. How does this come about? Several mechanisms have been described. (1) All the individual organisms may be changed by contact with the drug and so become adapted to resist its action. If this were purely a response to environment it might be expected that such resistance would not be permanent, once the drug which stimulated it was stopped. (2) Since it is known that even in the purest of pure bacterial cultures no two bacteria are exactly alike, it is easy to see how, in the presence of a drug, resistant members of the bacterial population could survive its action by a simple process of natural selection. This could occur to some extent whether or not these resistant organisms were true mutants—if they were, the resistance developed would be more likely to be permanent. (3) A culture of predominantly drug-sensitive organisms may be replaced by foreign invaders of a different type from an outside source. Each of these mechanisms is known to operate in some circumstances, and sometimes it is possible that all may be operating together.

The problem of drug resistance is more serious with some drugs and with some organisms than with others. The value of streptomycin is greatly reduced by the ease with which almost all species of sensitive organisms develop resistance—for example, in coliform infections of the urinary tract and in tuberculosis. In tuberculosis isoniazid suffers from the same defect. For this reason neither streptomycin nor isoniazid should be used alone if it can possibly be avoided, and it is now well known that development of resistance can be greatly delayed by the combined use of more than one drug at a time or perhaps in rapid rotation. With penicillin, on the other hand, the development of drug resistance has not proved a serious menace except in staphylococcal infections, and there the incidence of penicillin-resistant organisms has increased greatly, especially in institutions in which there is opportunity for resistant strains to become dominant. With the sulphonamides drug resistance has provided a serious problem in streptococcal and gonococcal infections, yet in meningococcal infections it is seldom important clinically. With the newer antibiotics examples of drug resistance are being more frequently reported as their use becomes more widespread, and here too it seems that staphylococcal infections may present the most serious problem.

Drug Concentrations in Body Fluids

The laboratory is often asked to determine the concentration of drugs in the blood, the cerebrospinal fluid, or other material. Such estimations are of greatest value when new drugs are being tested out for the first time, or when new routes of administration or new preparations of

drugs are being tried. It is worth remembering, however, that, in any particular case, failure to respond may be due to failure of the drug to reach the site of infection rather than to development of resistance, and therefore the measurement of blood levels may be of value—for example, as evidence of whether a patient has in fact been taking a drug at all.

With some drugs chemical methods of estimation are available; with others it is necessary to use microbiological methods similar to those described above for determining the drug sensitivity of organisms, using as standard an organism of known sensitivity to the particular drug concerned. It is obvious that the situation can become very complicated when the patient is receiving more than one drug at a time, and the laboratory work involved may become very time-consuming.

Prevention of Undesirable Side-effects

It is gradually being realized that the powerful chemotherapeutic drugs which are now being used, like all other drugs, can be dangerous either by direct toxic action or by giving rise to a state of hypersensitivity (allergy). Examples of direct toxic action are the deafness and vestibular damage produced by prolonged administration of streptomycin in large doses and perhaps the gastro-intestinal disorders caused by aureomycin. Examples of hypersensitivity are the skin reactions produced by penicillin and streptomycin and perhaps the agranulocytosis or aplastic anaemia produced by chloramphenicol.

The laboratory can sometimes help in preventing these and other dangerous side-effects—for example, by regular blood counts on patients receiving chloramphenicol, and examination of throat swabs, faeces, and other material for the presence of fungi which may replace bacteria and cause fatal complications.

General Conclusions

It is clear that the laboratory control of chemotherapy is no simple matter. There cannot be hard-and-fast rules laying down what kinds of sensitivity tests should be carried out, when they should be performed, and how often they should be repeated during treatment. The need for such tests varies greatly both with the drug being used and with the nature of the infection. Laboratory tests of the sensitivity of organisms to drugs can be misleading, but so can the results of therapeutic trials. Discrepancies between the two can be resolved only if there is opportunity for frequent personal consultation between clinician and laboratory worker.

Next article on Clinical Pathology.—“Biopsies,” by Dr. Raymond Whitehead.

Refresher Course Book.—The first collection of articles in the Refresher Course for General Practitioners (fully revised) are available as a book containing 55 chapters, price 25s. Copies can be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

Although approved medical schools in the U.S.A. are now accepting their largest freshman classes, totalling nearly 7,500 students, for the fourth consecutive year there has been a decline in the number of applicants for admission, according to an article by Dr. John M. Stalnaker in the April issue of the *Journal of Medical Education*. Of those that apply about 57% are accepted, while of those who apply after rejection the year previously about 40% find places. It is said that the medical schools which limit their applications to State residents in many cases had to “scrape the bottom of the barrel” to secure a freshman class.

AMERICAN SURGEONS IN LONDON

THREE-DAY SECTIONAL MEETING AT ROYAL COLLEGE

The American College of Surgeons came to London this week as a body for the first time to hold a three-day sectional meeting at the Royal College of Surgeons. More than 500 members attended (including about 50 Canadians), and were reinforced by a large contingent of British surgeons. The meeting was the first to be held in the spacious new hall of the Royal College, which has a seating capacity of 700. The meeting in London was only a portion of the American itinerary. The members had already attended the annual meeting of the Association of Surgeons of Great Britain and Ireland, held at Harrogate, and were going on to further meetings in Paris and Brussels.

The papers, which numbered between 60 and 70, followed one another according to a strict schedule, and even at the luncheon tables informal discussions were held, including, on the first day, one on intestinal obstruction, with Mr. A. DICKSON WRIGHT as “moderator.” In the course of the meeting the president of the American College, Dr. F. W. RANKIN, conferred its honorary fellowship on Sir HENRY SESSIONS SOUTTAR, Sir CLEMENT PRICE THOMAS, and (*in absentia*) Sir ARTHUR KEITH.

Sir CECIL WAKELEY, P.R.C.S., presided over the first session on the morning of May 17, and the first event was the showing of a film, made chiefly at the Royal National Orthopaedic Hospital and designed for postgraduate instruction, on the reduction of surgical haemorrhage by controlled hypotension. Sir ARCHIBALD MCINDOE, in a brief commentary, spoke of the effects of posture and also of neuromuscular blocking agents.

Two papers were next given on abdominal emergencies in infancy, the first by Professor C. W. MCLAUGHLIN (Omaha), who discussed duodenal and small bowel obstruction, and the other by Mr. G. H. MACNAB (Westminster Hospital), who confined his remarks to intestinal atresia. He described the treatment of jejuno-ileal atresia by resection and end-to-back anastomosis.

Internal Fixation of Fractures

Sir REGINALD WATSON-JONES (London Hospital) introduced the subject of internal fixation of fractures. He urged that no surgeon should undertake internal fixation until he was fully trained and experienced in every other method of fracture treatment. He showed a specimen from the College museum of a fracture sustained 5,000 years ago and treated by external splinting and bandaging, a method which was used to-day in a very large number of fractures and which, he had no doubt, would still be used 5,000 years hence. Internal fixation was needed in only a very small proportion of fractures. It was important that the metal used should be non-toxic and of sufficient strength, and that recognized physiological principles should obtain, for it was not with metal they were dealing but with living bone, and the less metal used the better. This matter must not be interpreted in terms of engineering but in terms of physiology.

Professor E. F. CAVE (Boston) said that the use of metals for internal fixation still evoked controversy in the United States. A joint committee was now sitting for the standardization of the most suitable materials. There were, for example, more than fifty grades of stainless steel.

Professor I. S. RAVDIN (Philadelphia) read the first of two papers on operative cholangiography. He pleaded that surgeons should be more sure of the absence of stones in the common duct. At present many such stones were not removed at primary operation. It was now generally agreed that cholangiography represented a distinct advance in the diagnosis of biliary abnormalities. It was of value pre- and post-operatively as well as at the operation itself.

Mr. R. J. MCNEILL LOVE (Royal Northern Hospital) said that cholangiography served a dual purpose. A normal

cholangiogram rendered exploration unnecessary in otherwise doubtful cases, and on the other hand the information obtained sometimes prevented the surgeon from overlooking a duct which demanded exploration or some other operative interference. He had used cholangiography in over 500 cases.

Vascular Spasm

Sir JAMES PATERSON ROSS (St. Bartholomew's) chose to speak on arterial spasm because it had so much to do with trauma, and he hoped that some of their American friends would relate their experiences of Korean casualties. The time had come to review what was known—and not merely suspected—about the part played by arterial spasm in organic disease. He indicated some reasons for doubt about the meaning or importance of the presence of spasm in organic arterial diseases. Dr. F. W. COOPER (Emory University, Georgia) followed with a paper on the same subject.

Dr. LESTER DRAGSTEDT (Chicago) closed the morning session with a discussion on physiological principles in surgical treatment of duodenal and gastric ulcers. He described some animal experiments as well as clinical observations which suggested that hypersecretion in duodenal ulcer patients was largely of nervous origin, confirmed by the evidence that such patients usually show a certain amount of nervous tension; whereas in gastric ulcer patients the hypersecretion was of humoral origin. In these latter vagotomy ought not to be performed; hypersecretion would be abolished by removal of the antrum.

Gynaecological Symposium

At the second session, with Dr. G. GAVIN MILLER (Montreal) presiding, a symposium on gynaecology was opened by Mr. DOUGLAS MACLEOD (St. Mary's), who read a comprehensive paper on endometriosis and its treatment in relation alike to patients in whom it was important to preserve fertility and in older patients after the menopause. Professor D. G. TOLLEFSON (Los Angeles) said that external endometriosis, next to malignant disease, was the most crippling condition with which gynaecologists had to deal. In a series of 600 gynaecological laparotomies for miscellaneous conditions the incidence of endometriosis was nearly 10%. He believed that the tension of modern living was causing an increased incidence. The greatest service to be rendered to a patient, once the diagnosis had been established, was early surgery.

Professor G. I. STRACHAN (Cardiff) discussed the diagnosis of carcinoma of the cervix. Duration of bleeding, he said, was no index to the extent of the condition likely to be found. There was no reliable early symptom. Any symptom found might be associated with it. Therefore clinical examination was of first importance, and once the diagnosis was established by such examination the case should be put back for investigation under anaesthesia.

Pre- and Post-operative Care

A panel discussion on various aspects of pre- and post-operative care was conducted by Dr. W. G. MADDOCK (Chicago), who himself brought forward the question of gastro-intestinal distension. He pointed out how exceedingly quickly air passed through the intestine. For treatment of intestinal distension any air already present should be removed and air should be prevented from entering the intestines by continuous aspiration of air from the stomach. Moderate to severe distension at operation could be relieved by not closing the incision over the distended intestine.

Professor F. A. R. STAMMERS (Birmingham) said that the dramatic leap forward of surgical progress had brought into prominence four special requirements: readily available compatible blood, refined anaesthesia, chemotherapy (including antibiotics), and the understanding of fluid and crystalloid balance. He discussed the last of these. In the immediate post-war period younger surgeons were inclined to forget the difference between the trauma of warfare and the conditions seen in civil practice, especially in older

people, in whom the question of physiological balance was of fundamental importance. Every patient undergoing more than slight operative interference should first be brought into physiological balance.

Professor J. GARROTT ALLEN (Chicago) discussed the advantages and disadvantages of the storage of pooled plasma at room temperature. In his view the advantages outweighed the disadvantages. Finally, Professor D. MACLEOD DOUGLAS (St. Andrews) discussed the management of operative incisions.

The concluding scientific event of the day was a Hunterian Lecture on progressive exophthalmos by Dr. HOWARD C. NAFFZIGER (San Francisco). It was delivered before the President and the full Council of the Royal College. The later proceedings of the Sectional Meeting will be reported in our next issue.

On the evening of Monday, May 17, the President and Council of the Royal College of Surgeons held a reception (through the generosity of Ethicon Suture Laboratories Ltd.) at the College. The Great Hall was filled with guests of many nationalities, and special displays were on view in the museum and library.

Reports of Societies

THE ANAESTHETIST AND THE MANAGEMENT OF PAIN

At a meeting of the Anaesthetic Section of the Royal Society of Medicine on May 7, with Professor R. R. MACINTOSH presiding, Dr. J. J. BONICA read a short paper on "The Role of the Anaesthetist in the Management of Pain." Dr. Bonica began by emphasizing the important part the anaesthetist could play if he was prepared to assume the responsibilities of a physician and also to devote sufficient time to a study of this subject. The management of cases of intractable pain had taxed the skill of the greatest physicians, and it still remained one of our most difficult problems. If the anaesthetist was to be adept at the various complicated techniques of local anaesthesia it was most important that he should use these methods in his everyday practice in surgical anaesthesia.

At the outset the diagnosis must be confirmed by a full history and a thorough physical examination performed. Once this had been achieved, taken against a background of the knowledge of the various pathways of pain, the anaesthetist must determine whether a nerve-block was indicated. It was important to recognize the predominant psychological element of pain, particularly in the intractable variety, and the anaesthetist must always exhibit to the patient full confidence in his methods.

The indications for analgesic injections or nerve-blocks fell into three main clinical categories—namely, diagnosis, prognosis, and therapy. Diagnostic blocks could be used to determine the pathways of the pain and to aid in the differential diagnosis of diseases with confusing signs and symptoms, such as coronary occlusion, pancreatitis, cholecystitis, renal colic, and ruptured peptic ulcer. Prognostic blocks were frequently performed to afford the patient the opportunity of temporarily experiencing the effects of interruption of a nerve-block before the interruption was made permanent and at the same time to allow the neurosurgeon to prognosticate on the possible value of a surgical operation. This type of block was of particular value in such conditions as tic douloureux, angina pectoris, causalgia, and other reflex sympathetic dystrophies. Therapeutic nerve-blocks might be usefully employed in a wide variety of pain syndromes, such as thrombophlebitis, post-operative pain, herpes zoster, and various types of visceral pain.

The proper choice of solution for injection was important. For diagnostic and prognostic blocks a 1-2% solution of lignocaine hydrochloride was the most satisfactory. For

¹Beard, R. L., *Bulletin* 562, Connecticut Agricultural Experiment Station, New Haven, 1952.

prolonged blocking various local analgesic agents in oily solution had been advocated, but these had not been found satisfactory, for the blocks were often incomplete and unpredictable. Recently a solution of procaine base and hydrochloride in polyethylene and propylene glycol, called "efocaine," had been introduced for the purpose of producing analgesic blocks of several days' duration. Recent reports indicated that it was not an innocuous drug.

Benzyl alcohol in 0.75-2.0% concentration was a satisfactory agent for prolonged blocking, and although neuritis was occasionally seen after its use it was mild and of short duration. Absolute alcohol remained one of the most effective drugs for prolonged interruption of nerve impulses. Unfortunately, its use was frequently followed by post-injection neuritis, but this was usually mild and lasted only a few weeks. It remained, however, the method of choice in the treatment of intractable pain from an inoperable malignant condition. Disturbance in function of the bladder and rectum might be experienced, but Dr. Bonica felt that the benefits usually obtained were sufficient to justify the risk of this complication. In conclusion, Dr. Bonica emphasized the importance of a nerve-block clinic, run by an anaesthetist as part of the activities of a pain clinic.

Wasp Venom and Anaesthesia

Dr. E. H. SEWARD, in a paper entitled "Wasp Venom and Anaesthesia," pointed out that there were two types of wasp, the social wasp and the solitary or hunting type. The social wasps were so called because they lived in communities, and were familiar by virtue of their anti-social behaviour. Their sting was purely defensive and they usually killed other insects by biting them. The solitary wasps were less well known, for they rarely came in contact with man. There were many hundreds of varieties, and peculiar to them all was the power of paralyzing certain other insects by stinging them. Only the female could sting; she selected her prey and then stung it when she was ready to lay her eggs. The prey was almost instantly paralysed and was then taken by the wasp to a safe place, where she laid her eggs around it. When in due course the grubs hatched out, the victim was still alive but unable to move, so that it supplied a ready source of fresh meat on which the grubs could prosper.

Though the behaviour of solitary wasps had been quite extensively studied, the toxicology and pharmacology of their venom had received little attention. However, Beard¹ in America had recently shown that one type of solitary wasp—the *Habrobracon*—possessed a very powerful sting and was able to paralyse its prey almost instantly by a single sting. The injected venom, which was capable of producing a permanent paralysis in larvae in a concentration of one part in 200 million, was carried by the blood stream.

The evidence available at present suggested that, in this one solitary wasp at least, the paralysis produced by its venom was due to an action at the neuromuscular junction; and in all probability the venom of other wasps acted in a similar way. Curare, however, did not produce paralysis in those insects which had so far been tested, but the effect of depolarizing drugs which produced paralysis in vertebrates had not yet been studied. The venom was either a protein or a protein-like material, water-soluble, and was carried in the plasma portion of the blood.

THE OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM

ANNUAL CONGRESS AT NEWCASTLE

The Ophthalmological Society of the United Kingdom held its seventy-fourth annual Congress at Newcastle-upon-Tyne from April 22 to 24, under the presidency of Mr. ALEXANDER MACRAE. The main discussion this year was on "Inflam-

matory Vascular Diseases Affecting the Eye," the three opening speakers being Mr. R. C. DAVENPORT (London), Dr. S. P. MEADOWS (London), and Professor J. B. DUGUID (Newcastle-upon-Tyne).

Retinal Vasculitis

Mr. DAVENPORT took for his subject retinal vasculitis, with particular reference to its association with various forms of uveitis. Four features of this association had impressed him: the long interval which may separate the retinal and uveal inflammations; their occasional alteration or simultaneous appearance; the fact that the retinal changes may affect either arteries or veins, alone or together; and the occasional siting of a venous lesion entirely within the nerve head. He described four cases illustrating these features. The first developed bilateral iridocyclitis 20 years after an attack of bilateral retinal phlebitis. In the second, unilateral sclerokeratitis associated with cervical adenopathy was followed, 15 years later, by retinal phlebitis in the same eye. In the third, intermittent attacks of retinal phlebitis, uveitis, and episcleritis continued during 13 years. The fourth suffered from mild anterior uveitis, some degree of retinal vasculitis, and bilateral papillitis for two years. In every case all investigations were negative, showing that the cause of the diseases in question remained a matter for further research. In conclusion, the speaker alluded to the association of retinal vasculitis with lesions of the central nervous system, particularly disseminated sclerosis.

Temporal Arteritis

Dr. MEADOWS's theme, based on 12 personal cases, was "Temporal Arteritis and Loss of Vision." After describing the distribution, incidence, and pathology of the disease he outlined the clinical picture. There is often an initial period of malaise, anorexia, and slight fever, followed by headache and tenderness of the scalp. Forty per cent. of cases show ocular signs, of which the most common (25%) is blindness of rapid onset in one or both eyes, the second eye being affected at the same time or within a few days of the first. Ophthalmoscopy shows retinal arterial occlusion in a few instances but, more commonly, only moderate papilloedema. Sometimes the fundi are normal. Other neurological changes such as hemiplegia and dementia occur. The diagnosis is confirmed by the nodular, tender, usually pulseless temporal artery or arteries, and by temporal artery biopsy. The sedimentation rate is raised. The disease is self-limiting, lasting for three to four months, and though sight rarely recovers the general prognosis is surprisingly good. Treatment by anticoagulants and cortisone has been disappointing, though the latter is theoretically the most promising drug.

Periarteritis Nodosa

Professor DUGUID discussed the aetiology of periarteritis nodosa. Consideration of the haphazard distribution of this disease and of the fact that in the kidney it causes infarction had led the speaker to the tentative conclusion that its lesions are caused by embolism or thrombosis. The objection to such a hypothesis is that histological sections of affected vessels often show no evidence of such events. The answer to this was, first, that in the histological examination of the course of a vessel a small lesion was easy to miss. Secondly, as a series of personal experiments demonstrated, when an embolus or thrombus was lodged in a vessel it rapidly became covered by endothelium and incorporated in the vessel wall, so that its original nature became difficult to identify. Although the application of this theory to lesions affecting large vessels was not easy, with small vessels there was no insuperable objection to it on histological grounds, and it did, in Professor Duguid's opinion, offer the most satisfactory explanation of observed facts.

Other subjects discussed included: "The Changes in the Incidence of the Eye Affections of Coal-miners in the Last 25 Years," in which Dr. DOROTHY CAMPBELL, Mr. W. J. WELLWOOD FERGUSON, and Dr. G. I. SCOTT took part; and a symposium on "Gonioscopy after Glaucoma Operations"

was introduced by Mr. H. E. HOBBS and Mr. REDMOND SMITH. There was also a series of interesting short papers. The meeting had been opened with a presentation of the Nettleship Medal to Dr. Norman Ashton, director of pathology at the Institute of Ophthalmology in London, in recognition of his valuable contributions to ophthalmology.

This was in all respects a most successful congress. The annual dinner was held at the Station Hotel on the night of April 22, and the next evening a civic reception was held by the Lord Mayor of Newcastle-upon-Tyne at the Laing Art Gallery. The following morning an expedition was arranged for 70 members under the guidance of Professor Ian Richmond to visit the Roman Wall.

Correspondence

Cortisone Therapy in Rheumatoid Arthritis

SIR,—Cortisone has now been used in the treatment of rheumatoid arthritis for some five years. After the initial enthusiasm the inevitable negative reaction set in and we are now, at last, nearing an accurate unemotional assessment of this form of suppressive therapy. Leaving aside its short-term use in rehabilitation and orthopaedic manoeuvres, there are certain types of the disease that we feel are very suitable for this therapy. The acute, florid type of rheumatoid arthritis, rapidly progressing in the face of orthodox measures, and the relapsing-remitting case with much soft-tissue swelling and minimal irreversible change, are usually entirely suitable for cortisone therapy. Unfortunately it is impossible to forecast what the future course of the disease in any individual case is likely to be, and there is no simple clinical or side-room test which will help us in our choice of patient. The previous history of the case may help, the steadily progressive unremitting case appearing less suitable than the one with long periods of remission. In the final analysis, however, one has to proceed hopefully and expectantly, keeping a rather closer watch and control of the case than with other forms of therapy, and using, in addition, the same basic orthodox regimen of graded rest and exercise, local and general, as in all cases.

Last week you published an informative report on this subject by Dr. W. S. C. Copeman and others (*Journal*, May 15, p. 1109). In our unit we have cases of rheumatoid arthritis taking part in the Empire Rheumatism Council's controlled cortisone-aspirin trial now nearing completion. We have in addition a long-term uncontrolled trial of which the facts and figures are, on assessment at May 13, as follows: 22 patients, 12 female and 10 male, have now been on continued suppressive cortisone therapy in our unit for over six months. Five are receiving 25-37½ mg., 17, 50-75 mg. a day; none are on higher dosage. The ages of these patients range from 27 to 65, only three being under 40 years of age; in 15 the ages lie between 40 and 60. Nine patients had had rheumatoid arthritis, prior to cortisone treatment, for six months to one year, six had been afflicted between one and four years, seven between five and 24 years. Treatment has lasted 6-11 months in 16 cases, 12-17 months in five, and over 18 months in one. The following is our assessment of their progress at this date as compared with their pre-treatment assessment:

	No. of Patients			
	Improved	Worse	No Change	Not Assessable
Grip	7	2	2	11
Finger swelling .. .	8	0	7	7
Employment capacity ..	4	4*	14	0
General functional ability ..	10	4	8	0
Joint tenderness .. .	4	2	4	12
Patients' own assessment ..	15	2	5	0

* These 4 patients are the only ones unfit now for work.

The last line is the measure of the patient's own opinion of, and satisfaction with, this form of treatment. Our own feelings as to the results might be expressed as satisfactory in 13 cases, unsatisfactory in four, unchanged in five. Grip was measured by a metal grip meter, finger swelling by jeweller's rings. Employment capacity was assessed on whether the patient was capable of the same work as before therapy, or increased or decreased duties. Function was a rough assessment of the sum of the day's simple activities. Tenderness refers to finger tenderness only.

One point that has appeared to us of interest is that, where finger swelling was adequately reduced on cortisone therapy and remained diminished (eight out of 15 cases), increased functional ability usually ran parallel. As this is a measure of the reduction of tissue swelling, it is not surprising. Those patients who showed a satisfactory diminution in finger swelling early and who maintained it after two to three months were usually the worth-while ones. One patient with a duodenal ulcer and one with a gastric ulcer have been maintained without trouble on 50 mg. a day. One patient developed duodenal ulceration, has had to discontinue cortisone, and has relapsed. In addition to the above 22 patients, six other patients showed insufficient improvement after 4-16 weeks' therapy rising to full dosage (100 mg. daily), and their treatment was therefore discontinued. The 22 patients detailed above were therefore in a sense a selected group. Although the series is uncontrolled, all the patients were put on to cortisone because of failure to respond to simpler measures with plentiful analgesic cover; in one sense each was his or her own control.

To summarize our findings in this series of 22 patients, four could do more than before therapy, four less, and 14 the same job of work. Patients showing prompt reduction of soft tissue swelling appeared to benefit most from continued cortisone therapy. Fifteen of the 22, however, experienced increased relief from those annoying and distressing symptoms which, while hardly appearing in statistical surveys, do make the lot of the rheumatoid sufferer somewhat easier. The present orthodox treatment of rheumatoid arthritis is not so dramatic or so effective as to allow us to neglect any new form of therapy, even if it helps only a modest percentage of sufferers.

Our thanks are due to Dr. Augustus Gibson, of Merck & Co., Rahway, New Jersey, for a generous gift of cortisone which helped greatly in the above trial.

—We are, etc.,

J. C. LEONARD.
FORDE CAYLEY.

Herpes Zoster and Chicken-pox

SIR,—The case of herpes zoster followed by chicken-pox reported by Dr. C. Spencer Whitehouse (*Journal*, May 8, p. 1097) is consistent with previous cases which were reviewed by Dr. D. I. McCallum (*Journal*, March 8, 1952, p. 520) under the very apt title "Herpes Zoster Varicellousus." A brief review of the literature will be found in that article. Dr. E. G. L. Mark (*Journal*, May 12, 1951, p. 1079) reports a case in which the varicella eruption followed herpes zoster within 12 hours.—I am, etc.,
London, S.E.5.

T. D. SAYER.

SIR,—The case of herpes recorded by Dr. C. Spencer Whitehouse in his letter (*Journal*, May 8, p. 1097) closely resembles a case which I reported in a letter to the *Journal* some 20 years ago (*Journal*, 1933, 2, 1152). Like Dr. Whitehouse, I regarded my case as one of true chicken-pox occurring within a few days of the appearance of a herpes eruption, but after the publication of my letter a note was published from the then professor of medicine at Bristol University (*Journal*, 1933, 2, 1240) stating his opinion that the case I had described was one, not of chicken-pox following on a herpetic eruption, but of *herpes generalisatus*, an exceedingly rare condition and one having special interest in regard to the virus theory. My patient, who was aged 60, had had an attack of chicken-pox at the age of 5. Further reports and opinions on such cases would be of great interest.—I am, etc.,
London, N.W.11.

SYLVIA G. CHAPMAN.

SIR,—Dr. C. Spencer Whitehouse (*Journal*, May 8, p. 1097) asks whether the simultaneous appearance of chicken-pox and herpes zoster has been seen before. In March this year I was asked to visit a man of 83 who had ophthalmic zoster with some ocular involvement. On examining him I was surprised to see that the zoster eruption, although otherwise characteristic, widely transgressed the midline on the forehead, and I discovered that there were also spots widely distributed over the trunk. Being now unfamiliar with the exanthemata, I asked the opinion of the patient's general practitioner, Dr. D. R. Harris, of Falmouth, who told me that, although lacking the typical vesiculation, the eruption resembled chicken-pox in distribution and there seemed no other likely explanation. This case, alone, seemed too inconclusive to record, but may corroborate Dr. Whitehouse's observation.—I am, etc.,

Redruth.

CHRISTOPHER HEATH.

SIR,—I saw a man of 48 with shingles on the right side of his abdomen on October 13, 1952. A generalized varicella rash appeared in the same patient on October 18. By October 28 the varicella and half the shingles lesions were scabbed, and on December 21 the shingles lesions were still very painful. He retains the zoster scars to this day, and one chicken-pox scar on his face.

In my small experience shingles in young children is exceptional, but a child of 9 presented with the rash of herpes zoster on the left side of his chest on March 16, 1953. Pain was not experienced until three days later, and lasted one week in all. His brother, aged 5½, developed chicken-pox on April 1. Incidentally, at the other extreme of life I have seen very mild chicken-pox in a man more than 70 years old.—I am, etc.,

Ilford.

R. N. C. SMITH.

* Letters recording cases of chicken-pox following herpes zoster have also been received from Drs. E. Banji, H. Banks, C. Barnett, M. Fishman, W. Henderson, and F. Rose.—ED., B.M.J.

Jelly Test in Tuberculosis

SIR,—Dr. P. D. Mulkern (*Journal*, May 1, p. 1039) has suggested a syndrome in children characterized by upper respiratory catarrh, a negative Mantoux reaction, and a positive jelly test. It would be interesting to know whether Dr. Mulkern employed the plain or the flourpaper technique for his jelly testing. If the plain technique was used, the association of a negative Mantoux reaction and a positive plain jelly test is a surprising one. In a recent investigation which we conducted we failed to find such an association in over 400 East London schoolchildren. The reverse of Dr. Mulkern's finding, a positive Mantoux and a negative plain jelly, is of course common experience.

If, on the other hand, Dr. Mulkern employed the flourpaper technique his findings are not unusual. In our investigation we showed that experienced observers using the flourpaper technique found a much higher percentage of positive reactors than was found by the Mantoux test done at the same time. But, whereas there was virtually no disagreement over the Mantoux findings, there was considerable disagreement between the flourpaper test observers as to which reactions were positive and which were negative. In our view this test is a fallacious one. If Dr. Mulkern used this test, then we suggest he has observed a non-specific reaction due to the trauma of flourpaper occurring in a tuberculin-negative catarrhal subject. After all, the response to tuberculin in a sensitive subject is specific and as likely to be observed with an intradermal injection of tuberculin as with the percutaneous application of tuberculin jelly, which contains only old tuberculin in a tragacanth base.—We are, etc.,

M. CAPLIN.
C. P. SILVER.
S. GRZYBOWSKI.

London, E.2.

Changes in Skin Response in Asthma

SIR,—I write to add a few observations to your correspondence on this subject, because, in an indeed limited experience of allergy, I have been forming the impression that the apparent dubiety of the skin-test depends in fact on variations in behaviour which might prove exceedingly instructive if effort could be directed to studying them for their own sake instead of trying to iron them out by generalizations.

First, the magnitude of response to any standard test procedure is influenced by the physiological state of the skin. To exclude this in recording "true" variations of skin response in a single subject it may be well to use a comparative method in which simultaneous tests are done with appropriate concentrations of histamine. Some observations have also suggested a possible dependence of the gradient, relating size of test response to concentration of antigen used, and consequently also of the size of response to any standard concentration of antigen, on the threshold concentration of histamine needed at the time to secure minimal skin response. Alternatively, direct determination of the antigen threshold concentration for skin response, by a standard method of the observer's own choice, may be more independent of such variation and more convenient.

Beyond these questions is that of immunologically determined variation, and here there seem to be intrinsically different patterns of behaviour quite apart from the effects of treatment. For example, in certain pollen asthmatics a moderate skin reaction (of the order: prick response to 25,000 N.U./ml. = prick response to 1/1,000 histamine or higher) has been elicited in September and then a virtually negative reaction in the following January, while others have appeared to be maintaining a more uniformly brisk response throughout the year. The interest of characterizing such types is both theoretical and very practical if there is any relation to the clinical features and mode of response to desensitization treatments.

Within such superficially homogeneous groups as pure grass-pollen asthma or grass-pollen hay-fever patients there is, in fact, much clinical diversity if attention is paid to the timing of the symptoms. Broadly, three types appear to be emerging: (1) patients with immediate attack reaction to direct exposure, (2) with delayed attack reaction to exposure, and (3) with a regular 24-hour cycle of symptoms during periods of exposure but not related directly to exposure. Much more observation than I have yet had opportunity of making would be necessary to establish properly the impression I am at present receiving that rather small and variable skin responses are mainly characteristic of the third type. This has a bearing on the assessment of a patient's sensitivity from the skin response; within the first and perhaps the second group above this assessment may be valid, but a small skin response or a high threshold of response is certainly no indication of relative insensitivity and of presumptive tolerance to a high desensitizing dose in patients of the third type. These patients may have delayed symptomatic reactions to treatment with a very low dose; they seem, however, far less liable to urticarial reactions than are low skin threshold patients of types 1 or 2.

Such preliminary impressions obviously need much correction and amplification before statements of fact can be made firmly on these very complicated matters, but I want to suggest that there is much scope for a more positive type of clinical study of skin responses in relation to other aspects of case histories. There appears to be an equal richness of variety in other allergies than pollen, and one may suspect that quite a diversity of immunological mechanisms may be involved in phenomena which there is a tendency to regard as homogeneous. There is particular interest in the variable character of skin response in food allergies where the positiveness or otherwise of the response is broadly related to the interval between taking the food and the onset of symptoms rather than to any more simple manifestation of the degree of "sensitivity"; one explanation of this has been that in cases with delayed reaction and absent skin response the true allergen is a transformation product of the native food protein, but it is also possible that the difference in behaviour depends on a difference in immunological mechanism.—I am, etc.,
Oxford.

R. M. MORRIS-OWEN.

Mondor's Disease

SIR,—I was most interested in the article on Mondor's disease by my friends Mr. G. M. Lunn and Mr. J. M. Potter (*Journal*, May 8, p. 1074) in which they record five cases of this uncommon condition and give a helpful review of it. All their cases were in women, and some had a lesion in the breast. I thought, therefore, that it might be of interest to refer to a case of this condition in a male whom I saw in November, 1950.

He was a medical practitioner, in good health, and for about a week had noticed a little discomfort in the upper part of his abdominal wall and had himself felt a thin elongated swelling. There was no history of trauma or unusual exercise. In my note, made at the time, I described it as "a peculiar subcutaneous cord-like structure about four inches long lying obliquely." It was in the upper part of the epigastrium on the right side and came over the costal margin for a short way. Its oblique direction was as described by the present authors. I had not seen anything like it before in this position and recorded it as a case of superficial venous thrombosis, not then being acquainted with Mondor's disease. No treatment was prescribed and the lesion gradually and spontaneously cleared up. The patient has had no subsequent thrombosis.—I am, etc.,

London, W.1.

JOHN HOSFORD.

SIR,—The very interesting article on this subject by Mr. G. M. Lunn and Mr. J. M. Potter (*Journal*, May 8, p. 1074) clarifies a condition personally observed on several occasions. It is, perhaps, worth adding to the clinical picture the fact that one such case showed linear elevation of the skin running down from the lower thorax to the upper abdomen in the anterior axillary line on raising the arms in a man. Another case, a young probationer nurse, developed a tight bowstring spanning the right antecubital fossa. On this occasion, as she was prevented from full extension of the elbow by pain, the string was divided and a piece excised. It proved to be a narrowed sclerotic vein.

In this odd type of phlebitis the vein shrinks in length as well as thickness. The condition is not limited to the female and can occur in the limbs as well as the anterior trunk.—I am, etc.,

London, W.1.

F. HARWOOD STEVENSON.

Animal Technicians

SIR,—My attention has been drawn to the annotation on animal technicians (*Journal*, April 3, p. 808) and the two letters thereon by Mr. A. E. Brown (*Journal*, April 24, p. 983) and Mr. F. Mather (p. 984). One can agree with the annotator until he claims that "the animal technician shares, or should share, equal status with the laboratory technician." It seems obvious that the writer can have little knowledge of what is required of the present-day technician in hospital laboratories and cannot, therefore, be in a position to make a comparison.

A statement in the letter from F. Mather is to be greatly deplored. His opinion expressed in the second paragraph on the responsibility of the pathologist in relation to the interpretation of results in no way reflects the views of the Institute of Medical Laboratory Technology, nor that of the vast majority of its six thousand members. Such statements as these can do much harm to the laboratory services. In the last paragraph of his letter there is a reference to the senior technician teaching laboratory technique to young medical men commencing their laboratory careers in pathology. With his wide knowledge and long practical experience, who should be better able to guide the beginner through the intricacies of modern laboratory technique? This has been customary for as long as I can remember and I hope it will continue in the same atmosphere of goodwill and mutual respect as has been evident in the past.—I am, etc.,

London, W.1.

A. NORMAN,
Chairman,
Institute of Medical Laboratory Technology.

Single Incision for Bilateral Orchidectomy

SIR,—I am in turn dismayed by Mr. C. J. Cellan-Jones's comments (*Journal*, May 1, p. 1039) on Sir Heneage Ogilvie's letter (*Journal*, April 17, p. 934). As one of the young, though greying, surgeons whom he apostrophizes I should like to advocate as strongly as I can the scrotal approach to the testis wherever possible. I have used it in all cases of hydrocele and spermatocele for the last seven years with uniformly satisfactory results, nor have any of the chiefs for whom I have worked in that time ever criticized it.

The position of the scrotum does not interfere with its adequate cleansing: all that is necessary is a pair of forceps to hold it up. The scrotum is not corrugated, but smooth and lax, in a normally heated operating theatre. The approach to the testis is direct and easy, and avoids the manipulation and trauma involved in hauling a sometimes bulky hydrocele up into the groin, thereby opening further tissue planes which will ooze post-operatively and which cannot be dealt with from the inguinal incision at the time of operation. The inguinal canal is left undisturbed and unnecessary handling of the cord obviated. Furthermore, incisions in the scrotum heal better, and with less scarring, than those in almost any other part of the body: even the jagged and infected lacerations that one sometimes sees almost invariably heal without complications. Lastly, the patient is less conscious of the irritating sequelae of the unavoidable division of small cutaneous nerve twigs by the inguinal approach.

The tendency to scrotal haematoma, common after both approaches, but in my experience more widespread after the inguinal, is easily frustrated by a simple manoeuvre, for which I claim no originality, but which does not seem to be as widely known as it deserves. At the end of the operation, after wide cleansing with spirit to remove grease, the most dependent part of the scrotum is seized by tissue forceps, and held vertically upward, with the skin of the scrotum in a taut cone. After applying a small dressing to the sutured wound a strip of "elastoplast" about an inch wide is wound firmly in a spiral round the cone of scrotum from apex to base. The testis will have fallen to the base, or neck, of the scrotum, and is not included in the spiral. If desired, further strips of elastoplast may be applied, more gently, over and round the base. This dressing is left on four or five days, and causes little or no discomfort—certainly less than stitching the scrotum to the abdominal wall, supporting it on a shelf of strapping between the thighs, or any of the other methods of varying effectiveness which are advocated. After removal of the dressing—which slips off easily, without having to be unwound—there is no haematoma formation, and the testis drops immediately back into its normal position.

I cannot help feeling that Mr. Cellan-Jones was unusually unfortunate in his experience 25 years ago, and even more so in the lesson which he learnt from it. And now we have antibiotics, too.—I am, etc.,

Beaconsfield, Bucks.

MICHAEL REILLY.

Immunization Against Tetanus

SIR,—With reference to Dr. G. M. Bailey's letter (*Journal*, February 20, p. 454) which has just reached me in distant Australia's bush, will you please permit me to make a remark or two? Dr. Bailey claims that only one booster dose of tetanus toxoid should be adequate within ten years of active immunization with three doses of the toxoid. Is this claim arbitrary or authoritative? If the latter, will he please quote the same?

He concludes his letter with some disapproval, if not disparagement, of Service men in uniform being given "3,000 A.T.S." by casualty officers. It calls for little experience to know that tetanus can result from an almost invisible wound as from an extensive battle injury where A.T.S. is given with all possible speed in the regimental aid post in the British Army (the Americans, I understand, still stick to toxoid). What would be the legal position of the casualty officer who, on the reasoning advocated by Dr. Bailey,

omitted the "3,000 A.T.S." and found himself sued by the relatives of a patient dying from tetanus? Your expert's advice in "Any Questions?" dating back to December 3, 1949 (p. 1305), in the concluding sentence is relevant and contrary to what Dr. Bailey would have us do.

Lastly, is it not true that some individuals, including Service men of course, are resistant to active immunization; and, this being so, how is a casualty officer to know the case which is not? In the face of these and many more unsettled views and conflicting opinions, Sir, some of us have the temerity to call medicine a science.—I am, etc.,

Boulia, Queensland, Australia.

B. J. BOUCHÉ.

Relief for Entropion Sufferers

SIR,—I quite agree with Dr. Cecil W. C. Robinson (*Journal*, May 1, p. 1037) that the removal of a piece of skin from the lower eyelid or a skin and muscle operation is often unsuccessful in the relief of entropion, and I thought that these operations had fallen into disrepute. On the other hand, Wheeler's operation, where a strip of orbicularis muscle is attached to the periosteum of the malar bone, or the simple operation of an overlap of the orbicularis muscle, seldom fails.

Entropion of the lower lid is due to buckling of the tarsal plate which has become thin in the middle, and therefore a shortening of the orbicularis muscle is the obvious treatment from a mechanical point of view, as it will prevent the tarsal plate from buckling. This operation takes longer than a skin and muscle operation, but I should think anything is preferable to wearing a contraption on one's reading spectacles, and, also, in many cases an uncured entropion will cause constant irritation.—I am, etc.,

Camberley.

LESLIE HARTLEY.

Notification of Epidemic Diseases

SIR,—It would be interesting to know what the criteria are which determine the notifiability of epidemic diseases. It is, one supposes, a matter of ministerial policy, and one wonders whether it is guided by medical men. In my practice at present there are minor epidemics of infective hepatitis, of mumps, and of chicken-pox, none of which are notifiable: if there were also an epidemic of rubella, that also would not be notifiable; yet with the Australian experience of this disease one would have thought it very important to all pregnant women. But surely the whole absurd business of notification of some diseases and disregard of others equally infectious brings the whole apparatus of notification into disrepute. I well remember, about 1947, a small epidemic of glandular fever which was most interesting and unusual, yet it could not be brought to the notice of the public health authority simply because it was not notifiable. Yet pneumococcal pneumonia, which seems to have largely lost its epidemic quality and which can almost be relegated to the rank of a minor malady, is retained as a notifiable disease. There undoubtedly has been a profound shift in the importance relatively of a number of epidemic diseases: some, such as encephalitis lethargica, have virtually disappeared; others, such as erysipelas, are both milder and more easily dealt with; while yet others, such as poliomyelitis, have attained a much greater importance than they have ever had before. Surely this calls for a review of the situation?—I am, etc.,

Leeds.

C. E. GOLDSBOROUGH.

Appointment with Fear

SIR,—I read with interest the letter of Dr. P. R. Saville (*Journal*, April 17, p. 932) and that of Sir John Nicholson (*Journal*, May 8, p. 1094), and I heartily agree with the latter that "what most people dread is a sense of uncertainty and the unknown." This is particularly true of cancer. Dr. Saville and many other medical men do not seem to realize that "apprehension" about this disease (true cancerphobia is fortunately rare) already exists in nearly 100% of the population. There are a great many causes for this apprehension, ignorance and uncertainty being at the top of the list, but death itself is at the bottom.

as Sir John Nicholson suggests. Pain is high up, as is the idea that all cancer patients "die in agony." This misapprehension on the part of Dr. Saville and many other practitioners concerning the attitude of the public in regard to cancer is very serious, as it is preventing some local authorities embarking on a scheme of cancer education such as is advocated by the Ministry of Health. Dr. Saville cannot put the clock back. The public from childhood to the grave is being encouraged to be interested in all sides of life, and people cannot be expected to lower an iron curtain where their own health and bodies are concerned.

Many medical men think that if a patient does not talk about cancer they are not thinking or worrying about it, whereas the exact opposite is true. It is only by encouraging people to talk about it and bringing it to the surface that apprehension can be diminished. Emerson was right when he wrote: "Knowledge is the antidote to fear."—I am, etc.,

York.

MALCOLM DONALDSON.

"Lobster Claw" Hands

SIR,—An East African negro boy of the Maragoli tribe, aged 12 years. His first three fingers of the right hand are enlarged very much both in length and thickness. There is a deep cleft between the index and the second finger. The small finger and the ring finger are of normal size. He uses these to eat and to hold things. All the fingers of the left hand are enormously enlarged. He has no defect of feet or of any other part of the body. His brain is very alert and he earns a good living by begging, at which he is an expert in exploiting his deformity. He has no pain and has not been suffering from any other illness. His hands were examined and his blood tested for filarial disease. The result was negative. He is quite cheerful and resigned to his condition. When asked what he thought of it, he replied, "Shauri ya Mungu," which means in Swahili, "It is God's will."

His father and mother state that he was born with this deformity of the hands, and the child confirms that he has always had this condition since infancy. None of the other members of the family are affected.

This congenital anomaly of the hands has three factors in it: (1) lobster claw deformity, because of the cleft between the fingers; (2) megalodactylism, because of the enormously enlarged fingers and their corresponding bones; (3) crab claw hand, because the left hand has all five fingers enormously enlarged.—I am, etc.,

Nairobi.

AYRES L. RIBEIRO.

Heart Failure and Phenylbutazone

SIR,—In view of Drs. D. J. O'Brien and Geoffrey Storey's report of a patient dying with heart failure after phenylbutazone (*Journal*, April 3, p. 792), the following may also serve as a warning specially regarding the use of this drug in patients with established heart disease.

A 42-year-old English school-teacher was admitted to hospital on September 19, 1953, with severe heart failure. There was

no previous history suggesting rheumatic fever, but on entry to university (age 17) he was graded A2 on "account of his heart." Four years later the same doctor examined him and said his heart was "now all right." He had routine medical examinations for the Fire Brigade, Ministry of Supply, and Army. No comment was made about his health. During the war he performed an active job inspecting coastal defences without difficulty. He first noted undue breathlessness on walking quickly in 1950 (age 39), but this symptom disappeared after three months, and he was then able to run upstairs without any undue dyspnoea. In 1952 he was examined for £1,000 life insurance policy. The premium was not loaded.

On September 5, 1953, he tripped and fell on his back. Following this he had considerable lumbar pain which was not much relieved by massage and salicylate. On September 15 1 g. phenylbutazone was injected intramuscularly at 11 a.m. One hour later the pain had gone and he felt fine. That night he started to cough and became breathless. During the next four days the breathlessness became progressively worse. On admission he was in considerable distress with marked orthopnoea, ventricular rate 140, blood pressure 130/80, slapping apical first heart sound, apical diastolic rumble, and widespread crepitations at both lung bases. There was slight leg oedema. X-ray showed an enlarged heart shadow with mitral configuration (later confirmed by screening) and the fan-shaped opacities of pulmonary oedema. Electrocardiograph confirmed auricular fibrillation and right ventricular dominance. He responded well to rest, digitalization, and mersalyl, and was discharged on October 7. Fibrillation has since continued, and when digitalis was stopped a month after returning to work undue breathlessness recurred. Probably permanent digitalization will now be necessary. X-ray seven months later (April, 1954) showed clearing of the lung fields but little change in the heart shadow.

The onset of symptoms 12 hours after the phenylbutazone injection and his previous good health make it very probable that this drug precipitated the heart failure. This could be due to direct action on the myocardium or water retention effect. It would seem therefore that established heart disease is a contraindication to use of phenylbutazone.—I am, etc.,

Penang, Malaya.

H. A. REID.

Clergy and Doctors

SIR,—As both clergy and doctors are so deeply concerned with the Ministry of Healing in its faltest sense, it is surprising and lamentable that there should be any lack of co-operation between them, as is suggested by the letters of the Rev. Tony Clemens (*Journal*, April 24, p. 983) and Dr. F. Gray (*Journal*, May 1, p. 1041). Where it does exist it must be due to shyness of approach, or to ignorance on the part of the one of the help and co-operation which the other is willing and anxious to give.

To overcome both these difficulties in this area, the Torquay and District Medical Society organized a meeting of clergy and doctors some time ago, at which the Bishop of Exeter and one of the doctors initiated a most useful discussion. A desire was expressed at the meeting that regular joint meetings should be held, and the Bishop instructed one of the rural deans present to form a small committee to arrange them. This was done, two further meetings have been held, and it is intended to continue them three or four times a year. They have been well attended on both sides, and have already abundantly proved their value. B.M.A. Divisions, medical societies, and rural deans, please copy!—I am, etc.,

Newton Abbot.

G. M. TANNER.

SIR,—As a member of the medical profession, I would like to endorse the opinions stated by the Rev. Tony Clemens in his letter (*Journal*, April 24, p. 983) under the above heading. It must be painfully obvious that there is something wrong in a country in which, despite all the "benefits" of the Welfare State, we are told that "50% of the hospital beds are occupied by psychological cases," and that "75% of the cases seen by the average G.P. are in some degree of neurotic." Is it possible that the strain of living has increased since 1948? Is there some truth in the assertion that the institution of the N.H.S. has fostered hypochondria? Are all these patients neurotic from choice, because

it doesn't cost them anything, or is there something missing in our "free world"?

I venture to suggest that one of the main reasons for the increase in neurosis lies in the fact that because of the N.H.S. the average doctor can no longer be the friend and adviser his predecessors were to their patients. The "old" G.P. was an excellent psychologist, and his abilities were, to my mind, the reason why his patients brought their worries to him for solution. To-day, few medical men have the time or inclination to just sit and listen to matters outside the "normal" sphere of work, so that the patient who is worried can find no other alleviation for his worry than phenobarb. He continues to worry and develops neurosis in one form or another.

Although I am not a particularly religious person I still feel that the "common man" can find much solace in religion, and that his particular minister can be of help to him in much the same way as the "old" G.P. in the solution of his personal problems. My own practice is based on the treatment of psychosomatic conditions, and I am impressed by the number of patients who lose their physical ailments once they have been able to talk-out their worries. In many cases I refer patients to their clergyman, because I believe that in this scientific age there is a greater than ever need for spiritual balm. Thus I feel that there are positive indications for closer co-operation between medicine and the church.—I am, etc.,

Manchester, 2.

S. F. GILBERT.

Women in Medicine

SIR,—With reference to your interesting annotation on "Women in Medicine" (*Journal*, May 15, p. 1143), there is an important correction which we are sure you will be anxious to make. One of our members very kindly undertook the task of counting the number of medical women listed in the 1954 issue of the *Medical Directory*. The result of her labours was reported to our Council at its meeting in Sheffield last week, and the figures, right up to date, are 13,374 women's names, included in the *Directory*, of whom 12,500 are in active work.—I am, etc.,

JOSEPHINE BARNES,
Honorary Secretary,
Medical Women's Federation.

London, W.C.1.

** According to another source of information, in January, 1954, there were 10,800 women in the *Medical Register*, of whom 7,600 were known to be in active work.—ED., B.M.J.

Dangers of Induced Hypotension

SIR,—I should like to endorse Dr. Florence Faulkner's letter (*Journal*, May 1, p. 1041) drawing attention to the dangers of poor anaesthetic technique associated with the methonium drugs. I believe there are many surgical procedures where blood loss may be detrimental to the patient, or may so fog the surgical field as to render the operation almost impossible.

It is a remarkable fact that after a correctly administered hypotensive technique patients are much more fit the next day than those given ordinary routine anaesthetics. Although this may be due to the low blood loss, it is perhaps, in such cases as operations on the vagina and pelvis, due to a splanchnic block produced by the ganglion-blocking agent. Like all new methods, it is condemned by the few catastrophes, but these are due to bad technique or a misjudged choice of patient. These patients with low pressure must have oxygen "all the time, and after." Too much premedication—excess of thiopentone or of pethidine—will reduce the respiratory exchange, possibly as much as a deficient airway. Full oxygenation is essential, and must be produced by a high oxygen mixture even, if necessary, by assisted respiration throughout; oxygenated blood must reach the cerebral circulation during the four hours that the pressure remains low after return to the ward: this

means a thoroughly competent nursing ward staff well schooled in the technique.

I quite agree that "hypotensive" methods are dangerous, and should be embarked on warily by the uninitiated. As new "ganglion-blocking" agents are produced, controlled hypotension will one day become "controlled." It will be safer when an efficient antidote, similar to the action of neostigmine on tubocurarine, is obtainable.—I am, etc.,

Manchester.

WILLIAM B. BACON.

Ring Incorporated in Finger

SIR,—The following is an unusual case that I thought might interest readers.

A woman, aged 56 years, appeared in casualty recently. The accompanying photographs show more clearly than words the way her wedding ring has been incorporated in her finger. She had had the ring on for almost 40 years, and for the last 10 had noticed it gradually being covered by folds of skin on the palmar surface. She would admit to no incidents of infection or ulceration. Her doctor had noticed the condition on visiting her for another ailment.

The finger was greatly hypertrophied, especially on the palmar surface, but there was no induration except around the sinus of the ring. The palmar surface showed normal skin with some accentuation of the proximal skin fold but no obvious scarring. There was nearly an inch (2.5 cm.) of normal tissue in front of the ring. The x rays show erosion of bone on the flexor surface, but the flexor tendons are functioning.

My thanks are due to Mr. G. N. Golden for permission to publish this case.—I am, etc.,

Guildford.

J. H. NEAME.

World Population and Food Supplies

SIR,—Your "Medical Notes in Parliament" (*Journal*, May 8, p. 1100) on world population and food supplies gives one the impression that opinion was sharply divided between increased food production and birth control as the answer to the problem of the rapidly increasing world population. Is this division of opinion entirely necessary? Surely an improvement in the standards of living in Eastern countries would lead to a diminution in the size of the family even as it has already done in the West, so that in time the Orientals would be faced with the Occidental problem of an ageing and hence potentially declining population. If priority was given to increased food production much acrimony over methods of birth control would be avoided, for the Indians and Japanese would then adopt these methods in conformity with their own codes.—I am, etc.,

Dublin.

JOSEPH BARNES.

A Question of Seniority

SIR,—But London's two greatest hospitals—St. Bartholomew's founded by Rufus's courtier, Rahere, in the Smithfield Marshes, and the even older St. Thomas's in Southwark for sick and needy travellers—had been established by Augustinian canons in the twelfth century. Such spitals were very small: St. Thomas's, rebuilt after the fire of 1207, had rush beds for forty patients, and a staff of four canons, three nursing sisters, and a warden." This quotation from

The Story of England: Makers of the Realm, by Arthur Bryant, caught my eye shortly after a brisk discussion with an eminent surgical alumnus of St. Bartholomew's, a fanatical follower of Rahere.

Is it not possible for this highly debatable problem to be brought up to date by the elimination of legend and the citation of the existing documentary evidence? After the heat engendered by this process has subsided, the medical profession will at long last know which is *primus inter pares*.—I am, etc.,

Bideford.

M. W. LITTLEWOOD.

¹ *The Story of England: Makers of the Realm*, 1953, p. 326. London.

Visit to Poland

SIR,—On May 3 I returned from a ten-day visit to Warsaw and other parts of Poland, where I had been as a member of a peace delegation. As a recently retired assistant county medical officer, I was particularly interested in the care of children and provision made for them in crèches, kindergartens, schools, youth clubs, and hospitals. For the children of working women there are crèches and kindergartens attached to factories and elsewhere in adequate numbers. Most women in Warsaw appear to go to work. They are not compelled in any way to do so, but when one sees the ruins which remain still after the vast amount of reconstruction which has already taken place one can well accept the fact that every pair of hands is welcome in rebuilding the city which Hitler so wantonly destroyed and which is rising like a beautiful phoenix from its ruins.

Among medical institutions visited was a premature baby unit in Warsaw where 1,500 premature babies have been admitted in the last four and a half years. We were told by the young woman paediatrician in charge that their mortality rate is 30%. The hospital appeared very well equipped and up to date, and all the staff keenly interested in their work. I was very much impressed by a sanatorium in the Tatra Mountains. This modern, excellently equipped hospital was built in 1949, the workers of Silesia subscribing 60% of the money required and the State providing the rest. We were taken over every corner of the sanatorium and were able to mix freely with the small patients. It had 580 beds, all occupied with cases of lung, gland, and bone tuberculosis. On one vast semicircular balcony we saw numbers of spinal cases, looking very brown and extraordinarily cheerful, playing with a great variety of didactic and other toys. The teachers of these younger children appear utterly devoted to their small charges, and have a four-hour day of work, as so much is demanded of them in the way of patience and interest. There is nothing lacking in the way of education for the older children, as teacher members of our delegation soon found after numerous questions and inspection of class-rooms, science laboratories, art rooms, etc.

To-day 1.3–1.5% of the population have tuberculosis; 10% require hospital treatment. Mortality before the war was 20 per thousand. This increased very much during and after the war, but has now been reduced to 8 per thousand. Before the war the number of beds available for tuberculosis was 8,000. To-day there are 13,000 beds for adults and 95,000 for children. As the chief sufferers from tuberculosis are babies, a vast campaign is being waged. Every baby born in hospital is given B.C.G., and wherever possible also those born at home. Since the campaign began a few years ago 8,000,000 children have received B.C.G. Factory and other workers have mass x-ray examinations every 4–6 months, and mobile x-ray units are sent to villages in rural areas.

I was extremely favourably impressed by the way Poland is caring for her children, ill and well, not only with efficiency but with loving kindness. The doctors we met were keen and kindly colleagues, and, apart from language difficulties, no vestige of an iron curtain separated us.—I am, etc.,

Dunmow, Essex.

WINIFRED M. COPPARD.

POINTS FROM LETTERS

Unwrapping the "Journal"

Dr. W. BRUCE FRAY (Sydney, Australia) writes: Some weeks ago I had a small accumulation of *Journals* which required opening and reading. I became irritated with the difficulty of unwrapping and cast around for a simple method. By grasping the protruding end of the wrapper with thumb and forefinger and exerting pressure on the *Journal* with third and fourth fingers it was found comparatively easy to remove the wrapper in its entirety without damaging the *Journal*. Coincidentally, the first *Journal* to be opened by this method contained the first reference (*Journal*, December 12, 1953, p. 1326) to the difficulty being experienced by others.

Teaching Bacteriology in Schools

Dr. A. J. ESSEX-CATER (Swansea) writes: In reference to a comment by Dr. Arthur Turnbull in "Points from Letters" (*Journal*, April 10, p. 878) I am pleased to be able to inform him that a few secondary modern schools do include lessons and demonstrations on the bacteriology of simple human pathogens. It is naturally difficult for schools to obtain the necessary slides, but I am sure public health departments or public health service laboratories would be only too happy to help interested science teachers. I certainly share your correspondent's opinion that the teaching of elementary bacteriology in all schools would be of great value in sharpening the general public's interest in health.

Fear of Litigation

Dr. MAURICE ANDERSON (Birmingham, 14) writes: Dr. C. J. Cellan-Jones (*Journal*, April 10, p. 876) is perfectly correct when he points out how unfair it was for a barrister to make sweeping (and derogatory) generalizations about doctors and hospitals on the grounds of the evidence in one single case. Abbott's *Elements of Logic* contain the axiom: "*E particulare ad universalem, consequentia non valet*." Learned counsel, however good he may be at law, would appear to be unsound in logic.

Ulcerative Colitis

Dr. F. E. TILLYARD (Worthing) writes: With reference to the letter by Mr. C. Horvitz in "Points from Letters" (*Journal*, April 17, p. 937), when at Edinburgh University about 1912 Arbuthnot Lane addressed a meeting of surgeons and medical students. I think that he had just returned from the U.S.A. He recounted how on the voyage home he asked the ship's librarian to recommend him a novel (I forget the name) and "there I read the story of two constipated females." He continued: "The other day a lady hobbled into my consulting-room on two sticks. I looked at her and said, 'Madam, I will give you a new pair of boots through your abdomen.'"

Cancer of the Lung

Dr. A. A. CLAY (Newport Pagnell, Bucks) writes: With carcinoma of the lung looming large in the minds of both lay people and medical practitioners, I feel, as a general practitioner, that something should be done to expedite admission in suspected cases. I find that cases picked up by the mass radiography unit may have to wait a month or more to be admitted to hospital. The only way to ensure adequate results from operation is to see that such cases are treated—as well as diagnosed—at the earliest possible moment, and many of us feel that carcinoma of the lung—indeed, most cases of carcinoma—should be treated with almost the same priority as an acute abdomen.

Clergy and Doctors

Dr. J. B. GURNEY SMITH (Redhill) writes: I read the Rev. Tony Clemens's letter (*Journal*, April 24, p. 983) with interest. He would appear to plead for co-operation between the two callings of the church and medicine. I would like to inform him of the existence of the Union of St. Luke. This Union was founded in 1948 to deepen the spiritual lives of communicant Anglican doctors and to foster a warm-hearted alliance with the clergy. In six years the Union has over 60 doctors as members and associates and a number of clerical associates. The Union circulates newsletters and holds retreats from time to time, especially at St. Luke's tide. Mr. Clemens is cordially invited to become a clerical associate. I feel sure my friend, the honorary secretary of the Union of St. Luke, Dr. R. H. Hardy, 1, Rolfe Villas, Exmouth, would be very glad to hear from intending members of the Union.

Obituary

MABEL L. RAMSAY, M.D., F.R.C.S.Ed.,
M.R.C.O.G., D.P.H.

The sudden death of Dr. Mabel L. Ramsay while attending a council meeting of the Medical Women's Federation at Sheffield on May 9 has removed a vivid personality from the ranks of the medical women in this country. She was 75 years of age.

Mabel Lida Ramsay was born in London in 1878, the daughter of Paymaster-in-Chief A. J. Ramsay, R.N., and as a girl she expressed the desire to become a surgeon, an ambition not easy of accomplishment by a woman in those days. Born with the spirit of a fighter, however, and having decided on the career she wished to pursue, she studied at the Medical College for Women, Edinburgh, and at Owens College, Manchester, but before enrolling as a medical student she trained for two years as a gymnast, with the idea that such training would help her in the orthopaedic work in which, at first, she planned to specialize. She graduated M.B., Ch.B. at Edinburgh in 1906, took the Cambridge D.P.H. in 1908, and proceeded to the M.D. two years later. In 1921 she was elected F.R.C.S.Ed., and in 1929 was admitted a foundation Member of the Royal College of Obstetricians and Gynaecologists. After qualifying she held the appointments of house-surgeon at the Glasgow Maternity Hospital and then for a time was in the public health service as assistant medical officer of health at Huddersfield. Later, she was senior house-surgeon at the Women and Children's Hospital, Leeds. She went to Plymouth a few years before the outbreak of the first world war in 1914, during which she worked for a time as a surgeon with the Women's Imperial Service at hospitals in Belgium and France.

It was as an obstetrician and gynaecologist that Mabel Ramsay came to specialize and not as an orthopaedic surgeon. At Plymouth she became in due course consulting gynaecologist to the City Hospital and to the Infirmary; consulting obstetrician to the Three Towns Maternity Home, to the Salvation Army Maternity Home, and to the counties of Devon and Cornwall; and consulting surgeon to Plymouth Public Dispensary. She also lectured to midwives in the district and examined for the Royal College of Nursing.

For many years she was a familiar figure at the headquarters of the British Medical Association. She served on the old Insurance Acts Committee from 1919 to 1938, on the Additional Benefits Subcommittee from 1928 to 1938, and on a number of other committees, including the one concerned with the causation of puerperal morbidity and mortality. When the Association held its Annual Meeting at Plymouth in 1938 she acted as one of the vice-presidents of the Section of Obstetrics and Gynaecology. A founder member of the Medical Women's Federation, she had been its honorary secretary and in 1932-3 and again in 1933-4 its president. In 1934 she offered herself for election to the General Medical Council as a direct representative in the place of Sir Henry Brackenbury, whose term of office had expired; but the opposition was too strong. Locally, she was the first woman member of the Plymouth Medical Society and its president in 1930-1, and for a time she was honorary treasurer of the Plymouth Panel Committee and honorary secretary of the Plymouth Local Medical Committee. She was also a former honorary

secretary of the Plymouth Citizens' Association and a past president of the Plymouth Soroptimist Club.

Mabel Ramsay's life was spent in one long fight for the rights of women. Recalling the days of the suffragettes, she could tell how her mother, then over 60 years of age, was one of the band of pilgrims who walked from Land's End to London in 1914. Dr. Ramsay herself accompanied the pilgrimage as far as Taunton, but then had to return to Plymouth to fulfil her professional duties. She loved to recall the excitement caused in those early days by the suffragettes, and with relish she would relate how once it had been said of her, "Dr. Mabel Ramsay is a devil: we must watch her." She was certainly watched, and admired, for many years thereafter.

We are indebted to Dr. ANNIE BRYCE for the following appreciation: The medical women of the South-west, and indeed medical women generally, will sadly miss the gallant figure of Mabel Ramsay. She herself would be delighted to know that she ended her days still in harness, and at a council meeting of the Medical Women's Federation. She was a founder member of the Medical Women's Federation, and the medical women of to-day owe much to her energy and fire and enthusiasm, which played such a big part in getting them equality with their male colleagues. She never lost her energy and drive, and was always fighting for some minority cause. She was a steadfast friend to the young and newly qualified, and I have many grateful memories of her kindness to me when I timidly started out in general practice thirty years ago. Our friendship never faltered, and her example spurred me on to undertake many things I may otherwise have shunned and therefore failed in my duty to medical women. A pleasant memory is her last Christmas card, with its usual little doggerel written by herself, ending: "And so I jog along, singing my happy little song."

A. A. MUSSEN, M.D., D.P.H.

Many of the older members of the public health service will have learnt with regret of the death of Dr. A. A. Mussen, formerly medical officer of health for Liverpool and a vice-president of the Liverpool Medical Institution, at Harrogate on May 3. He was 84 years of age.

Arthur Augustus Mussen was born in Antrim on April 4, 1870, and received his medical training at Trinity College, Dublin, where he obtained the degrees of M.B., B.Ch. in 1892, proceeding to the M.D. three years later. Like so many of those who intended to make public health their career at that time, Mussen studied this subject at Cambridge, taking the D.P.H. there in 1899. Before he joined the Liverpool public health department in 1900, then and for many years after under the direction of the late Professor E. W. Hope, Mussen spent several years in hospital appointments and gained some useful experience as assistant medical officer of health for Huddersfield. In 1909 he was appointed to a similar post at Liverpool, and thus began his long career in that city. He retired in 1931.

When Mussen went to Liverpool some interest was being shown by Hope in the experimental work which was being done by Variot, in Paris, and Nathan Strauss, in New York, on the subject of the artificial feeding of infants. The first milk depot in Liverpool was opened in 1901, and this step initiated the great advances which were to take place there in the care of infants and young children, in which Mussen played a notable part. The personal health services—begun in Liverpool by the appointment of health visitors, the supply of special milk feeds, and the opening of child welfare clinics—

were broadened by the setting up of the school medical service in 1907 and the tuberculosis service in 1912. Mussen, who could have truly said with Abou Ben Adhem that he loved his fellow men, brought much energy and enthusiasm in those early days to the organization and development of the personal services; but, with his appointment as deputy medical officer of health in 1912 and the strengthening of the medical staff of a rapidly growing department, he began to spend more and more of his time on the purely administrative side of his work. He twice held office at Annual Meetings of the British Medical Association: at Toronto, in 1906, he was one of the honorary secretaries of the Section of State Medicine, and at Liverpool, in 1912, he was a vice-president of the Section of State Medicine and Industrial Diseases.

His work in the Liverpool public health department was interrupted by the outbreak of war in 1914, during which he saw service in France, first in a mobile hospital and later as a specialist sanitary officer, attaining the rank of major. When Hope retired in 1924 Mussen was asked to take over the appointment of medical officer of health. Although he had been lecturer in practical sanitation in the University of Liverpool for a good many years, Mussen was not anxious to accept the more serious responsibility of the professorship of public health, and so Hope continued to occupy the chair until 1931. Mussen was not an ambitious man at this stage of his career, when he was in the middle fifties, and throughout his official life rather tended to shun the limelight, perhaps, indeed, to the advantage of the work of his department.

He was keenly interested in sport in his younger days, especially in skating and climbing. He was a member of the Liverpool Racquets Club, the Liverpool Athenaeum, and the Liverpool Chess Club, and for a time he was chairman of the Philharmonic Society. On his retirement he and Mrs. Mussen moved to Surrey, but during the last few years they had lived in a hotel at Harrogate. The sympathy of his colleagues will be extended to his widow in her bereavement.—W. M. F.

W. L. BURGESS, C.B.E., M.D., F.R.C.P.Ed., D.P.H.
The death of Professor William Leslie Burgess at his home in Dundee on April 22 has deprived public health of one of its most outstanding exponents, while the school of medicine of the University of St. Andrews mourns the loss of a distinguished teacher.

Born in Aberdeenshire 68 years ago, he received his medical education at the University of Edinburgh, graduating M.B., Ch.B., with first-class honours, in 1909. His interest in preventive medicine dated from his undergraduate days and was maintained throughout his life. Within three years from graduating he obtained the Diplomas of Public Health and of Tropical Medicine and Hygiene, while, in addition, he proceeded to the higher degree of M.D. in 1912, his thesis being awarded a commendation.

Burgess went to Dundee in 1913 as chief tuberculosis officer, and, after service with the Scottish Horse in the first world war, returned in 1918 to become medical officer of health, a post which he held until 1951. During his tenure of office as medical officer of health the development of public health, from both the professional and administrative points of view, was rapid: his clinical acumen ensured that the professional advances were put to the best advantage of the population he served with such devotion, and his ripe judgment that admini-

strative changes were introduced with minimum disturbance of continuity. Professor Burgess was of that generation of public health officers who maintained an active interest in the practice of medicine, and he was as able a physician as he was an administrator. His sustained contact with clinical work made him an exceedingly valuable colleague of the practitioners in the city, and also gave stimulus to his interest in research. His collaboration made advances in the diagnosis of smallpox possible, while his willing co-operation allowed of accurate information being obtained concerning some very puzzling aspects of the epidemiology of diphtheria. Of his achievements, that which gave him most solid satisfaction was, however, the marked reduction which took place in the infantile mortality rate in Dundee during his tenure of office.

When the National Health Service was instituted it was but natural that the Eastern Regional Hospital Board of Scotland should benefit from his wide experience of clinical medicine, of hospital management, and of public health administration, and his sage counsel was as much appreciated by that body as it had been by the municipality.

His service to medical education was no less notable than his contribution to public health. Appointed lecturer in public health in the school of medicine of the University of St. Andrews in 1918, he was responsible as lecturer and as reader for instruction therein until 1951, when he was invited to become the first incumbent of the James Mackenzie Chair of Public Health and Social Medicine. Many generations of students have benefited from his lucid and logical teaching, while his academic colleagues were indebted to him for wise guidance on Faculty and on Senate. Possessed of the qualities of experience, judgment, patience, and tolerance, he was called upon to serve on many committees of national importance, and he was as unsparing of himself in performing work of this nature as he was in fulfilling his more obvious duties: for his services he was appointed C.B.E. in 1944.

Of his attributes as a man, those which were perhaps most outstanding were his breadth of vision, his consideration of others—his staff was a happy family—and his kindness to all. The sympathy of those who had the good fortune to know him goes out in full measure to his widow and son.—W. J. T.

ALISTER T. MACKENZIE, M.D., D.P.H.

Dr. Alister T. Mackenzie, one of the pioneers of health education and physical education in Scotland, died at Glasgow on January 5 at the age of 70.

A native of Alness, Ross-shire, Alister Thomas Mackenzie was born on June 27, 1883, and educated at Tain Royal Academy and Edinburgh University. When he entered the University he combined the work of two faculties—arts and medicine—and during the next six years obtained concurrently the degrees of M.A. and M.B., Ch.B., besides devoting a considerable amount of time to research. He held numerous bursaries and scholarships during his courses. Immediately after graduating in 1907 he was awarded a Carnegie Research Scholarship and worked under the late Sir Thomas R. Fraser. In 1909 he proceeded to the degree of M.D., being awarded a gold medal for his thesis. He was also awarded the Milner Fothergill Gold Medal in therapeutics and the Crichton Research Scholarship in Materia Medica and was appointed a research fellow of the University of Edinburgh.

After spending some time on the staff of the Edinburgh City Fever Hospital, Dr. Mackenzie obtained the Cambridge D.P.H. in 1910 and in the same year was appointed lecturer in anatomy and physiology in the Dunfermline College of Physical Education and Hygiene. This was the beginning of his lifelong interest in school medical work and in physical education, to which he brought not only his outstanding intellectual gifts but also the fruits of his visits to Norway and Sweden, where he had studied the work being done in those fields. In 1912 he was appointed principal medical officer to the Carnegie Trust and principal of the College of Physical Education. He continued to hold the two posts until 1931, although the College was taken over by the National Committee for the Training of Teachers in 1921. During the first world war he served as a major in the R.A.M.C.

As medical officer to the Carnegie Trust, Dr. Mackenzie was responsible for initiating many activities to do with children which we now regard as commonplace. He persuaded the Trust to found their well-known children's holiday home at Bandrum. Medical inspection for schoolchildren, remedial clinics, a school for mothers, and a school for mentally defective children were other aspects of work in Dunfermline owing their inception to Dr. Mackenzie's enthusiasm and foresight. During his term of office as principal, the new college buildings and clinic were erected for the Scottish School of Physical Education in Dunfermline, and a three-year course was developed for the training of men and women teachers of physical education. Because of this expansion of the school, the men students were moved to Jordanhill Training College, Glasgow, in 1931. Dr. Mackenzie then became principal medical officer of the Training College and held that office as well as acting as head of the Scottish School of Physical Education for Men until his retirement in 1948.

A man of wide culture, great personal charm, and a quick and acute mind, Dr. Mackenzie might well have secured a place in the world of medicine much more conspicuous than that obtainable in the somewhat restricted sphere of teacher-training. He chose his field deliberately, and many generations of Scottish teachers have cause to be glad of it. Clear, thorough, and up-to-date, his work was further distinguished by its wit and its crisp and polished style. In his particular field he had the satisfaction of finding his views and his methods securing an ever-widening approval. Men of the Scottish School of Physical Education and Hygiene are to be found to-day all over the English-speaking world. They have taken with them not only the fruits of his experience, his constant study, and his wisdom, but that interest in youth, that belief in their subject, and that readiness to test and adopt new ideas that were an integral part of his teaching.

Dr. Mackenzie married in 1916 and leaves a widow and a son and daughter.—H. P. W.

H. J. ROBINSON, M.R.C.S.

One of the oldest doctors in this country, if not the oldest, Dr. H. J. Robinson died at his home at Simonstone, near Burnley, Lancashire, on May 13, nine days before his 102nd birthday.

Henry James Robinson was born near Dudley Castle on May 22, 1852. After taking the Cambridge B.A.,

he became a Wesleyan minister and travelled in various circuits, chiefly in Yorkshire, before resigning from the ministry to become a medical student at Manchester University. He qualified M.R.C.S., L.R.C.P. in 1893 and set up in practice at Burnley, where he had lived for some years. He became medical officer to the Burnley Union Institution and later medical officer of health to the Burnley Rural District Council, retaining the latter appointment until his 90th year. Dr. Robinson's work as a general practitioner did not prevent him from taking a keen interest in the affairs of the Wesleyan Church, and his services were in demand as a local preacher. In the early years of this century he was an active member of the British Medical Association and represented his constituency at six Annual Representative Meetings from 1912 to 1917. A familiar personality in Burnley and the district, his sympathetic understanding of people, his interest in social welfare work, and his influence for good in the life of the community made him many friends. His long life was remarkably free from illness, for at the age of 100 he could recall only an attack of rheumatic fever when he was 21 and a broken arm in 1951.

Dr. F. J. CHILD, formerly consulting surgeon to the Royal Hampshire County Hospital, Winchester, died at his home at Bournemouth, where he had been living in retirement, on April 28 at the age of 78. Francis Joseph Child was born on October 24, 1875, and was educated at Christ's College, Cambridge, and at St. Thomas's Hospital, where he gained the Sutton Sams memorial prize in gynaecology in 1900. He obtained the degrees of M.B., B.Chir. in 1901, and proceeded to the M.D. four years later. After qualification he held a number of house appointments at St. Thomas's Hospital, and then for a time was resident medical officer at St. Thomas's Home. In 1905 he settled in general practice at Winchester, becoming also honorary surgeon to the Royal Hampshire County Hospital and medical officer to Winchester College. He retired from practice in 1929, when he went to live at Torquay. From 1930 to 1934 he was resident at Bordighera, in Italy, and then returned to Torquay until 1937, when he moved to Bournemouth. The last months of his life were saddened by the loss of his eldest daughter, who died in September, 1953.

J. T. writes: A kind and gentle man and a good neighbour, Dr. F. J. Child was one of my chiefs at the Royal Hampshire County Hospital, where I worked with him until his retirement. His kindness and sympathy to his patients and his patience and forbearance with his juniors are among my chief recollections of him. His technique was scrupulous, and he was always willing to pass on his wealth of experience to those whom he taught. He was never in a hurry and was never known to be late for any hospital commitment. He always appeared to be pleased to be summoned to the hospital, whether it was early morning or late at night; and his calm and deliberate assessment of any problem was a comfort to the patients and to his colleagues. Until he retired it was a common sight to see him on his bicycle at 8.30 a.m., going to pay his daily visit to Winchester College before the start of his ordinary day's work. He was a man much beloved and universally respected, and there are many still living in the Winchester district who think of him with gratitude for his skill in their treatment and who will mourn his passing. I personally look back with gratitude to him for what he taught me, not only in surgery, but in the better understanding of the individual patient and the assessment of his particular problems.

The recent death of Dr. DAVID KINLEY, who was a general practitioner in Belfast, has removed a well-known personality from the medical profession in Northern Ireland. Born at Gilford, Co. Down, he was educated at Lurgan College, and then served in the first world war, losing a leg in Mesopotamia. On returning to civilian life, he entered Queen's University, Belfast, as a medical student, and graduated M.B., B.Ch. in 1924. He then settled in general practice in the city, where he led a busy life for thirty years. During the air raids on Belfast in the last war his work for the casualty services was outstanding.

Dr. R. ENGLISH writes: It was with deep regret that I learnt of the death of Dr. David Kinley ("Davy" as he was known to a great number of the medical profession in Northern Ireland). I was closely associated with him, first in the City Hospital about thirty years ago, then subsequently as a dispensary medical officer. It was in the changes which occurred in our status owing to the introduction in 1930 and 1948 of the various Health Acts which made Davy Kinley our leader. His knowledge of the various Acts of Parliament was phenomenal, and he was our backbone in the discussions with the Ministry of Health and Local Government. He was outstanding as a man who would defend his friends and fight for any cause he thought was just. He conducted a very successful practice in the north of Belfast, and many of his patients, especially ex-Service men, have every reason to be grateful for his efforts on their behalf. David Kinley was a keen fisherman, and he and the wooden leg had many a tussle with a salmon on the banks of the Bush river in Co. Antrim. He also took a keen interest in Rugby football. Endowed by nature with a happy disposition, he was always the life and soul of a party. He is survived by his widow and two sons, both of whom are undergraduates of his old university. To them the deepest sympathy is extended.

Mr. L. G. SCOLAR, who was senior ophthalmic surgeon at the Royal London Homoeopathic Hospital, died in University College Hospital on May 4. Leslie Gemmill Scoular was born on February 4, 1901, and was educated at Glasgow University, where he graduated M.B., Ch.B. in 1924. He took the D.O.M.S. of the English Royal Colleges in 1934 and proceeded to the M.D. four years later. After graduation he held appointments in the ophthalmic departments of various hospitals in London, later becoming senior house-surgeon at the Glasgow Eye Infirmary and ophthalmic house-surgeon at Hull Royal Infirmary, before finally settling in practice in London in 1931. Four years later he gave up general practice to become a consultant ophthalmic surgeon, and in due course was appointed to the staff of the Royal London Homoeopathic Hospital, and, later, to the North Middlesex Hospital and Hornsey Central Hospital. Joining the R.A.F.V.R. a few months before the outbreak of war in 1939, he served until August, 1945, having attained the rank of wing commander.

A. J. M. B. writes: The untimely death of Leslie G. Scoular at the age of 53 has appalled an exceptionally wide circle of sorrowing friends. He had a genius for making lasting friendships, and was at his best when entertaining his friends. All who knew him will long remember his good looks and boisterous laugh, and his engaging way of bringing a party to life by making some deliberately provocative remark and then defending his thesis against all comers. His interests were protean, and included gardening, music, and golf. His reading covered a wide field, especially philosophical works. He was gifted, too, with an inventive faculty, and his description of an improved undine to facilitate the work of nurses was published in the *Journal* of January 9 last. After six years of war service in the R.A.F. he resumed work in London, and, despite long hours of professional work, contrived to find time for his numerous social and cultural activities, including the duties of honorary secretary of the Glasgow University Club of London. As ophthalmic surgeon at the Royal London Homoeopathic Hospital, his skill

and conscientiousness were known to all his colleagues, and his many patients had good cause to be grateful for his thoroughness, kindness, and consideration. All his friends mourn his loss and will wish to extend deep sympathy to his widow, sister, and brothers.

Dr. MARGARET E. PEAKER, an assistant medical officer in the Middlesbrough school health service, died suddenly while on sick leave on April 27 at the age of 54. Born on July 16, 1899, the daughter of the late Mr. Frederick Peaker, a former president of the Institute of Journalists, Margaret Eveline Peaker was educated at Sydenham High School for Girls and at King's College Hospital, qualifying M.R.C.S., L.R.C.P. in 1928. She held resident posts at the Sheffield Children's Hospital and at the East Anglian Children's Sanatorium, Nayland, near Colchester, and in 1932 she became a school medical inspector under the West Riding County Council, her work there being interrupted by service in the R.A.M.C. in the last war from 1942 to 1946. After demobilization she obtained the appointment at Middlesbrough. Dr. Peaker was a very capable school medical officer, being particularly keen on the social side of her work. Her sunny disposition and interest in each child made her popular with patients and staff alike. During the last few years of her life she had frequent illnesses, but she worked on with great fortitude almost to the end. A pleasant memory of a real lover of children is left with her colleagues and her friends.

Medico-Legal

DANGER TO WIFE'S HEALTH

"Deliberate failure of a husband suffering from tuberculosis to take precautions recommended for the protection of his family" was held by the Divorce Divisional Court on May 3 to constitute cruelty towards his wife. The appeal by Mr. P. N. Enticknap, of Hull, against the finding of the Hull stipendiary magistrate on August 14, 1953, that he had treated his wife with persistent cruelty, was dismissed. Mr. and Mrs. Enticknap were married in 1943. There were three children.

Lord Merriman, giving judgment, said the wife complained of two acts of violence separated by 3½ years—which it was impossible to characterize as persistent cruelty—together with acts of neglect in connexion with his disease. Mr. Enticknap was found to have tuberculosis in 1951 and was off work for six months. The disease became quiescent, but there was a further outbreak in September, 1952, which continued to the following April. The magistrate found that during the second period Mr. Enticknap "persistently and flagrantly disregarded the precautions he had been enjoined to take, and in particular flouted the instructions as to the disposal of sputum." Mr. Enticknap had been informed that his disease was active and infectious and was told he should take precautions against the spread of the infection—the use of a separate bedroom, the use of separate bed linen and crockery, and, particularly, safeguards for the disposal of sputum. The wife repeatedly remonstrated with him, and these remonstrances later became of great frequency. The husband's attitude, according to the wife, was that he would always agree on the surface, but in his actions he carried on in the same way.

Two of the children developed a tuberculous infection, his lordship added, and, though he was not saying that the husband infected either of them, it might be so. It was sufficient for the court to be satisfied that the husband knew that by his acts he was endangering the health of his family. His lordship had no hesitation in all the circumstances in attributing such knowledge to the husband. It was said acts of omission could not be "aimed at" the victim, but, applying the test laid down as to what was meant by "aimed at," he found it was amply justified. "If

Davy, M. G. D. Davys, Cecile R. Doniger, Stefanie Felsenburg, N. Goldman, J. D. Haldane, T. H. Kaplan, R. R. Knowles, T. A. Lambo, Stephanie M. Leese, J. Newcombe, H. Rifkin, W. Rodger, D. C. V. Stewart, W. H. Tait, B. B. Zeitlyn.

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.—A. W. Duke, W. M. McCutcheon, R. N. Mitra, K. Saakwa-Mante, D. R. P. Suriapperuma, K. S. Tun, E. E. Vella.

DIPLOMA IN INDUSTRIAL HEALTH.—P. K. Bose, W. R. Brown, Patricia M. Elliott, B. Ghose, R. Malan, C. R. A. Martin, F. G. Neild, M. K. Qureshi-ul-Hashmi, T. Simpson, W. J. Smither.

DIPLOMA IN PATHOLOGY.—P. B. Adamson, G. Aung, A. J. E. Brafield, P. W. Harvey, Phyllida M. M. Roberts, B. Ruebner, B. A. Woodger.

DIPLOMA IN CHILD HEALTH.—D. E. Williams.

DIPLOMA IN MEDICAL RADIODIAGNOSIS.—J. D. Nelson.

At a meeting of the Council of the College held on February 11, with Sir Cecil Wakeley, President, in the chair, an Honorary Fellowship of the College was awarded to Professor Arthur Steindler, of Iowa City, U.S.A.

A Moynihan Lectureship was awarded to Dr. Walter C. Mackenzie, of Edmonton, Alberta, Canada.

Professor Merle D'Aubigné (Paris) was appointed Robert Jones Lecturer for 1954.

Mr. R. G. Macbeth (Oxford) was admitted as an *ad eundem* Fellow.

The Hallett Prize was awarded to Asitkumar Mitra (Calcutta).

The Handcock Prize was awarded to Sheila C. Hay (Sheffield) and to Margaret S. Meyer (Royal Free).

It was agreed to hold a Primary Fellowship Examination in Colombo in November, 1954.

Regulations were approved for the award of the Edridge-Green Lectureship in Ophthalmology.

Diplomas of Membership of the College were granted to the candidates whose names are printed in the report of the meeting of the Royal College of Physicians of London (p. 1217 of this Journal) as recipients of the L.R.C.P.

Diplomas in Anaesthetics and in Public Health were granted, jointly with the Royal College of Physicians of London, to the successful candidates whose names are printed in the report of the meeting of the Royal College of Physicians of London (p. 1217 of this Journal).

Vital Statistics

Infectious Diseases

The largest variations in the trends of infectious diseases in England and Wales during the week ending May 1 were decreases of 226 for measles, from 2,196 to 1,970, and 166 for scarlet fever, from 789 to 623, and an increase of 100 for whooping-cough, from 2,133 to 2,233.

The largest fluctuations in the local trends of measles were falls of 86 in Cheshire, from 191 to 105, 66 in Lancashire, from 437 to 371, 62 in Yorkshire West Riding, from 221 to 159, and 46 in Norfolk, from 372 to 326, and a rise of 85 in Durham, from 79 to 164. Only small variations in the number of notifications of whooping-cough were recorded in local trends. The only variation of note in the returns of scarlet fever was a decrease of 35 in the number of notifications in Essex from 67 to 32, 12 cases of diphtheria were notified, the same as in the preceding week. Half of the cases of diphtheria were notified in Lancashire.

20 cases of acute poliomyelitis were notified. These were 9 more for paralytic and 1 more for non-paralytic cases than in the preceding week. The largest returns were 3 cases in Yorkshire West Riding and in Staffordshire (Cannock U.D. 2) and 2 cases in London, Worcestershire, and Lancashire.

759 cases of dysentery were notified, being 48 more than in the previous week. The largest returns were Lancashire 143 (Blackpool C.B. 27, Denton U.D. 15, Liverpool C.B. 13, Salford C.B. 13), Yorkshire West Riding 120 (Sheffield C.B. 27, Dewsbury C.B. 14, Leeds C.B. 13), London 108 (Islington 30, Lewisham 12), Leicestershire 85 (Leicester C.B. 80), Cheshire 33 (Ellesmere Port U.D. 27), Devonshire 28 (Plymouth C.B. 19), Sussex 26 (Brighton C.B. 24), Glamorgan-shire 26 (Llchwyr U.D. 18), and Middlesex 20.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1945-53 are shown thus -----, the figures for 1954 thus ————. Except for the curves showing notifications in 1954, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Week Ending May 8

The notifications of infectious diseases in England and Wales during the week included pneumonia 506, scarlet fever 719, whooping-cough 2,381, diphtheria 9, measles 1,734, dysentery 948, acute poliomyelitis 23, paratyphoid fever 13, and typhoid fever 2.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending May 1 (No. 17) and corresponding week 1953.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Medical News

Honorary Degrees at Annual Meeting.—During the Annual Meeting of the B.M.A. in Glasgow this year the University of Glasgow will confer the honorary degree of Doctor of Laws on the following distinguished medical men: Sir Andrew Davidson, formerly Chief Medical Officer of the Department of Health for Scotland; Dr. J. B. Miller, a Vice-president of the B.M.A. and former chairman of the Representative Body; Mr. J. W. Tudor Thomas, President of the B.M.A. in 1953-4; and Sir Lionel Whitby, President of the B.M.A. in 1948-9. The degrees will be conferred at a special ceremony on July 8.

Surgeons Honoured.—The Princess Royal, Chancellor of Leeds University, on May 14 conferred the honorary degree of doctor of laws on Sir Cecil Wakeley, P.R.C.S., and Professor Everts A. Graham, chairman of the board of regents of the American College of Surgeons. They were attending the conference held last week of the Association of Surgeons of Great Britain and Ireland. On the same day Mr. Philip Allison, thoracic surgeon of Leeds United Hospitals, and Professor Digby Chamberlain, of Leeds University, were made honorary fellows of the American College of Surgeons. Professor A. Blalock gave the Moynihan Lecture at Leeds University.

Surgeons at Edinburgh.—A reception was held on May 11 at the Royal College of Surgeons of Edinburgh in honour of Fellows of the American College of Surgeons attending meetings in Edinburgh. The President, Professor Walter Mercer, presided over a large audience including the Lord and Lady Provost of the City of Edinburgh. The proceedings were opened by the Very Reverend Dr. C. L. Warr, Dean of the Thistle and Chapel Royal and Chaplain to the Royal College of Surgeons, who read the prayer of the College attributed to John Knox. Dr. Alfred Blalock, Dr. Everts A. Graham, Dr. Henry W. Cave, and Dr. Frederick A. Collier were admitted honorary Fellows of the College. After Dr. Blalock had replied on behalf of the new honorary Fellows, Professor Mercer was admitted to the honorary Fellowship of the American College of Surgeons.

Chelsea Clinical Society.—The Chelsea Clinical Society has a well-earned reputation for a high standard of after-dinner speaking. As the retiring president, Dr. J. Nigel Loring, said at the annual dinner last week, it is a characteristic of the Society to correlate medical interests with other human activities, and he referred to some of the successful and well-attended meetings of the past session. The toast to the Society was proposed by Sir Terence Nugent, Comptroller of the Lord Chamberlain's Office, who was entertaining, and reassuring, about the censorship of stage shows. Mr. S. H. Wass proposed the health of the guests in a lively and epigrammatic speech. In reply His Honour Judge J. B. Blagden showed that the legal profession is capable of taking an even gloomier view of mankind than the medical profession; and it was left to Sir Heneage Ogilvie to cheer the company up with some excellent stories. At the end of the dinner Dr. Loring transferred his badge of office to the new president, Mr. Victor H. Riddell.

Harveian Society of London.—The Buckston-Browne-Gray-Hill dinner was held at the Charing Cross Hotel on May 12, with the president, Dr. R. Cove-Smith, in the chair. In speaking to the toast of the Harveian Society of London the Bishop of Willesden deplored the diminishing sense of personal responsibility in modern society: without a feeling of intimate concern for one another, all that the Welfare State was trying to achieve would be doomed to failure. In reply Dr. Cove-Smith mentioned the various activities of the Society designed to honour the memory of William Harvey, and referred particularly to the successful efforts of the present Mayor of Folkestone to inaugurate in that town, Harvey's birthplace, an annual

ceremony of remembrance. The Society had endowed a prize at the Harvey Grammar School of Folkestone—founded by Harvey's nephew with money left by Harvey—for original research in any subject carried out by a pupil of the school. Dr. Cove-Smith underlined the Bishop of Willesden's remarks about personal responsibility, an ideal which the learned societies could do much to foster. The profession's future, he added, was in a poor state if the possession of higher degrees reduced the chances of a young doctor getting into general practice. This attitude of mind must be challenged and the better qualification of the doctor be encouraged rather than discouraged. The health of the guests was proposed by Dr. D. G. H. Sylvester, and the Mayor of Folkestone, Alderman J. Moncrieff, unabashed at having to stand in at a moment's notice for Sir William Wavell Wakefield, made an urbane and entertaining reply. Mr. C. Hamblen Thomas also replied for the guests.

Obstetrics Prizes.—The Royal College of Obstetricians and Gynaecologists offers the following: the appointment of one or more William Blair-Bell Memorial lecturers (honorarium 20 guineas); Green-Armytage Short-term Travelling Scholarship (value £75); Bernhard Baron Travelling Scholarship (value £500); Edgar-Gentili Research Scholarship in the form of grants or research fellowships (£850 per annum); Leverhulme Scholarships (value up to £500 per annum); prize of £50 for the best original work on "Methods for improving the results of forceps delivery." Entries for the last and applications for the others (or recommendations for the first) must reach the honorary secretary of the College before September 1. Full details should be obtained from him at 58, Queen Anne Street, London, W.1.

W.H.O.'s New President.—Saying that W.H.O. was the first world-wide organization to elect "a true African as its president," Dr. J. N. Togba, on behalf of Liberia and all Africans, expressed his gratitude for the honour placed on him. He added that in W.H.O. "the concept of democracy is being translated into action without regard to size or development of a country, race, colour, or creed."

London University.—Dr. R. B. Lucas has been appointed professor of oral pathology in respect of his post at the Royal Dental Hospital of London School of Dental Surgery. Dr. F. T. G. Prunty has been appointed professor of chemical pathology in respect of his post at St. Thomas's Hospital Medical School. Dr. R. A. Kekwick, D.Sc., has been appointed reader in chemical biophysics in respect of his post at the Lister Institute of Preventive Medicine.

Birmingham University.—Professor H. L. Saha, of Calcutta University, and Dr. Bernard Shaw have been made University Research Fellows in medicine and pharmacology respectively during the tenure of their posts at the University.

Edinburgh University.—Dr. G. J. Romanes has been appointed professor of anatomy in succession to Professor J. C. Brash, and Dr. G. L. Montgomery has been appointed professor of pathology in succession to Professor A. M. Drennan.

New Zealand Honour.—Professor W. E. Le Gros Clark, of Oxford University, has been elected an honorary member of the Royal Society of New Zealand.

Beit Memorial Fellowships.—Professor T. R. Elliott, F.R.S., has resigned from the board of trustees after 19 years' service, and his place has been filled by Sir Alan Drury, F.R.S. The following elections have been made to Junior Fellowships (£630 a year): Dr. R. G. Tucker, to investigate the action of divalent metals on the multiplication of bacteriophage, at the Sir William Dunn School of Pathology, University of Oxford; Dr. D. S. H. W. Nicol, to study the chemistry and pharmacology of peptide fractions of insulin, at the Dunn Institute of Biochemistry, University of Cambridge; Mr. B. T. Donovan, B.Sc., to study the hypothalamic control of the secretions of anterior pituitary hormones, at the University of London Institute of Psychiatry.

COMING EVENTS

Newcastle-upon-Tyne Consultants and Specialists.—A meeting of the Consultants and Specialists Committee, Newcastle-upon-Tyne Region, will be held in the New Lecture Theatre, Royal Victoria Infirmary, Newcastle-upon-Tyne, on Monday, May 24, at 8.30 p.m. Mr. John Pringle (Public Relations Officer of the British Medical Association) will address the meeting on "Public Opinion and the Hospital Medical Service." The meeting is open to consultants, S.H.M.O.s, registrars, and other hospital medical staff in the region.

Atomic Energy.—Members of the B.M.A. are invited to apply for tickets for a reception to be held by the Institute of Atomic Information for the Layman at the Royal Society of Arts, Adelphi, London, W.C., on Saturday, May 29, 8 to 10.30 p.m., when Lord Hore-Belisha will open the proceedings. Dr. J. Cranston, D.Sc., will speak on "The Discovery of Isotopes" and Professor F. Soddy, F.R.S., will give a demonstration. Details from Major Howorth, 55, Park Lane, London, W.1.

Florence Nightingale Centenary Concert.—The United Hospitals Festival Choir, with the London Symphony Orchestra, will give a concert with distinguished soloists, including Dame Myra Hess, at the Royal Albert Hall on June 3 at 7.30 p.m. The concert is in aid of the National Florence Nightingale Memorial Fund. Tickets from the box office and the usual agents.

Polish Medical Association in Great Britain.—The annual meeting will be held at the White Eagle Club, 2, Albert Gate, Knightsbridge, London, S.W.1, on June 5 and 6. Further information may be obtained from the honorary secretary of the association, 14, Collingham Gardens, London, S.W.5.

The Diabetic Association.—The Banting Memorial Lecture and Scientific Meeting will be held at University College Hospital Medical School, London, W.C.1, on July 16 and 17. Scientific contributions are invited. Dr. K. Hallas-Møller, of Denmark, will deliver the Banting memorial lecture on July 16 at 2.30 p.m. He will speak on the new insulins. Further information may be obtained from the Diabetic Association, 152, Harley Street, London, W.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked *. Application should be made first to the institution concerned.

Monday, May 24
LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.—5.15 p.m., Newholme Lecture by Professor W. M. Frazer: State Medicine in the Nineteenth Century—The Industrial Era.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. A. C. Donohorst: Respiratory Function in Failure.

Tuesday, May 25
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. F. R. Bettley: Eczema-asthma Syndrome.
INSTITUTE OF NEUROLOGY.—5.30 p.m., Dr. D. McAlpine: Intracranial Hypertension and Hypotension.
INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Hammersmith Hospital, 3 p.m., Professor J. Louw (Capetown): Constriction Ring Dystocia.
LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.—5.45 p.m., Newholme Lecture by Professor W. M. Frazer: State Medicine in the Nineteenth Century—The State and Medical Research.
ROYAL SOCIETY OF ARTS: COMMONWEALTH SECTION.—5.15 p.m., Sir Leonard Rogers, F.R.S.: Progress Towards the Eradication of Leprosy from the British Commonwealth. (Illustrated by lantern slides.)
ROYAL STATISTICAL SOCIETY: STUDY CIRCLE ON GENERAL STATISTICS.—At Westminster Medical School, 5.45 p.m., annual general meeting. Debate: This House Welcomes the Growing Influence of Statistics in all Branches of Medicine. Proposer, Dr. R. A. J. Asher; Opposer, Mr. R. S. Murley.
SENATE HOUSE.—5.30 p.m., Special University Lecture by Air Marshal Sir Harold Whittingham: Medical Science and Problems of Flying.
WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY.—5 p.m., Altmouth Wright Lecture by Professor G. Payling Wright: Recent Studies on Tetanus.

Wednesday, May 26
EUGENICS SOCIETY.—At Royal Society, 5.30 p.m., Lord Simon of Wythenshawe: Some Aspects of World Population and Food Resources.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Miss B. M. Partridge: Mycology—Diagnosis of Ringworm Infections.
INSTITUTE OF ORTHOPAEDICS.—At 234, Great Portland Street, W., 8 p.m., Senior Clinical Conference with Mr. M. Pilcher: Preventive Tendon Transplantation in Poliomyelitis.
LIVERPOOL MEDICAL INSTITUTION.—At Liverpool Royal Southern Hospital, Dr. G. W. Bamber: demonstration of dermatological cases.
LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.—5.15 p.m., Newholme Lecture by Professor W. M. Frazer: State Medicine in the Nineteenth Century—State Hospital Policy.

LONDON UNIVERSITY.—At King's College, Strand, W.C., 5.15 p.m., Special University Lecture in Physiology by Professor C. J. Wiggers (Ohio, U.S.A.): Basic Studies on Ventricular Fibrillation and Defibrillation.
PHARMACEUTICAL SOCIETY: DARTFORD AND DISTRICT BRANCH.—At the Welcome Club, High Street, Dartford, 8 p.m., Dr. F. E. Camps: What Shall We Do with the Barbiturates?
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. A. C. Thackray: Pathological Conditions in the Salivary Glands.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Arnott Demonstration by Dr. D. R. Haynes: Relations of the Facial Nerve in the Temporal Bone.
ROYAL EYE HOSPITAL.—5.30 p.m., Mr. G. C. Pritchard: Visual Fields (1).
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Dr. E. A. Bennet: Lecture-demonstration in psychiatry.

Thursday, May 27
CAMBRIDGE MEDICAL SOCIETY.—8.30 p.m., B.M.A. Lecture by Dr. F. E. Camps: Disposal of the Body.
HONYMAN GILLESPIE LECTURE.—At University New Buildings, Edinburgh, 5 p.m., Dr. J. Ralston Paterson: Some Radio-sensitive Tumours.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. O. Oliver: Inflammation and Other Complications of Fractured Skull.
ROYAL SOCIETY.—4.30 p.m., Croonian Lecture by Sir Howard Florey, F.R.S.: Mucins and the Protection of the Body.
ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Dr. J. E. Caughey (Dundee, N.Z.): Some Aspects in the Treatment of Acute Poliomyelitis.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., psychiatry demonstration by Dr. D. Curran.
SENATE HOUSE.—5.30 p.m., Special University Lecture by Air Marshal Sir Harold Whittingham: Air Transport of Sick and Wounded.

Friday, May 28
BELMONT HOSPITAL, Sutton, Surrey.—3 p.m., Dr. M. N. Pai: demonstration of psychiatric treatment.
BIRMINGHAM MEDICAL INSTITUTE: SECTION OF PSYCHIATRY.—At St. George's Hospital, Stafford, 4 p.m., subject: Surgery in Psychiatric Disorders.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. P. J. Hare: Necrobiosis Lipoidica and Granuloma Annulare.
INSTITUTE OF LARYNGOLOGY AND OTOLARYNGOLOGY.—3.30 p.m., Mr. Wallace Black: Ulcers of the Mouth and Tharynx.
INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Queen Charlotte's Hospital, 2 p.m., Professor J. Louw (Capetown): Diabetes in Pregnancy.
LONDON UNIVERSITY.—At Physiology Lecture Theatre, University College, 5.30 p.m., special university lecture in psychology by Professor B. R. Flaher, Ph.D. (Wisconsin): Study of the "Projection" of Attitudes Towards Social Groups.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Professor G. A. G. Mitchell: Innervation of Blood Vessels, 4 p.m., Dr. I. C. Gilliland: Diabetic Control and Allied Disorders.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Sir William Gilliat: Minor Disturbances of Pregnancy.

Saturday, May 29
INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Chelsea Hospital for Women, 11 a.m., Professor J. Louw (Capetown): Enterococci.

APPOINTMENTS

ROGERS, W. J. BLACHFORD, M.B., B.Chir., M.R.C.P., D.P.M., Whole-time Consultant Child Psychiatrist, Crichton Royal, Dumfries.
SOMERVILLE, W. M.D., M.R.C.P., Consultant Assistant Physician to Department of Cardiology, Middlesex Hospital, London, W.
TAGGART, JAMES, M.C.A., M.B., B.Ch., D.P.H., D.P.A., Deputy Medical Officer of Health and Deputy Port Medical Officer, County Borough of Belfast.
WALTON, H. C. M., M.B., B.Ch., Lieutenant-Colonel, R.A.M.C., Consultant Pathologist, Glantawe H.M.C., Swansea, Glamorgan.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS
Bowker.—On March 19, 1954, in Lisbon, Portugal, to Margaret (formerly Lyon), M.R.C.S., L.R.C.P., wife of Dr. Colin M. Bowker, a brother for Elsie and Andrew-David.
Brown.—On May 7, 1954, at King's College Hospital, London, S.E., to Jean, wife of Dr. R. J. K. Brown, a daughter.
Frain-Bell.—On May 10, 1954, at Cardiff, to Dr. Catherine Frain-Bell (formerly Sharp), wife of Dr. W. Frain-Bell, a daughter.
Harrison.—On May 11, 1954, to Mary (formerly Marryat), wife of Kent Harrison, F.R.C.S., a son.
Maclure.—On April 15, 1954, at Bromhead Maternity Home, Lincoln, to Nancy (formerly Macfarlane), M.B., Ch.B., wife of Dr. W. Alastair Maclure, a son—Alexander Graeme.
Mathers.—On May 1, 1954, at Stroud, Gloucestershire, to Diana (formerly Mould), S.R.N., wife of Dr. G. C. Mathers, a sister for Richard—Gillian Diana.
Mulhern.—On April 30, 1954, at the Queen Elizabeth Hospital, Birmingham, to Ruth (formerly Heller), L.D.S., wife of Dr. P. H. Mulhern, a daughter.

MARRIAGES
Batty Shaw-Heckels.—On May 7, 1954, at Epsom, Anthony Batty Shaw, D.M., to Patricia Heckels.
Fletcher-Astill.—On April 22, 1954, at St. Andrews Church, Aylesstone, Leicester, Ronald Frank Fletcher, M.B., Ch.B., of Bromsgrove, Worcs., to June Margaret Astill, M.B., Ch.B., of Leicester.

DEATHS
Anderson.—On April 11, 1954, in an infirmary, James George Anderson, M.B., Ch.B., D.P.H., of "Kilrenny," Abbots Grange Road, Grange-mouth, Strirlingshire.
Apperly.—In February, 1954, Herbert Claude Apperly, M.R.C.S., L.R.C.P., L.D.S., of 37, Crossways, Sutton, Surrey, and 92, Harley Street, London, W., aged 59.
Costes.—On April 10, 1954, Thomas Seymour Costes, C.B., O.B.E., M.B., B.S., Major-General, A.M.S., late R.A.M.C., retired, of 1, Metropole Court, Folkestone, Kent, aged 74.
Donelan.—On April 10, 1954, at Sydn, Foxrock, Co. Dublin, John O'Connor Donelan, L.R.C.P.S.I. & L.M.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Liability of Diabetics to Peptic Ulceration

Q.—Is there any evidence that diabetics suffer from peptic ulceration less frequently than others?

A.—Clinical impression strongly suggests that peptic ulcer, particularly duodenal ulcer, is less common among diabetics than among the general population. Wilder¹ found an incidence of 2.3% among 2,584 diabetics during 1935-47, when the incidence of peptic ulcer in other patients at the Mayo Clinic was 3.5%. Joslin² found peptic ulcer only rarely among his diabetic population. Dibold³ was able to find only seven peptic ulcers in 800 diabetics, Landé⁴ 10 peptic ulcers in 2,000 diabetics, and Rothenberg and Teicher⁵ found an incidence of ulcer of 1.49% in 130,500 general admissions, while in 3,525 diabetic admissions only 0.25% suffered from ulcer. Portis and Jaffé⁶, in discussing the post-mortem findings in 339 peptic ulcer cases, mentioned that only one of the patients had diabetes.

It is interesting to note that Marple⁷ found that the incidence of achlorhydria was 32.8% in 399 diabetics. The usual incidence of achlorhydria in patients above 40 years is 10 to 15%. A proper comparison really needs to be made by age and sex groups. Muir⁸ found that raising the blood sugar depressed the gastric acidity response.

Industrial Dermatitis and Chloronaphthalene Wax

Q.—What treatment is advised for cases of industrial dermatitis? How may one due to a naphthalene-based wax (used in chromium plating) be prevented?

A.—Industrial dermatitis is not a clinical entity. The majority of cases diagnosed as industrial dermatitis are due to primary irritation from the various materials encountered, such as acids, alkalis, solvents, etc., and the basic principle of treatment is to protect the inflamed skin from further damage. For such conditions the use of a bland application such as calamine lotion in the early stages is important. It is very easy to produce exacerbations by the use of strong ointments. Usually the patient may remain at work provided adequate cover and protective clothing are available, but this decision should be based upon the severity of the eruption and the nature of the job. Infection of the lesions should be avoided by the use of sterile materials and a good dressing technique. The use of antibiotic creams (such as penicillin cream 500 units per gramme) is indicated in the presence of infection. The risks of sensitization to antibiotics, however, make it desirable for these drugs to be used under specialist guidance. In the later stages, when drying and fissuring tend to occur, oily applications are desirable. Suitable preparations are: zinc paste and olive oil in equal parts or calamine compound cream (B.P.C.). The questioner will find further information in the appropriate chapters of Schwartz, Tulipan, and Peck,¹ and in the paper by Squire, Cruickshank, and Topley.²

The naphthalene-based wax to which reference is made is probably a chlorinated compound, chloronaphthalene. This is sometimes used for "stopping-up" in the electroplating

process. "Stopping-up" refers to the covering of areas of metal with an insulating wax when it is desired to prevent deposition of chromium on these parts.

The chlorinated naphthalenes are very apt to produce comedones and acne. These comedones and acne-like lesions may be distinguished histologically from acne vulgaris. As under some circumstances systemic poisoning from these substances has been reported,¹ considerable care is required in their handling.

The use of chlorinated naphthalenes in the electroplating process is not widespread and many plants function efficiently using a non-irritating, paraffin-type wax. It would therefore be worth finding out whether the former substances are really necessary: to change the type of wax would solve the problem. Should this be impossible, special attention should be paid to the cleanliness of the plant and to the clothing of the people handling the wax. Clean overalls with long sleeves and gloves should be provided. These should be changed every day, and there should be double lockers for each worker. Adequate changing and washing facilities are necessary. Periodic inspection for lesions is essential. The ease with which these substances cause acne makes it important that all the means of preventive medicine should be employed.

Water Softener for a Sterilizer

Q.—I sterilize my glass and metal syringes by boiling them in a saucepan. The deposit from the hard water is spoiling them. Can you advise a suitable substance for softening the water?

A.—The water should be made slightly alkaline and a small quantity of sodium hexametaphosphate ("calgon") added. From 1 in 100,000 to 1 in 50,000 usually suffices, but more may be added if necessary, as the substance is harmless.

Is it a True 24-hour Specimen?

Q.—Does the estimation of the total creatinine content of a supposed 24-hour collection of urine provide a reasonable check on the completeness of the collection? Is the urinary output of creatinine influenced by diet or disease?

A.—The urinary excretion of creatinine in normal people is almost constant for the individual, being related to the body weight, and more particularly to the muscle content of the body, and is therefore regarded as a useful check on the accuracy of a 24-hour collection of urine.

It is not influenced by a change in the protein of the diet unless creatinine or creatine be included in such diet. In disease it is the creatine content of the urine that is generally increased, usually with a corresponding decrease in the creatinine. This will occur in all wasting diseases and starvation, and is particularly marked in the muscular dystrophies, where the creatine reaches its highest levels but the total creatinine + creatine remains relatively constant at least for some time.

Bone Regeneration after Mastoidectomy and Antrostomy

Q.—To what extent does bone regeneration occur in the temporal bone after a mastoidectomy, and in the lateral wall of the nose after an antrostomy? What are the factors which control regeneration?

A.—After a mastoidectomy a layer of new bone may form subperiosteally, closing over the cavity made in the substance of the mastoid process. After a cortical mastoidectomy this is concentric and has a central opening; where the posterior osseous wall has been removed the layer of bone forms eccentrically and leaves a dehiscence over the aditus and even the antrum. The bone does not intrude on the cavity. Bone reformation occurs mostly in children and adolescents, especially if there is residual or recurrent sepsis.

After antrostomy, a certain amount of new bone formation occurs around the edges of the opening made between the antrum and the inferior meatus of the nose, and if small fragments of bone are left adherent to the mucous membrane of either nose or antrum the new bone formation is more likely to occur. This is also more likely to occur in children and where there is persistent infection. The bone formation causes progressive narrowing of the opening until it may become completely closed, and the thin layer of bone separating the two cavities may be replaced by a thicker and tougher one. There is, however, no encroachment on the cavity of the nose or antrum.

Treatment of Recurrent Corneal Herpes

Q.—What symptomatic treatment is advised for long-standing recurrent corneal herpes? Antibiotics, autogenous vaccines, etc., have all failed to bring relief.

A.—As various previous treatments have failed to give relief, the best plan would be to avoid, in so far as they can be avoided, all things which tend to provoke an attack. Other useful palliative measures are anti-glare spectacles and saline drops. If the trouble persists in spite of such precautions then the question of x-ray treatment would be worth considering, but such treatment should be carried out only by a radiologist who has had special experience of eye conditions.

Scarlet Fever in a School

Q.—Throat swabs have been taken from apparently healthy children in a school where many of their classmates are at present down with scarlet fever. In quite a number haemolytic streptococci have been found. Should these carriers be treated, and should they be excluded from school until a negative swab is obtained?

A.—Children whose swabs produce profuse growths of streptococci, especially if they have also a nasopharyngeal discharge, should preferably be kept at home. If the culture plate reveals relatively few haemolytic streptococci (30% or less) in a mixed growth, such children, especially in the absence of any local lesion, may be regarded as relatively harmless.

The treatment of carriers is unsatisfactory. In military units in the U.S.A. where streptococci were rampant, success has been claimed in cutting down the number of cases of scarlet fever and associated conditions by giving 0.5 g. of sulphadiazine daily to all contacts while the outbreak lasted. But such schemes should be under strict medical control, and the possibility of creating a drug-resistant strain through prolonged and unchecked chemotherapy should be borne in mind. There are obvious objections to the use of penicillin, either locally or parenterally, for healthy carriers. Where, however, a heavy streptococcal growth is associated with a nasopharyngeal discharge, parenteral penicillin therapy is often successful.

"Any Questions?" Book.—The second book of selected "Any Questions?" is available, price 7s. 6d. (postage 6d.). Copies may be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

A COMPARISON OF CORTISONE AND ASPIRIN IN THE TREATMENT OF EARLY CASES OF RHEUMATOID ARTHRITIS

A REPORT BY THE JOINT COMMITTEE OF THE MEDICAL RESEARCH COUNCIL AND NUFFIELD FOUNDATION ON CLINICAL TRIALS OF CORTISONE, A.C.T.H., AND OTHER THERAPEUTIC MEASURES IN CHRONIC RHEUMATIC DISEASES

In 1951 the Medical Research Council and Nuffield Foundation Joint Committee on Clinical Trials of Cortisone, A.C.T.H., and Other Therapeutic Measures in Chronic Rheumatic Diseases decided that, for an effective assessment of the value of cortisone within its field of study, it was essential to carry out relatively small-scale but carefully controlled clinical trials. One of these trials, it was agreed, should deal with the important problem of the treatment of patients in the early stages of rheumatoid arthritis. The aim would be to measure the therapeutic effects of cortisone treatment upon the rheumatoid process while that process is still uncomplicated, either by severe anatomical changes in the joints or by metabolic or endocrine disturbances resulting from a prolonged and debilitating disease. In short, such a trial would have two objects: first, to compare the relative efficacy of cortisone and another drug usually regarded as efficacious in relieving symptoms and in improving the patient's functional capacity; and, secondly, to study the evolution of the rheumatoid process during prolonged therapy with these different agents. A scheme for this trial was drawn up by a subcommittee of the Joint Committee, and six centres in England and Scotland agreed to take part.*

Type of Patient

It was agreed that the patients to be included in the trial must (a) be within the ages of 2 to 59 years inclusive; (b) have a polyarthritis of rheumatoid type affecting at least four joints and bilateral involvement of either

*The members of the Joint Committee are: Sir Henry Cohen (chairman), Dr. E. G. L. Bywaters, Dr. W. S. C. Copeman, Sir Charles Dodds, Dr. J. J. R. Duthie, Professor A. Bradford Hill, Mr. H. Osmond-Clarke, Dr. F. T. G. Prunty, Dr. J. Reid, Dr. H. F. West, Professor J. H. Kellgren and Mr. W. A. Sanderson (joint secretaries).

The Subcommittee and participating centres were: Professor J. H. Kellgren (chairman), Rheumatism Research Centre, Manchester; Dr. E. G. L. Bywaters, Postgraduate Medical School of Chester; London and Canadian Red Cross Memorial Hospital, Taplow; Dr. W. S. C. Copeman, West London Hospital; Dr. J. J. R. Duthie, Northern General Hospital, Edinburgh; Dr. H. F. West, Sheffield Centre for the Investigation and Treatment of Rheumatic Diseases; Professor A. Bradford Hill; and Dr. F. T. G. Prunty.

The Subcommittee was assisted at these centres by the following workers, to whom it expresses its thanks: Dr. B. Ansell, Dr. C. K. Crawford, Dr. G. Fearnley, Dr. H. Lackner, Dr. I. Meanock, Dr. J. Redmill, Dr. O. A. Savage, Dr. J. Sharp, and Dr. M. Thompson.

The results of the trial were analysed by Dr. J. T. Boyd, of the Statistical Research Unit of the Medical Research Council, London School of Hygiene and Tropical Medicine, and the Subcommittee is greatly indebted to him for his work.

hands or feet, ankles, or wrists; and (c) have had the disease at their time of entry to the trial for not less than three months and not more than nine months. In deciding upon this duration it was required that the initial symptoms of the present illness, which had brought the patient to the centre, should be the first evidence of any rheumatoid disease in the patient—except that a previous episode of polyarthritis suggestive of rheumatoid disease would not exclude the patient from the trial provided that this episode had been of less than 12 months' duration, had left no residual signs, and had resolved completely at least one year before the onset of the present illness. A previous history of a painful incident of up to three weeks' duration would not be considered evidence of previous rheumatoid disease.

No other diagnostic criteria were considered necessary, but centres were asked to make every effort to exclude other diseases such as rheumatic fever, Reiter's disease, and neisserian infection. In addition the sheep-cell agglutination test first described by Rose *et al.* (1948) was performed in most of the patients, and usually on several occasions.

Allocation to Treatment

In a long-term trial of this nature it was obviously out of the question, on ethical grounds, to set up a control group on a dummy treatment. The contrast must lie between treatment by cortisone and another drug usually regarded as efficacious in the treatment of rheumatoid arthritis. The two modes of treatment adopted, and allocated at random, were therefore (1) cortisone and (2) aspirin, with both groups receiving the same basic regime of splints, physiotherapy, etc. No patient would, of course, be brought into the trial unless he or she could be regarded as a suitable case for treatment by either of these agents.

Because clinicians at the participating centres would have to select patients for admission to the trial it was necessary to ensure that they would not know whether each patient, in the event of being brought in, would be on cortisone or on aspirin. The procedure adopted was as follows. The clinician at the centre accepted a patient as suitable on the basis of the criteria laid down. Having done so he applied to a central office to know whether the treatment of that patient should be with cortisone or aspirin. At the central office a register had been constructed showing the order in which the

treatments were to be applied. It was held by one person. Such a random order of treatments was constructed separately for each of 48 small subgroups of patients—namely, according to whether they were (a) male or female, (b) aged 2–16 or 17–59 years, (c) had a duration of symptoms of three to five months or seven to nine months, and (d) were treated at one or other of the six centres. Within each of these small subgroups random sampling numbers were used to give approximately equal numbers of patients on cortisone and aspirin. In summation, therefore, the cortisone and aspirin groups would be very similar in these four characteristics—sex, age, duration of illness, and treatment centre.

In detail, the technique was that on admitting a patient a treatment centre would send particulars of the sex, age, and duration of illness to the holder of the register. The prepared list for a person of that sex, age, and duration would be consulted, the patient's name entered on the next available line, and the nature of the treatment already inscribed on that line would, with supplies of hormone or aspirin, be sent to the treatment centre.

Treatment

Each patient was admitted to hospital for a minimum period of four weeks, but subsequently could be treated and observed as an out-patient. It proved impossible to make up cortisone and aspirin suspensions to look alike. The aspirin was therefore given in brown tablets with a bitter flavour so that they would be unrecognizable by the patient as "merely aspirin." They were labelled "Tabs. Rheumatic C."* Cortisone acetate was given orally either in tablet form or as a suspension made up in syrup. It was labelled "Tabs. (or Mist.) Rheumatic A." Patients were asked not to take additional drugs or tablets. For the first year of treatment it was laid down that therapy would be given in twelve-weeks courses separated by one week off treatment. Each course would start with a standard dosage, after which the physician was free to adjust the dose to suit the requirements of individual patients. The specified courses for adult patients, given in divided doses not fewer than three times a day, were as follows:

		Cortisone	Aspirin
First week:	Day 1	300 mg.	6 g.
" "	" 2	200 "	6 "
" "	" 3 to day 7	100 " daily	6 " daily
Second week:	" 8	100 "	6 "
" "	" 9	50 "	2 "
Third to twelfth week:	" 15 " " 84	Individualized at 25 to 200 mg. daily with graded withdrawal in week 12	Individualized at 1 to 8 g. daily with graded withdrawal in week 12

In the "free" period—that is, the third to twelfth week—the physician was asked to employ the minimum dosage that would restore maximal functional efficiency without producing serious side-effects. In the thirteenth week no treatment by cortisone or aspirin was given, observations and measurements being made (in this week analgesics other than aspirin could, if necessary, be given). If symptoms recurred the twelve-weeks course was repeated, except that the selected dose for the individual patient replaced the standard dose of the second week.

Assessment of Patient

Clinical assessment of each patient (including measurement of the haemoglobin level and blood sedimentation rate) was required one week before and also immediately before the start of treatment. After therapy had begun, an assessment of some or all characteristics was called for at the end of the first, second, fourth, eighth, twelfth, and thirteenth weeks of the first course, and at the end of the

*The Committee is indebted to Mr. J. B. Lloyd, chief pharmacist at the Manchester Royal Infirmary, for the preparation of the tablets.

first, eighth, and thirteenth weeks of the second and subsequent courses.

The clinical assessment included (a) a defined judgment of the patient's general functional capacity (for the five grades laid down, see Table VII); (b) a judgment of the activity of the disease as inactive, slightly active, or very active; and (c) a statement whether the patient appeared to be in remission. In addition to these subjective assessments the clinician was required to measure the strength of grip for each hand. (The patient had to squeeze an oblong rubber bag 5 by 3 in. (12.5 by 7.5 cm.) inflated at a pressure of 10 mm. Hg, and the figure recorded was the average of three grips.) Two tests of dexterity were applied—namely, in patients with affected hands the time taken to tie six double knots with 12-in. (30-cm.) pieces of household string, and in patients with affected legs the time taken to go up and down ten steps. Estimates were also made of joint tenderness and of range of movement, and the number and site of any new joints involved were recorded as well as of previously affected joints which had recovered. Complications and side-effects were noted. The only obligatory laboratory tests were the blood sedimentation rate and the haemoglobin level.

The Analysis of the Data

In total, 62 adult patients (aged 17 to 59) and 14 children were admitted to the trial. The latter are too few to be informative, and the present report is confined to the adult group. One of these patients, allotted to the aspirin group, refused to co-operate, so that the numbers available are 30 on cortisone and 31 on aspirin. In 53 cases the results of a sheep-cell agglutination test are available. They are lacking for three patients on aspirin who were lost to the trial at an early stage (see below) and for five other patients who were followed up for the first year but never tested (three on aspirin and two on cortisone). The cases admitted at Edinburgh, Sheffield, and Manchester were tested by the method of Ball (1950), the test being regarded as positive if agglutination occurred in a titre of 1:4 or higher when read at one hour, or 1:32 or higher when read at 18 hours; a positive result was obtained on at least one occasion in 29 out of 40 patients (73%). The cases admitted at Ham-mersmith and West London were tested by the original method of Rose, in which the test is considered positive if the two titres recorded show a ratio of 1:16 or higher; in 9 out of 13 cases a positive result was obtained on at least one occasion (69%). In view of the close similarity of the results given by the two methods the data from the different centres may be added in comparing the two treatment groups. It is then found that 18 of the 28 patients on cortisone who were tested were positive at one time or another (64%), and 20 of the 25 patients on aspirin who were tested (80%). In other words, each treatment group had a high proportion of positive tests and there is no statistically significant difference between them.

Ball, whose method was principally used in this trial, has reported 50% of positive results in a large unselected series of out-patients diagnosed as suffering from rheumatoid arthritis; and in a carefully selected series of typical cases of varying duration admitted to the Manchester Royal Infirmary for special study 41 out of 61 (67%) gave a positive test (Ball, 1952). Scott (1952), using the Rose method, has reported positive results (a ratio of 1:16 or more) in 60% of an unselected series of 124 confirmed rheumatoid arthritis patients. The 38 positive results in 53 patients in the present trial (72%) compare very favourably with these various figures. They are good evidence of the accuracy of the diagnosis of rheumatoid arthritis in the patients admitted to the trial.

Details of the patients by centre, sex, age, and duration of symptoms are given in Table I. The data show how effective the method of allocation has been in equalizing the two treatment groups in these respects. Their initial equalities or inequalities in other characteristics will be seen

TABLE I.—Comparison of the Patients on Cortisone and Aspirin at Start of Treatment

Treatment Centre	No. of Patients on			Male		Female	
	Corti-sone	As-pirin		Corti-sone	As-pirin	Corti-sone	As-pirin

Total	30	31	Total	13	11	17	20

in each of the tables that follow, where these initial assessments are set alongside the subsequent observations.

It must be noted that during the first year of treatment and observation three patients, all on aspirin, were lost to sight. The reasons were as follows:

- (1) Male aged 48, West London Centre. After some preliminary improvement his condition deteriorated and he did not, after six months, feel that he was gaining any benefit from the tablets.
- (2) Female aged 53, Sheffield Centre. Relapsed on leaving hospital, had a psychological breakdown and declined to return (at week 12).
- (3) Female aged 60, Edinburgh Centre. Left the country for New Zealand (at week 30).

The first two must clearly be counted as failures of treatment and must be remembered in considering the results. The third patient was responding satisfactorily up to week 30, and subsequent information has confirmed that she continues to do well on aspirin. For the remaining 58 patients assessments were available towards the end of the first year. The centres, however, were not able invariably to fulfil the agreed schedule, and it was found that the number of patients off treatment in week 52, as required by it, was not sufficient to allow an effective analysis at that point (only about half had the off-treatment week at the end of the year). On the other hand, assessments were available for all 58 patients at some point close to the end of the year while they were still on their personal dosage. The week chosen for analysis, therefore, was, for each patient, that week of personal dosage which provided assessments and was nearest to week 52—with the proviso that it must lie at least four weeks before an off-treatment week—that is, before any "tapering off" of dosage would have begun. There were six patients (four on cortisone and two on aspirin) who at the end of the year had been off treatment for periods varying from 9 to 26 weeks. In these cases the personal dosage was taken to be nil and the week nearest to the end of the year was chosen for inclusion. The actual points taken lay between the 46th and 54th week in all but three cases (which were at the 42nd, 44th, and 45th week).

Results

(a) Joint Tenderness

The changes in joint tenderness are shown in Table II. In reaching the figures there set out an overall "tenderness" index was first computed separately for each patient by taking the average of his recorded joints. The mean of these averages gave, at each point of time, an index for the treatment group as a whole. It will be seen that the average position at the start of treatment is almost identical in both there is a significant and considerable reduction in pain in the first week of treatment, when the averages fall by 0.80 and 0.72 respectively. This fall continues, though

TABLE II.—The Average Changes Observed in the Joint Tenderness Index*

Joints Measured	Treatment Group	Average Joint Tenderness in Week 0	Average Changes in Joint Tenderness			Joint Tenderness at 1 Year	
			Week 0 to Week 1	Week 1 to Week 8	Week 8 to 1 Year	Average	As % of Average at Week 0
All relevant joints (including wrist and hand, given below)	Corti-sone	1.91	-0.80†	-0.29	-0.09	0.74	39
	Aspirin	1.89	-0.72	-0.21	-0.15	0.76	40
Wrist-joints	Corti-sone	1.80	-0.83	-0.10	+0.13	1.00	56
	Aspirin	1.93	-0.79	-0.21	+0.08	0.96	50
Small joints of hand	Corti-sone	2.25	-0.93	-0.50	-0.25	0.58	26
	Aspirin	2.05	-0.82	-0.24	-0.34	0.53	26

* Tenderness was graded on the scale 0 for no pain, 1 for slight pain, 2 for wincing, and 3 for wincing and withdrawal. The records have been used as an ordinary numerical scale.

† In this and subsequent tables, values in italics are statistically significant changes between specified times, and in the penultimate column between the beginning and end of the year ($P < 0.05$).

more slowly, up to week 8, and very slightly thereafter, between week 8 and the end of the year. As a result the final averages are still almost identical, though at a much lower level (0.74 cortisone and 0.76 aspirin); the percentage reduction over the year has been some 60% in each group.

In the second and third rows of Table II similar figures are given separately for the wrist-joints and the small joints of the hand. Though the changes are not statistically significant, it appears that with each of the treatments the average levels of pain tended to continue to decrease up to the end of the year in respect of the small joints of the hand, but to show some increases after week 8 in the wrist-joints. In both instances, however, the initial and final averages are closely similar for the cortisone- and aspirin-treated groups.

(b) Range of Movement and Strength of Grip

Table III gives the figures for range of movement in the wrists and strength of grip. In these respects the cortisone group reveals, by chance, some advantage before treatment was started—the average range of movement and average strength of grip were greater. (The difference in the average range of movement is statistically significant.) It is not possible, however, to detect any material difference between the two groups in their responses to treatment. There is, in each characteristic, a substantial improvement in the first week of treatment; week 1 to week 8 and

TABLE III.—The Average Changes in (a) Range of Wrist Movement and (b) Strength of Grip

Characteristic Measured	Treatment Group	Average Measurement in Week 0	Average Changes in Measurement			Measurement at 1 Year	
			Week 0 to Week 1	Week 1 to Week 8	Week 8 to 1 Year	Average	As % of Average at Week 0
Range of wrist movement (in degrees)	Corti-sone	99*	+13.9	+4.6	+1.1	120*	121
	Aspirin	78	+23.2	-1.8	+2.3	103	132
Strength of grip (in mm. Hg) left hand	Corti-sone	138	+33.3	+17.8	+12.2	202*	146
	Aspirin	111	+35.3	+8.5	+0.4	164	148
Strength of grip (in mm. Hg) right hand	Corti-sone	134	+46.7	+2.5	+3.7	187	140
	Aspirin	116	+34.5	+15.1	-7.1	166	143

* The mean of the cortisone group was significantly greater than the mean of the aspirin group.

week 8 to 1 year reveal, on the whole, some further increases, but the changes are much smaller and very variable. At the end of the year the average for the cortisone group, compared with the aspirin group, is significantly greater for the range of movement in the wrists but by no more than it was initially. In respect of strength of grip the averages for the cortisone group at the end of the year are also above those for the aspirin group, but once again by no more than they were initially. In other words, the mean percentage changes have been remarkably similar—an increase of 20-30% in range of wrist movement and of 40-50% in strength of grip.

(e) Tests of Dexterity

Table IV gives the results of the timing tests. The average starting-points of the two groups are reasonably alike, and the progression under treatment and the end-results are again very similar. Each treatment group shows an average improvement of some 20-25%.

TABLE IV.—The Average Changes in Time Taken to (a) Tie Six Knots and (b) Go Up and Down Ten Steps, by Patients With Affected Hands and Legs Respectively

Characteristic Measured	Treatment Group	Average Measurement in Week 0	Average Changes in Measurement			Measurement at 1 Year	
			Week 0 to Week 1	Week 1 to Week 8	Week 8 to 1 Year	Average	% Change
Time (in seconds) to tie 6 knots	Cortisone	38	-4.2	-0.2	-4.2	29	76
	Aspirin	41	-3.0	-3.9	-0.8	34	83
Time (in seconds) to go up and down 10 steps	Cortisone	14	-1.3	-2.6	+0.6	11	79
	Aspirin	18	-4.5	+0.8	-0.2	13	72

(d) Haemoglobin Level and Blood Sedimentation Rate

The changes in the level of haemoglobin and in the blood sedimentation rate are shown in Table V. In both these respects there is apparent some difference between the cortisone- and aspirin-treated groups. In haemoglobin level they start alike with mean values of 12.2 and 12.1 g.%. Under treatment the patients on cortisone show, on the average, an improvement, and at the end of the year the mean has reached 13.1 g.%. The corresponding changes under aspirin are erratic and statistically insignificant, with the final average of 11.3 g.%, rather below the initial level and significantly below the average for the cortisone group.

TABLE V.—The Average Changes in (a) Haemoglobin and (b) Blood Sedimentation Rate

Characteristic Measured	Treatment Group	Average Measurement in Week 0	Average Changes in Measurement			Measurement at 1 Year	
			Week 0 to Week 1	Week 1 to Week 8	Week 8 to 1 Year	Average	% Change
Haemoglobin (in g.%)	Cortisone	12.2	+0.2*	+0.6	+0.1*	13.1*	107
	Aspirin	12.1	-0.4	+0.4	+0.8	11.3	93
E.S.R. (mm./hr.)	Cortisone	42	-18.1*	-4.4	+5.5	27	64
	Aspirin	42	-1.4	+0.4	-6.1	35	83

* The averages shown by the cortisone and aspirin groups differ significantly.

The mean blood sedimentation rate at the start of treatment was identical—42 mm./hour in each group. In the first week of treatment there was a pronounced fall in the cortisone group and an insignificant fall in the aspirin group. Subsequent mean changes were slight, and at the

end of the year of observation the final averages of 27 mm./hour for patients on cortisone and 35 mm./hour for patients on aspirin do not differ appreciably, though still slightly favouring the former group. On the other hand, in each treatment group five patients had a value of 10 mm./hour or below at the end of the year.

(e) Clinical Assessments

At the end of the year two patients on cortisone and three on aspirin were reported to be in remission (though two of those on aspirin were still on maintenance doses of 4 g. and 1.7 g. respectively). There were a further

TABLE VI.—Clinical Assessments of Activity at One Year

Grade	Cortisone No.	Aspirin No.
Inactive	2	2
Slightly active	21	19
Very	7	7
Total	30	28

two patients on cortisone and a further one on aspirin who had not been on treatment for 10, 40, and 20 weeks respectively. Thus four patients in each group were regarded as either in remission or as not requiring treatment at that time. The overall assessments of condition and progress at the end of the first year are shown in Table VI, and reveal little difference between the two groups. If the two aspirin patients who progressed unfavourably and were lost to view are included as "very active" the picture would not be materially altered.

The assessments of functional capacity are given in Table VII, and once again the two treatment groups are more remarkable for their similarity than for their dissimilarity. At the start of treatment the majority of

TABLE VII.—Number of Patients with Given Functional Capacity at Different Points of Treatment*

Treatment Group	Time of Assessment	Functional Capacity			Total
		1 or 2	3	4 or 5	
Cortisone	Week 0	4	18	8	30
Aspirin	Week 0	5	18	6	29
Cortisone	" 8	18	11	1	30
Aspirin	" 8	15	11	3	29
Cortisone	" 13	10	16	4	30
Aspirin	" 13	10	13	5	28
Cortisone	1 year	23	5	2	30
Aspirin	1 year	21	5	0	26

* Functional capacity grades were:
Grade 1: Fully employed or employable in usual work and able to undertake normal physical recreation.
" 2: Doing light or part-time work and only limited physical recreation. For housewives, all except the heaviest housework.
" 3: Not employed and unemployable. No physical recreations. Housewives, only light housework and limited shopping.
" 4: Confined to house or wheel-chair, but able to look after themselves in essentials of life. Hospital patients confined to bed.
" 5: Completely bedridden.
† No record was made in this respect for two patients, and, as stated previously, three were subsequently lost to view.

patients were placed in grade 3—not employed and unemployable, no physical recreations. By the eighth week many had been moved to the higher grades—full or light work, etc. In the week off treatment, the thirteenth, a number returned to the lower grades, but by the close of the year about four-fifths of the patients were capable of either full (grade 1) or light work (grade 2). Division of these patients into grades 1 and 2 separately gives 13 and 10 patients on cortisone and 11 and 10 on aspirin, or approximately 40%, with full functional capacity in each treatment group. Only two patients, both on cortisone, were bedridden at the end of the year. The two missing aspirin cases may be set against these—that is, putting the most unfavourable complexion upon them.

(f) Side-effects

Side-effects were recorded for 19 patients in the cortisone group and 21 patients in the aspirin group. Most of these patients had more than one complication, the most frequent in the cortisone group being moon-face or rubicundity (11 patients), depression (5 patients), and euphoria (4 patients), and in the aspirin group tinnitus (11 patients), deafness (10 patients), nausea, dyspepsia, or anorexia (13 patients). There were no severe complications in the cortisone group necessitating discontinuance of treatment despite a final personal dosage at the end of the year of between 100 and 125 mg. a day in 11 of the 26 patients.

The numbers of patients showing side-effects in each consecutive three months of this first year's treatment were 14, 15, 11, and 12 in patients on cortisone, and 16, 10, 6, and 6 in patients on aspirin. In other words, the numbers with these minor complications were equal in the early months of treatment, but became less in the aspirin group as time passed.

Discussion

This trial, as emphasized in the early paragraphs of the report, was designed to answer a specific but very important question—namely, in early and uncomplicated cases of rheumatoid arthritis is it possible to maintain the patient's well-being more efficiently by treatment with cortisone than by treatment with aspirin? Simultaneously, if the trial can be continued into a second or third year, as is envisaged, light may be thrown upon the evolution of the rheumatoid process during prolonged therapy with these different agents. While scientifically it would obviously be of much value to be able to compare the changes in both these treated groups with those taking place in a group receiving neither cortisone nor aspirin, ethically such a course is impossible. One or other agent, it was held, must be administered—together with any other basic treatment that might be required (splints, physiotherapy, etc.).

It was, however, decided that treatment should be tapered off at the end of each three-months period and then withheld for one week to allow of assessment of the patient's condition. Analysis of the data thus provided at the end of the first course—that is, at the thirteenth week—revealed a distinct "relapse" in some of the patients, though an equal degree of "relapse" occurred on the two forms of treatment. For example, the average joint tenderness at the start of treatment was 1.91 in the cortisone group and 1.89 in the aspirin group (see Table II). By week 8 the average had declined by 1.09 in the cortisone group and by 0.93 in the aspirin group. In the week off treatment it increased again by 0.49 and 0.31 respectively, giving average levels in the thirteenth week of 1.32 on cortisone and 1.29 on aspirin.

Very similar reversals were seen in all the other characteristics measured or observed. In Table VII they have already been shown for the functional capacity. It is, however, apparent that the two treatment groups have, on the whole, kept remarkably in step. They closely parallel one another in their immediate and favourable reaction to the first week of treatment; in the continuation of that reaction, but at a much slower rate, up to the observations made at week 8; in their unfavourable response to the cessation of treatment in week 13; and, finally, in their position at the end of the first year of the trial.

The haemoglobin levels and blood sedimentation rates have responded rather more favourably to cortisone than to aspirin. In all other respects there has been little to choose between the two agents. On each form of treatment joint tenderness is substantially reduced, on each form the disease is judged at the end of one year to be inactive, or only slightly active, in three-quarters of the patients, on each form two-fifths of the patients were regarded at the end of one year as capable of normal work and activity. As usual with cortisone treatment, certain more intangible differences have been observed. Some patients appear to experience a

sense of well-being, and sometimes an almost excessive and inappropriate cheerfulness during therapy, followed by a swing to a mood of depression during the periods off treatment. On the other hand, the patients receiving aspirin tend to have changes in mood which are more in keeping with the increase and decrease in their symptoms. For practical purposes, however, there seems to have been surprisingly little to choose between cortisone and aspirin as adjuvants in the management of these 61 early cases of rheumatoid arthritis. The maintenance doses that were being employed at the end of the first year to produce these results are shown in Table VIII.

TABLE VIII.—Daily Maintenance Doses being Administered at the End of the First Year (Before any Tapering-off)

Cortisone (mg./day)	No. of Patients on Given Dose	Aspirin (g./day)	No. of Patients on Given Dose
125	2	6	8
100*	9	5	2
75†	7	4	13
62½	2	3	1
50	4	2	1
37½	1	1.7	1
25	1		
Total	26	Total	26
Nil (off treatment)	4	Nil (off treatment)	2
Mean value for those on treatment	80 mg.	Mean value for those on treatment	4.5 g.

* Including 1 at 105 mg. † Including 1 at 80 mg.

In the second year of the trial it is intended that treatment shall be continuous—unless the patient is in remission or is held to require no maintenance dose.

Summary

Sixty-one patients in the early stages of rheumatoid arthritis, and regarded as suitable for treatment with either cortisone or aspirin, have been allocated at random to treatment with one or other agent (cortisone 30 cases, aspirin 31 cases). Two comparable groups of these early cases were thus constructed and have now been treated and observed for one year. For most of the year treatment was "individualized" by the physician in charge of the patient at a level sufficient to restore maximal functional efficiency without producing serious side-effects.

Observations made one week, eight weeks, thirteen weeks, and approximately one year after the start of treatment reveal that the two groups have run a closely parallel course in nearly all the recorded characteristics—namely, joint tenderness, range of movement in the wrist, strength of grip, tests of dexterity of hand and foot, and clinical judgments of the activity of the disease and of the patient's functional capacity. The haemoglobin level and blood sedimentation rate were slightly more favourably influenced by cortisone, but in no other respect do the two groups differ materially.

On each form of treatment the disease was judged at the end of one year to be inactive, or only slightly active, in about three-quarters of the patients, and on each treatment some two-fifths of the patients were regarded as capable of normal work and activity. For practical purposes, therefore, there appears to have been surprisingly little to choose between cortisone and aspirin in the management of these 61 patients in the early stages of rheumatoid arthritis.

THE ARTIFICIAL MENOPAUSE

WITH PARTICULAR REFERENCE TO THE
OCCURRENCE OF SPINAL POROSIS

BY

IAN A. DONALDSON, F.R.C.S., M.R.C.O.G.

First Assistant in Gynaecology and Obstetrics, St. George's
Hospital, London

AND

J. R. NASSIM, F.R.C.P.

Physician, St. George's Hospital and the Royal National
Orthopaedic Hospital

Many states of ill-health have been attributed to the menopause, and it has been suggested that these manifest themselves more severely if the menopause is produced artificially. In addition to the disorders already recognized there has been added in recent years the occurrence of osteoporosis affecting mainly the spine and pelvis. Thus Albright and Reifenstein (1948) state that "a moderate degree of osteoporosis of the spine is almost physiological after the menopause: its degree increases as the time during which the post-menopausal state has existed increased." This statement implies that one should expect to encounter a larger number of cases of spinal porosis, possibly at an earlier age, in women who have been subjected to an artificial menopause.

It was with the idea of investigating this problem that the present inquiry was instituted, and an opportunity was taken to study other manifestations attributed to the menopause.

In discussing post-menopausal osteoporosis we are adhering to the definition of Albright and his associates presented in a series of recent publications. The term implies a condition in which there is no abnormality in either calcium or phosphorus metabolism, but in which there is a depression of osteoblastic activity, presumably due to hormone imbalance brought about by oestrogen lack; and the serum calcium, phosphorus, and alkaline phosphates are within normal limits, though there is a tendency for the serum phosphate to be slightly higher (Reifenstein, Kinsell, and Albright 1946).

Post-menopausal Osteoporosis: Clinical Investigation

Two groups of patients formed the basis of this investigation. The first group consisted of 94 women who had been subjected to an artificial menopause either by surgery or by radium at St. George's Hospital at least eighteen months prior to this study. For comparison a second group was studied; this consisted of 28 women who attended hospital because of backache and were found to have spinal porosis. All but two of these patients were seen at the Royal National Orthopaedic Hospital. Both groups were interviewed and clinically examined by one of us (J.R.N.). Particular attention was given to the following points: (1) radiological evidence of osteoporosis, (2) estimation of serum phosphate, (3) dietary history, (4) blood pressure, (5) changes in weight, (6) the incidence of hot flushes, and (7) changes in libido.

Radiological Evidence.—The radiological evidence of the early stages of osteoporosis of the spine is difficult of interpretation, and we were fortunate in having all the films assessed by the same radiologist. For convenience the abnormalities found have been divided into three grades: (1) A marked stencilling of the vertebral bodies with coarsening of bone trabeculation. (2) The above, together with swelling of the intervertebral disks, giving rise to biconcavity and the so-called codfish vertebrae. (3) The above with, in addition, crush fractures.

Group 1

In the first group of patients follow-up inquiries were sent to 150, but 56 could not be traced. Of the 94 patients who were interviewed and examined, 82 had had surgical removal of both ovaries and 12 had had the menopause induced by radium. The interval between operation and interview ranged from 18 months to 13 years. The age of the patients at the time of operation varied from 26 to 73 years, but the majority were in the fifth decade (56 patients) and the sixth decade (28 patients). Nineteen were spinsters, and of the remaining 75 who had been married 9 had never been pregnant.

Three of the 82 patients who had had surgical removal of the ovaries failed to have a radiological examination of the spine. Ten (12.6%) of the remaining 79 showed radiological evidence of osteoporosis. Only one of them complained of backache. Details of these 10 cases are:

Age at examination	49	51	55	56	58	59	61	69	69	76
Age at operation	43	48	42	50	55	56	58	67	65	73
Interval in years	6	3	13	6	3	3	3	2	4	3

Only 2 of the 12 patients who had been subjected to a radium menopause showed evidence of osteoporosis. They were aged 59 and 62 at the time of the examination, and 46 and 49 at operation, giving an interval of 13 years in both cases.

Thus of the 94 patients, 12 (12.7%) showed some radiological evidence of osteoporosis, and 3 of them were over 65 at the time of examination. Not one of these 12 patients showed a porosis which was of a greater severity than grade I, which can most certainly be regarded as physiological in the three patients over 65, and open to argument with regard to the remainder.

The average level of serum phosphate for the group which had undergone surgical menopause was 2.6 mg. per 100 ml. and for the 12 patients subjected to radium menopause it was 3 mg. per 100 ml. of serum.

All these patients were asked about their dietary habits, and no information was obtained indicating any marked deviation from normal.

In this series of patients the incidence of osteoporosis can be regarded as within the physiological range, and no significant abnormality in serum phosphate was observed.

Group 2

The second group, comprising 28 patients, all came to hospital with a specific complaint of pain in the back. Details are shown in Table I. The average age at examination

N. = Natural. A. = Artificial. C. = Number of children. Mla. = Number of miscarriages.

tion and investigation of these patients was 61.6 years. Their individual ages ranged from 43 to 73. Nine patients were over 65, and 15 had had no pregnancies. Of these 28, 9 had been subjected to some form of pelvic surgery, with removal of either one or both ovaries. An accurate history of the surgical procedure was impossible to obtain in all cases.

Eighteen of these patients had grade 3 porosis and 10 had grade 2.

Of the 27 patients for whom serum phosphate figures were available the average was 3.6 mg. per 100 ml. This finding of an increase in the serum phosphate level is in agreement with the observations of Albright, Smith, and Richardson (1941).

The age of these women at the time of the menopause, whether artificial or natural, ranged from 23 to 53. The ages at the time of operation could be ascertained, but it must be understood that, particularly among the older women, the exact date of the menopause was difficult to obtain, but was probably accurate to within a year or two. The onset of symptoms after the menopause, whether artificial or natural, varied from 2 to 42 years. The average time of onset of symptoms in the 9 patients on whom an operation had been performed was 21.6 years from the time of operation. In the 19 patients on whom no operation was performed the average time of onset of symptoms from the date of their menopause was 15.2 years. We feel that this disparity is due to the small number of cases in this series.

Comment.—Albright, Smith, and Richardson (1941) gave clinical data about 42 patients with spinal osteoporosis, 40 women and 2 men. Because of the possibility of senescence being a factor no patient over the age of 65 was included. Of the 40 women in their series, 10 had been subjected to an artificial menopause. The average time of onset of symptoms in these 10 patients following the operation was 13.4 years, whilst in the remaining 27 (three women were excluded because of complicating thyrotoxicosis) the average time was 9½ years. The difference between these values was not regarded as being statistically significant.

Observations on Blood Pressure

A blood-pressure reading of over 150/90 was regarded as abnormal. In the first group of 94 patients 28 had a raised blood pressure; of these, 7 had a high blood pressure recorded prior to operation, and 20 (including 5 of the 7) gave a family history of severe cardiovascular disease in one or other parent. Thus 6 (6.3%) of the 94 patients had an unexplained rise of blood pressure, and the average age was 55.3 years.

Changes in Body Weight

In the first group of 94 patients, 54 stated that they had gained over 14 lb. (6.4 kg.) since the operation, 20 noted no change in weight, and 5 had lost weight. This confirms the impression that, following an artificial menopause, a gain in weight is to be expected, though it does not invariably occur. In 26.5% of patients the weight remained unchanged or decreased. Bland-Sutton and Giles (1926) were of the opinion that complete removal of both ovaries "may cause obesity in a woman who has a tendency to form fat." There was a correlation between marked increase in weight and severe hot flushes, and vice versa, in 70% of patients. Whether there is any significance in this observation is uncertain.

Incidence and Duration of Hot Flushes

These were studied in the first group of patients. In Table II this series is analysed according to age groups and method of induction of the menopause; the results of other observers are included for comparison. Approximately 75% of patients complained of hot flushes after removal of both ovaries; this agrees with the investigations of other

workers. The duration varied between 4 and 24 months. The younger the women were at the time of the menopause the greater was the increase in percentage. In the younger age groups the flushes were more severe, but the total duration tended to be shorter. It has been suggested that the flushes are worse after a radium-induced menopause; this contention is not supported by this small series, in which 66.6% developed this symptom. McLaren (1950) stated that 50% developed hot flushes. The incidence of hot flushes occurring in association with the natural menopause is obtained from two investigations into a larger series of women.

The Council of the Medical Women's Federation (1933) found that 62.3% of 1,000 women complained of hot flushes. The duration varied from 2 years up to 20 years. McDowell and Paterson (1940) found that 75% of 111 women between 40 and 45 complained of hot flushes.

It is interesting to note that about 20 to 25% of women do not complain of hot flushes after the artificial menopause. The reason for this, like the cause of the hot flush, has yet to be elucidated.

Changes in Libido

Alteration in libido following removal of the ovaries has long been studied. Battey (1876), writing about the "extirpation of the functionally active ovaries for the remedy of otherwise incurable diseases," was of the opinion that the aphrodisiac propensity was not annulled after the removal of the ovaries. Goodell (1879) was of the opinion that removal of the ovaries does not unsex a woman, and he quoted Koerberlé to the same effect.

Interrogation of the married patients in the first group showed that libido was decreased in 65%. These findings are further analysed in Table III with those of other workers for comparison.

A varying percentage of patients have decreased libido following removal of the ovaries; this is to be expected when the host of factors which influence libido are considered. Lewis and Jackson (1940) found that assessment was difficult because so many were frigid before operation.

The percentage tends to be higher in the younger age groups, though Filler and Drezner (1944), who studied 36 negroes in their series of 41 cases, did not confirm this, and

TABLE III.—Change in Libido Following Artificial Menopause

Huffman (1950)	26-40	68	10.2	89.7	—
Richards (1951)	Under 45	33	60	—	6

Huffman (1950), by careful supervision, reported only a small percentage with decreased libido.

In all series there is a significant percentage in which the libido is unchanged after artificial menopause; this stresses the fact that the ovary is not essential for sexual libido and demonstrates the importance of complex factors, including upbringing, education, and marital relationships. Bland-Sutton and Giles (1926) stated that "facts are accumulating which tend to show that the ovaries are not the seat of the sexual passion... the complete removal of both ovaries is followed in adult women by sterility and persistent amenorrhoea, and these are the only two constant effects attributed to it."

Novak (1948) stated: "In the human being the ovary has very little to do with libido, the sex sense... in the human female; the seat of libido is in the psyche with certain auxiliary erogenous zones such as the vagina, the clitoris, and the mammary gland. The ovaries in themselves are not essential at all to sex gratification."

These points have been further studied in pre- and post-operative discussions with patients not included in this series. Reassurance and correction of preconceived and erroneous beliefs has permitted return of libido, and it has been established beyond question that a full orgasm can subsequently be obtained. Adequate briefing should be considered as essential in the management of such patients.

Conclusions

There was no evidence that osteoporosis of significant degree was precipitated by an artificial menopause, or that, in patients with established osteoporosis, it occurred at an earlier age following an artificial menopause.

The occurrence of post-menopausal osteoporosis is unpredictable; the time of its onset or severity cannot be related to the age at which the menopause—natural or artificial—occurs, or to the number or frequency of pregnancies. The tendency for the serum phosphate level to be raised in patients with fully developed porosis is confirmed.

There was no evidence that hypertension was attributable to the artificial menopause. The hereditary factor was clearly demonstrated by the high proportion of those hypertensive patients who gave a family history of severe cardiovascular conditions in one or other parent.

An increase in weight occurs in most patients, but there was no increase or even a decrease in weight in 26.5%.

Hot flushes occurred in approximately 75% of patients. The duration varied between 4 and 24 months. The incidence is higher and the duration tends to be shorter in the younger age groups. There was no significant difference between patients who had had a surgical menopause and those with a radium menopause. The incidence and duration are similar to those following the natural menopause in comparable age groups.

After an artificial menopause libido was decreased in approximately 65% of patients. The fact that the ovary is not essential for the maintenance of the libido is shown by the percentage of patients who were unaffected.

This investigation emphasizes that the only two constant effects of removal of the ovaries are amenorrhoea and sterility.

Summary

The occurrence of post-menopausal osteoporosis is discussed. The incidence of osteoporosis in 94 patients following artificial menopause is analysed. A group of 28 patients with definite osteoporosis is investigated in relation to the lapse of time after a natural or artificial menopause.

The serum phosphate levels in both groups of patients are given.

The incidence of unexplained raised blood pressure after an artificial menopause is recorded and discussed. The change in weight following artificial menopause is recorded.

The incidence and duration of hot flushes in 94 patients who had an artificial menopause are detailed.

The change in libido in patients after induced menopause is discussed.

We are grateful to the gynaecological staff at St. George's Hospital for allowing us to use their material and to Dr. E. H. Allen for his kindness in assessing the radiological evidence.

Turning down the \$10,300,000 recommended by its committee on programme and budget, the Seventh World Health Assembly adopted a regular budget of \$9,500,000 for 1955, an increase of \$1,000,000 over last year's. This decision was taken by a vote of 28 to 24, with 7 abstentions. The United States proposal for an even smaller budget of \$8,607,000 was rejected by 35 votes to 21, with 6 abstentions. The Indian proposal for a budget of \$9,900,000 did not come to a vote, and the ceiling of \$9,500,000 adopted by the Health Assembly came from a proposal of the United Kingdom. By unanimous vote the Federation of Rhodesia and Nyasaland, established eight months ago, was admitted to Associate Membership in the World Health Organization. Other W.H.O. Associate Members are Tunisia and Morocco. The Assembly has also recommended that the next Assembly consider methods of assessing only active members for the regular effective budget, and invited those States which have not been actively participating in the work of the organization to resume participation at the earliest date.

VARICOCELE IN GROUPS OF FERTILE AND SUBFERTILE MALES*

BY

J. K. RUSSELL, M.B., M.R.C.O.G.

Lecturer, Department of Obstetrics and Gynaecology, University of Durham

In the course of a study entailing physical examination and semen analyses in groups of fertile and subfertile men I have noted a higher incidence of varicocele in men with poor quality semen. Varicocele is a relatively common condition mainly affecting young men (Skinner, 1941; Turner, 1943; Boyd, 1947; Aird, 1949), and Bailey and Love (1941) quote an incidence of 5 to 10% in men between the ages of puberty and 35. Marriage and the passage of years usually bring about a diminution in the size of the varicocele (Skinner, 1941; Turner, 1943; Aird, 1949), so that the incidence is likely to decrease as age increases.

In this country the traditional attitude adopted by surgeons to varicocele is given by Professor Charles Wells (1948): "In civilian practice very little importance is attached to this condition. On the assumption that the condition is little more than an exaggeration of the normal with an added neurosis, reassurance and local support with a suspensory bandage may safely be advocated as the treatment in most cases."

Wells (1953, personal communication) has emphasized the very real danger of damage to the testis caused by active surgical treatment. Douglas (1921) and Campbell (1928) have also drawn attention to the inadvisability of operative treatment. Douglas followed up 106 cases of varicocele treated by operation and found that 41 of the men had hydrocele and 4 had atrophy of the testis. Haemorrhage, hydrocele, infection, epididymitis, and loss of a functioning testis by atrophy are possible complications of operative treatment (Douglas, 1921).

The investigation reported in this paper was begun in the Gynaecological Department of the Aberdeen Royal Infirmary in 1947 and continued in the Department of Obstetrics and Gynaecology in the University of Durham. The diagnosis of varicocele is a matter of opinion, but in this investigation there was one observer, and the criteria for diagnosis remained constant. Only in those cases in which there was palpable and visible enlargement of the pampiniform plexus was a diagnosis of varicocele made.

Clinical Material

The incidence of varicocele in the following groups is reported.

Group I.—This comprised 52 men of high fertility. All had had five or more children and their semen was of excellent quality. The spermatozoon counts ranged from 64,000,000 to 250,000,000 per ml. In each case the man's wife had been delivered recently either in the Aberdeen Maternity Hospital or in the Princess Mary Maternity Hospital, Newcastle-upon-Tyne.

Group II.—This consisted of 48 men who had had two, three, or four children. Their spermatozoon counts ranged from 37,000,000 to 250,000,000 per ml. Their wives had been delivered recently either in the Aberdeen Maternity Hospital or in the Princess Mary Maternity Hospital.

*Based on a paper delivered to the Society for the Study of Fertility, Liverpool, June, 1953.

Group III.—This comprised 144 men examined at subfertility clinics in Aberdeen or Newcastle-upon-Tyne. Their wives had had no children, but these men were found to have good quality semen. In each case the count was above 75,000,000 per ml.

Group IV.—This consisted of 119 men examined at subfertility clinics in Aberdeen or Newcastle-upon-Tyne. Their wives had had no children, and in each case the spermatozoon count was below 50,000,000 per ml.

For the purpose of this paper spermatozoon density has been used as the criterion of semen quality. It is generally agreed that as the spermatozoon count per ml. falls other defects in semen quality increase (Hammen, 1944; MacLeod and Hotchkiss, 1946; Simmons, 1947; Tyler, 1951).

A standard method of collecting semen specimens was employed throughout the study. In each case a period of abstinence of at least four days was stipulated, and ejaculation took place into a clean glass jar. The specimens were analysed within three hours of production. One sample was examined from each of the fertile men in Groups I and II and from the 144 men attending the subfertility clinics who were found to have spermatozoon counts above 75,000,000 per ml.

Most of the men in Group IV had at least two analyses made, and in some of them had repeated analyses over periods of several months. The average figure has been calculated for each man in this group.

Percentage of patients in the groups studied. The actual number of patients in the various groups is given in parentheses and the shaded areas at the bottom of certain columns, with figures alongside, show the actual number of cases of varicocele and how they were distributed throughout the groups.

Results

Fertile Men

Group I.—No case of varicocele was discovered in these highly fertile men.

Group II.—There were two cases of varicocele in this group. The first was in a man aged 27 who had been

married three years and had had two children. No abnormality was detected in the testes, and the spermatozoon count was 129,000,000 per ml. The other case was that of a man aged 29 who had been married four years and had had two children. The testes appeared normal and the spermatozoon count was 68,000,000 per ml.

Men Examined at Subfertility Clinics

Group III.—Among these men with good quality semen two were found to have varicocele (1.4%). One was a man aged 32 who had been married two and a half years and whose wife had failed to conceive. The testes were normal in size and consistence, and the spermatozoon count was 78,000,000 per ml. The other was a man aged 27 who had been married three years and whose wife had failed to conceive. The testes were normal in size and consistence, and the spermatozoon count was 94,000,000 per ml.

Group IV.—Among these 119 men with poor quality semen 11 were found to have varicocele (9.2%). Details are given in the Table.

11 Cases of Varicocele Among 119 Men with Poor Quality Semen

Case	Age	Occupation	No. of Years Married	Site of Varicocele	Testes	Average Spermatozoon Count per ml.

Discussion

Hotchkiss (1945), a leading authority on male fertility, points out that there is no agreement on the exact relationship which varicocele bears to infertility.

A number of authors record the finding of cases of varicocele among men examined at subfertility clinics, but details of age, duration of marriage, etc., are not given. Hammen (1944), for example, reports the finding of varicocele, in varying degrees, in 11.9% of 291 patients referred to his subfertility clinic in the Kommune Hospital, Copenhagen—not all of these 291 patients were subfertile. He found that 92% of the patients with varicocele had spermatozoon counts below 60,000,000 per ml. Tyler (1951) found a "significant" degree of varicocele in 6 out of 82 men with spermatozoon counts between 20,000,000 and 59,000,000 per ml.—an incidence of 7.3%; among 53 men with counts above 60,000,000 per ml. the incidence was 3.8%. Jeffcoate (1946) found the condition present in nine men whose wives had been referred to him on account of childlessness. Seven of these men had poor quality semen.

On the other hand, Michelson and Michelson (1947) examined 519 men with poor quality semen and discussed the aetiological factors which were found, but the occurrence of varicocele in these men is not mentioned.

A number of interesting features are shown in the results of the present study. In men with poor quality semen (Group IV) the incidence of varicocele was found to be 9.2%, as compared with 2% among fertile men (Groups I and II) and 1.4% among men who, although their wives had failed to conceive, were found to have good quality semen (Group III).

It was stated above that the condition tends to affect young men, and it was therefore important to analyse the groups by age—the results are shown in the Chart. The highly fertile men in Group I were on the average a few

years older than the men in the other groups—73% were 35 or over. There was, however, little difference in age between the men in Groups II, III, and IV, the number of men of 35 and over being 44%, 42%, and 45% respectively. There is therefore the possibility that the greater average age of the highly fertile men in Group I may have been in part responsible for the absence of varicocele in these men. On the other hand, the men in Groups II, III, and IV are comparable so far as age is concerned, yet varicocele occurred almost seven times more frequently in the men with poor quality semen (Group IV). Although the number of cases of varicocele is small there is a significant increase in incidence in the subfertile group of men—the probability is less than 0.01.

One further point in regard to age is of some interest. Varicocele was found four times in men with good quality semen (Groups I, II, and III)—all were young men, the oldest being 32. Of the 11 men with poor quality semen who were found to have varicocele (Group IV) only one was under 30 and six were 35 or older (see Table). This suggests that a varicocele which persists beyond the age of 30 years is more liable to be associated with subfertility, and, conversely, one which disappears before the age of 30 is not likely to interfere with fertility. This is only a suggestion and may not be true, as it is equally possible that a number of cases of unexplained atrophy and softening of the testes among subfertile men may in fact be legacies from varicoceles which have regressed.

Although it is beyond the scope of this paper to discuss the aetiology of varicocele, I could find no evidence to support the view that late marriage is an important cause of the condition. The Table shows the age of marriage of the 11 men with varicocele in Group IV: most of them had married at an early age and had been married for several years.

The Table also shows the predilection of varicocele for the left side; this tendency is widely recognized and has been reported in the literature by many workers. Softening and even atrophy of the left testis is not unusual, and was noted in 3 of the 11 cases of varicocele occurring in the subfertile men. Hammen (1944) found diminution in size or consistency of the testis on the same side in 35.3% of his patients with varicocele. It is difficult to explain why a lesion which is generally one-sided should affect spermatogenesis in the other testis. A possible explanation is a slight but prolonged alteration in temperature within the scrotum, affecting both testes.

Summary and Conclusions

This study points to an important association between varicocele and subfertility, for the incidence of the condition is much higher in men with poor quality semen. The more frequent occurrence in subfertile than in fertile men cannot be explained entirely by their being in different age groups.

There is evidence to support the view that a varicocele persisting beyond the age of 30 is particularly apt to be associated with poor quality semen, but this study gives no information of the proportion of varicoceles that do continue beyond the age of 30.

The purpose of this paper is not to plead for more active treatment (indeed, attention has been drawn to the dangers of active surgical treatment), but rather to challenge the traditional attitude that varicocele is an innocuous condition and to stress the need for more extensive investigation into the natural history of varicocele and the effect which it may have upon fertility.

I am most grateful to Professor Harvey Evers and Mr. Frank Stabler for their encouragement and helpful criticism. The statistical significance of the increased incidence of varicocele in the subfertile men was confirmed by Mr. Hubert Campbell, statistical assistant in industrial health, University of Durham.

THE AURICULO-TEMPORAL SYNDROME

BY

PHILIP D. GOATCHER, M.B., F.R.C.S., F.R.C.S.Ed.
 Late First Senior Surgical Registrar, St. Paul's Hospital, London; Formerly Surgical Registrar, Whiston County Hospital, Liverpool

In 1897 Parkes Weber demonstrated the strange case of a youth who, following a suppurating lesion in the region of his left parotid gland, sweated on that side of his face when he ate food. Accompanying this there was a flushing on the same side of his face. Because the area involved corresponds to the cutaneous distribution of the auriculo-temporal nerve this condition became known as the auriculo-temporal syndrome. Lucie Frey described it again in 1923, and because of her work on the subject it is also known as Frey's syndrome.

The auriculo-temporal syndrome consists of redness and sweating over the temporal and pre-auricular areas evoked by eating. It is a sequel of penetrating wounds, surgical incisions, or suppuration in the region of the parotid gland. The redness and sweating are not synchronous in appearance, the vasodilatation occurring first. Nor are they continuous in distribution. There may be pain during eating, and sensory changes in the form of diminished or increased sensation in the same area are commonly present.

Case Report

A woman of 36 had the superficial part of her right parotid gland and adjacent fibrous tissue excised for chronic parotitis. From 2 years of age she had suffered from repeated attacks of painful inflammation, and periglandular fibrosis had produced a partial false ankylosis of the right temporo-mandibular joint. The operation prevented further attacks of parotitis and she was enabled to open her mouth enough to take food normally. Six months later it was noticed that during a meal sweat appeared on the side of her face and trickled down her cheek.

Examination

On examination a 4-in. (10-cm.) scar was seen running parallel to, behind, and below the right ramus, angle, and body of the mandible. Skin sensation was normal. The parotid gland was palpable, and the orifice of Stensen's duct appeared normal, and saliva issued from it. When the patient was given a caramel to eat the skin on the affected side of the face became red. The hyperaemia extended over the forehead, temple, cheek, and ear. Within

a minute, pinpoint spots of sweat appeared over a less extensive area (see Fig.). Within five minutes the sweat had accumulated into drops large enough to run down the cheek. When she stopped eating the sweating ceased, the hyperaemia faded, and the skin returned to normal.

Anatomy and Aetiology

It is necessary to consider the anatomy, so far as it is known, in order to appreciate the theories that have been produced to explain the mechanism. Secretory parasympathetic fibres from the glossopharyngeal nerve pass to the auriculo-temporal nerve, providing the parotid gland with secretory motor fibres. The sweat glands of the face are innervated by the sympathetic outflow, the post-ganglionic fibres of which are believed by Wilson (1936) to be distributed with the peripheral branches of the trigeminal nerve. Sweating of the face in response to heat is mediated by sympathetic pathways, for destruction of the cervical sympathetic chain reduces heat sweating (Guttmann, 1940). List and Peet (1938) suggest that there is parasympathetic innervation of sweat glands of the face. Wilson (1936) concluded that such fibres join the trigeminal nerve at some point distal to the sensory root. There is no evidence to suggest that they play any part in sweating under normal physiological conditions.

The auriculo-temporal syndrome occurs most often as a sequel of suppurative parotitis, which is so severe as either to rupture spontaneously or to require surgical incision and drainage (Parkes Weber, 1897; List and Peet, 1938; Freedberg *et al.*, 1948; Pfeffer and Gellis, 1951). Triumhoff (1926) reported 14 cases having an antecedent history of suppurative parotitis and mainly secondary to typhoid or typhus fevers. Frey's case followed a gunshot wound which caused a secondary parotitis. Cases have been reported following excision of parotid tumours, and it has been described following mumps and in cases of syringomyelia (Kaminsky, 1929; Wilson 1936).

Mechanism

The hyperaemia and sweating are a reflex response, the afferent component of which is stimulated by taste. It appears that the disorder lies in the efferent arc which involves nerve fibres in the region of the auriculo-temporal nerve.

It has been suggested that scar tissue involves and anchors autonomic fibres which are subjected to pressure when the parotid gland distends, as it does when food is tasted.

Those cases in which the syndrome occurs promptly after a salivary fistula closes support this theory. Needles (1936) reported a case of temporary parotid fistula complicating the excision of a parotid tumour. The appearance of the auriculo-temporal syndrome coincided with the closure of the fistula. Needles referred to a case of bilateral parotitis. One side had a fistula and the other none. The auriculo-temporal syndrome occurred only on the side where there was no fistula. However, the phenomenon may occur when the parotid is either atrophied or functionless, and is not produced when pressure is exerted in the region of the scar.

Frey considered that the reflex was essentially a normal one, but that it had been accentuated through injury to the

The black area represents the region of sweating. The stippled area represents the region of hyperaemia.

auriculo-temporal nerve with subsequent irritation of vasodilator fibres in the cicatrix of the sclerotic parotid gland. In that way she incriminated scar tissue.

Another hypothesis is that it is due to faulty regeneration of parotid secretory fibres (Thomas, 1927; Ford and Woodhall, 1938).

Since one cholinergic fibre can replace another (Dale, 1935), a fibre originally destined for salivary glands may communicate with a sympathetic fibre passing to the skin. In that way a stimulus which would normally produce salivation evokes sweating. The frequently associated evidence of nerve injury supports this view. This includes abnormalities of skin sensation, decreased sweating in response to heat, pain, and facial palsy which is either transient or permanent.

The time interval that occurs between the injury and the appearance of the syndrome also supports this hypothesis. Time must be allowed for Wallerian degeneration and subsequent regeneration to take place. This theory fails to explain those cases in which the latent period is only of a few days' duration. Furthermore, one would expect the sudomotor fibres of the auriculo-temporal nerve, coming from the cervical sympathetic, to produce vasoconstriction and pallor and not the reverse when they are stimulated.

Freedberg *et al.* (1948) offer the explanation that the auriculo-temporal syndrome represents a response of denervated and hypersensitive sweat glands to previously unapparent cranial sudomotor impulses.

Hypersensitivity of afferent structures following denervation is an accepted physiological finding in both cholinergic and adrenergic nerves. It is a logical expectation that hypersensitivity of the sweat glands of the face may follow division of sympathetic fibres in the auriculo-temporal nerve. Freedberg *et al.* (1948) and Langenskiöld (1946) demonstrated this sensitivity.

Haxton's (1948) observation that sympathetic block in the upper thorax stops the response suggests that acetylcholine comes from intact nerve endings.

From the above findings it becomes apparent that the mechanism of the auriculo-temporal syndrome is not fully explained.

Allied Conditions

There are other conditions which at least superficially resemble the auriculo-temporal syndrome. The slight symmetrical sweating that occurs on the faces of normal individuals when they eat spicy food is accepted as a normal reflex. Sometimes this reflex is exaggerated and the sweating excessive. Its relation to the auriculo-temporal gustatory sweating is hypothetical but suggestive. Pfeffer and Gellis (1951) refer to Mellenkoff's case of an infant with a transient phase of sweating from a small area in the region of one tibial tubercle when milk was taken.

The syndrome of "crocodile tears," which consists of lacrimation occurring as a reflex response to eating, resembles the auriculo-temporal syndrome. It follows facial palsy, usually with the site of lesion in the region of the geniculate ganglion. Another condition which resembles the auriculo-temporal syndrome was reported by Uprus *et al.* (1934). Their patient had previously had cervical glands excised. Gustatory sweating subsequently developed in the submandibular region on the same side as the operation.

Prognosis and Treatment

The hyperaemia and sweating may continue for the remainder of the patient's life, but a diminution of symptoms sometimes occurs (Payne, 1940).

Since the auriculo-temporal syndrome is benign and non-progressive the patient can be reassured. If the discomfort warrants treatment the auriculo-temporal nerve may be divided surgically, but there are few records of this being done. Alcohol injection of the nerve is to be avoided because of possible injury to the facial nerve, and the value of radiotherapy is doubtful.

Summary

A case of the auriculo-temporal syndrome is reported. The anatomy is considered. Aetiology is discussed. Theories of explanation are reviewed. Reference is made to allied conditions. Prognosis and treatment are described.

I wish to thank Mr. J. A. Martinez for his permission to report this case.

RADIO-IODINE MEASUREMENTS OF THYROID FUNCTION DURING AND AFTER P.A.S. TREATMENT OF TUBERCULOSIS

BY

J. A. BALINT, M.B., M.R.C.P.

Medical Registrar, Central Middlesex Hospital

RUSSELL FRASER, M.D., F.R.C.P.

Reader in Medicine, Postgraduate Medical School of London

AND

M. G. W. HANNO, M.D., M.R.C.P.Ed.

Lecturer in Medicine and Therapeutics, Alexandria University, Egypt

(From the Department of Medicine, Postgraduate Medical School of London)

Over the past three years there have been reported nine cases of hypothyroidism with goitre occurring during para-amino salicylic acid (P.A.S.) treatment (Bergqvist and Maré, 1951, 1952; Clausen and Kjerulf-Jensen, 1951; Komrower, 1951; Librach, 1952; Davies and Galbraith, 1953). As many thousands of patients have received this treatment this seems a small incidence which may have depended on some special susceptibility in these few patients. Others have reported simple enlargement of the thyroid gland without signs of disordered thyroid function during P.A.S. treatment—that is, lesser antithyroid effects (Bergqvist and Maré, 1951, 1952; Hamilton, 1953); indeed, in some of the cases reported as goitre with myxoedema the evidence of thyroid deficiency has been slight. Because of these reports we have endeavoured to assess whether doses of P.A.S. commonly used clinically entail much risk to thyroid function. Radio-iodine tests of thyroid uptake have therefore been carried out on an un-

selected* series of 30 patients at the conclusion of their period of P.A.S. treatment; one test being given just before and the other four to seven days after the drug was stopped. The difference between the pair of tests should indicate whether this P.A.S. dosage had influenced thyroid uptake of iodide; and an excessive thyroid uptake should be seen on the second test when any hyperplasia and iodine deficiency had been induced by the period of P.A.S. administration. In addition, by an *in vitro* test, one of us (M.H.) has compared the antithyroid potency of P.A.S. with that of 2-thiouracil.

Like other amino-benzene compounds (Astwood *et al.*, 1945), P.A.S. might be expected to be an antithyroid drug interfering with the normal iodination of the thyroid hormone, provided that P.A.S. entered the thyroid gland. This action is indicated by our *in vitro* test results and animal experiments (Kjerulf-Jensen and Wolffbrandt, 1951), but its potency in the dosage used clinically cannot be predicted from its formula nor from the *in vitro* measurements, which take no account of its entry into the thyroid gland. Horn and Bogsch (1950) observed a retardation of radio-iodine uptake during P.A.S. administration in one patient, and Hanngren (1952) found an inhibition of radio-iodine uptake for four hours after an intravenous dose of 10.5 g. of P.A.S. in another patient. Davies and Galbraith (1953) found an increased uptake of iodine in their patient after withdrawal of P.A.S., suggesting that some hyperplasia had been introduced. Hamilton (1953) noted that a goitre which developed during P.A.S. treatment decreased with thyroid administration, suggesting that its development had depended on the drug's antithyroid action. Sutherland (1953), in the United States of America, registered maximum retardation of radio-iodine uptake after four to six weeks of P.A.S. therapy. He also states that iodine uptake returns to normal one to two weeks after cessation of treatment. No cases of goitre were reported in this series, but it is not stated whether any patient was tested after prolonged P.A.S. administration.

Method

Unselected patients available for assessment at the conclusion of their period of treatment were each given two tests—one just before and the other at four to seven days after stopping the drug. Most patients had had approximately three months' continuous chemotherapy, and some had had the drug for a longer period; the dosage of P.A.S. had mostly been 20 g. daily, but other drugs had also been given to most of the patients. Details of the dosage of P.A.S. and associated drugs are given in Table IV. The test used was the urinary excretion of radio-iodine as described by Fraser *et al.* (1953); following the radio-iodine dose the urinary excretion was measured in three periods, 0-8, 8-24, and 24-48 hours after the dose. The excretion in 8-24 hours offers an inverse index of thyroid uptake. Since the P.A.S. level might have fluctuated during the period of the first test, the 0-48 hour excretion has also been used to provide a similar index—its modifiability by abnormal renal function should not matter with these patients, and its reflection of thyroid uptake would not be invalidated by any fluctuation in P.A.S. level during the first test.

The *in vitro* method used to assess antithyroid potency was that described by Pitney and Fraser in 1953. It measures the inhibition of the peroxide-iodination of protein by various concentrations of a drug, in a test in which

*After the first cases were tested special search was made for patients given the drug for long periods; the cases were otherwise unselected.

the peroxide is provided by added milk enzyme powder and substrate. The antithyroid action of the drug is measured by the extent to which various concentrations of the drug inhibit the iodination of protein, and the data thus obtained have been referred to those obtained with 2-thiouracil for comparison.

Results

The results of the radio-iodine tests on the patients are summarized in Table I, and given in fuller detail in Table IV. The tests on the patients during P.A.S. administration are not clearly abnormal, but show more excretion of radio-iodine than do those after its withdrawal (Table I). The

TABLE I.—Radio-iodine Test Results on Patients During and After Stopping P.A.S.

Group	No. of Patients	Urinary Excretion of ¹³¹ I (As Percentage of Administered Dose)			
		In 8-24 Hours		In 0-48 Hours	
		Mean ± S.E.	S.D. (Range)	Mean ± S.E.	S.D. (Range)
(a) Normals	32	13.6 ± 0.65	3.7 (7-20)	55.8 ± 1.54	8.7 (35-70)
(b) Tuberculous patients: While on P.A.S. for 3 months or more	30	19.9 ± 1.95	10.7 (2.5-42.5)	55.3 ± 2.96	16.2 (22.1-91.8)
(c) 4-7 days after stopping P.A.S.	30	8.8 ± 0.93	5.1 (0.9-20.2)	33.2 ± 1.88	10.3 (14.9-57.6)
Difference (b)-(c)		11.1 ± 2.16		22.1 ± 3.41	
(a)-(c)		4.8 ± 1.14		22.6 ± 2.43	

The tests after cessation of the P.A.S. show more thyroid uptake than those during the drug administration and also than those of the normal patients—the excretions in either period are significantly higher.

8-24 hour excretion is high, but the 0-48 hour excretion is normal; clearly this dosage of P.A.S. had some antithyroid effect. Evidently the thyroid uptake of radio-iodine during P.A.S. administration is slowed but ultimately occurs to an approximately normal extent. Probably the slight compensatory thyroid hyperplasia induced over the previous months of P.A.S. administration is usually nearly enough to balance the weak antithyroid effect produced by the usual dosage of P.A.S.

As a group the tests on the patients after withdrawal of P.A.S. show less radio-iodine excretion in both periods than those of a normal group (Table I)—that is, there is a tendency to increased thyroid uptake of iodide after P.A.S. withdrawal, indicating some depletion of the thyroid hormone store during the previous drug therapy. These tests after withdrawal tend to show more abnormality when P.A.S. treatment has been more prolonged, particularly when it has exceeded six months (Table II). The increase of thyroid uptake is, however, usually slight, for, while the mean excretions for the groups are abnormal, few individual excretions are beyond the normal range, except when the drug has been given for over six months. Apparently slight compensatory thyroid hyperplasia had occurred during the previous months of P.A.S. administration, and usually it is only after more than six months of drug administration that much exhaustion of the thyroid hormone store is discernible. Probably the patients varied in their susceptibility to the drug, for among those given it for less than six months are several with one or both tests normal; and the differences between individual results (see Table IV) are greater than those between groupings according to the total duration of P.A.S. therapy.

Of the 11 patients given P.A.S. for over six months, 10 were found to have an obviously avid uptake of radio-iodine on P.A.S. withdrawal (Table II), and four were noted to have developed a small goitre of 40-50 g., first noticed 6½ months (Cases 29 and 30) and 8 months (Cases 27 and 28) after starting the drug. None showed any myxoedematous features. After the tests reported above, the first two patients (Cases 29 and 30) were given potassium iodide, 10 mg. daily for one week, and when seen one month later, while still off P.A.S., the radio-iodine uptake

TABLE II.—Radio-iodine Tests After Withdrawal of P.A.S.

Duration of P.A.S. Therapy (at 20 g./Day)	No.	Mean Urinary Excretion of I^{131} as % of Dose	
		In 8-24 Hours	In 0-48 Hours
Under 3 months*	8	10.7	39.2
3 months	8	11.5	37.1
3-4 "	3	10.2	33.4
6-10 "	11	4.3	26.0
(Normal group)	(32)	(13.6)	(55.8)

* Includes two cases receiving 10 g. P.A.S. daily for three months.

† On P.A.S. 20 g. daily for three months, then 15 g. daily.

had become normal, and the thyroid enlargement had subsided. Neither had previously noted a goitre; the third and fourth patients were not retested after iodide, but one had a family history of goitre and may have had some goitre before his treatment.

TABLE III.—In vitro Measurement of the Antithyroid Potency of P.A.S. and Isoniazid Compared with that of 2-Thiouracil

Drug	Antithyroid Potency (Relative to 2-Thiouracil)	
	For 50% Effect*	Speed of Increase with Rising Concentration†
2-Thiouracil	(1)	(1)
P.A.S.	(0.085)	(0.02)
Isoniazid	(0.025)	(0.18)

* Potency for 50% inhibition equals reciprocal of that molar concentration of the drug which gives 50% inhibition on enzymic iodination test; for this the molar concentration is expressed as equivalents of the iodide present in the test.

† Speed of increase of antithyroid potency with rising concentration = molar concentration for 10% inhibition / molar concentration for 90% inhibition on same enzymic iodination test.

Table III shows the results of the *in vitro* measurements of the antithyroid potency of P.A.S. and also of isoniazid expressed relative to the values found for 2-thiouracil. Both drugs appear to be weakly antithyroid, showing less than one-tenth of the potency of 2-thiouracil, and isoniazid

about one-third the potency of P.A.S. Their antithyroid potency also increases much more slowly with rising concentration than does that of 2-thiouracil. These tests take no account of the degree to which the drugs can enter the thyroid, but are in conformity with the clinical findings that these are very weak antithyroid drugs.

Summary and Conclusions

Tests on 30 patients before and after withdrawal of P.A.S. treatment showed that the drug causes a slight interference with the uptake of iodine by the thyroid: during less than six months' administration this seems usually to be adequately compensated by slight thyroid hyperplasia. *In vitro* testing of antithyroid potency showed P.A.S. to be a weak antithyroid drug, and isoniazid to be even weaker. Except possibly in occasional patients exceptionally susceptible to the drug, and in those given P.A.S. for over six months, this effect probably has no clinical importance.

When the drug is given for over six months at a dose of about 20 g. a day thyroid function may be affected. 10 out of 11 patients having shown on withdrawal of the drug an avid iodine uptake indicating previous iodine depletion, and 4 out of the 11 having noticed the development of a goitre. In two of these patients these abnormalities were shown to be correctable by iodide administration. We suggest that when P.A.S. is to be given for over six months, a weekly dose of iodide should be given to avoid these thyroid effects—for example, a weekly potassium iodide pill (4 gr., or 20 mg.).

We wish to thank the sisters and nurses for their help in the collection of specimens, and Miss M. Magee for the radio-iodine estimations. Our thanks are also due to Drs. J. C. Hoyle, W. Oswald, A. L. Punch, F. H. Scadding, and F. H. Young for permission to carry out these tests on patients under their care.

ASSAY OF PLASMA INSULIN ACTIVITY BY THE RAT-DIAPHRAGM METHOD

BY

P. J. RANDLE,* M.B., B.Chir.

From the Department of Biochemistry, University of Cambridge and Addenbrooke's Hospital, Cambridge

Bornstein (1950) described a method for the assay of insulin in human plasma which was based on the fall of blood sugar of alloxan-diabetic hypophysectomized adrenalectomized rats (A.D.H.A. rats). Subsequently Bornstein and his colleagues determined the insulin content of plasma from various types of diabetic by this method (Bornstein and Trehella, 1951; Bornstein and Lawrence, 1951a, 1951b). The published results of these workers were of such interest as to merit further study.

A.D.H.A. rats prepared in this laboratory have proved to be too delicate and to possess too unstable a blood sugar to permit their use for accurate insulin assay. Groen *et al.* (1952) described a method for the detection and assay of insulin in human plasma which was based on the glucose uptake of the isolated normal rat diaphragm surviving *in vitro*; as was first shown by Gemmill (1940), this uptake is raised by the *in vitro* addition of insulin to the fluid in which the isolated diaphragm is suspended. This method has been critically investigated as a quantitative procedure for the assay of insulin and a modified procedure applied to the determination of the insulin activity of normal human plasma.

Methods

Animals.—The hemidiaphragms of normal male albino Wistar rats of 100-150 g. were used in these experiments. The animals were starved for 18 to 24 hours before use.

For the preparation of alloxan-diabetic hypophysectomized rats (A.D.H. rats) male albino Wistar rats of 170-220 g. were used. They were first of all hypophysectomized, and then, one week later, made diabetic by the intravenous administration of alloxan.

Insulin.—A single sample of crystalline insulin (Boots) of potency 23.2 units per mg. was used as standard in these experiments. Solutions of this were freshly prepared for each assay.

Human Subjects.—The different samples of plasma collected from human subjects are designated as ran-

*In receipt of a full-time grant from the Medical Research Council.

dom (collected without previous preparation of the subject) or fed (collected from subjects two and a half hours after the oral administration of 50 g. of glucose).

Chemical Analysis.—Blood glucose and the glucose content of the incubation fluid in the insulin assay was determined colorimetrically by the method of Somogyi (1945).

Procedure

For the qualitative detection of insulin activity in human plasma the glucose uptakes of rat hemidiaphragms suspended in buffer were compared with the glucose uptakes of rat hemidiaphragms suspended in buffer to which the plasma had been added.

For the quantitative assay of insulin activity in human plasma two methods have been used, the single standard method and a four-point assay.

In the single standard method, the absolute glucose uptake of rat diaphragm in the presence of plasma was compared with the absolute glucose uptake of rat diaphragm in the presence of a single standard dose of insulin (2 milliunits per ml.). In each assay (unless otherwise stated) four hemidiaphragms (from different rats) were used for the determination of the basal glucose uptake and six for the determinations of the glucose uptakes in the presence of plasma and of insulin respectively. A standard dose of insulin of 2 milliunits per ml. was chosen, since this gave results very similar to those yielded by normal human plasma under these conditions.

In four-point assays the glucose uptakes of rat hemidiaphragms in the presence of two dilutions of plasma (1:16 and 1:4) and two concentrations of insulin (0.5 and 2 milliunits per ml.) were simultaneously determined.

Experimental Procedure

The basal glucose uptake of the isolated rat diaphragm was determined in buffer (Gey and Gey, 1936) containing 2.5 mg. per ml. of glucose. The glucose uptake in the presence of insulin was determined in buffer-glucose containing the appropriate concentration of insulin. For the determination of the glucose uptake in the presence of plasma, buffer-plasma mixtures were prepared containing 2.5 mg. of glucose and 0.25 ml. of plasma in each ml. of mixture. In all cases the gas phase during incubation was 93% O₂, 7% CO₂.

In typical experiments, human blood was drawn from the antecubital vein by a dry sterile syringe. The blood was transferred to centrifuge cups containing a little heparin and the plasma separated by centrifugation. The plasma sugar was then determined, and after preparation of the buffer-plasma mixture 1-ml. samples of the incubation fluids were placed in the main compartments of Warburg manometer flasks. Normal rats were then killed by decapitation and their diaphragms removed, divided, and washed for exactly five minutes at room temperature in buffer-glucose (glucose concentration 2.5 mg. per ml.) previously saturated with 93% O₂, 7% CO₂. The hemidiaphragms were then lightly blotted, transferred to the manometer flasks, and incubated for three hours at 37° C. at a shake rate of 100 cycles a minute.

After incubation the flasks were removed from the bath, cooled, and 0.2 ml. of the fluid taken for glucose estimation. The hemidiaphragms were then blotted dry and weighed on a torsion balance.

Calculation of Results

The glucose uptake of the diaphragm was calculated as mg. glucose/g. wet wt. diaphragm/hour. The estimate of variance given in the tables is the standard error of the mean.

In single standard assays the insulin activity of the plasma was calculated from a log-dose (of insulin)/response curve previously determined, the standard dose of insulin incorporated in the assay being used to fix the position of this

log-dose response curve. In this calculation the slope of the log-dose response curve was assumed to be constant. The limits of error ($P=0.05$) were calculated from previously determined regression data for crystalline insulin, since the variance in different assays did not differ significantly.

In four-point assays the insulin activity of the plasma and limits of error were calculated from the assay data by the usual means.

The insulin activity of the plasma is expressed as milliunits of insulin per ml. of plasma (1 milliunit is 10^{-3} unit).

Results

Response of Rat Diaphragm to Insulin Added In Vitro

Table I and Fig. 1 record the glucose uptake of rat diaphragm in the presence of different concentrations of insulin added *in vitro*. The results are the mean values of data collected on six separate occasions during a two-week period in September, 1953.

FIG. 1.—The effect of increasing concentrations of insulin upon the glucose utilization of the isolated rat diaphragm expressed as a log-dose (of insulin) response curve.

FIG. 2.—Four-point assays of the insulin activity of normal human plasma, by the rat-diaphragm method. Slopes of log-dose response curve for two concentrations of insulin and two dilutions of plasma. Insulin concentrations plotted as log dose (of insulin) in microunits per ml. Plasma insulin activity plotted as insulin concentrations in arbitrary units.

precision ($\lambda=s/b$) was 0.36. The slope of the log-dose (of insulin) response curve has been recently redetermined (January, 1954) and found to be 0.7081, in good agreement with the previous value.

The Insulin Activity of Normal Human Plasma

The method described has been applied to the determination of the insulin activity of plasma collected from normal human volunteers two and a half hours after the oral administration of 50 g. of glucose. The results of similar assays in acromegaly and hypopituitarism have been described in separate papers (Randie, 1954a, 1954b).

TABLE I.—Effect of Increasing Concentrations of Insulin, Added In Vitro, Upon the Glucose Utilization of the Isolated Rat Diaphragm

Insulin Concentration Microunits/ml. ($=10^{-4}$ unit)	Absolute Glucose Uptake	$\sqrt{(\text{Absolute Glucose uptake} \times 100)}$		No. of Hemidiaphragms
		Observed	Calculated from Linear Regression	
0	2.32 $\pm$ 0.05	—	—	16
125	2.96 $\pm$ 0.09	6.665	6.679	16
500	3.55 $\pm$ 0.08	7.081	7.090	16
2,000	4.25 $\pm$ 0.06	7.518	7.505	16
8,000	5.03 $\pm$ 0.09	7.952	7.910	16
32,000	5.73 $\pm$ 0.10	8.307	8.321	16

All glucose uptakes with insulin were significantly greater than the basal glucose uptake. Each increase in dose recorded produced a significant increment in response.

The mean plasma insulin activity by the single standard method was 13.5 milliunits per ml. (limits of error 12 to 19.8 milliunits per ml.); by four-point assays the mean plasma insulin activity was 12.4 milliunits per ml. (limits of error 6 to 24 milliunits per ml.). The experimental details and individual results are recorded in Tables II and III and Fig. 2.

TABLE II.—Insulin Activity of Plasma from Normal Human Subjects 2½ Hours After Oral Glucose, as Assayed by the Single Standard Method

Normal Human Subjects (Fed)	Blood Sugar	Glucose Uptake in Presence of		Plasma Insulin mU./ml.	Limits of error $P=0.05$	N
		Plasma Diluted 1:4	Insulin 2 mU./ml.			
1	103	3.95 $\pm$ 0.17	3.52 $\pm$ 0.23	20	8 to 53	12
2	77	4.18 $\pm$ 0.03	4.03 $\pm$ 0.08	11	5 to 28	12

4	72	4.16 $\pm$ 0.17	4.10 $\pm$ 0.14	9	3 to 26	12
5	80	4.27 $\pm$ 0.12	3.84 $\pm$ 0.22	19	6 to 62	8
6	89	4.65 $\pm$ 0.14	4.51 $\pm$ 0.14	10	3 to 32	8
7	90	4.26 $\pm$ 0.42	3.76 $\pm$ 0.11	22	8 to 63	11
		Mean:		13.50	12 to 19.8	(75)

N is total number of hemidiaphragms used for determining the mean glucose uptake in the presence of plasma and of insulin.

TABLE III.—Insulin Activity of Plasma from Normal Human Subjects 2½ Hours After Oral Glucose, as Assayed by Four-point Assays

Assay No.	Glucose Uptake with Insulin		Glucose Uptake with Plasma		Plasma Insulin mU./ml.	Fiducial Limits P. 0.05
	Concentrations		Dilutions			
	0.5 mU./ml.	2 mU./ml.	1 : 16	1 : 4		
1	3.14 ± 0.18	3.84 ± 0.22	3.48 ± 0.19	4.27 ± 0.12	16.7	7 to 38
2	2.93 ± 0.12	4.51 ± 0.14	3.10 ± 0.14	4.65 ± 0.14	10	7 to 14
Mean:					12.4	6 to 24

Four observations at each dose level.
All glucose uptakes significantly greater than the basal glucose uptake.

Recovery of Insulin Added to Plasma In Vitro

In Table IV are recorded the results of experiments in which the insulin activity of insulin-plasma mixtures prepared *in vitro* was assayed. In these experiments insulin

TABLE IV.—Recovery of Insulin Added In Vitro to Buffer-plasma Mixtures Prepared in the Usual Way

Basal Glucose Uptake	Glucose uptake due to plasma with insulin added <i>in vitro</i> to give a total estimated concentration of 8.25 mU./ml.	Glucose uptake due to Insulin. Concentration, 8 mU./ml.
2.54 $\pm$ 0.18 (4)	5.02 $\pm$ 0.27 (6)	5.08 $\pm$ 0.27 (6)
2.30 $\pm$ 0.05 (4)	4.33 $\pm$ 0.21 (6)	4.08 $\pm$ 0.10 (6)

Both estimates performed with a single sample of normal human plasma collected 2½ hours after oral administration of 50 g. of glucose. Insulin content, 13 mU./ml.

Figures in parentheses = number of hemidiaphragms.
For first assay, estimated insulin content of insulin-plasma mixture is 7.7 mU./ml. (limits of error, $P=0.05$, 2 to 30 mU./ml.).
For second assay, estimated insulin content of insulin-plasma mixture is 12.6 mU./ml. (limits of error $P=0.05$, 3 to 33 mU./ml.).
Recovery of added insulin not significantly different from 100% in either case.

was added, *in vitro*, to buffer-plasma mixtures prepared in the usual way, to bring the insulin content to a calculated value of approximately 8 milliunits per ml. The glucose uptake of the diaphragm in this mixture was then compared with the glucose uptake of the diaphragm in the presence of insulin at a concentration of 8 milliunits per ml. The recovery of insulin added to plasma *in vitro* and assayed in this way did not differ significantly from 100%.

Insulin Activity of Normal Human Plasma Assayed in the A.D.H. Rat

Previous workers have reported the insulin content of normal human plasma, collected after a glucose meal, to be 0.34 milliunit per ml. (Bornstein and Lawrence, 1951b), 1 milliunit per ml. (Groen and Willebrands, personal communication), and 0.1 to 0.6 milliunit per ml. (Vallance-Owen and Hurlock, 1954). The value obtained by the rat-diaphragm assay described in this paper is considerably greater than these reported values.

The discrepancy between whole-animal methods and the rat-diaphragm technique described in this paper is illustrated by the assay using A.D.H. rats (Table V). In this experiment the change in blood sugar of A.D.H. rats over

TABLE V.—Effects of Intravenously Administered Saline, Normal Human Plasma, and Insulin Upon the Blood Sugar of Alloxan-diabetic Hypophysectomized Rats

Nature of Injected Material	Mean Fall of Blood Sugar $\pm$ S.E. Mean	No. of A.D.H. Rats	t	P
1. Saline (1 ml.)	4.6 $\pm$ 4.1	8	—	—
2. Normal human plasma* (1 ml.)	13.8 $\pm$ 8.8	5	—	—
3. 2 milliunits of insulin in 1 ml. of saline	41.5 $\pm$ 5.2	5	t for 1 v. 3 is 9.3 t for 2 v. 3 is 6.8	<0.001 <0.001

* 1 ml. of this plasma possessed activity equal to that of 13 mU. of insulin in the rat-diaphragm assay.

a period of 20 minutes following the intravenous injection of normal human plasma was measured. It was observed that plasma, assayed by the rat-diaphragm method to contain 13 milliunits of insulin per ml., had no effect upon the blood sugar of A.D.H. rats. By contrast 2 milliunits of insulin produced a highly significant fall of blood sugar in the same A.D.H. rats under similar experimental conditions.

Insulin Activity of Cysteine-treated Plasma

Du Vigneaud *et al.* (1931) observed that cysteine treatment inactivated insulin. Other workers who have used the rat-diaphragm assay for insulin have reported that cysteine will abolish the insulin activity of human plasma or serum. This observation has been confirmed in experiments in which normal human plasma was incubated with cysteine (concentration 20 mg. per ml.) for 12 to 18 hours. The experiments were controlled by simultaneous incubation of the same plasma in the absence of cysteine. It was observed that incubation with cysteine consistently abolished the insulin activity of plasma, whereas plasma incubated

TABLE VI.—Insulin Activity of Human Plasma After Dialysis and After Treatment with Cysteine as Detected by the Rat-diaphragm Technique

Addition to medium of:	Change in Glucose Utilization	N	t	P
Dialysed normal human plasma	1.07 $\pm$ 0.19	6	3.5	<0.02 >0.01
Buffer incubated with cysteine	0.05 $\pm$ 0.09	6	—	—
Normal human plasma (1)	—	—	—	—
Incubated with cysteine	0.57 $\pm$ 0.10	6	4.40	<0.01
Incubated without cysteine	1.00 $\pm$ 0.12	6	5.50	<0.01
Normal human plasma (2)	—	—	—	—
Incubated with cysteine	0.14 $\pm$ 0.21	6	—	—
Incubated with cysteine and dialysed	0.14 $\pm$ 0.22	6	—	—

Glucose uptakes expressed as increments over the basal glucose uptake $\pm$ S.E. of mean.
N is $N_1 + N_2 - 2$ where N_1 and N_2 are the number of hemidiaphragms used for determining the basal glucose uptake and the glucose uptake in the presence of plasma or other added material.
All samples of plasma were random samples.

without cysteine still possessed significant insulin activity. It was observed in additional experiments that the basal glucose uptake determined in buffer incubated with cysteine was similar to the basal glucose uptake in untreated buffer. The results of typical experiments are recorded in Table VI. Some samples of cysteine-treated plasma were found to inhibit the glucose utilization of rat diaphragm, but this effect was not consistently seen (Table VI).

Samples of cysteine-treated plasma which had been dialysed against buffer for 18 hours, to remove residual cysteine, were also without insulin activity (Table VI). By contrast, untreated human plasma does not lose its insulin activity when dialysed against buffer (Table VI).

Discussion

Assay of Insulin by the Isolated Rat Diaphragm

The rat-diaphragm technique for the assay of insulin has not previously been critically investigated by conventional statistical methods. The results of statistical appraisal of the rat-diaphragm technique, reported in this paper, suggest that it is not a very precise method for the assay of insulin, though the index of precision ($\lambda=0.36$) compares favourably with that of some methods at present used for the bio-assay of other hormones—for example, the tibial band assay for growth hormone. It is difficult to compare the results of this investigation of the rat-diaphragm assay for insulin with those previously reported, since other workers have not supplied comparable statistical data. The variance encountered in the experiments reported in this paper is similar to that found by other workers who have studied the glucose uptake of the isolated rat diaphragm—for example, see Ottaway (1953).

The sensitivity of the isolated rat diaphragm to insulin was found in these experiments to vary considerably from time to time and the variation in sensitivity was not necessarily seasonal; in disagreement with previous reports (*Groen *et al.*, 1952; Vallance-Owen and Hurlock, 1954). The minimum effective concentration of insulin in these experiments was 10^{-4} unit per ml., though some workers have claimed that as little as 5×10^{-4} unit of insulin per ml. will increase the glucose utilization of the isolated rat diaphragm (Groen *et al.*, 1952).

Specificity of the Rat-diaphragm Assay for Insulin in Plasma

Many workers have previously reported that the plasma of normal animals will increase the glucose uptake of rat diaphragm when added to the fluid in which the isolated diaphragm is suspended. This effect has been variously attributed to non-specific effects of plasma protein (Park, 1952), or to insulin in the plasma (Tuerkischer and Wertheimer, 1948; Groen *et al.*, 1952; Vallance-Owen and Hurlock, 1954).

Park attributed the insulin activity of normal rat plasma in the rat-diaphragm assay to non-specific effects of plasma protein, since he found that crystalline bovine serum albumin and A.D.H. rat plasma would stimulate the glucose uptake of the isolated rat diaphragm. However, these experiments do not prove conclusively that the effects of normal plasma are not due to insulin, since crystalline bovine serum albumin and A.D.H. rat plasma may well contain insulin. In this connexion Gemmill (1940) reported that crystalline ovalbumin did not increase the glucose utilization of the isolated rat diaphragm.

Groen *et al.* concluded from their experiments that the insulin-like activity of plasma from normal human subjects and dogs in the rat-diaphragm assay was due to insulin, since the activity was not found in plasma obtained from severely diabetic patients and depancreatized dogs. The validity of this conclusion is, however, doubtful, since Park (1952) and Bornstein (1953) have reported that the plasma of alloxan-diabetic rats contains endocrine factors which inhibit the glucose utilization of the isolated rat diaphragm. The failure of Groen *et al.* to detect insulin-like activity

*Groen and Willebrands (personal communication) have more recently concluded that this variation in sensitivity is not seasonal.

in the plasma of severely diabetic patients and depancreatized dogs, by the rat-diaphragm technique, may be due to the presence of inhibitors in these plasma samples and not to their low insulin content. The fractionation and identification of the material in human plasma responsible for its insulin-like activity in the rat-diaphragm assay would appear to merit urgent attention.

Insulin Content of Normal Human Plasma*

The insulin activity of normal human plasma assayed by the rat-diaphragm technique reported in this paper was found to be 13 milliunits per ml. This is considerably greater than the value of 0.34 milliunit per ml. reported by Bornstein *et al.* (1951b), who used the A.D.H.A. rat assay for insulin. This discrepancy between animal methods and the rat-diaphragm technique described in this paper is illustrated by the A.D.H. rat assay (Table V). In this experiment normal human plasma, assayed by the rat-diaphragm method to contain 13 milliunits of insulin per ml., was found to have no hypoglycaemic effect when injected into A.D.H. rats, though 2 milliunits of insulin produced a highly significant fall of blood-sugar when injected into the same animals under similar experimental conditions. This discrepancy could be due to insulin antagonists in human plasma which antagonize the hypoglycaemic action of insulin in animals but which do not antagonize the action of insulin upon the isolated rat diaphragm *in vitro*, or it could be due to non-specificity of the rat-diaphragm assay for insulin in plasma. Some evidence for the former belief is provided by the report of Weitze and Hagedorn (Hagedorn, 1952). These authors, utilizing the fall in blood sugar of alloxan-diabetic hypophysectomized adrenalectomized rats to assay insulin, reported the insulin activity of normal human plasma after acid alcohol extraction to be ten times the value obtained by Bornstein *et al.* (1951b) for untreated plasma. The high value could result from a separation of insulin from insulin antagonists in the plasma by the extraction procedure which these authors used.

The reason for the discrepancy between the values obtained for the insulin activity of normal human plasma by various workers who have used the rat-diaphragm assay for plasma insulin is not clear. It may be due to differences in specificity between diaphragms obtained from different strains of rat, since some workers have reported wide differences in the sensitivity of the isolated rat diaphragm to insulin. The high values reported in this paper are not due to minor modifications of the technique (Randle, unpublished experiments). Since Ottaway (1953) has reported that small quantities of growth hormone *in vitro* will enhance the glucose utilization of rat diaphragm, the high values for the insulin activity of normal human plasma reported in this paper may result from the presence of growth hormone in the plasma. The insulin activity of acromegalic plasma assayed by the rat-diaphragm method is considerably greater than the insulin activity of normal human plasma, and it may be that this difference is also attributable to the presence of growth hormone in the plasma (Randle, 1954a). The nature of the material responsible for the insulin-like activity of human plasma in the rat-diaphragm assay is being further investigated.

Summary

The claim of Groen *et al.* that normal human plasma will increase the glucose utilization of the isolated rat diaphragm has been confirmed and the evidence for attributing this effect to insulin in the plasma critically re-examined.

The rat-diaphragm technique has been critically explored as a quantitative assay for small amounts of

*Bioassay methods for insulin in plasma almost certainly measure the resultant of the contra-actions of insulin and insulin antagonists present in the plasma. For this reason the term *insulin activity* has been used in this paper in referring to the biologically determined insulin content of plasma.

insulin and applied to the determination of the insulin activity of normal human plasma. By this technique the insulin activity of plasma collected from normal human subjects after a glucose meal was found to be approximately 13 milliunits per ml. This estimate of the insulin activity of normal human plasma is considerably greater than those previously reported by other workers. The possible reasons for this discrepancy are discussed in brief.

The importance of specificity in bioassays for plasma insulin is stressed.

The author wishes to express his gratitude to Professor F. G. Young for much helpful advice and criticism during the course of this work and the preparation of this paper; to Dr. N. R. Lawrie, of the John Bonnett Clinical Laboratories, Addenbrooke's Hospital, Cambridge, for the maintenance and sterilization of syringes; to Mr. G. Baker and Miss D. Cope for technical assistance in these experiments and for the preparation of the figures in this paper. It is a pleasure to thank Mr. D. R. Cox, of the Department of Mathematics, University of Cambridge, for assistance in the statistical analysis of the regression and assay data. The author is indebted to Boots Pure Drug Co., Ltd., for generous supplies of crystalline insulin.

The cost of this work was largely defrayed by an expenses grant from the Medical Research Council.

Meat is easily contaminated, and is an important source of food poisoning. According to figures collected at the seminar, in the United States from 1945 to 1947 32% of the food-poisoning outbreaks were due to meat. In England and Wales in 1950, 68% of the outbreaks affecting more than one person in which the source was identified were due to contaminated meat.

CONGENITAL HEART DISEASE REPORT ON AN UNUSUALLY HIGH INCIDENCE IN ONE FAMILY

BY

J. CYRIL JOYCE, M.B., D.C.H., D.P.H.
Assistant County Medical Officer, Roscommon

AND

SEAN P. O'TOOLE, M.D., F.R.C.P.I.
Consultant Cardiologist, St. Patrick's Chest Hospital,
Castlerea, Co. Roscommon

Congenital heart disease in more than one member of a family, although relatively uncommon, has been reported in the literature on a number of occasions. Abbott (1927) found 11 pairs of brothers and sisters, and Brown (1939) reported six instances. Taussig (1947) has seen four families in which more than one member was affected, and in two of these the condition was transmitted through more than one generation.

The purpose of this paper is to report four cases occurring in one sibship. This is exceedingly rare, and, so far as we can ascertain from the literature, has been reported only once previously. That was by Walker and Ellis (1940-1), who described a father and four out of eight children with persistent ductus arteriosus.

The Family

1. The eldest child was a boy aged 11 years. Signs of persistent ductus were discovered at routine school medical inspection. There was a typical Gibson murmur with thrill, and confirmatory radiological signs. He is awaiting operation.

2. A girl aged 9 showed no cardiac abnormality.

3. A boy aged 8. Signs of persistent ductus were discovered at routine school medical inspection. His lesion was more severe than that of the eldest child. Surgical ligation of ductus was successfully carried out.

4. A girl died in 1946 at the age of 6 months, from what was believed to be pneumonia.

5. A boy aged 5 showed no cardiac abnormality.

6. A boy aged 4. He was the third member of the family with persistent ductus. His was the most severe lesion of the three, there being marked cardiac enlargement and gross engorgement of pulmonary vessels. A successful operation has been carried out.

7. A girl died in 1949, only 13 days old. She was found dead in bed, and the cause was not definitely ascertained.

8. A girl aged 2 years showed no evidence of cardiac abnormality.

9. A boy, a "blue baby," died at the age of 7 weeks. He was seen by one of us a few days before death, and a diagnosis of congenital heart disease was made on the basis of central cyanosis and a moderately loud systolic murmur audible all over the praecordium.

Both parents were examined and found to be normal. There was nothing significant in their past histories; maternal rubella had not occurred, and circumstances were such that adequate nutrition was available. Consanguinity was not admitted. Only a limited investigation of ascendants was possible owing to the fact that most of them resided outside Ireland. No significant abnormality was detected in those examined.

Comment.—In this family there were four definite cases of congenital heart disease, three of them having persistent ductus arteriosus and one cyanotic disease of undetermined type. In addition, two other siblings died in infancy from causes which were not definitely ascertained. In view of

the family history it is possible that a congenital heart lesion may have been a factor in the cause of death. The finding of such an incidence prompted us to review the literature and to consider possible aetiological factors, with particular reference to modern views on the subject.

Aetiology of Congenital Heart Disease

Congenital heart disease and congenital defects in general are believed to be due to genetic or environmental factors.

Genetic transmission, although difficult to prove, has always been considered important. In recent years, however, it has been shown that environment can play a part. Gregg (1941), in a series of 78 cases of congenital cataract occurring after maternal rubella during the early months of pregnancy, found that congenital heart lesions were present in 44. Swan *et al.* (1943) collected details of 31 congenital defects following maternal rubella, 17 of which were cardiac. Of these, seven had patent ductus; the others were varied, but cyanotic cases were not mentioned.

While this is strong evidence in favour of an environmental factor, it does not necessarily mean that maternal rubella is a very important factor in the transmission of congenital heart disease in general. In fact, the available evidence is to the contrary. In Campbell's (1949) series of 300 cases a history of maternal rubella was present in only four instances. In our own experience with a smaller number of cases no instance of maternal rubella has been found. Other environmental factors such as maternal nutritional deficiency have been suggested by Hale (1935) and Warkany (1944). Animal experiments by these workers have shown that congenital defects could be produced in the offspring if the maternal diet was deficient in certain vitamins. Can similar deficiencies cause congenital heart disease in man?

The answer would be obtained if the incidence of congenital heart disease in nutritionally deficient mothers as compared with the normal were known. Needless to say, this would have to be a large-scale survey, carried out as early as possible during pregnancy. So far as we are aware, such a survey has not been done, so that in the present state of our knowledge there is no evidence that maternal nutritional deficiency can cause congenital heart disease in man.

Genetic Factors

The best evidence of a genetic factor would be a positive family history. This is not forthcoming, and may be due to the fact that few women with congenital heart disease marry and have children (Campbell, 1949). However, as Campbell points out, the incidence in collaterals is more common than would be expected by chance. That would certainly be true of the family reported above, in which a genetic factor seems most likely. The collection of further evidence on this matter should be possible in future, in view of the developments of modern surgery. This applies particularly to persistent ductus.

We were unable, in a review of the literature, to obtain figures of the incidence of persistent ductus in population groups, with particular reference to schools. As additional evidence in favour of a genetic transmission of this lesion, we feel that the figures obtained by one of us at school medical inspection in County Roscommon may be of interest.

County Roscommon has a population of 68,000; land acreage is 608,540. The largest urban population is 2,000, so that the population is rural, mainly engaged in farming. The primary school-going population is 10,500, and of these 9,250 were examined routinely at school medical inspection over a three-year period. Fifteen cases of persistent ductus were observed among those examined. Twelve of these were confirmed subsequently by operation, and two of the remaining three by cardiac catheterization. Thus the incidence of persistent ductus among schoolchildren in this county is 1 in 616, or 1.6 per 1,000 examined between the ages of 4 and 15. There was no history of maternal rubella in any of these cases, and, in fact, rubella appears to be

uncommon in rural areas. Consanguinity was not admitted in any case. However, the tendency of farming or village populations to marry locally may be of importance.

This apparently high incidence in a rural population, if confirmed by a larger survey, would be additional evidence of a recessive genetic factor in the transmission of persistent ductus, and perhaps of congenital heart disease in general.

Summary and Conclusions

Details of four siblings with congenital heart disease are presented.

They include three cases with persistent ductus and one with cyanotic heart disease.

The aetiology of congenital heart disease is discussed and evidence indicating the importance of a genetic factor is presented.

Addendum.—Since this paper was sent for publication the diagnosis of persistent ductus in the boy aged 11 has been confirmed at operation.

PANCREATICO-DUODENECTOMY FOR RELAPSING PANCREATITIS

BY

T. EDWARD WILSON, M.D., M.S., F.R.C.S.

Sydney, Australia

The following case is reported as an example of the excellent result which may be obtained in relapsing acute pancreatitis following a pancreatrico-duodenectomy. Although such a result does not help to elucidate the problem of the aetiology of this disease, freedom from further attacks should follow that operation. However, it is not denied that excellent results, either temporary or permanent, may also sometimes be obtained by the use of splanchnicectomy, choledochoduodenostomy, etc.

For a variety of reasons a number of surgical measures have been proposed for the treatment of relapsing pancreatitis. These include cholecystectomy and choledochostomy (Mowat, 1951); choledochoduodenostomy (Burt, 1953); choledochoduodenostomy with total diversion of the bile (Barclay, 1950); splanchnicectomy, unilateral (Mallet-Guy and de Beaujeu, 1950) or bilateral (Connolly and Richards, 1950); subtotal gastrectomy, to cut off the secretin mechanism (Richman and Colp, 1950); sphincterotomy (Doubilet and Mulholland, 1948); and pancreatrico-duodenectomy (Cattell and Warren, 1952). There is no doubt that pancreatrico-duodenectomy would be the accepted method of treatment in cases with demoralizing pain if it were not for the magnitude of the operation and the risks it entails. Nevertheless, whatever operation is performed it should allow the pancreas and other abdominal viscera to be explored. It is especially important to determine whether or not the gall-bladder and common bile duct are normal.

According to Horton (1950) the first successful pancreatrico-duodenectomy for pancreatitis was carried out in 1944 by Clagett. Horton was of the opinion that pancreatitis should be treated by pancreatrico-duodenectomy only in most exceptional cases. On the other hand, in 1952 Cattell and Warren concluded that of the procedures they had used pancreatrico-duodenectomy had given the best results, and they considered it the current method of choice in the treatment of relapsing pancreatitis.

Case Report

A man aged 40 was referred to me by Dr. R. Jennaway and was admitted to Sydney Hospital on May 23, 1953. For 18 months he had complained of attacks of epigastric pain, often extremely severe and sometimes lasting for 24 hours, but not related to meals. The pain extended to both sides of the abdomen and was only partly relieved by morphine. Rarely, it radiated to the back. At first the attacks occurred every two to three weeks, but for the previous three months attacks occurred every two or three days. On a few occasions vomiting accompanied the pain. Between the attacks his appetite had been good. He had never been jaundiced, and Graham's test showed no abnormality in March, 1952. On February 10, 1953, laparotomy revealed an enlarged indurated head of the pancreas, and the surgeon considered this to be malignant. Other viscera, including the biliary tract, appeared normal, and there was no evidence of any metastasis. Three days later during a severe attack of pain the urinary diastase level was 100 units. Despite the severity of the attacks of pain there was no evidence of alcoholism or drug addiction.

On May 23 his general condition was still good despite the loss of 2 stone (12.7 kg.) in weight during the previous three months, and examination of the abdomen showed no abnormality. His serum bilirubin level was 0.1 mg. per 100 ml. On May 26 a barium-meal examination showed that the stomach was empty in four hours. A deformity with some constriction of the second part of the duodenum was present, and this was producing a mild partial obstruction. (Similar appearances have been reported by Cattell and Warren (1952) in relapsing pancreatitis.)

On May 28 a pancreatrico-duodenectomy was performed. Through an upper midline incision the pancreas was palpated and the replacement of its head and body by a hard irregular mass was confirmed, but the consistency of this mass was not uniform. The terminal portion of the tail of the pancreas appeared normal. The mucosa of the duodenum was intact though slightly hypertrophic, and no obstruction of the lumen of the duodenum was demonstrable. The biliary tract and liver appeared normal. There were a few small soft lymph nodes along the upper border of the pancreas, but no definite metastasis was detected.

The peritoneum to the right of the second part of the duodenum was incised, the stomach was divided immediately proximal to the pylorus, and the supraduodenal portion of the common bile duct was divided. The duodenum, together with the head and the body of the pancreas, was dissected free from the superior mesenteric vessels and other structures, and the tail of the pancreas was divided through what appeared to be normal pancreatic tissue about an inch (2.5 cm.) to the right of the hilum of the spleen. Reconstruction was then carried out in the order shown in the diagram. The end of the jejunum was closed about a small tube and was sutured to the peritoneum at the upper end of the abdominal wound. The inner end of this tube (which contained several holes) was passed down the jejunum and into the common bile duct, while its outer end was brought out through the wound. The anastomosis between the common bile duct and the jejunum was made with an outer interrupted layer of cotton sutures and an inner continuous layer of 00 catgut. The cut end of the remnant of the pancreas was fixed into an incision in the side of the jejunum with two layers of interrupted cotton sutures. No

tube was inserted into the pancreatic duct, which did not appear to be dilated. The severed end of the stomach was anastomosed end to side to the jejunum with an outer interrupted layer of cotton sutures and two continuous inner layers of 00 catgut. A drainage tube was inserted down to the area from which the head of the pancreas had been removed.

The pathologist (Dr. L. R. Finlay-Jones) reported that the excised specimen consisted of a segment of duodenum

Diagram showing the order of reconstruction after pancreatrico-duodenectomy. The remnant of the pancreas was implanted end to side in the jejunum between the common bile duct (CBD) and the stomach. The end of the jejunum was closed around a tube and then fixed to the parietal peritoneum (P).

15 cm. long and 3 cm. in diameter, attached to which was a hard irregular piece of pancreas 8.5 cm. long and 5 cm. in diameter, and containing a cyst about 1.5 cm. in diameter. The ampulla of Vater and the main pancreatic duct were patent. Microscopic examination showed that the pancreatic parenchyma was traversed by bands of cellular scar tissue and granulation tissue. There were collections of inflammatory infiltrate consisting of eosinophils, plasma cells, and polymorphs; and pigment-containing histiocytes were conspicuous in many regions. The muscle coat of the attached duodenum showed similar inflammatory changes. The appearances were consistent with recent attacks of pancreatitis. No evidence of carcinoma was found.

For the first 48 hours after operation the stomach was aspirated, and at the same time 4% glucose in N/5 saline was given intravenously. Thereafter the diet was increased gradually. Only a few ounces of bile a day drained from the tube in the common bile duct. This tube was removed after eight days, and the wound was healed within a further five days.

On June 19 the serum bilirubin level was 0.5 mg. per 100 ml. and a glucose-tolerance test gave readings of 98, 105, 128, 117, and 120 mg. per 100 ml.; there was no glycosuria. On June 24 the dried faeces contained total fat 57% (unsplit fat 42%, split fat 15%); and the urinary diastase level was 5 units.

Convalescence was uneventful. The patient was discharged home on June 27 with the wound healed, and has remained symptom-free. He resumed work as a mechanic on July 13.

Discussion

Prior to operation the lack of jaundice, the recurrent attacks of severe abdominal pain, the well-being of the patient, and the elevated urinary diastase during an attack of pain all suggested a diagnosis of relapsing acute pancreatitis rather than carcinoma of the pancreas. At operation the small areas of calcification, which incidentally had not been shown by radiography, the lack of uniform hardness of the gland, and the absence of metastases were also in keeping with the former diagnosis.

Pain is a frequent accompaniment of carcinoma of the pancreas, but it is not usually in the form of intermittent severe attacks. Also, the urinary diastase level is rarely

more than slightly raised in the presence of a carcinoma of the pancreas. In this case the destruction of the pancreas had not been extreme and had not led to diabetes or to steatorrhoea. Even after operation no insulin or pancreatin had been required.

Biopsy of the mass in the pancreas was not performed, and is probably never indicated. There is always the doubt whether the portions selected for examination are representative; and biopsy may be followed by dissemination of malignant cells or a pancreatic fistula may develop.

Although the mucosa of the pyloric antrum was retained, its resection may be advisable, as the chance of jejunal ulceration would then be reduced. However, this patient has had the good fortune not to develop that or any other complication.

Because of the high operative mortality rate and the high recurrence rate doubt has been thrown on the possibility of cure of carcinoma of the pancreas by pancreatectomy (Cattell and Pyrek, 1949). It is, however, reasonable to assume that the mortality rate for pancreatrico-duodenectomy will be much less in relapsing pancreatitis than in patients with carcinoma of the pancreas, and it may be concluded that pancreatrico-duodenectomy has a place in the treatment of relapsing pancreatitis whenever there is any doubt about the coexistence of a carcinoma or when the condition has failed to respond satisfactorily to other methods of treatment.

PANCREATICO-DUODENECTOMY OPERATION ON TWO ELDERLY PATIENTS

BY

GORDON FERGUSON, M.B., F.R.C.S.

Late Senior Surgical Registrar, Hastings Hospital Group
