It is noteworthy that one patient, who had been burnt with nitric acid, had a fistula into the trachea and false passages in his oesophagus, the results of attempts at oesophagoscopy dilatation. Another patient, who had swallowed hydrochloric acid, had burnt the lower end of the oesophagus and also the pylorus, producing a stricture at each site. Yet another patient had had what appeared to be complete obliteration of his oesophagus for a period of 19 years. Patience is required in treating strictures of this nature by autodilatation, and the treatment must be continued for several years, but the final result should be a complete return to normal. Ten patients have been treated in this way in the past 20 years.

Congenital Atresia of the Oesophagus

It is very pleasant to finish my address by mentioning the great progress which has been made in the treatment of this anomaly. The condition was described by Gibson in 1697 and again by Sir Arthur Keith (1910) and others, but no patient was successfully operated upon until 1939, when a staged operation was carried out by Ladd (1944). The first completely successful operation of direct anastomosis was carried out in 1941 and reported by Haight and Towsley in 1943.

The commonest type of deformity is an atresia of the oesophagus at the level of the vena azygos arch, with the lower segment of the oesophagus arising from the trachea. This type of deformity accounts for 80% of the patients,

FIG. 4.—Radiological appearance of congenital atresia of the oesophagus with fistula. The blind upper segment can be seen, and the fact that air is present in the stomach and intestines shows that there is a fistula between the lower segment and the trachea.

and in most of the others there is an upper and lower blind segment without any communication with the trachea. It is difficult to estimate the frequency of this anomaly because even now many infants die from what is attributed to pulmonary or cerebral conditions and the true diagnosis is not suspected. Similarly death may be attributed to an imperforate anus when the real cause is an oesophageal anomaly. Cyanosis and attacks of choking in the newborn infant should at once suggest the possibility of an atresia of the oesophagus, and if a well-lubricated catheter, passed down the oesophagus via the mouth, is arrested at a point 10 cm. from the alveolar margin it is almost certain that the condition exists. The infant should then be transferred to a centre where x-ray confirmation and operation can be carried out (Fig. 4).

Both the operation and the anaesthesia require special experience and must be carried out very delicately. The subsequent nursing is of equal importance, and unless experienced and conscientious nursing is available it is useless to attempt the surgical treatment of these patients.

In my own first successful case the patient is now 7 years old, and altogether I have 17 patients who have recovered from the operation.

Conclusion

Many of the procedures in oesophageal surgery have now passed the pioneer stage and taken their place amongst the accepted operations. Some of them will always carry a very great risk, and for this reason it is essential that diagnosis should be accurate and that due consideration is given to the problem before embarking on this form of surgery. The treatment of cancer is still largely palliative but is none the less well worth while carrying out. Reflux oesophagitis presents a complex problem affecting patients of all ages. The symptoms may vary from a minor disturbance to a crippling or killing disease, and much work is needed to elucidate the underlying causes. The gastric secretion in infants requires further investigation and in adults there is scope for the simultaneous estimation of gastric and oesophageal pressures. The association of duodenal ulcer with reflux oesophagitis demands close study, always bearing in mind the possibility that in some patients at least the reflux oesophagitis appears to precede the formation of the hernia.

The problems connected with the diagnosis and treatment of oesophageal conditions require special methods and technique. This does not imply still narrower specialization, and in fact a broad approach is needed, because to understand and appreciate the various conditions affecting the oesophagus it is essential to have a knowledge of abdominal conditions in general and peptic ulceration and its complications in particular. Familiarity with the oesophagoscope and experience in paediatric surgery are also required. In fact the narrower the field the more general must be the approach.

AMYLOIDOSIS IN RHEUMATOID ARTHRITIS, AND SIGNIFICANCE OF "UNEXPLAINED" ALBUMINURIA

A REPORT OF EIGHT CASES

BY

GEORGE R. FEARNLEY, M.D., M.R.C.P.

Physician and Lecturer in Medicine

AND

RITA LACKNER, M.D., M.R.C.P.

Medical Registrar

Department of Medicine, Postgraduate Medical School of London, W.12

The complication of rheumatoid arthritis by amyloidosis is more often diagnosed by the pathologist than by the clinician. Fingerman and Andrus (1943) found amyloid deposition in 13 of 61 (21%) necropsied cases of rheumatoid arthritis. Teilum and Lindahl (1954) have reported an instance of 60%. By contrast, Hench and co-workers (1948) have stated that "the association of amyloidosis and rheumatoid arthritis rarely occurs, and then only in severe cases of long duration." On the clinical side, reports have been for the most part confined to single or at most two cases. The only clinical investigation of a population of rheumatoid arthritis for amyloidosis has been that of Unger *et al.* (1948).

who studied 52 rheumatoid patients by means of a modified Congo-red test, and found the complication to be present in six. Reece and Reynolds (1954) found five instances of amyloidosis with rheumatoid arthritis when all patients with the latter condition who attended their hospital from 1935 onwards were reviewed.

Our interest in the association of these two conditions was aroused when a patient with mild rheumatoid arthritis of about four years' duration died of renal failure. The ante-mortem diagnosis was chronic nephritis; at necropsy the cause of the renal failure was found to be amyloidosis, a possibility not entertained because the arthritis was so mild and of such short duration. We therefore decided to find out whether this complication could be recognized during life with greater certainty than previously. The initial problem was to find a clinical pointer. Splenomegaly and sometimes hepatomegaly occur not infrequently in uncomplicated rheumatoid arthritis and therefore cannot be taken to indicate the presence of amyloidosis. Since the essential morbidity of the complication is due to renal involvement, it seemed likely, that the most reliable guide would be albuminuria. We therefore screened all patients with rheumatoid arthritis seen by us over a one-year period (July, 1953, to July, 1954) for albuminuria, and investigated its cause when found.

Clinical Material

A total of 183 cases, both in-patients and out-patients, were seen by us. Each of these patients had, in our opinion, unequivocal rheumatoid arthritis; patients whose diagnosis was doubtful were not included. Fig. 1 shows the age and sex distribution of the patients. Fig. 2 shows the duration of their rheumatoid arthritis. It can be seen that there was a fairly high proportion of patients whose disease was of short duration.

FIG. 1.—Age distribution of 183 patients with rheumatoid arthritis.

FIG. 2.—Duration of disease in 183 patients with rheumatoid arthritis.

a week. The number of tests per patient varied from 1 to 25, depending on the number of out-patient attendances or the duration of stay in hospital, or a combination of both. A trace of albumin on only one occasion was disregarded. Those patients who showed a more persistent albuminuria were further investigated; a catheter or mid-stream specimen was taken and, where necessary, the appropriate urological investigation made. Of the 183 patients, 24 were found to have significant albuminuria: 5 of the 24 had urinary infection, 2 G.U. tuberculosis, 3 congestive heart failure, 1 chronic nephritis, 1 drug reaction, and 12 cases were unexplained. Of the latter 12 patients, one (F.P.) died of an acute surgical emergency before she could be further investigated, and at necropsy extensive amyloidosis with renal involvement was found. For various reasons it was not possible to investigate a further four of these patients. The seven remaining cases were investigated by the modified Congo-red test of Unger *et al.* (1948) or by liver biopsy, or by both methods.

Modified Congo-Red Test of Unger

Unger *et al.* have introduced a modification of the Congo-red absorption test, which we believe to be greatly superior to the test as usually performed. In brief, their modification consists in obtaining frequent samples during the first ten minutes after the injection of the dye, so that a zero time concentration can be obtained by extrapolation. The advantages over the standard Congo-red test in which a two- or four-minute sample is taken and the absorption calculated at one hour are as follows: errors due to incomplete mixing, which may take up to ten minutes or longer, are avoided; false-negative results due to very rapid fixation of the dye by massive amyloid deposits are also avoided. With the standard Congo-red test at least 90% absorption at one hour is required to constitute a positive result: Unger *et al.* believe that 35% or greater absorption at 30 minutes is good evidence of amyloidosis when their method is used: we have no reason to differ from their conclusion.

We modified the method slightly in that we set up a slow saline drip (10 drops a minute) which could be discontinued for the obtaining of blood samples, thus avoiding the discomfort to the patient of frequent venepunctures. Before each sample was obtained about 5 ml. of blood was aspirated and discarded in order to avoid error from saline dilution. Where necessary the volume of blood removed during the test was replaced by cross-matched bank blood.

Results

Fig. 3 shows the data obtained when the Congo-red test, as described above, was performed on three patients. The logarithm of Congo-red concentration is plotted against time, and then the theoretical zero time concentration is obtained by extrapolation from the readings made during the first 10 minutes after injection.

Patient A.H.—Rheumatoid arthritis with splenomegaly

FIG. 3.—Congo-red absorption curves in three patients.

and hepatomegaly, but without albuminuria. The test was negative, there being only 19% absorption at 0-30 minutes. The test was also negative when the absorption at 60 minutes was calculated from the two-minute or four-minute sample (36% and 31% respectively), as is done with the standard Congo-red absorption test.

Patient A.C.—Rheumatoid arthritis with albuminuria. The test was positive, there being 55.7% absorption at 0-30 minutes. Note that when the absorption at 60 minutes was calculated from the two-minute or the four-minute sample, as in the standard test, the result was negative.

Patient H.S.—Rheumatoid arthritis, splenomegaly, hepatomegaly, and albuminuria. The test at 0-30 minutes was strongly positive (92%), as was also the absorption at 60 minutes calculated from either the two-minute or four-minute sample (97% and 95% respectively).

The table shows the data of the seven patients investigated and of the patient who showed amyloidosis at necropsy. Albuminuria was constant in every case except the latter, who showed only two positive tests out of five. The diagnosis was confirmed by liver biopsy in the first four patients

Case	Sex and Age	Duration	Liver	Spleen	No. of Urine Tests	Positive Albumin Tests	Congo Red 0-30 min. Absorption	Liver Biopsy
H.S.	M 30	1 yr.	+	+	25	25	92%	+
J.L.	M 74	8 "	+	0	10	10	90.9%	+
W.R.	F 38	16 "	+	0	12	12	77.9%	+
A.S.	F 61	11 "	+	0	13	13	53.5%	+
F.L.	F 67	18 "	0	+	13	12	Not done	+
A.C.	M 39	12 "	0	+	15	15	28.5% 55.7% 77%	Not done
N.B.	M 55	15 "	0	+	3	3	P.m. confirmation extensive amyloidosis	+
F.P.	F 69	18 "	+	0	5	2		+

of the table. In Case F.L. severe flexion contractions of the elbows made it impracticable to perform the Congo-red test, and the diagnosis was made by liver biopsy alone. A liver biopsy was considered to be unnecessary for the next two patients. In Case A.C. the Congo-red test two months after the onset of albuminuria was negative. The albuminuria persisted, and when the test was repeated ten months later it had become positive with 55.7% absorption from

FIG. 4.—Data of Case A.C.

0-30 minutes (see Fig. 4). In Case N.B. 77% absorption from 0-30 minutes was considered to be sufficiently good evidence of amyloidosis.

The duration of rheumatoid arthritis in these patients at the time the diagnosis of amyloidosis was made ranged from one to eighteen years, and six of the eight patients had had their disease for more than ten years. Both liver and spleen were palpably enlarged in only one patient, H.S. Hepatomegaly alone was present in four patients, and splenomegaly alone in three. This confirms that amyloidosis may be present without enlargement of both the liver and spleen,

and, conversely, both these organs may be palpable when the quantitative Congo-red test is strictly negative (Case A.H., Fig. 3).

In two patients, H.S. and W.R., there was a past history of tuberculosis. Patient W.R. had had pulmonary tuberculosis some twenty years previously, complicated by tuberculous involvement of one knee-joint, for which arthrodesis had been performed. Her rheumatoid arthritis is relatively mild, and there is no evidence of active tuberculosis. Case H.S. is described briefly below.

This patient was aged 28 on his first admission to Hammersmith Hospital in July, 1952. In 1948 bilateral pulmonary tuberculosis had been diagnosed. Chemotherapy and a right pneumothorax failed to control the disease in the right lung, although the lesions in the left lung became inactive. In May, 1950, a right thoracoplasty was done, since when to the time of writing there has been no evidence of active tuberculosis. In July, 1952, he was admitted to Hammersmith Hospital with fever, tachycardia, and flitting polyarthritides, the onset of which was preceded by a sore throat three weeks before. A diagnosis of rheumatic fever was made, and sodium salicylate, 120 gr. (8 g.) a day, was given. At first his fever and joint symptoms responded, but, in spite of continued salicylate therapy, both fever and joint involvement reappeared a fortnight later. Gradually over the next three months the picture of rheumatoid arthritis appeared, with symmetrical involvement of hands, elbows, knees, and feet. Until May, 1953, the urine was free from albumin, and in that month albuminuria first appeared. Albuminuria (4.6 g. a day) then became persistent. In July, 1953, he was readmitted for further investigation. At that time the spleen but not the liver was palpably enlarged. Congo-red absorption and liver biopsy were as shown in the table. Subsequently the liver enlarged 6 in. (15 cm.) below the costal margin.

It should be noted that this patient had a past history of extensive tuberculosis, and it is entirely probable that this may have contributed to the development of amyloidosis. That the rheumatoid arthritis played a part, however, is indicated by the absence of the albuminuria until the arthritis had been present for a year, and by the subsequent rapid enlargement of the liver—all in the absence of any evidence of tuberculous reactivation.

Comment

Amyloidosis is one of the few potentially fatal complications of rheumatoid arthritis. Its recognition is therefore of some importance for prognosis. The finding of eight patients with this complication out of 183 patients with rheumatoid arthritis seen throughout a year suggests that amyloidosis in this disease is by no means rare. Since rheumatoid arthritis is extremely common, and since conditions which in the past produced amyloid deposition are now largely controlled by chemotherapy, it seems probable that rheumatoid arthritis may come to be the principal cause of amyloidosis. Missen and Taylor (1955), in a survey of necropsy material at the Postgraduate Medical School, found amyloidosis to be present in 8 of 48 patients with rheumatoid arthritis; each of these cases had shown proteinuria during life. We believe that attention to the presence of albumin in the urine of patients with rheumatoid arthritis would bring to light more of these cases.

Summary

Out of 183 patients with rheumatoid arthritis seen throughout a one-year period, eight were found to be suffering from amyloidosis.

The clinical pointer to the complication was albuminuria, unexplained by routine investigations.

The modified Congo-red test of Unger *et al.* was found to be more reliable than the standard Congo-red test in making the diagnosis.

In all patients the rheumatoid arthritis could be held responsible for the complication; in one, pre-existing tuberculosis may have played a part.

We wish to thank Dr. Sheila Sherlock and members of her firm for the liver biopsies; our colleagues, especially Dr. E. G. L. Bywaters, for permission to study their patients; and Miss Jeanette Pirkis for very efficient technical assistance and for drawing the illustrations.

MALARIAL THERAPY IN THE NEPHROTIC SYNDROME

BY

A. G. SHAPER, M.B., Ch.B., D.T.M.&H.

From the Tropical Diseases Centre, Sefton General
Hospital, Liverpool

The effect of infection on the nephrotic syndrome has long been known, and massive diuresis with disappearance of oedema and great diminution in proteinuria has been observed to follow a variety of agents, including measles, chicken-pox, pneumonia, infusions of plasma or dextran, large doses of urea, or corticotrophin. The occasional dramatic response elicited by one or other of these agents has led several physicians to the use of malaria, as this was an acute fever that could be easily induced and readily controlled. The reasons for using malaria as a therapeutic agent have varied from that of Gairdner (1952), who considered that there was sufficient clinical evidence for the empirical use of acute febrile infections, to that of Byrne (1952), who holds that the response shown is due to stimulation of the acute defence phase of the adaptation syndrome of Selye. In conditions such as the nephrotic syndrome, where treatment after treatment may follow with no sign of symptomatic relief, "it behoves the physician to attempt in turn those agents which are known to have initiated remissions, as, in the earliest stages at least, this condition may be reversible" (Gairdner, 1952).

There is still much discussion and dispute regarding the nomenclature and classification of renal disease, and for the purpose of this report the term "nephrotic syndrome" is used. This term (Squire, 1953) is applied to those cases with oedema, proteinuria, and hypoalbuminaemia, but without hypertension, nitrogen retention, or electrolyte disorder, and without an appreciable excess of red blood cells in the urine. The majority of cases in this series can be regarded as Ellis Type II nephritis, but as this description implies the presence of particular pathological changes, and as in so many patients with renal disease the essential pathology is not known, it is justifiable to use a wider descriptive term.

Malarial therapy has been used over a period of several years in the Tropical Diseases Centre, using strains of benign tertian malaria, and occasionally *Plasmodium ovale*, in patients with the nephrotic syndrome. In some it was used as a primary procedure, in others as a last resort after many varied and unsuccessful forms of therapy. Brief clinical reports are given of seven patients in whom the infection had been sufficiently severe and long-continued to regard them as having undergone "malarial therapy." The methods of infection and the management of induced malaria are dealt with by Shute (1952).

Method

Selection of Cases.—There are no precise indications for the use of malarial therapy. It is usually reserved for patients with a nephrotic syndrome which has failed to respond to more conservative forms of treatment.

Duration of Treatment.—The patient should be allowed to have as many rigors as he is capable of withstanding. The indications for cutting short the treatment are a marked deterioration in general condition, sustained fever, or severe oliguria.

Interruption of Quotidian Fever.—In most cases the fever initially assumes a quotidian periodicity but then settles down to a tertian periodicity. In some the quotidian fever persists, and in order to procure relief from the daily paroxysm a single dose of bismuth sodium thioglycollate ("thio-bismol"), 0.2 g. intramuscularly, may be given. This will usually cause the fever to become tertian in periodicity. Alternatively, small doses of quinine may be given for one day. This may stop the fever, but it will relapse in a week or two.

Method of Eradication of Malarial Infection.—In all patients the fever can rapidly be terminated by giving full doses of chloroquine, mepacrine, or quinine for a few days. In those infected by blood inoculation from other patients suffering from malaria this will eradicate the infection. In patients infected by parenteral injection of sporozoites, or by feeding infected anopheline mosquitoes, the treatment must be continued with a ten-day course of pamaquin, 10 mg. three times a day (Adams and Maegraith, 1953), to sterilize the exo-erythrocytic cycle of parasite development which results from this mode of infection, or a relapse will occur.

Case 1

The patient, a man aged 29, had a history of oedema of the lower limbs and puffiness of the face, associated with some lumbar backache over a period of six weeks. On admission there was pitting oedema of the lower limbs of moderate severity and the urine contained a moderate amount of protein, granular casts, and a few red blood cells. The blood pressure was 130/80 mm. Hg; the retinal vessels were normal. Other findings were: haemoglobin, 100%; serum proteins, 2.45 g.%, with reversal of the albumin/globulin ratio; blood urea, 28 mg. per 100 ml. and serum cholesterol, 262 mg. per 100 ml. The patient was observed for three months, during which time he was treated with a high-protein salt-free diet; although the serum protein level rose to 5.67 g.% the oedema gradually increased in severity until it was generalized and extreme.

Malarial Therapy.—He was infected with a strain of *P. vivax*, using infected anopheline mosquitoes. After a short initial period of irregular fever the temperature assumed the usual tertian periodicity. After four pyrexial episodes associated with severe rigors, his oedema had further increased, so that even in the sitting position it extended to his cervical region. There was a marked reduction in urinary output, accompanied by gross haematuria. The fever was stopped with chloroquine.

Four days after the subsidence of fever his urinary output increased to 80–100 fl. oz. (2,270–2,840 ml.) daily, on an intake of 40–50 fl. oz. (1,140–1,420 ml.). This diuresis continued for four weeks, leaving only minor residual oedema of the legs and sacrum. The diuresis then ceased, and over the next two weeks there was a slight increase in the oedema. As a relapse had not occurred the patient was reinfected with benign tertian malaria, and developed a gross haematuria, followed after 24 hours by a temperature rise and a rigor. After four pyrexial episodes, the haematuria was still present and the oedema was more marked. The fever was interrupted for one week with bismuth sodium thioglycollate, and its reappearance was again preceded by gross haematuria, followed by increasing oedema. After a further five pyrexial episodes the fever was arrested with chloroquine. During the next eleven days

there was a moderate diuresis, the urinary output exceeding fluid intake by an average of 10 fl. oz. (284 ml.) daily. At this stage the general condition was very good, there was minimal oedema of the ankles on walking, and the urine showed a trace of protein but no blood or casts.

Frequent estimations of the blood urea during the course of the malaria showed fluctuations up to 50 mg. per 100 ml. The serum protein fell to 3.77 g.% in the first week of fever, rising after two weeks to 5.02 g.% and falling to 4.7 g.% at the termination of the infection six weeks after commencement. There was constant reversal of the A/G ratio.

Six months later the patient was readmitted, having suffered a relapse of his initial sporozoite infection. This had again been heralded by haematuria, followed two days later by fever. In the interim he had remained extremely well, with only slight swelling of the ankles on moderate exercise—for example, dancing. On examination he had no oedema, and his blood pressure was 110/65 mm. Hg. The serum proteins were 6.79 g.% (albumin 2.54 g., globulin 4.25 g.), and the blood urea 25 mg. per 100 ml.; the urine contained a moderate amount of protein, a few granular casts, and a small number of red blood cells. During the ten days over which the patient was observed during treatment with quinine and pamaquin his urinary output exceeded his intake by an average of 19 fl. oz. (540 ml.) daily.

Subsequent History.—Eighteen months after the start of malarial treatment the patient remained well and was carrying on his employment as a travelling salesman. He felt tired occasionally, but had no swelling of the legs even on continued exercise. There was no sacral or limb oedema, the fundi were normal, and the blood pressure was 130/90 mm. Hg. The urine contained a small amount of protein, a few granular casts, and some red blood cells. The serum proteins were 7.1 g.% (albumin 4.04 g., globulin 3.06 g.); serum cholesterol, 274 mg. per 100 ml.; and blood urea, 25 mg. per 100 ml.

Case 2

The patient, a man aged 47, had suffered from swelling of the lower limbs, which slowly increased over the 20 months prior to his admission. On admission there was marked pitting oedema of the lower limbs, scrotum, and sacrum, with ascites and oedema of the lower abdominal wall. The blood pressure was 180/95 mm. Hg; blood urea 54 mg. per 100 ml.; and serum cholesterol, 199 mg. per 100 ml.; the urine contained a trace of protein, with granular casts and a few red blood cells. Abdominal paracentesis was done on several occasions.

Malarial Therapy.—The patient was infected intravenously with sporozoites of benign tertian malaria, and became febrile after 12 days; he subsequently had eight severe paroxysms with rigors. During this period his oedema and ascites increased, his haemoglobin level dropped from 85% to 37%, and there was a marked reduction in his urinary output. The blood urea rose to 60 mg. per 100 ml., and on account of his poor general condition the malaria was stopped with chloroquine. The plasma proteins after malaria therapy were 4 g.% (albumin 2.53 g., globulin 1.47 g.). In the next four weeks no diuresis occurred and abdominal paracentesis had to be repeated on several occasions. The patient returned home and remained in bed, taking a self-prescribed remedy of lemon-juice, tartaric acid, and magnesium sulphate. After three weeks at home he noticed an obvious increase in his daily urinary output, and one week later his sporozoite-induced malaria relapsed. He continued to have paroxysms for three weeks before he returned to hospital. He then had no ascites or oedema of the abdominal wall, and there was only minimal pitting oedema of the lower limbs. After two further rigors in hospital the malarial infection was eradicated with a course of quinine and pamaquin. The blood pressure was 130/80 mm. Hg; blood urea, 60 mg. per 100 ml.; and the urine showed a heavy albumin deposit, with granular casts and occasional red blood cells. No estimation of serum proteins was made.

Subsequent History.—One year later he was back at work as a lorry driver. He had had no swelling of his legs, but there was slight breathlessness on exertion. There was no anaemia or oedema of his lower limbs, and his fundi were normal. The blood pressure was 180/100 mm. Hg, and the urine contained a large amount of protein but no casts or blood cells. Serum proteins were 5.4 g.% (albumin 4.2 g., globulin 1.2 g.); serum cholesterol, 187 mg. per 100 ml.; and blood urea, 138 mg. per 100 ml.

Case 3

A man aged 52 complained of increasing swelling of the lower limbs, puffiness of the face, and dyspnoea on exertion over the two months prior to admission. On admission there was moderately severe oedema of the lower limbs and sacrum, the blood pressure was 160/95 mm. Hg and the urine contained protein and hyaline and granular casts. The serum proteins were 4.56 g.%, with a reversed A/G ratio; blood urea, 32 mg. per 100 ml. and serum cholesterol, 250 mg. per 100 ml.

Malarial Therapy.—The patient was infected with benign tertian malaria by intravenous blood inoculation; after seven days his temperature rose sharply, and he had malarial paroxysms on 14 successive days. A small dose of quinine was given, and this produced an apyrexial period of seven days, which was followed by a further five rigors before the malaria was arrested therapeutically. Over this period the haemoglobin dropped from 85% to 30%, the blood urea rose to 54 mg. per 100 ml., and the serum proteins fell to 4.04 g.% (albumin 1.41 g., globulin 2.63 g.).

During the 24 days of malarial treatment the urinary output varied from 20 to 50 fl. oz. (570 to 1,420 ml.), but at no time did the output exceed the fluid intake. Two days after the malaria had been treated a diuresis began; this persisted for three weeks, during which the patient remained in hospital. The average daily excess of output over intake was 20 fl. oz. (570 ml.), no allowance being made in this calculation for the fluid loss via skin, respiration, and stools. On discharge the patient still had a moderate degree of pitting oedema of the lower limbs, but the diuresis did not seem to be diminishing. The urine still contained protein and casts.

Subsequent History.—For one year after discharge he led a sedentary life and had not returned to work. He remained dyspnoeic on exertion, and noticed slight swelling of his ankles on moderate exercise, but there had been no marked oedema. On examination his general condition was good, but there was a small left pleural effusion. His blood pressure was 200/120 mm. Hg; blood urea, 64 mg. per 100 ml.; serum cholesterol, 350 mg. per 100 ml.; and serum proteins, 5.21 g.% (albumin 2.9 g., globulin 2.31 g.). The urine contained a moderate amount of protein, granular and epithelial casts, and a few red blood cells.

Case 4

This patient, a youth of 18, was admitted three months after the gradual onset of swelling of the legs and face, associated with a feeling of tiredness. He had been treated with antibiotics, mersalyl, ion-exchange resins, and dietary measures, all without success. On admission there was marked ascites with oedema of the lower limbs, sacrum, genitalia, and arms, and in addition there were bilateral pleural effusions. The blood pressure was 135/90 mm. Hg; serum proteins, 4.18 g.% (albumin 1.11 g., globulin 3.07 g.); serum cholesterol, 395 mg. per 100 ml.; and blood urea 68 mg. per 100 ml. The urine contained protein, many granular casts, a few hyaline casts, and a few red blood cells.

Malarial Therapy.—He was infected with *P. vivax* by intravenous blood inoculation, and within a period of four days (April 26) developed gross haematuria, followed by pyrexia, and a sudden increase in the oedema. He then suffered nine malarial paroxysms, and during this period showed no tendency to diuresis. His urinary output fell

gradually to about 15 fl. oz. (420 ml.) daily, his haemoglobin dropped from 80% to 30%, and there was a marked deterioration in his general condition. The malaria was interrupted by subcurative quinine treatment (May 11), and an abdominal paracentesis relieved his distress. Twelve days (May 23) later fever recommenced, and he suffered a further nine paroxysms. There was no diuresis during this time, and further abdominal paracentesis was required. The malarial infection was then eradicated with chloroquine (June 4). During the next three months no diuresis occurred. Details of the blood chemistry are set out in the Table.

Blood Chemistry at Intervals During the Malarial Fever in Case 4

	April 29	May 4	May 9	May 14	May 24	June 1	July 31
Total protein (g.%)	4.91	4.46	3.79	4.30	3.46	3.26	2.96
Albumin (g.%)	1.61	2.24	1.46	1.63	1.45	1.41	1.52
Globulin (g.%)	3.92	2.22	2.46	2.67	2.01	1.85	1.44
Blood urea (mg. per 100 ml.)	80	68	60	61	46	53	51
Cholesterol (mg. per 100 ml.)							543

Subsequent History.—Over a period of four months following malarial therapy he remained on a high-protein diet with gradual decrease in the oedema. He has been discharged from hospital with pitting oedema of a moderate degree.

Case 5

A woman aged 25 had noticed a gradual swelling of the lower limbs, with progressive increase in weight over a period of eight months. On admission she had gross oedema of the lower limbs and thighs. The blood pressure was 140/95 mm. Hg, and the urine contained protein, granular casts, and an occasional red blood corpuscle. The blood urea was 32 mg. per 100 ml.; cholesterol, 696 mg. per 100 ml.; and total serum proteins 5.01 g.%.

Malarial Therapy.—The patient was infected by blood inoculation with benign tertian malaria, and after ten days' incubation had nine paroxysms. There was marked constitutional upset with an increase in the proteinuria and she became very distressed. The malarial infection was stopped. She was observed for a further two months, during which time there was no diuresis or improvement in her clinical condition. At this stage the serum proteins were 4.9 g.%, the blood urea was 27 mg. per 100 ml., and the serum cholesterol had dropped to 350 mg. per 100 ml. Two months later the oedema had increased considerably, and the serum cholesterol had risen to 530 mg. per 100 ml. The patient has been watched for a further two years; although there has been a gradual improvement in her physical condition, she still has protein and casts in the urine. Her blood pressure has remained at normal levels, and she has slight oedema on exercise only.

Case 6

The patient, a woman aged 52, was admitted with oedema of the lower limbs, abdominal wall, and arms, and some puffiness of the face of two weeks' duration. There had been no preceding acute infection, and she was considered to be suffering from an exacerbation of a latent nephritis. On admission she had bilateral pleural effusions, the blood pressure was 180/100 mm. Hg, and the urine contained protein, granular casts, and a few red blood cells. The serum proteins were 4.56 g.%; blood urea, 50 mg. per 100 ml.; and serum cholesterol 127 mg. per 100 ml. There was no response to infusions of dextran or to high-protein salt-free diet.

Malarial Therapy.—The patient was infected with benign tertian malaria by intravenous blood inoculation, and became pyrexial after two weeks; she was allowed to have five paroxysms of fever. She was very exhausted and cyanosed during each attack, so the fever was discontinued by chloroquine treatment. Four days later there was a slight increase in the urinary output, but this moderate diuresis

was sustained for only 48 hours, and it made no clinical difference to her oedema. Her condition one month after malarial therapy was slightly worse than initially, her protein level was 5.46 g.%, and her blood urea was 52 mg. per 100 ml. Two months later she died from pulmonary oedema and generalized oedema due to chronic nephritis.

Case 7

A woman aged 22 had suffered a gradual onset of generalized oedema, thought to be due to Ellis Type II nephritis, for which she had been treated for nine months. On admission she had marked oedema of the lower limbs, gross ascites and oedema of the abdominal wall, and a large right pleural effusion. The blood pressure was 120/90 mm. Hg, the urine contained protein, granular and epithelial casts, and red blood cells. The blood urea was 34 mg. per 100 ml. and the serum cholesterol 214 mg. per 100 ml. She was observed for a further four months on various treatments, during which time there was a gradual deterioration in her condition, with increase in the oedema.

Malarial Therapy.—The patient was infected by blood inoculation with *P. ovale*, and after eight days she became pyrexial. There was a sudden and marked increase in the amount of oedema and ascites, and she thereafter suffered seven very mild paroxysms, with only minor fever, and at times no rigors. At no period did she show any clinical signs of improvement in her renal condition, and there was no diuresis. Her haemoglobin fell from 80% to 50%, her blood urea rose to 52 mg. per 100 ml., and repeated abdominal paracenteses were necessary. The malaria remitted spontaneously at this stage, and she remained apyrexial for two weeks. She then relapsed, but, apart from two or three minor pyrexial episodes, the presence of malaria parasites in the blood was not associated with any marked constitutional effects. The infection was eradicated with proguanil. One month later her condition was still unchanged, so she was reinfected, this time with benign tertian malaria by intravenous blood inoculation. After two minor pyrexial episodes her physical condition began to deteriorate rapidly, so the infection was stopped. Two weeks later she died.

Comment

Of these seven nephrotic patients treated by malarial infection three have had a marked remission of symptoms. Case 1 showed a most dramatic response, which has been well sustained. Cases 2 and 3 have been free of symptoms for a year, and the former, despite a high blood urea level, is working full time and feels well. The improvement shown in Case 4 cannot be closely associated with the malarial therapy—it is probably due to the high-protein diet—while the improvement in Case 5 cannot be associated with malarial therapy. The last two patients (Cases 6 and 7) died of their basic condition, but as they were both severely ill and the malarial paroxysms were poor or curtailed in number it would be unfair to say that malarial therapy had failed. Since the aetiology of the renal condition in these seven patients is not known, one can but speculate on the mechanisms by which the improvement has been initiated in Cases 1, 2, and 3. These cases do, however, encourage the continued trial of malarial therapy in this type of renal disease.

In Cases 1 and 4 the onset of malarial fever was preceded by macroscopic haematuria; this may have been an indication of increased damage to the renal tissues. In malaria the serum proteins, particularly the serum albumin, are usually reduced and there may be considerable increase in the serum globulin. Blood urea levels were not raised to any significant extent, despite pre-existing renal damage. The behaviour of serum cholesterol is extremely important, as it has been postulated by Gairdner that the beneficial effects of malarial therapy may be due to reduction in the serum cholesterol level. Most workers have reported a reduction in the cholesterol concentration at some time during the course of the malarial attack. Crespin and Zaky (1919) showed that the level fell to below normal values

just before the onset of a paroxysm, became normal or slightly raised in the pyrexial period, and fell to normal in the latent periods between attacks. Fairley and Bromfield (1933) in cases of induced malaria, showed that although hypocholesterolaemia occurred in some cases of well-established malaria, the levels rose to normal upon the termination of the attack.

A point in assessing the effects of malarial therapy is to preclude any diuretic action on the part of the drugs used to terminate or eradicate the infection. To this end fluid-balance charts were examined from 20 National Service men admitted to the Tropical Diseases Centre suffering from acute benign tertian malaria. They were all treated with chloroquine, quinine, and pamaquin; in none of them was any significant or prolonged diuresis noted as a consequence. It was therefore concluded that if a diuresis did occur following the use of antimalarial drugs in patients with the nephrotic syndrome it was in no way related to the action of these drugs.

Summary

Seven cases of the "nephrotic syndrome" have been treated by malarial therapy.

Three cases have had marked remission of symptoms lasting over one year.

It is considered that there is an indication for the continued use of malarial treatment in nephrotic patients who do not respond to more conservative treatment.

I wish to thank Dr. A. R. D. Adams, Professor B. G. Macgrath, and Dr. C. S. McKendrick, under whose care these patients were admitted. I am grateful to Dr. A. R. D. Adams for his advice and assistance in preparing this paper.

Medical Memoranda

A Fatal Case of Pernicious Anaemia Associated with Chloramphenicol Treatment

An increasing number of deaths from aplastic anaemia after treatment with chloramphenicol are being reported. A case of pernicious anaemia is described below which, on account of numerous intercurrent infections, was treated with two courses of chloramphenicol. Subsequently the patient developed an aplastic anaemia and died five months after the second course.

CASE HISTORY

A married woman aged 65 was admitted to hospital on August 1, 1952, with a six-months history of dyspnoea on exertion, swelling of the ankles, and increasing pallor.

On examination there was extreme pallor with a lemon-yellow tint. The tongue was smooth and she had a pyrexia of 99 to 100° F. (37.2 to 37.8° C.). There were signs of congestive cardiac failure, with normal heart sounds, and a blood pressure of 130/50 mm. Hg. No abnormalities were found in the chest, abdomen, or central nervous system. A catheter specimen of urine showed a heavy pyuria with a growth of *Bact. coli* organisms. A blood count gave: Hb, 2.5 g. (14.8 g. = 100%); red cells, 570,000 per c.mm.; C.I., 1.5; M.C.V., 123 cubic μ ; M.C.H.C., 35.7%; white cells, 4,950 per c.mm. (polymorphs 57%, lymphocytes 43%). Nucleated red cells were seen in the peripheral blood films.

The serum bilirubin was 0.9 mg. per 100 ml. Histamine-fast achlorhydria was present. Iliac bone puncture revealed a megaloblastic marrow. A diagnosis of pernicious anaemia was made on the above findings.

After an initial transfusion of $\frac{1}{2}$ pint (280 ml.) of packed red cells, treatment with vitamin B₁₂ was begun on August 5. For the first fortnight she was given 100 μ g. weekly, and thereafter until she left hospital on September 10 she had 100 μ g. fortnightly. A maximum reticulocyte response of 11% occurred five days after the onset of specific treatment. Although the response seemed a low one in view of the initial red cell count, it is known that intercurrent infections will considerably modify the reticulocyte peak, and at this stage the patient had a heavy urinary infection. Furthermore, a reticulocyte crisis may be reduced if specific treatment is preceded, as in this case, by a blood transfusion. The blood count on August 23 was: Hb, 6.5 g.%; red cells, 2,220,000 per c.mm.; C.I., 1. On August 25 it was: Hb, 10.7 g.%; red cells, 3,820,000 per c.mm.; C.I., 0.9; white cells, 22,400 per c.mm. (polymorphs 82%). By September 16, when she left hospital, the blood count was: Hb, 11.7 g.%; red cells, 4,100,000 per c.mm.; C.I., 0.96.

In the meantime, starting on August 3, a five-day course of "sulphatriad" (8 g.) was given for the urinary infection. By August 9 the urine was sterile. On the 10th a ten-day course of 19 g. of chloramphenicol was started on account of a left basal pneumonia. By the end of August frequency and dysuria had returned, and a further catheter specimen on September 8 showed a heavy growth of *Bact. coli*, which *in vitro* tests showed to be sensitive only to chloramphenicol. A further course of 9 g. of this drug was therefore given between September 10 and 15. The urine again became sterile, but before leaving hospital a further reinfection with *Bact. coli* was treated with 12 g. of chlor-tetracycline. During all this time the blood urea was never higher than 50 mg. per 100 ml.

On September 16 the patient left hospital symptom-free on a maintenance dose of 100 μ g. of vitamin B₁₂ fortnightly. She was next seen on November 28, when the blood count was: Hb, 6.5 g.%; red cells, 2,360,000 per c.mm.; C.I., 0.90. At this stage the amount of vitamin B₁₂ was increased to 100 μ g. twice weekly. A fortnight later the blood count was approximately unchanged, but by December 19 it had fallen to: Hb, 5.6 g.%; red cells, 2,100,000 per c.mm.; platelets, 62,000 per c.mm. She had had numerous epistaxes during the previous three weeks.

She was readmitted on December 20 and given a small blood transfusion. Also liver treatment consisting of "hepastab," 2 ml. on alternate days, was started. On January 2, 1953, a blood count showed Hb, 6.8 g.%; red cells, 2,350,000 per c.mm.; C.I., 1; white cells, 2,600 per c.mm. (polymorphs 37%, lymphocytes 63%). On the same day an iliac puncture suggested an aplastic anaemia. The total nucleated count was 7,600 per c.mm. and myeloid hypoplasia together with a relative erythroid hyperplasia was present, giving a total myeloid-erythroid ratio of 2:1 respectively. Ten days later, in spite of a further transfusion, the blood count was Hb, 7.04 g.%; red cells, 2,270,000 per c.mm.; C.I., 1; platelets, 41,000 per c.mm. Thereafter she developed numerous petechial haemorrhages and died on February 19.

Necropsy.—The body was that of a thin woman with numerous petechial haemorrhages in the skin and subcutaneous tissue. The lungs were pale but otherwise normal. The myocardium showed fatty degeneration and numerous haemorrhages. The gastro-intestinal mucous membrane was congested and haemorrhagic, the stomach otherwise appearing normal. The liver showed fatty degeneration, and the spleen numerous old infarctions. The kidneys showed bilateral arteriosclerosis with disruption of the renal pattern. The ureters and bladder were normal. The bone marrow of the sternum and iliac bones and femur were pale and fatty. The pancreas and adrenals appeared normal.

Histology.—There was fatty degeneration of the liver, and the splenic pulp showed poorly defined Malpighian

corpuscles and excess of reticulum cells. Bone-marrow sections cut from the ilium showed hypoplasia affecting granulopoiesis more than erythropoiesis. The number of mature granulocytes was greatly reduced and very few megakaryocytes were seen. The number of reticulum cells was increased. The lymphocytes appeared to be normal. As regards the red-cell series, there seemed to be a maturation defect at the normoblast stage.

COMMENT

It is known that untreated cases of pernicious anaemia may terminate spontaneously in aplastic anaemia. Blackburn *et al.* (1952) recommended a maintenance dose of at least 50 µg. of vitamin B₁₂ a fortnight for patients with pernicious anaemia uncomplicated by neurological involvement. In the above case the maintenance dose was never less than 100 µg. fortnightly.

Sulphonamides are occasionally responsible for the development of aplastic anaemia (Strauss, 1943). Usually only the white-cell series is affected, and granulopenia develops within a month. However, in the above case the white cells numbered 22,400 per c.mm. (polymorphs 81%) seven weeks after the end of the sulphonamide course, and three weeks later, when the patient left hospital, there was still no evidence of aplastic anaemia. Nevertheless, as Hodgkinson (1954) states, sulphonamides may have an additive effect in cases of aplastic anaemia primarily due to chloramphenicol.

In the above case two courses of chloramphenicol of 19 and 9 g. respectively were given. Judged by the standards of Hodgkinson (1954) the dosage of the individual courses was not heavy, although the total dosage was high.

In conclusion it is submitted that any drug that is known to be able to cause marrow aplasia, such as chloramphenicol, should be used with the greatest caution, if at all, in pernicious anaemia. In this respect Witts (1941) reported a relapse in a case of pernicious anaemia, after a good response to treatment, upon the administration of "allonal." The latter contains amidopyrine, which, like chloramphenicol, belongs to the benzamine group of drugs. It is probable that similar care should be taken in using chloramphenicol in other blood diseases in which the bone marrow already shows a disturbance of its normal function and appearance.

I am indebted to Dr. J. H. Cobb, of the Royal Surrey County Hospital, Guildford, for permission to publish this case. I wish to thank Dr. S. Keys for his reports on the pathological investigations.

Accidental Poisoning with Tetrachlorethane

Three cases of accidental poisoning with tetrachlorethane are reported, it having been given in mistake for tetrachlorethylene.

Normally, owing to its cheapness, I treat cases of hook-worm disease with carbon tetrachloride, but in children and adults who are underweight tetrachlorethylene is given owing to less risk of toxic effects.

CASE REPORTS

Ancylostoma duodenale ova were isolated from the faeces of all three patients, who were admitted for starvation followed by tetrachlorethylene. The patients were a young African man, weight 102 lb. (46.3 kg.), a young African woman, weight 108 lb. (49 kg.), and an African girl aged about 12 years, weight 60 lb. (27.2 kg.). The doses of tetrachlorethylene were 3 ml., 3 ml., and 2 ml. respectively,

and were given at 7.15 a.m. An hour and a half later an orderly noticed that the man appeared to be sleeping, and that he could not be roused. Shortly afterwards a nurse reported that the woman was in exactly the same state.

On examination the man was deeply unconscious and both corneal and pupil reflexes were absent; the pupils were moderately contracted. The limbs were flaccid and the breathing was shallow; the respiratory rate was 12 a minute. Gastric lavage was started immediately and 20 mg. of amphetamine sulphate was left in the stomach. The pulse rate was 90 and the volume poor; blood pressure 60/46 mm. Hg. Nikethamide, 5 ml., was injected intravenously, following which the systolic pressure rose to over 80 and the breathing improved.

The woman was also deeply unconscious, and the findings were essentially the same as in the man; she was treated in a similar way. Meanwhile the child, who seemed unaffected, was given a strong emetic with very good effect, for she did not lose consciousness or suffer any other ill effect.

During the course of the next two hours a close watch was kept on them, and the adults each had to have further doses of nikethamide owing to the falling blood pressure and reduced respiratory excursions. However, the depth of unconsciousness became less and both were able to respond to the spoken word at about 11.15 a.m.—that is, some four hours after the administration of the doses. They seemed euphoric for a few hours but suffered no harm from their experience; however, as a precaution they were kept in hospital for a week on high glucose intake, "casilan," and injections of crude liver extract and vitamin B complex.

A month later the man could not be traced as he had been discharged from his work, but the other two were in excellent health, and microscopical examination revealed that there were no ova in the stools.

At the first indication of trouble I sent for the bottle, which was a new one and seemed to be in order, but it was only when I mentally spelt the word that I saw it was tetrachlorethane and not tetrachlorethylene which had been requested from the suppliers.

COMMENT

Tetrachlorethane is a colourless liquid with an odour resembling carbon tetrachloride. It is used in many industrial processes as a solvent for cellulose acetate and nitrate, bitumin, waxes, resins, pitch, tar, sulphur, rubber, and oils. It is the most toxic of the chlorinated hydrocarbons, exerting a narcotic effect and causing profound metabolic injury, especially liver atrophy. It has been the cause of many cases of poisoning when its vapour has been inhaled: in 1914 and 1915 there were at least 70 cases of jaundice, with 12 deaths, among workers using aeroplane "dope" (Willcox *et al.*, 1915).

Only two cases of poisoning following its ingestion have been reported (Hepple, 1927; Elliott, 1933). Both these men became deeply unconscious and cyanosed with loss of reflexes and died. Post-mortem findings were chiefly of congestion of the respiratory and gastric mucosae, although one case also showed marked cloudy swelling of the cells of the liver and convoluted tubules of the kidney.

In Hepple's case 12 ml. was distilled from the stomach contents after death, so the amount must have been much greater, as gastric lavage had been performed. It must have considerably exceeded the lethal dose, which cannot be very much more than 3 ml. Gastric lavage should be thorough and persistent, as tetrachlorethane has a higher specific gravity than water and is not miscible with it, and so may defy efforts to remove it.

Reviews

MEDICAL EDUCATION IN BRITAIN AND THE U.S.A.

Medical Students and Medical Sciences: Some Problems of Education in Britain and the United States. By D. C. Sinclair, M.A., M.D. (Pp. 154+x. 25s.) London, New York, Toronto: Oxford University Press, 1955.

Dr. Sinclair, who has frequently published articles on medical education in this country and in America, has had the advantage of a Rockefeller Foundation grant enabling him to spend three months in the U.S.A., where he made a study of education in the "medical sciences." This has allowed him to produce an admirable book concerning medical education in Britain and the United States, the two countries in which the subject can be said to be most advanced. He draws a lively contrast between the requirements and the practices of the two countries, and shrewdly analyses the approach of each towards its own particular problems, which, indeed, are not identical.

The title "Medical Sciences" restricts the author, by his own definition, to what is often referred to as the pre-clinical stage of medical education—namely, anatomy, physiology, biochemistry, pharmacology, pathology, bacteriology, and a number of other subjects which vary from one school to another. The book, in four sections, deals with the student himself, his selection, and his problems in general; with the teacher (as distinct from the research worker), his teaching, and the methods for assessing the knowledge of the teacher's pupils; with the material which is taught; and with present-day educational experiments. One is left with the impression that the author believes that the present curriculum for the medical sciences has no glaring faults when presented by competent teachers, but that it could with advantage be reasonably pruned of late nineteenth and early twentieth century shibboleths and be (sacred word) "integrated" for the benefit of the student. It is easier to advocate this than to effect it, since heads of departments are often allergic even to the idea, and how much more to its execution. One has to admit, also, that whatever reforms are made in individual schools must necessarily be uncontrolled experiments, even as the "vertical teaching" at Western Reserve University must be so regarded.

This book can be read with considerable profit, much enjoyment, and with many a quiet chuckle, since the author has an attractive style, a dry, even pungent wit, a gift of phrase, and an aptitude for making his points. It can be commended to all, but especially to those who feel that medical education is a dull subject or one which can look after itself.

LIONEL WHITBY.

OBSTETRIC PROBLEMS

Practical Obstetric Problems. By Ian Donald, M.B.E., M.D., B.S., B.A., M.R.C.S., L.R.C.P., M.R.C.O.G. (Pp. 578; illustrated. 45s.) London: Lloyd-Luke (Medical Books) Ltd. 1955.

The author's warning (or promise) that his natural exuberance may bubble into the text, and the dust-cover comment that there should be no place for dullness in textbooks, arouse expectation of fireworks. Nor is the reader disappointed, though the display is one of roman candles which emit bright lights of knowledge interrupted by good illustrations and occasional sparks rather than one of breath-taking jet-propelled rockets. Anatomy, physiology, and the routine clinical aspects of normal pregnancy and labour are excluded as "dreary irrelevance"; and so they are—to those who already know them, as should the post-graduate students for whom this book must be intended. Professor Donald shows admirable courage in other ways too, and so far as possible shuns qualifying phrases. So aetiology and pathology are clearly stated and there are delightfully dogmatic accounts of treatment. Take, for example, puerperal deep thrombosis and embolism, con-

ditions on which there still remains much vacillation on the part of clinicians: for these there is only one treatment—heparin intravenously in adequate doses accompanied by active movement of the patient; other anticoagulants, and even heparin intramuscularly, are condemned. By and large each chapter deals with a clinical problem—prolonged labour, antepartum haemorrhage, heart disease, symptom complexes, and the like. Recent authoritative articles on the various subjects have evidently been abstracted and combined to make a rational picture, due acknowledgments being given in short bibliographies. Contributors of chapters are H. M. Carey (toxaemia of pregnancy), G. W. Garland (malpresentations), Hilda Roberts (obstetric analgesia), and William Hayes (use and misuse of antibiotics). The contribution of the last-named calls for special commendation.

One striking and pleasing feature which reflects modern obstetric practice is the omission of any chapter on destructive operations on the foetus. Indeed, craniotomy is mentioned only twice—once in the treatment of hydrocephaly, and again (to be dismissed) in relation to outlet contraction.

The more one reads and re-reads various sections the more valuable this book appears to be for those who are regularly engaged in caring for pregnant and parturient women. There is no better concise yet reasonable statement of the modern practice of obstetrics. If there are too few frills for the embryo consultant, there are enough for the established one, and perhaps more than enough for the general-practitioner obstetrician. It is natural to wonder why Professor Donald has added to the very large number of works on obstetrics, and it is difficult not to conclude that he wrote this book for the fun of doing it. What better reason could there be, and what better guarantee of quality?

T. N. A. JEFFCOATE.

ARTERIAL THROMBOSIS

Congrès International de la Thrombose Artérielle. Organisé par la Station de Royat à l'occasion du Centenaire de son Établissement Thermal, 6-7-8 Juin, 1953. Rapports et Discussions. (Pp. 320; illustrated. No price.) Paris: J. B. Baillière et Fils, Éditeurs. 1954.

The *Reports and Discussions* of the International Congress on Arterial Thrombosis, which was held in June, 1953, at Royat, is now available. It covers a fairly wide field, and reflects very well the current opinion in France on this subject. As the title would indicate, the whole of the arterial system comes under consideration. Naturally a good number of the reports are concerned with the effects of thrombosis on the coronary arteries. To begin with there are three papers on the problems of the causes of unusual blood coagulation. The investigation of the lipoproteins by electrophoresis and the effects of infarction of the septum on the conducting tissues also receive consideration. Two papers deal with vectorcardiography, and there are two more on the surgical treatment of arterial thrombosis in the limbs. Some of the papers have references and some have summaries in English. The reports of the discussions are fairly short.

This book is a good summary of present-day views on arterial thrombosis in France and is well worth looking into. The paper is good and the illustrations are clear.

TERENCE EAST.

TECHNIQUES IN CLINICAL CHEMISTRY

Techniques in Clinical Chemistry: A Handbook for Medical Laboratory Technicians. By Frederick N. Bullock, F.I.M.L.T., F.R.M.S., F.C.S. (Pp. 171+ix; illustrated. 16s. 6d.) Bristol: John Wright and Sons, Ltd. 1954.

In *Techniques in Clinical Chemistry* the author has produced a useful book, more especially for the student and junior technician. This value is well shown in the first chapter, devoted to fundamentals, as even more advanced technicians often spend years carrying out complex biochemical investigations without any real knowledge of the

basic principles involved in the test, and more advanced and complete textbooks cannot spare the space for these very necessary explanations.

The chapter on specimen collection is clear in its instructions, but the suggestion that the measurement of 24-hour specimens of urine be carried out in the wards is a very retrograde step and would inevitably result in error. The instructions on the collection of faeces have one important omission—namely, the precise procedure in their collection over a measured period by using markers such as carmine or charcoal at the beginning and end of the test period. Most nursing staffs have, very naturally, great difficulty in grasping the principles of this procedure unless it is given in detail. In the chapters on blood analysis the methods are well described and alternative procedures given.

In the determination of blood chlorides, most workers have experienced difficulty in obtaining a sharp end-point with thiocyanate titration owing to the interaction of the silver chloride and iron thiocyanate. This can easily be avoided by making the silver-nitrate-blood-filtrate mixture up to a known volume, filtering, and titrating an aliquot of this filtrate, now free from silver chloride. The end-point is then sharp and persistent. The method of determining serum chlorides by direct titration with mercuric nitrate (Schaes and Schaes) should be included in another edition, as this is a great time-saver in a busy routine laboratory. Direct titration of the chlorides of cerebrospinal fluid with a chromate indicator has many advantages. In the section on phosphatases there might be more emphasis on the high levels of alkaline phosphatase in all forms of obstructive jaundice.

The urine section is well done, but some tests of rather doubtful value are included. Bence Jones protein is best identified by its low coagulation temperature and re-solution on boiling, or alternatively the procedure of Osgood and Haskins may be used. The salicyl-sulphonic acid and Bradshaw tests described are of no real value.

The author is to be congratulated on producing a very useful contribution to the routine chemical pathological laboratory equipment.

H. E. ARCHER.

FORENSIC PATHOLOGY AND TOXICOLOGY

Legal Medicine: Pathology and Toxicology. By Thomas A. Gonzales, M.D., Morgan Vance, M.D., Milton Helsen, M.D., and Charles J. Umberger, Ph.D. Introduction by Harrison S. Martland. Second edition. (Pp. 1349+xii; illustrated. \$22.) New York: Appleton-Century-Crofts, Inc. 1954.

The second edition of this authoritative volume by the Medical Examiners of the City of New York adds the experience of another 14 years of active practice and greatly increases the scope of the book. Its great virtue lies in the fact that it is based almost entirely on the personal experience of the authors, whose views are amply supported by an extensive bibliography which is completely up-to-date.

The Medical Examiners in New York are responsible for the investigation of deaths which in this country might be styled "coroners' cases." The investigation of some 20,000 deaths annually in the city is centralized and conducted by medical officers actively practising pathology, serology, and toxicology. While necropsies are conducted at several mortuaries, the actual statistical material is correlated in the Chief Medical Examiner's office, and the data so obtained between 1918 and 1951 have been incorporated in various chapters to indicate the frequency of deaths from natural and violent causes.

Since the edition of 1940 new chapters have been added on the necropsy findings on embalmed bodies—a difficulty not entirely confined to the United States—cardiac contusion, traumatic cerebral oedema, injuries in sport, the Rh factor, pathological findings in poison cases, uranium compounds, the recent organic drugs, and anaesthetic and operative deaths, while in the last six chapters a fresh approach has

been made to the identification of poisons. This exhaustive analysis must be of great interest, not only to the forensic toxicologist but also to the hospital biochemist. Similarly the chapters on sudden and unexpected death contain much material of great value to the hospital pathologist.

The book is profusely illustrated with first-hand and first-class material, though some of the black-and-white reproductions of photographs are indistinct and require a more descriptive caption. It is expensive and essentially a book of reference, but as an exposition of modern knowledge of legal medicine it is without equal.

DONALD TEARE.

MOSQUITO BIONOMICS

Mosquitoes: Their Bionomics and Relation to Disease. By William R. Horsfall. (Pp. 723+viii. \$16.) New York: The Ronald Press Company. 1955.

In preparing this work the author, himself a well-known authority on mosquito bionomics, has undertaken the formidable task of summarizing in a single volume all available information relating to this important subject. Preliminary consideration is given to the characteristics common to the sub-family as a whole and to those peculiar to each genus. Each individual species is thereafter treated separately in respect of nomenclature, subspecific variants, and synonyms, number of generations, and any known data regarding hybridization. The bionomics of the egg, larva, pupa, and adult insect are dealt with under separate headings, and the importance of each species in relation to the transmission of disease is fully discussed.

The bibliography contains references to more than 4,000 scientific works. To consult all these in the original would be beyond the capacity of any single individual, and the author has had perforce to rely in some cases on citations made by others. In such circumstances errors are unavoidable, as, for instance, where Natvig is quoted as stating that the work of Shute indicated that *Aedes cantans* produces several generations every year; whereas in point of fact the latter author emphasized that this species, in common with *Aedes punctator* and *rusticus*, has only a single brood each year. Such errors will no doubt be corrected in subsequent editions.

The general format of the volume is excellent; the mass of material is well arranged and clearly presented, data relating to lesser-known species being set out in tabular form. With the introduction of modern methods of mosquito control a detailed knowledge of the life history of each insect vector has become more essential than ever. The book will prove an invaluable work of reference, especially to those actively engaged in the control of mosquito-borne diseases.

GORDON COVELL.

Some years ago King George's Jubilee Trust instituted an inquiry into "the causes of wastage from youth organizations and to throw light on the problems of attracting to them boys and girls in the changed conditions of to-day, and of recruiting to their service men and women with the generosity and capacity to lead and inspire youth." The result has recently been published as *Some Young People*, compiled by Pearl Jephcott. The survey was conducted in several different areas: two in London, one in Nottingham, and two in Oxfordshire villages. The book gives a brief glimpse of some of the adolescents between 14 and 17 years of age who were interviewed; their backgrounds, interests, and forms of entertainment. It provides statistics of education and numbers in youth organizations. The report brings out the general apathy of adolescents towards a creative use of their leisure time. Various reasons are given for the lack of response to the aims of youth organizations: shyness; dislike of further control and discipline; the number of young members; the fact that the leaders are often middle-aged and possibly out of touch with the ideas of youth—to name only a few. In conclusion the report stresses the importance to the adolescent of personal contacts and the example of adults in their daily lives. *Some Young People*, which is published by George Allen and Unwin Ltd., 40, Museum Street, W.C.1, costs 12s. 6d.

NEW WORK ON TRANSPLANTATION

The likelihood of surgery making another great step forward—on the same scale as the advances resulting from the discoveries of anaesthesia and asepsis—may depend on finding a solution of the homograft problem, so making it possible for surgeons to transplant skin grafts, kidneys, and other tissues and organs from one individual to another. This would be a great accomplishment, not all the benefits of which can at present be foreseen. Research on the problem is not lacking. Three symposia¹ have been devoted to it in recent years and more are planned. Indeed, in the laboratory the problem has already been solved, but in a way that does not lend itself to clinical application. R. E. Billingham, L. Brent, and P. B. Medawar^{2,3} have shown that skin homografts (the most intractable of all) can be successfully exchanged between adult mammals or birds by taking advantage of the phenomenon which they call actively acquired tolerance. The principle underlying it is simple. It is a commonplace of immunology that embryos and very young animals cannot form antibodies, and that their only defences against infection are those which have been acquired at second hand. The novelty of the concept of tolerance lies in the demonstration that an animal's power to react against a specific antigen may be permanently impaired and perhaps completely abolished by exposing it to that antigen before its immunological faculties have matured. Thus a skin graft can be successfully transplanted from one adult to another, A to B, if B was injected in foetal life with cells derived from A. The embryos so treated not only fail to react against the tissue antigens: they may never acquire the capacity to do so in later life. The inhibition is highly specific; animal B becomes tolerant of tissues grafted

from A, but remains as intolerant as ever to tissues grafted from another donor, C. Acquired tolerance may not be a general phenomenon in immunology, though both theory⁴ and practice,⁵ so far as they go at present, suggest that it probably is. Its theoretical importance is obvious. Biochemistry would not be the science it is if there were no specific inhibitors, but only substrates, to work with. Immunology has hitherto had no specific inhibitors in its armoury: "tolerance" may fill the gap.

A second important contribution has been made by N. A. Mitchison,⁶ who found that transplantation immunity could be passively transferred from an immunized to a normal animal. He removed the regional lymph nodes—those which drained the grafted areas—from an actively immunized mouse and transplanted them into a second mouse belonging to the same strain. This second host thereupon behaved exactly as if it had itself been actively immunized—and so, in a certain sense, it had been. The transfer could not be carried out in the orthodox way by serum, nor by nodes other than those draining the grafted area, nor by dead cells of any kind. Mitchison's work has been fully confirmed by Billingham, Brent, and Medawar,⁷ and both parties are agreed that the transfer is not brought about by preformed antibodies or by antigens carried over from the donor of the lymph nodes to their recipient. The term "passive immunity" is therefore inappropriate or misleading, and "adoptive immunity" has accordingly been proposed.⁷ Mitchison's work shows that transplantation immunity is orthodox enough in one sense—namely, that the seat of the host's reaction against homografts is the regional node.

In one other respect it is clearly unorthodox, at least when judged by the standards of bacterial immunology. Free serum antibodies are exceedingly difficult to detect, and the homograft reaction cannot be reproduced *in vitro*. It seems to be necessary that the antibodies should attack the homograft *in vivo*, in a vascular situation, and it is at the vascular frontiers of the graft that the first signs of distress are revealed.⁸ By complex and indirect means, protective antibodies have nevertheless been demonstrated by P. A. Gorer⁹ and by R. E. Billingham and E. M. Sparrow¹⁰; agglutinating antibodies are also formed, as Gorer has long since demonstrated, and may agglutinate leucocytes¹¹ as well as red blood cells. Unfortunately, there are grounds for reasonable doubt about the effectiveness of agglutinins in the homograft reaction, and until these doubts have been cleared up their status will remain obscure.

The reaction against homografts has every distinguishing mark of an immunological process. At one

time, when the modern study of homografts was only beginning, evidence of conformity to the orthodox pattern was eagerly sought, and duly found. Departures from orthodoxy can now be looked for with an easy conscience, and it is quite possible that an entirely new kind of immunological response may be found. There is some evidence, for example, that immunity against homografts can develop long before immunity against bacterial antigens and distantly foreign proteins. Sheep are already able to react against homografts when only two-thirds of the way through foetal life (though already more highly developed, in an anatomical sense, than a newborn mouse).¹² This is a remarkable fact, for foetal sheep, like other foetal ungulates, are—in a literal but not clinical sense—agammaglobulinaemic: they acquire their gamma globulins, with their antibodies, after birth, and only later on do they begin to make their own. R. A. Good and R. L. Varco's recent demonstration¹³ that an agammaglobulinaemic boy had no power to react against skin homografts is good evidence that the reaction against homografts is immunological; but it is not (and does not purport to be) evidence that the reaction is mediated by orthodox antibodies present in the gamma globulin fraction of blood. The cautious inference is that the failure of immunological mechanisms which has agammaglobulinaemia as one of its symptoms has tolerance of homografts as another.

CYCLOSERINE

The daily press on both sides of the Atlantic reported last February the discovery of a new antibiotic for the treatment of tuberculosis. The basis of the report was a paper read to the 14th Veterans Administration Conference on the Chemotherapy of Tuberculosis held at Atlanta last February. This paper, by I. G. Epstein, K. G. S. Nair, and L. J. Boyd¹ has now appeared in print, following another by H. Welch, L. E. Putnam, and W. A. Randall² of the Food and Drug Administration, Washington, which gives a little more information about this antibiotic. It appears to have very unusual properties, and some surprise may be felt that it should have had fairly extensive clinical trial before any announcement had been made of the results of such laboratory studies as usually precede this. The information about these studies is still very scanty—it is merely stated, for instance, that the antibiotic has "an extremely low toxicity," a future paper in confirmation being promised—and on what seems a slender basis some speculative ideas are put forward about its mode of action.

¹ *Antibiot. Med.*, 1955, 1, 83.
² *Ibid.*, 1955, 1, 72.

Cycloserine is produced by *Streptomyces orchidaceus* and was discovered by members of the staff of the Commercial Solvents Corporation. Eli Lilly and Co. have collaborated in its study and their trade name for it is "seromycin." It is water-soluble, has a molecular weight of only 102, and, as would be expected from so small a molecule, appears to be freely diffusible: the concentrations attained by the drug in the cerebrospinal fluid, pleural fluid, and sputum are said to be approximately equal to those in the blood, though the published papers give no detailed particulars. Minimum inhibitory concentrations for various bacteria as determined by Welch and his colleagues were mostly from 50 to 250 µg./ml., Gram-positive and Gram-negative species being about equally susceptible. There is no description of how these tests were done; hence it remains possible that by varying some factor, such as inoculum size or the composition of the medium, a degree of *in vitro* activity might be demonstrated which would accord more closely with that thought to have been observed *in vivo*. The list of species tested does not include *Myco. tuberculosis*, and indeed there is no information at all in either paper about the *in vitro* activity of cycloserine against this organism except in a footnote giving the findings of two other workers, between which there is a twelve-fold discrepancy. Presumably much more extensive and positive information on this vital matter will be forthcoming shortly. The paper by Welch and his colleagues also reproduces some of the data in personal communications from two surgeons who have used cycloserine for the treatment of urinary tract infections with some success: not enough information is given to judge the degree of this. It finally records the results of a pharmacological study in 40 normal subjects given single and repeated doses in oral capsules. The blood and urine concentrations attained were high and remarkably sustained, and repeated doses had a cumulative effect, reaching a maximum in three days of about 50 and 1,000 µg./ml. in the blood and urine respectively. It seems, therefore, that part of what cycloserine lacks in antibacterial activity it compensates for by the high concentrations attained in the body. Nevertheless these authors think these concentrations inadequate to explain the therapeutic effect, and speculate on other possible modes of action—"... the production of physiologic conditions in the host, resulting in a more unfavourable environment for multiplication or survival of micro-organisms," or "the production of humoral factors that act with the drug in combating infections."

The paper by Epstein and his colleagues, which deals exclusively with the treatment of pulmonary tuberculosis, is strongly reminiscent of the enthusiastic

first reports on the effects of isoniazid in 1952. Even patients with far advanced disease unresponsive to previous chemotherapy began to gain weight and had less cough and sputum: of 29 such patients, 22 became sputum-negative and 20 showed radiological improvement. Eight further patients with more recent and previously untreated, though extensive, disease, classified as moderately advanced in four and far advanced in four, were treated with evidently more dramatic results: fever abated promptly and weight gains were up to 23 lb. (11.5 kg.). All showed radiological improvement and all became sputum-negative. There is no information about any tests of the sensitivity of these patients' tubercle bacilli to cycloserine, though it is said that "an extensive study is now under way" to obtain data on the emergence of resistant organisms. Yet the authors subscribe to the idea in the previous paper that "cycloserine owes its salutary effects *in vivo* to factors not directly connected with its *in vitro* antibiotic activity." There seems to be no need for this assumption if one of the two discrepant figures obtained by other workers is accepted as the minimum inhibitory concentration of cycloserine for *Myco. tuberculosis*. This, obtained with the H37Rv strain, was 2.5-5.0 µg./ml., well below the concentration maintainable in the blood. It has also to be remembered that so diffusible a substance may penetrate infected cells and perhaps avascular lesions much more readily than other drugs. It is profitless to speculate further on fragmentary data, and the process of filling the gaps in this story will be watched attentively.

HEALTH SERVICES IN INDIA

A Health Survey and Development Committee was set up by the Government of India about fifteen years ago and reported in 1946, with blueprints for future health activities. At that time the maternal mortality rate was 20 for every 1,000 live births; the expectation of life for the Indian was 27 years; the proportion of qualified doctors to the population was one in 6,300; and the average population served by a hospital or dispensary in rural areas was 50,000, and in urban areas 30,000. The *India 1954 Annual Review*¹ does not contain up-to-date figures, but even by 1951 all the mortality rates seem to have fallen (the infant mortality rate from 158 to 124.4), and the expectation of life had risen to 32 years. The number of medical colleges had increased by 50%, and the annual admissions of students had almost doubled. There was a recession in deaths from infectious diseases, plague was on the wane, and malaria was

¹ Published by the Information Service, India House, Aldwych, London, W.C.2.

less of a scourge. The health section of the *Annual Review* is written by Rajkumari Amit Kaur, the Minister of Health. She mentions that one of her first acts as Minister was to end the dichotomy between curative and preventive health services by combining the functions, discharged hitherto by separate bodies, of medical and public health advisers, and to commend similar action to the States, nearly all of which followed the central example. The result has been greater co-ordination and team-work. The comparative isolation of the independent medical profession from the official health "hierarchy" is also being ended.

A state health insurance scheme for industrial labour has been started during the last three years. At present it embraces only 60,000 workers, but with its extension to Bombay it will cover half a million. Another health insurance scheme has been started by the central Government for its staff in the capital city and covers a quarter of a million persons for general practitioner, specialist, and hospital services. These efforts touch only the fringe of the problem, but the Minister says they are indications of the trend. A national malaria control programme was launched two years ago and is making rapid strides against a disease which in 1946 was estimated to affect 100 million people and to cause two million deaths. Nearly 90 antimalarial units, each covering a population of one million, are already in operation, and another 35 are coming into existence shortly. By the end of the second five-year plan (1961) it is hoped that malaria will be under control. Tuberculosis, too—with an average number of deaths in a year amounting to 500,000—is being actively combated. A mass B.C.G. vaccination scheme has 120 teams in the field, and they have tested 33 million persons and vaccinated one in three. An All-India Institute of Medical Sciences—costing about £3,750,000—is expected to be inaugurated within the next two or three years. It will combine undergraduate and postgraduate education with research, and will turn out, it is hoped, an increasingly large number of well-trained teachers for the medical colleges. Acts relating to the professions of pharmacy, nursing, and dentistry have recently been passed, and legislation is being considered for the prevention of practice by unqualified and unregistered persons, and for the regulation of the training which is given in indigenous systems of medicine.

Family planning movements are gradually taking shape, assisted by many independent and voluntary organizations. This has a direct bearing on the food problem of India, and here again progress is being

made. The five-year plan fixed an increase of 7.6 million tons in cereal output by 1955-6, and already the estimated increase in 1953-4 is 9.5 million tons. Before the relaxation of controls in the middle of 1952, 108 million people were subject to rationing. A year ago the number had dropped to 44 million, and to-day rationing is only a memory. These are all encouraging signs that the Government of India is grappling successfully with health and social problems which, in spite of recent efforts, remain of enormous complexity, for the inhabitants of India number about one-seventh of mankind.

PUBLIC HEALTH SALARIES

It is four and a half years since the salaries of medical men and women in the public health service were raised in accordance with the terms of the award¹ of the Industrial Court, to which, in 1950, the staff and management sides of Whitley Council Committee C agreed to submit their differences. Although the staff side did not get all it wanted from that award, there was satisfaction that substantial gains had been made. Nevertheless the award to assistant medical officers was disappointingly small—the salary being on a scale from £850 to £1,150 per annum. The staff side made persistent efforts to have this improved without success, and again, in 1953, the differences between staff and management on this point had to be resolved by the Industrial Court. The salary awarded² this time to assistant medical officers was £950 rising to £1,300. Meanwhile all the other medical officers in the public health service have been paid salaries at the rates awarded in 1950.

The case for improving these salaries has been overwhelming for some time past, for not only has there been a great rise in the cost of living, but members of the public health service have seen their colleagues in general practice benefit from the Danckwerts award in 1952 and their colleagues in the hospital service from the increases negotiated last year. But once again the two sides of Whitley Committee C failed to agree on the amounts by which public health salaries should be increased and once again the differences were laid before the Industrial Court. The dispute was clear cut. The staff side urged the Court to take into account the salaries being paid to doctors in other branches of the Health Service; whereas the management side "felt that it would be right to give increases of such an amount as would bring the salaries of medical officers of health into line with those of the other professional officers (in local government) of comparable status" (who, it may be said, had negotiated certain percentage increases to take effect from January 1 this year). The award announced last week and published in the *Supplement* this

week (p. 214) shows that the Court has favoured the management side's view, though this result cannot have been due to any fault in presentation of the staff side's case: scrutiny of the minutes of the proceedings of the Court shows how cogently this was argued by counsel briefed by the Public Health Service Defence Trust.

The immediate effect of the award will be some disappointment that the staff side's reasonable requests have not been met, but also some satisfaction that the increases which have been granted will help to ease the financial burdens that fall particularly heavily on salaried medical men and women whose earnings are definitely on the low side for highly trained professional people. These increases, as can be seen from the details in the *Supplement*, amount to about £175 a year for medical officers of health in areas with a population not exceeding 100,000 and about £200 a year in areas where the population is over that figure; senior medical officers obtain a rise of £165 per annum at the minimum of the scale and £180 at the maximum; and assistant medical officers (who, as stated above, had the minimum of their salaries raised by £100 and the maximum by £150 under the 1953 award) go up another £25 at the minimum end of the scale and £75 at the maximum (£1,375 under the new award). Under a previous agreement³ the salaries of deputies are linked with those of their chiefs (66½% of the minimum scale adopted by the employing authority for the post of medical officer of health, with annual increments equivalent to those of the M.O.H.); and the staff and management sides had already announced that, when an award was made in respect of the three groups of officers specifically dealt with, they would be able to reach agreement on the salaries of the remaining categories of medical officers of health. In so far as they go, then, these awards will bring public health salaries nearer to the incomes of doctors in other branches of medicine. But the long-term effect on the National Health Service of the management side's obstinate resolve to keep the salaries of medical officers of health linked with those of other chief officers in the local government service is difficult to foresee, for, as one observer⁴ has put it, "One of the chief failures in co-operation between the hospital and local health authority service lies in the division of the medical profession into two salaried camps of grossly unequal status."

CANCER AND THYROID ACTIVITY

The discovery that the incidence of a disease corresponds with that of some social, physiological, or other peculiarity in the population or milieu is sometimes a first step towards learning how to overcome the disease or unravel its aetiology. Sceptics may say that many statistical correlations of this kind have been found in the past which seem to have led nowhere—but that may be because the story is not yet finished. Cancer research has shown several times that many years may elapse between the discovery of a correlation and the beginning of any serious attempt to explain it. In 1844

R. Stern¹ found from a study of Verona's statistics that breast cancer was more frequent in single than in married women, but 70 years passed before his observation was confirmed and its important implications began to be considered. In 1868 A. Haviland² addressed the Medical Society of London on the relationship between cancer death rates and geology in the registration districts of England and Wales, but only recently has serious research begun on soil in connexion with certain forms of cancer.

Another example concerns a statistical association between cancer and hypothyroidism, for which evidence was produced by Percy Stocks³ in 1924, following a suggestion by Bayard, of Zermatt, in 1919. By dividing Switzerland into 31 areas and correlating standardized death rates for cancer of the digestive tract in 1920 with the goitre frequencies in army recruits in 1921-2, Stocks obtained a coefficient of +0.636. He also found that the proportion of malignant growths comprised by cases of stomach cancer was positively related to the frequency of goitre in the U.S.A. and parts of Norway as well as in Switzerland. This was supported by the finding that thyroid anomalies were recorded in 21% of necropsies on cancer patients at the Middlesex Hospital, whereas the same pathologist had recorded them in only 4% of patients who had died from diseases other than cancer. A comment in this *Journal*⁴ on that paper remarked that "the refined analysis of cancer rates is an arduous task; he who undertakes it must be prepared for many disappointments." Thirty years have been a long time to wait for any direct follow-up of these findings, but now J. G. C. Spencer⁵ has re-examined the problem and produces confirmatory data of an association between cancer and goitre frequencies in other countries. He gathers together recent clinical, experimental, and pathological observations suggesting that the thyroid has some influence on the development of cancer.

O. Bayard⁶ thought that deficiency in the supply of thyro-iodine to cells might cause premature ageing of the tissues, and Spencer mentions the lower metabolic rate in diabetics as perhaps accounting for their raised liability to cancer, as found by Joslin. He suggests that the increased demand for iodine at puberty and during pregnancy may account for the greater likelihood of melanomata developing at those times. Animal experiments, cited by Spencer, have shown that administration of thyroxine in the diet is prejudicial to successful grafting of certain tumours from one mouse to another, and that simultaneous thyroxine injection reduces the tumour response to injection of dibenzanthracene, whereas feeding with thiouracil enhances the response. Regression of rat tumours has been brought about by natural thyroxine; and the increased rate of development of spon-

taneous mammary tumours in mice during pregnancy might, he thinks, be due to thyroid deficiency.

The therapeutic administration of oestrogens is believed to influence cancer growth indirectly by suppressing pituitary activity. Spencer argues that a high thyroxine level in the blood produces a similar effect and that thyroxine has advantages over oestrogens in that it is not carcinogenic, the pituitary is not known to become indifferent to it in time, and thyroxine in the tissues makes an environment unfavourable to tumour growth. The author is careful to point out: "A low metabolic rate or an insufficiency of thyroid substance can in no way be considered as a primary cause of cancer. Thyroid and related substances cannot therefore be considered as a cure for cancer. It is, however, suggested that thyroid function (or dysfunction) may be associated with the susceptibility or immunity to cancer." A. A. Loeser⁷ has advocated the administration of thyroid as an ancillary to the surgical and other treatment of cancer; and he and Spencer also suggest that, as a preventive measure, maintenance of a good level of thyroid activity during middle life might increase immunity to the action of carcinogenic substances. It is good news that long-term research on this important matter has been started at the Frenchay Hospital, Bristol, and that further papers may be expected when data become available.

NOMENCLATURE AND MORBIDITY SURVEYS

Team-work in medical research has a long history, as was made clear at a recent meeting of the Section of General Practice at the Royal Society of Medicine, when Dr. R. M. S. McConaghey¹ gave a historical review of collective medical investigations in this country based on observations and records of individual practitioners during the eighteenth and nineteenth centuries. Moving forward to a much more recent period, there has been the exploratory study by the General Register Office² in which about ten practitioners took part for several years: this has formed the basis for a much expanded twelve-month survey of morbidity in general practice which has started this month, organized jointly by the College of General Practitioners and the General Register Office, and in which over 100 general practitioners are taking part. As the latest Research Newsletter³ of the College observes, those taking part in the inquiry are going to face various difficulties, and one of these will be the nomenclature of the minor complaints seen so frequently in general practice, for which each doctor has his own favourite label and which may mean something quite different to his colleagues.

Medical statisticians make a clear distinction between "nomenclature" and "statistical classification" of

diseases. Basically, a medical nomenclature is a catalogue of approved terms, which has to be extensive so that every morbid condition that can be specifically described has its specific designation recorded. On the other hand, a statistical classification is intended for a quite different purpose—namely, to group diseases together that have something in common, so that their statistical study will be facilitated. The complete specificity of a nomenclature limits its suitability for use as a statistical classification, whereas a classification is not designed to guide doctors in their choice of the most acceptable medical terms. There is therefore a very clear difference, both in purpose and in content, between the *Nomenclature of Disease*⁴ of the Royal College of Physicians and the World Health Organization's *International Statistical Classification of Diseases, Injuries, and Causes of Death*,⁵ the seventh revision of which is now in course of preparation after the customary international revision conference in Paris in February of this year. Another important and well-known work is the *American Standard Nomenclature of Diseases and Operations*,⁶ which is primarily a nomenclature, as its title indicates, but contains cross references to corresponding categories in the *International Classification* and has been so constructed as to serve certain classificational purposes such as the indexing of hospital clinical records. Opinions differ about its advantages for this purpose over the *International Classification*, which, with appropriate *ad hoc* expansions, is being used successfully as a diagnostic index in a number of hospitals in this country.

The special problems of nomenclature and classification of minor symptomatic conditions will no doubt be engaging the minds of those responsible for the new morbidity survey in general practice, and it will be seen in due course whether the chosen methods of classifying disease will be adequate to cope with the vagaries of diagnostic terminology that the survey will encounter. It may be, as the College's Newsletter suggests, that a completely new approach to the nosology of the minor maladies met with in general practice is long overdue.

PARALYSIS FOLLOWING POLIOMYELITIS VACCINATION

Current reports that a number of children in the United States inoculated with the new poliomyelitis vaccine have since developed paralysis have come as an unwelcome shock after the exciting news of a fortnight ago. The present situation is obscure owing to a virtual absence of any concrete facts, but it would appear from reports in the American and British press that between 29 and 35 inoculated children have developed paralytic poliomyelitis. Two deaths are reported.

After the news of last year's vaccine trials, a large quantity of vaccine was released for use in the United States. The U.S. Public Health Service states that so far 2,270,000 children have been vaccinated in 42 states. Of these, 300,000 have received a vaccine prepared by

the Cutter Laboratories, Berkeley, California, and it would appear from press reports that 26 of the 29 paralytic cases were vaccinated with material from this source. A further report states that at least 10 of these 26 cases received vaccine from the same batch.

This is disquieting news. With the facts available three main possibilities for such an incident must be considered. First, it could be chance, the vaccine having been given just prior to the onset of poliomyelitis which would have developed in any case. Again, if the facts are correct, 26 cases from one source is rather too large a number for coincidence, and the figures for the weekly incidence of poliomyelitis (106) in 42 states do not suggest any major prevalence at present. The second possibility is the association between paralytic poliomyelitis and parenteral injections first described in this country by Martin,¹ and in Australia by McClosky.² In these cases paralysis followed immunization with diphtheria, pertussis, and combined prophylactics. These findings have been confirmed,³ but the onset of paralysis nearly always seems to occur between 8 and 28 days after inoculation. Bodian⁴ has provided experimental evidence to support the idea of the "provoking action" of trauma. In these recent reports from the U.S.A. the time interval appeared to be less than a week in some cases. What is not known is how many injections had been received. The third possibility is that live virus was present in a proportion of the formalized vaccine. This is the crucial consideration. Twenty years ago Leake⁵ reported a series of 12 cases of poliomyelitis in children receiving a chemically treated anti-poliomyelitis vaccine. Six children died. All 12 children had had an injection between 8 and 27 days before symptoms, and of these 8 had had a second injection between 1 and 6 days before symptoms. It is possible that if live virus were present the time interval between injection and the onset of paralysis might be shorter than in those cases already referred to following parenteral injection.

From the report in last week's *Journal* of the preliminary finding of the 1954 trials it appeared that the vaccine used in the trials was safe, and there is no cause to alter that opinion. It is by no means clear whether the same safety tests apply to-day. Unquestionably the most important requirement of a vaccine is its safety, and the tests to ensure this must be strict indeed. Meanwhile the general vaccination programme in the U.S.A. is continuing. Let us hope that before long the answer to the problems posed by the recent events in the United States will be forthcoming.

The next session of the General Medical Council will open on Tuesday, May 24, at 2 p.m., when the President, Sir David Campbell, will take the chair and deliver an address.

EMERGENCIES IN GENERAL PRACTICE

ANTE-PARTUM HAEMORRHAGE

BY

FRANK STABLER, M.D., F.R.C.S., F.R.C.O.G.

Assistant Gynaecologist, Royal Victoria Infirmary, Newcastle-upon-Tyne

It is proposed to discuss ante-partum haemorrhage not from the aspect of its types and their subdivisions, nor from that of its operative treatment, but from the aspect of the family doctor called to a patient's house in the later months of pregnancy because there is bleeding from the vagina.

The term "ante-partum haemorrhage" is restricted to bleeding after the twenty-eighth week of pregnancy. Its pathology is no different from bleeding earlier in pregnancy, but its consequences are likely to be more serious to the mother and management may need to take into consideration the life of the foetus. That it may be a serious condition is shown by the fact that it is still the fourth commonest cause of maternal death in England and Wales. The early management of these cases is of critical importance, and I hope to make it evident that what is *not* done is as important as what is done. The practitioner's first concern when called to his patient will not be whether she has placenta praevia, accidental haemorrhage, cervical polypus, carcinoma of the cervix, or a ruptured vaginal varix, but how much blood has been lost and what is her general condition.

Slight Haemorrhage

Slight haemorrhage has occurred and there is no disturbance of the woman's general condition.—To attempt to make an exact diagnosis is dangerous and unnecessary. Overshadowing all the management is the fact that the bleeding may be the first warning haemorrhage of placenta praevia. It is possible that vaginal examination will bring on profuse and dangerous bleeding. Even rough abdominal examination might lead to further bleeding. Gentle abdominal examination may show that the presenting part is in the pelvis. In this case, though placenta praevia is not excluded, one can say that a dangerous degree of praevia is not present and that the urgency is not great. If the presenting part is not engaged the diagnosis is not helped. If a high head or any malpresentation is found it is likely that a dangerous degree of placenta praevia is present. An unusual feature is that the primigravida is likely to be safer than the multigravida. Very seldom does the primigravida go on to profuse and alarming haemorrhage after the first show. The multigravida with her slacker, more accommodating uterus may have a drenching loss as the first evidence of the condition. If the foetal heart rate is altered the case is more likely to be one of accidental haemorrhage.

Without further ado every one of these patients should be referred to hospital for admission. There are many maternity units and nursing-homes staffed by general practitioners, and with his patient admitted the doctor may permit himself a further examination. He might examine with a Sims speculum to exclude polypus, carcinoma, and ruptured vaginal varix. Expert assistance is needed for the treatment of each of these. The removal of polypi from the cervix in pregnancy may lead to severe bleeding needing cautery or suture. The mattress suture needed for ruptured varices may bleed severely from the needle punctures. Carcinoma is of course a rare and dangerous problem.

A woman at the thirty-seventh week of her second pregnancy had a slight, painless loss. Without attempting to make a diagnosis her doctor sent her into hospital. She arrived in perfect

condition. After a week in bed in hospital there had been no further bleeding. The baby was lying somewhat obliquely with the head in the left iliac region. It was decided to examine her vaginally in the operating theatre, with everything set ready for caesarean section. A postgraduate class was invited to attend this examination. The apparently normal cervix was inspected and through the fornices a boggy mass could be felt. In order to press home the lesson that these cases should not be examined vaginally except under these special circumstances I passed a finger through the os, expecting a trickle of blood to ensue. When the finger was withdrawn a cascade of blood followed and soon began to form a steadily enlarging pool on the table. A rapid caesarean section ensued that neither mother nor baby came to any harm, but the class, and I, received a smart lesson.

Moderate Haemorrhage

Haemorrhage sufficient to affect the woman's general condition has occurred.—Here the practitioner's dilemma is not which cases should be sent to hospital (all should) but whether preliminary treatment is necessary before doing so. Let it be said at once that no woman who is still bleeding should be sent on an ambulance journey without some method of stopping the haemorrhage or of making up for what is lost. If pain is present, and especially if there are some evidences of toxæmia, the bleeding is likely to be due to accidental haemorrhage, but this does not affect the management. In all cases an intramuscular injection of $\frac{1}{4}$ gr. (16 mg.) of morphine should be given. The attendant should then consider such factors as the distance from the hospital, whether labour pains have started, the parity of the patient, how much blood has been lost, whether bleeding is still going on, and the aspect of the patient. I write "aspect," for one glance at a woman's face tells more than exact measurements of blood pressure and pulse rate. Indeed the blood pressure may be gravely misleading because of previously present hypertension.

He will lean towards immediate dispatch to hospital in those patients whose loss has not been excessive, those who have pain, and in primigravidae, but will not send in one who is still bleeding. For the rest there should be no woman in Great Britain beyond the reach of a domiciliary emergency service (the flying squad), or at least of a resuscitation organization. Whilst awaiting the arrival of the squad the patient should be induced to lie still and quiet. A tight binder may be applied. No doctor should ever feel at all guilty of having made a fuss if the squad arrives and finds the patient in quite good condition: he should feel proud. The converse is dreadful. An alarmed doctor makes hurried arrangements to bundle his patient into an ambulance and so out of his responsibility. One still hears of these patients arriving at hospital dead or expiring. In the experience of the Newcastle Obstetric Emergency Service all cases of accidental haemorrhage will need to be transported to hospital, but many of them will need transfusion of blood before the journey is made. Certainly all patients with placenta praevia will need admission. These emergency cases should all be given Group O rhesus-negative blood, for even if their grouping has been tested there are possibilities of error, technical and clerical. Once Group O rhesus-negative blood has been transfused it is best to continue with this even if the correct blood group has been ascertained.

A doctor's wife had been quite well in her fourth pregnancy until at the thirty-second week she awoke at 4 a.m. to find herself wet. Her husband found her to be in a pool of blood. He called his partner, who gave her morphine, sent for the flying

squad, and did no more. On the arrival of the squad her blood pressure was 60/40, pulse rate 82, and she had fainted twice. By 5.10 a.m. the second pint of blood was running in rapidly. A tight binder was applied and by 6 a.m. she was in hospital with a blood pressure of 100/70 and a pulse rate of 100. There was a stage IV placenta praevia. At 9 a.m. a caesarean section was done. In all 5 pints (2.8 litres) of blood was transfused. She left hospital with a haemoglobin of 82% and a baby thriving on the breast.

Alarming Haemorrhage or Severe Shock

The haemorrhage is alarmingly severe or the patient shows severe shock or pain.—There may again be placenta praevia, or there may be concealed accidental haemorrhage or, rarely, a true couvelaire uterus ("apoplexie utero-placentaire"). According to the degree of unexpelled blood so will be the degree of shock, until in the worst cases one finds a woman with ashen lips, dilated pupils, collapsed or anxiously restless, with hard tender uterus and in severe pain. All of these patients should be given an intramuscular injection of $\frac{1}{4}$ gr. (16 mg.) of morphine as a first step. None of them should be packed into an ambulance forthwith. Raising the foot of the bed is an ineffective procedure. To have any effect on the circulation the feet need to be 18 in. (45 cm.) above the head, and if this is done any benefit is counteracted by the repeated disturbance necessary to prevent the patient sliding into the bed-head. Overheating should be avoided. The cold skin is an evidence that the body is withdrawing blood to more vital parts. Heat will cause skin vasodilatation and lower the blood pressure further. Blood transfusion is imperative and should precede the ambulance journey or be given during it. If she is left quiet very seldom will a woman fail to improve. The initial catastrophe is usually followed by a rebound. It takes time for the body to muster its resources of hypotension and vasoconstriction, and once these are in action a temporary improvement sets in. By then the squad should have arrived. Manipulations and intervention can only add to the seriousness of the condition unless and until an improvement has been achieved by natural or surgical means.

What should be done if the patient is remote from help and transfusion is not available for at least an hour? To stand idle for longer than this may seem to imperil the patient's life. Many doctors keep a flask of dextran solution and a giving set ready for these emergencies. They should certainly be employed. The solution keeps indefinitely and will maintain blood volume effectively until such time as blood is available. The membranes may be ruptured artificially under certain circumstances: when one is sure that a placenta praevia of severe degree is not present (for example, when the presenting part is well engaged in the pelvis), when recurring labour pains are present, when the woman is a multipara, and especially if labour is premature. The first condition is the most difficult to fulfil, but it is the most important, for to attempt to rupture membranes when the placenta covers the os is dangerous.

Vaginal Plugging and Bimanual Compression

What is the attendant to do with a patient steadily bleeding and deteriorating and help is to be long in coming? Is there no means of staunching the flow as a first-aid, temporary measure? The old-fashioned vaginal plug is an effective means of stopping any ante-partum bleeding, but it was abandoned because it was almost never applied efficiently in domiciliary practice. To apply it certainly needs a general anaesthetic. Up to half a pound (0.22 kg.) of cotton-wool will be needed, and this, soaked in saline, will half fill a bucket. Each pledget when wrung out is packed into the vagina until it is distended to the pelvic walls. The final result will be a hard bolus the size of a foetal head completely filling the pelvic cavity. A tight binder and firm perineal band are then applied. Anything short of this would be useless. One or two sanitary towels placed in the vagina would be more likely to increase bleeding than to stop it. Vaginal plugging is a serious undertaking; never-

theless it is effective as a first-aid measure to stop the bleeding. It could be employed in special circumstances such as in a ship at sea or in a remote area.

A more readily applicable though short-term first-aid measure that can be used during the hour awaiting the arrival of help is bimanual compression. This has always been taught as a means of controlling post-partum haemorrhage, but many are unaware that ante-partum haemorrhage can be stopped by this means. In the desperate case that would decide the attendant to adopt this procedure an anaesthetic is not given. The operator lubricates his right hand (soap will do), forms it into a cone, and by pronating and supinating inserts the whole hand into the vagina. The vaginal vault will be found readily capacious and there a fist is made. The left hand presses on the fundus uteri and so the uterus is squeezed between the two hands.

Twenty-five years ago, when I was district obstetric officer to the Princess Mary Maternity Hospital, it was my duty to call daily on a woman 36 weeks pregnant who had been allowed home from the hospital after one or two small ante-partum haemorrhages because she lived near the hospital and beds were needed. One morning just as I walked in she began a dangerously profuse loss. I was alone and had no materials with me. Bimanual compression was applied and the attention of the neighbours attracted by kicking on the floor. It was an hour before help and an ambulance arrived, but during the whole of that time the bleeding, which was from central placenta praevia, was fully controlled and the patient arrived at hospital in good condition.

Subsequent Management

What is done for the patient after she arrives in hospital is less a matter for this article than for hospital staffs, but as any one of us may be called on to cope with these patients there are one or two principles that should be laid down. There is little room for definitive treatment between simple rupture of the membranes and caesarean section. A great deal of mismanagement has been occasioned by careless reading of Professor Macafee's admirable article on placenta praevia.* It has been asserted that he was against vaginal examination in cases of ante-partum haemorrhage for fear of inducing bleeding in a patient with placenta praevia. The fact is that Professor Macafee wrote, "A vaginal examination should be made in all cases of suspected placenta praevia," but he emphasized that that examination should never be undertaken anywhere but in hospital, and then only if one is prepared for an immediate caesarean section and that the choosing of the time of this examination is a matter for careful thought. There are few obstetricians who would disagree with these dicta. Another misinterpretation is that conservative treatment of placenta praevia can be carried to the extent of allowing patients with this condition to go home until they are nearer term. Such vagueness is perilous. Macafee restricts this licence decidedly to primigravidae who live near and who have been warned not to permit vaginal examination. It is safest never to allow a woman with any degree of placenta praevia to go home. There is strong evidence that many of the severe haemorrhages in placenta praevia have been precipitated by sexual intercourse.

Simple rupture of the membranes may be employed for placenta praevia type I and for most of type II, or for accidental haemorrhage revealed or mixed. On the other hand, lower segment caesarean section is best suited for placenta praevia types III and IV, and for some of type II in which the placenta is situated posteriorly. These are not clear-cut rules and other factors such as the viability of the child, degree of maturity, and parity may alter the decision. A few cases of concealed accidental haemorrhage may need caesarean section or even caesarean hysterectomy. Bringing down a leg in a breech or transverse lie and permitting spontaneous expulsion are still occasionally employed for either variety of ante-partum haemorrhage, notably in patients who are multigravid and in whom the foetus is dead or so premature that its life is valueless.

*J. Obstet. Gynaec. Brit. Emp., 1945, 52, 313.

Bipolar version, which carries such a high foetal mortality, is now little employed except in multiparae when foetal survival is unlikely, and then usually well before term. In any event it is doubtful whether it achieves anything more than to ensure thorough rupture of the membranes and escape of liquor amnii.

Conclusion

All cases of ante-partum haemorrhage are cases for hospital. Accurate diagnosis should not be attempted unless the patient is in hospital. In some cases restoration of the patient's general condition is advisable before she is sent in. If in doubt err on the side of safety, and call the obstetric emergency service. In grave and severe cases restorative measures should always be taken before an ambulance journey. If help is delayed there are first-aid measures that will stop the bleeding, but they should be used only in special circumstances.

Next article on Emergencies in General Practice.—"Acute Food-poisoning," by Dr. C. Hardwick.

PUBLIC HEALTH AND PREVENTIVE MEDICINE

ROYAL SANITARY INSTITUTE CONGRESS AT BOURNEMOUTH

About 2,500 delegates assembled at the annual health congress of the Royal Sanitary Institute, which was held at Bournemouth from April 26 to 29 under the presidency of the Duke of Wellington, Lord Lieutenant of Hampshire. The congress met in ten sections, and in addition there were five special conferences for different categories of workers in the public health service. Representatives from more than forty other countries attended, among them three professors from Moscow.

In his address from the chair of the congress the DUKE OF WELLINGTON said that although great improvement in hygiene had taken place during the eighty years of the Institute's existence, much still remained to be done. Visitors from Northern Europe were shocked at the open food shops still to be seen in this country. He wondered whether the rising incidence of cancer might be attributed to the enormously increased consumption of sterilized foods and the use in agriculture of chemical fertilizers. He knew that these possibilities were scouted by many eminent authorities, but every medical discovery had found many people who were unwilling to believe in it at first. He also criticized the pollution of rivers by industrial waste. Another outstanding problem concerned feeble-minded old people. A kind of institution between a mental home and an old people's home was wanted; it was one of the most difficult problems of local government.

The problem of the ageing population was also the theme of the presidential address in the Preventive Medicine Section by Dr. ARTHUR MASSEY, chief medical officer to the Ministry of Pensions and National Insurance. But he thought they were now beginning to see this problem in better perspective, and the idea that future workers would have increasing difficulty in supporting their aged community was becoming less insistent than in the recent past.

Training for Public Health

In the Preventive Medicine Section Professor R. H. PARRY (Bristol) called for closer integration of undergraduate medical training with the public health department and the general practitioner, so that the student might learn more about conditions in home, school, and factory. He believed that in time the general practitioner would be able to take over medical responsibilities at the health clinics and work in close association with the public health staff; but there

would always remain the need for certain full-time medical officers to be specially trained for other important duties of the health department.

While it was generally agreed that it was better to prevent than to cure, why was it, asked Professor THOMAS MCKEOWN (Birmingham), that when the opportunity was presented, as in the N.H.S., to plan a service on a national scale all the resources were devoted to the treatment of established disease? It was the result of a widespread belief that health depended mainly upon medical services and particularly upon the hospital service. Yet the improvement in health to-day, as compared with the previous century, was due primarily to the fact that people did not become ill rather than to the treatment they received when they were ill. Disease prevention deserved a higher priority than it was given.

Widening Horizons of Preventive Medicine

In their own special conference the medical officers of health discussed the widening horizons of preventive medicine. Dr. A. L. COCHRANE, after describing the work of the pneumoconiosis unit of the Medical Research Council, operating mainly in a Welsh mining area, said that the diseases which were likely to be important in the future were the chronic disabling diseases with a low case-mortality rate, of which rheumatoid arthritis was an example. The long-term programme of preventive medicine was to investigate the causes of these diseases in order to learn what could be done to prevent them. The first step was to measure the disease prevalence, and for this purpose he described how a representative sample of the community might be taken for survey. Then, with the help of different specialists for each disease, the prevalence in a complete population of bronchitis, diabetes, pulmonary disability, and so on could be estimated. Most techniques for this purpose were now sufficiently far advanced to enable medical officers of health to make a start in measuring the prevalence of some of these diseases in their own area.

Dr. J. H. F. BROTHERTON (London School of Hygiene and Tropical Medicine) said that the care of the elderly sick was in many ways the most challenging problem facing the health service to-day. The question must be considered in triple terms: (1) in clinical terms, because efficient diagnosis and treatment shortened the problem of care, reduced disability, and lessened the strain imposed on the social situation; (2) in terms of prevention, for every success in this direction prolonged the period of the old person's independence; and (3) in terms of the social background. In any foreseeable future there must remain limitations on the availability of hospital beds for old people, and methods must be found of increasing the contribution of the out-patient department by making it an institution which old people could use in comfort. But the general practitioner must always bear the main burden of looking after old people in their homes, and the elderly were becoming an increasing proportion of the responsibility. There was every reason why supporting services should be brought to his aid in the patient's home. Why should the services of physiotherapy, dietetics, social work, and the like be available only if the patient happened to go to hospital? "It is the extent to which the public health services are able to underpin the home situation which will determine the strength of that situation as a place where more extensive clinical care of old people can be carried out."

Noise at Work

One symposium at the Congress was devoted to the subject of noise at work, its effect on auditory acuity and on behaviour. Air Vice-Marshal E. D. D. DICKSON, consultant in otorhinolaryngology to the R.A.F., said that there was no doubt that, in occupations associated with continual exposure to loud noise, hearing impairment would result. In its early stages this impairment was in the little-used higher-pitch range and did not obviously manifest itself as a disability. An ear which had been exposed to intense noise was seriously injured in the organ of Corti. The

primary lesion was in the destruction of the outer hair cells of that organ. The organ might be ruptured and released from the basilar membrane. A sudden loud sound might cause immediate destruction, whereas a continuance of noise might bring about the process gradually. It was generally recognized that noise which exceeded in intensity a level of 90 decibels was responsible for acoustic trauma. The earliest onset of hearing loss would be detected by audiometry and appear as a dip or notch in the hearing range in the region of 4,000 cycles per second.

Air Vice-Marshal Dickson stressed the need for pre-employment evaluation of auditory function. In claims for compensation in respect of hearing impairment the difficulty was to eliminate that portion of the worker's deafness, if any, which was not due to his occupation, so that compensation was not paid for something which the work had not caused. Specifically to identify the acquired loss without pre-employment audiometric examination and careful history was often impossible. Equally difficult was the assessment of that portion of deafness which came with advancing age and its separation from the deafness caused by occupational impairment. On the question of protection against noise he urged that the planning and lay-out of factories from this point of view should receive more attention.

Two research workers from the Medical Research Council contributed to the symposium. One of them, Mr. T. S. LITTLE, suggested various methods for reducing or suppressing noise. The only way of ensuring sound insulation from the noise of aircraft and machinery was by building screening partitions of sufficient mass. Thick and heavy walls were the only effective insulators. Concerning the protection of the ear by earplugs and earcaps, he said that when the ear meatus was fitted with an efficient earplug there was a limit to the amount of noise reduction it produced, because quite an appreciable amount of sound by-passed the plugs and got into the ear through the cartilage of the meatus and the bones of the skull. When the noise hazard was still great, even after the use of a well-fitting plug, further protection could be obtained by the additional use of a noise-excluding pad, earcap, or helmet effectively covering the auricle.

Mr. D. E. BROADBENT, of the Applied Psychology Unit, Cambridge, discussed the effect of noise on behaviour. The result of such investigations as he had undertaken was that noise did not produce dramatic permanent change in mental health or behaviour; there might conceivably be subtle changes difficult to detect, but there was no convincing evidence either way. The question most urgently requiring an answer was whether noise produced temporary effects on work which did not involve hearing. His experiments had led him to the conclusion that noises did cause brief shifts of attention from the work in hand, and that such momentary shifts became more frequent in the presence of a high intensity noise.

Child Psychiatry

Several meetings during the Congress were devoted to maternal and child health, and the section on mental health was concerned with the child. Dr. KENNETH SODDY (Child Guidance Training Centre, London) discussed the promotion of mental health in the very early years, the first steps of the infant in adaptation to environment, the first relationship formations, the first steps in instinct modification. An important thing in the child's development was the formation of substitute relationships, for which home gave him the opportunity, the father to some extent replacing the mother, so that the child no longer entirely depended upon her, and grandparents and others coming into the picture and preparing the child for relationships with teachers and other adults who would figure in his later life. He spoke also of the influence of the nursery school in making the child a sociable being.

The child guidance clinics, when they came into being a quarter of a century ago, were looked upon as denoting a real advance in preventive psychiatry, but, said Dr. F. H. STONE, consultant in child psychiatry to the Royal Hospital

for Sick Children, Glasgow, subsequent events had been rather disappointing. It was true that a traditional team of psychiatrist, psychologist, and psychiatric social worker had elucidated a great deal about the aetiology of childhood emotional disorders. But the children who were referred to the clinics were already emotionally disturbed to such a degree that for treatment to be effective it must be intensive and prolonged. The dream of concentrating on very early and minor disorders had evaporated in the face of hard reality.

There was much still to be learned about disturbed parent-child relationships, about the influence of community stress upon inter-family relationships, about the conflict between child-rearing practice as propagated by newspaper articles or radio talks on the one hand and family tradition on the other. Surprisingly little was known about the mutual influences of physical and emotional growth. It was one thing to collect information about incomes, size of family, and so on, and quite another to investigate the personal and intimate feelings and attitudes which were the only available guides to the emotional lives of human beings. Dr. Stone suggested certain ways in which such research might proceed. The psychiatrist and psychiatric social worker should collaborate with the family doctor and health visitor, who were in a strong strategic position for reaching the parents or the parent-substitutes. They were the first-line forces. He also pointed out the need for maturity and sensitivity on the part of those engaging in this work.

Miss ELIZABETH IRVINE (Tavistock Clinic) spoke of the value of staff consultations, not so much because of what was said or done at them, but because of their effect in relieving the anxiety which any professional group was likely to feel in view of the vital responsibilities it carried in the mental health field.

The Health Visitor

Other discussions at the Congress concerned the contribution of processing techniques to the nutritional value of food, child health in the Tropics, and the health and welfare of the office worker. At a conference of health visitors Dr. H. D. CHALKE declared that health visiting was passing through the most important phase in its history. Already there was a noticeable change of attitude in the hospital service, which was using health visitors to an increasing extent. The position, he said, was not so good in the general-practitioner field, where fusion of interests seemed some way off yet and the old vendetta lingered in many places. It was the health visitor herself who could do most to break down old prejudices. A new generation of doctors and health visitors might achieve greater success than the present, and the coming of group practice might alter the picture.

EMPIRE RHEUMATISM COUNCIL

PLANS FOR A MOBILE RESEARCH UNIT

At the annual meeting of the Empire Rheumatism Council at the Royal College of Surgeons on April 27, Dr. W. S. C. COPEMAN, who was re-elected chairman of the Council, announced that it was proposed to establish a mobile field unit for research into aetiological and environmental factors in rheumatic disease. It would probably follow the pattern of the mobile unit being used to study pneumoconiosis among miners. Enlarging on the unit at a subsequent press conference, Dr. Copeman said it would be available for work in any part of the country and in any industrial setting, and possibly later in any part of the Commonwealth. The Council was prepared to put down £30,000 to complete the project, but support would also be needed from industry, which stood directly to benefit from the research. The running cost would be about £7,000 a year. The team would consist of a medical director, a radiographer, and a social worker, and the backing of a university department would be needed; probably Manchester would be asked to provide this. A medical director for the unit was now being sought. The unit would investigate any

kind of rheumatism, but it was thought that a start should be made with osteoarthritis, which was so widespread in industry.

Other Activities

Referring to the Chair of Rheumatology at Manchester University, which the Council had largely financed, Dr. Copeman said that the Nuffield Foundation had offered the University a further grant of £70,000 to develop research in rheumatism, thus providing the professor with the assurance of a well-endowed department. Two E.R.C. Fellows were at work—Dr. Norymberski at Sheffield, who was engaged in research on steroid chemistry, and Miss Muir at St. Mary's Hospital, Paddington, who was studying connective tissue polysaccharides. The Council had also decided to continue to support Dr. E. Wittkower's study at McGill University of rheumatoid arthritis in two contrasting communities. Dr. Copeman added that he himself had been invited to visit Australia in the autumn to help reorganize the Australian Rheumatism Council, and he had also been invited by the Minister of Health of the Dominion to visit New Zealand.

Mr. W. R. C. HALPIN, chairman of the Finance Committee of the Council, said that the total income for the year, exclusive of legacies, amounted to £19,091, compared with £13,775 in the previous year, and legacies had increased by over £3,000.

GENERAL ELECTION

MEDICAL CANDIDATES

On April 15 it was announced that a General Election would be held on May 26. At the last General Election, in 1951, 14 medical men and women stood as candidates and 10 were elected, the same number as in 1950. According to the information at present obtainable the following 14 members of the medical profession will be standing for Parliament at the forthcoming General Election.

The names of those who were Members of the last Parliament are indicated by an asterisk. It is not possible in all cases to give the age of the candidate, but the year of their qualification affords some guidance, and this has been given in parentheses.

*REGINALD FREDERICK BRITAIN BENNETT, V.R.D., Gosport and Fareham, Conservative. (1937.)

M.P. for Gosport and Fareham since February, 1950; Parliamentary Private Secretary to the Home Secretary, 1951-4, and to the Minister of Fuel and Power since November, 1954; secretary of the Conservative Parliamentary Committees on Air and Civil Aviation since 1951; psychiatrist to the Institute for the Study and Treatment of Delinquency since 1950; member of the South-west Metropolitan Regional Hospital Board since 1953; member of Steering Committee of Parliamentary and Scientific Committee, 1952-4; member, Inner Temple; surgeon lieutenant-commander, R.N.V.R.

*ALFRED DAVIES DEVONSHIRE BROUGHTON, Batley and Morley, Labour. (1929.)

M.P. for Batley and Morley since February, 1949; medical practitioner at Batley, 1932-40 and 1945-50; member of Batley Borough Council, 1946-9; former chairman of Dewsbury Division of B.M.A.; squadron leader, R.A.F.V.R.

*Rt. Hon. WALTER ELLIOT ELLIOT, P.C., M.C., Kelvingrove, Glasgow, Conservative. (1913.)

M.P. for Lanark, 1918-23; Kelvingrove, 1924-5; Scottish Universities, 1946-50; and Kelvingrove since 1950; Minister of Health, 1938-40; previously Secretary of State for Scotland and Minister of Agriculture; rector of Aberdeen University, 1933-6, and of Glasgow University, 1946-50.

*SOMERVILLE HASTINGS, Barking, Labour. (1902.)

M.P. for Reading, 1923-4 and 1929-31, and for Barking since 1945. Consulting surgeon and lecturer to ear and throat department, Middlesex Hospital; member of the North-east Metropolitan Regional Hospital Board; Past President, Socialist Medical Association; member of

London County Council for Mile End, 1932-46; chairman of Hospitals and Medical Services Committee of L.C.C., 1934-44; Chairman of London County Council, 1944-5.

*Rt. Hon. CHARLES HILL, P.C., Luton, Liberal and Conservative. (1927.)

M.P. for Luton since February, 1950; Parliamentary Secretary to the Ministry of Food, 1951-5; Postmaster-General since April 7 this year; Secretary, British Medical Association, 1944-50; President, World Medical Association, 1949-50; vice-president, and formerly chairman, Central Council for Health Education.

BERNARD HOMA, Hendon South, Labour. (1922.)

In general practice. Member of London County Council for over 20 years; member of board of governors of Charing Cross Hospital.

DONALD MCINTOSH JOHNSON, Carlisle, Conservative. (1926.)

Contested Chippenham Division of Wiltshire as a Liberal at the General Election in July, 1945; medical officer with East Greenland expedition in 1926 and, later, medical officer in Grenfell Mission to Labrador; left general practice to serve in the R.A.M.C. in the second world war; since founded publishing firm; member of Sutton and Cheam Borough Council.

ROBERT DOUGLAS MCINTYRE, Perth and East Perthshire, Perthshire and Kinross-shire, Scottish Nationalist. (1938.)

M.P. for Motherwell and Wishaw, April-July, 1945; chairman, Scottish National Party, consultant chest physician and supervising tuberculosis physician, Stirlingshire and Clackmannan since 1948.

CATHERINE EDITH ORR-EWING, Bermondsey, Conservative. (1926.)

Senior hospital medical officer, Royal Eye Hospital; school ophthalmologist, Southall, Heston, and Isleworth.

DOUGLAS RENE LOUIS MARCEL POIRIER, Louth, Lincolnshire, Labour. (1943.)

In general practice at Winterton, near Scunthorpe; appointed factory doctor; medical officer under the Ministry of Pensions and National Insurance.

FRANCIS REGINALD ROBERTS, Walsall, North, Conservative. (1928.)

In general practice; member since 1940, and chairman in 1949-50, Brownhills Urban District Council, and chairman of health committee for many years; recently elected to Staffordshire County Council.

*MALCOLM STODDART-SCOTT, O.B.E., T.D., Ripon, West Riding, Conservative. (1926.)

M.P. for Pudsey and Otley, 1945-50, and for Ripon since February, 1950; chairman of British Group of the Inter-Parliamentary Union since 1951; on medical staff of General Infirmary at Leeds, 1929-39; A.D.M.S., 48th Division, 1943-5; chairman, British Rheumatic Association.

*BARNET STROSS, Stoke-on-Trent Central, Labour. (1925.)

M.P. for Hanley Division of Stoke-on-Trent, 1945-50, and Central Division since 1950; formerly in general practice at Stoke-on-Trent.

*Rt. Hon. EDITH CLARA SUMMERSKILL, P.C., Warrington, Labour. (1924.)

M.P. for Fulham West since 1938; Parliamentary Secretary to the Ministry of Food, 1945-50; Minister of National Insurance, 1950-1; Chairman of Labour Party since September, 1954.

The Medical Sickness, Annuity and Life Assurance Society, Ltd., celebrated its recent move into larger premises at No. 3, Cavendish Square, by holding a reception there on April 26. Mr. R. J. MCNEILL LOVE and Sir CECIL WAKELEY, the chairman and vice-chairman of the Society, received the guests. The new offices are needed to cope with the expanding business of the Society, which now has a membership of over 15,000 doctors and dentists.

HEALTH AND POLITICS

The Conservative Party's general election manifesto¹ contains a section entitled "Home and Family," and the following appears under the heading "Good Health":

New hospital building was completely neglected by the Socialist Government. A start is now being made. Plans have been announced and will be carried out over the next few years for the building of new hospitals, both general and mental, and for the extension and modernization of many existing hospitals. We are making special arrangements to replace worn out and obsolete hospital plant and equipment. We shall seek to open new beds where they are most needed, to recruit extra staff and to provide better facilities. We desire to see steady progress in all forms of preventive work. These are our priorities: we rank them higher than free wigs or free aspirins.

We believe that private practice and contributory schemes have a part to play with the National Health Service and we shall therefore maintain the system of hospital amenity and hospital pay beds. We have cut away restrictions on voluntary effort in the hospital service. We shall continue to give every encouragement to voluntary work.

We welcome the increase in the provision of dental treatment, especially for mothers, children and young people, and we wish in co-operation with the profession to push forward with preventive measures.

The problems of the elderly must concern us all. In particular we shall encourage local health authorities to build up their home help services and to provide "half-way houses" for the old.

We shall introduce legislation to give effective status to those, known as medical auxiliaries, who assist doctors in investigation and treatment.

We are anxious to provide the best National Health Service the country can afford. We set up the Guillebaud Committee to study the problems involved and await its recommendations.

The steady fall in infant and maternal mortality rates is a wonderful measure of the nation's better health. Quarter by quarter the records are being broken. We are winning the fight against tuberculosis. Still a great challenge remains for all concerned with the prevention and cure of disease. We shall make sure that adequate funds are available for medical research, and in particular that hopeful lines of inquiry into cancer and polio are urgently pursued.

Air pollution is an enemy to good health, and can cause death. We wholeheartedly accept the need for a national "clean air" policy. The use of smokeless fuels must be encouraged wherever they can readily be made available, and comprehensive legislation on smoke abatement will be introduced.

The section in the Labour Party's manifesto² about "Helping the Family" include the following paragraphs under the heading "Health and Old Age."

Through the National Health Service and National Insurance, the Labour Government began to abolish the fear of old age, sickness and disablement which haunted working-class life before the war. We shall go forward with the job.

In order to restore a free Health Service, we shall abolish all charges, including those on teeth, spectacles and prescriptions. We shall stop queue-jumping by ensuring that the need for treatment and not ability to pay shall be the test for obtaining a bed in National Health Service hospitals.

Now social security must be carried one stage further. In order to remove the last taint of "public assistance," a Ministry of Social Welfare will be established to take over the work not only of the Ministry of Pensions and National Insurance, but also of the National Assistance Board.

To maintain the real purchasing power of these benefits, pensions and allowances, we shall institute an annual review, and in any year in which there has been an increase in the cost of living, the scale of payments will be increased accordingly.

One of the first acts of the next Labour Government will be to improve the rates of National Assistance fixed last February by the Tory Government, an increase which we regard as quite inadequate. We shall also deal with the anomalies of the National Insurance and Industrial Injuries schemes.

Also in the Labour Party's manifesto are promises to enforce clean food standards in shops and restaurants, and greatly to extend water supplies and bring them under public ownership.

IMPERIAL CANCER RESEARCH FUND

The 16th annual general meeting of the governors of the Imperial Cancer Research Fund was held at the Royal College of Surgeons on April 28, with Professor H. R. DEAN, chairman of the Council, in the chair. In presenting the annual report, which chiefly summarized the work of the central (Mill Hill) laboratory and the clinico-pathological laboratories at Lincoln's Inn Fields, Professor Dean said that the histo-pathological resources had been considerably augmented during the past year, and numerous minor alterations had been carried out and equipment added to facilitate the scientific work. Cancer research had grown to include every branch of chemistry and biology. As the report stated, a few years ago the Fund decided to open another laboratory for clinico-pathological studies, and for this the Royal College of Surgeons offered facilities and members of the staffs of London hospitals gave their assistance. An offer from the Royal College for the use of two adjacent sites in Lincoln's Inn Fields had been accepted, and as soon as the College was able to vacate these buildings—probably in the latter half of next year—the sites would be let to the Fund on a 99 years' lease, with the right to demolish the existing houses and rebuild in such a way as would give the clinico-pathological unit greatly increased space.

Latent Cancer

Professor Dean went on to say that it had long been known that the growth of cancer was not continuous, but that intervals might occur during which the tumour remained dormant, sometimes for many years, after which it resumed an active progress often terminating fatally. Recent research had shown that cancers might arise within the human body so small as to cause no symptoms or inconvenience, remaining dormant throughout the life of the individual. Of 220 men who had died from various causes, and whose organs were examined after death by Dr. L. M. Franks, a member of the scientific staff of the Fund, microscopic evidence of cancer of the prostate was found in 36%, and yet in all these cases the local and general effects associated with the presence of cancer were absent. Few were found in men under 50 years of age; with men in the sixties and seventies the tumours were found in about one-third of all cases; in men over 70 in nearly half; in men over 80 in three-quarters; and in nonagenarians in practically all cases. An investigation of latent cancer in other organs was being carried out by Dr. Franks and Dr. F. C. Chesterman in the thyroid, and by Dr. J. Stretton Young in the breast. The work involved a thorough survey of these organs and the use of large sections. A similar problem, investigated by Dr. J. Bamforth, concerned the relationship between hyperplasia of the endometrium and the occurrence of cancer in the uterine body. Dr. E. F. Scowen and his surgical colleagues at St. Bartholomew's Hospital, with the help of the Fund's laboratories, were making a combined clinico-pathological investigation into the human "soil" in which breast cancer flourishes.

Speaking of the work of Dr. James Craigie, director of the central laboratories, on the preservation of tumours by freezing, Professor Dean said that this allowed further study to be made of these tumours after months or years, and their comparison with other tumours. This work had shown that there were two distinct types of cells concerned in carcinoma. The investigations now in progress in the laboratories, varied as their objectives might appear, and varied as were the methods employed, were all in fact closely related to the advancement of knowledge of the cause, progress, and consequence of cancer.

Financial Position

The accounts of the Fund, presented by Mr. DICKSON WRIGHT, the honorary treasurer, showed an improvement in income from all sources, and the number of subscribers to

the Fund had again been much increased. The expenditure for the first time had exceeded £100,000, of which total only £6,582 had been spent on administration and £6,436 on publicity. The number of full-time people employed in the service of the Fund was eighty, and expenditure was always rising. The public had always been conscious of the claim that cancer research made upon their purses and the need for bringing nearer the day when the cause and cure of cancer were discovered.

Viscount Halifax was re-elected President of the Fund, and Mr. Dickson Wright treasurer. The two retiring governors, Lord Amulree and Sir Henry Dale, were re-elected, and the following were approved as "appointed members" of the Council representing the branch of science indicated: Professor H. R. Dean (pathology), Sir Charles Lovatt Evans (physiology), Dr. Cuthbert Dukes (pathology), and Sir Cecil Wakeley (surgery). A vote of thanks to the Chairman was moved by Sir Arthur MacNalty.

Reports of Societies

OUTLOOK FOR THE HYDROCEPHALIC INFANT

"Hydrocephalus of Infancy" was discussed at a meeting of the Paediatric Section of the Royal Society of Medicine on March 30, to which were invited members of the Section of Neurology.

Importance of Early Recognition

Dr. HUGH JOLLY (Plymouth) defined the subject of the meeting as internal hydrocephalus affecting children in the first year of life. Its incidence, he said, seemed to be about 0.2%. It was somewhat commoner among boys than girls, and increasing age of the mother made greater the risk of a child being hydrocephalic. Early diagnosis was essential. Hydrocephalus was suggested by a large globular head with relatively small features, in distinction to the flat top and relatively large features of a child with a large, but not hydrocephalic, head. The latter condition was sometimes familial. The size of the fontanelle was of little value in diagnosis, but a raised tension was of great importance. The eyes characteristically turned downwards in developing hydrocephalus, and might become central after tapping the ventricles. Irritability, spasticity, and decerebrate rigidity were terminal signs, continued Dr. Jolly, and papilloedema was not a feature, except in those cases where the hydrocephalus had been caused by a tumour. Loss of intelligence varied with loss of brain substance.

Investigations should include a radiograph of the skull to rule out intracranial calcification due to toxoplasmosis; routine examination of the cerebrospinal fluid, including a Wassermann reaction; and bilateral subdural taps to exclude subdural haematoma. These should be followed by a dye test, using indigo-carmin, to establish the site of obstruction, and by ventricular air studies, using not more than 50 ml. of air.

The choice of patient for treatment was determined by obvious lack of spontaneous arrest. Poor intellect was not necessarily a contraindication to operation, especially as the degree of attainable intelligence was most difficult to determine. Measurement of the thickness of the cerebral cortex provided some guide to this, and if it was less than 1 cm. mental deficiency was certain. The operation of lumbar arachnoid-peritoneostomy, as performed by Spitz, of Philadelphia, had been used successfully in Plymouth on three out of four recent cases by his surgical colleagues.

Dr. Jolly ended with a plea for more clinical research on hydrocephalus. Little was known of the natural history of the condition, and it was still impossible to forecast those cases which were likely to undergo spontaneous arrest. In view of the fact that the condition was less often fatal than

commonly believed, he felt that more cases should be offered surgery and that many of the children so treated would have an improved mentality, even if they could not become altogether normal.

Increased Formation of C.S.F. an Unlikely Cause

Professor DOROTHY RUSSELL (London) opened her communication by recapitulating the principal obstructive lesions that may be responsible for hydrocephalus in infancy. She criticized the hypothesis that increased formation of cerebrospinal fluid is a cause of this condition. In recent years it had been suggested that both vitamin-A deficiency and hypervitaminosis A produced hydrocephalus in this way. The repeated injection of trypan blue into female rats during pregnancy had a similar effect upon the offspring. The mechanism in these forms of disease had yet to be demonstrated.

The production of hydrocephalus from impaired absorption of cerebrospinal fluid remained a problem, went on Professor Russell. Sinus thrombosis might be associated with a variety of cerebral complications, and the factors responsible for these required further clinical investigation.

Results of Surgery

Mr. GEORGE MACNAB (London), the president of the Section of Paediatrics, discussed observations he had made during the study of 160 infants with hydrocephalus, of whom 105 had been submitted to operation. The first point in the distinction between an infant with a large head and one with hydrocephalus was the turning down of the eyes in progressive hydrocephalus; the eyes returned to the natural position when the hydrocephalus was arrested. The second point was that clinical estimation of tension in the anterior fontanelle as a sign of progressive hydrocephalus was unreliable. Tension was not clinically recognizable until the ventricular pressure in the horizontal position was around 250 mm., yet many cases of progressive hydrocephalus with rapid enlargement of the head had pressures of only 110 to 180 mm. The ventricular pressure ranged between 50 and 180 mm. where there was free communication between ventricular and spinal fluid, compared with pressures of 250 to 300 mm. in cases of intraventricular block.

In progressive hydrocephalus, continued Mr. Macnab, the average increase in the size of the head in the first three months of life was 3 in. (7.6 cm.); a similar increase was seen in the size of the head of a 30-week premature baby, as compared with an increase of 1.2 in. (3 cm.) in the normal full-term infant. In his series papilloedema was not seen, although excessive pallor of the disks was always present. Blindness, however, was a sudden and terminal event, and did not occur early.

A small group of cases had large, flat-topped heads and a wide anterior fontanelle. Air encephalograms showed air passing over the cortex and some dilatation of the ventricular system, with a ventricular pressure as high as 240 mm. These cases were probably due to a relative impairment of absorption, balance occurring at a higher pressure level than normal.

Out of the whole series 57 of the 160 cases became arrested. Five of these were of the type with a flat top to the head; 19 underwent natural arrest, and 33 following operative procedures.

Forty out of the 160 cases were due to the Arnold-Chiari malformation. Dr. A. H. Cameron had shown, said Mr. Macnab, that hydrocephalus at birth in association with the Arnold-Chiari malformation might be due to obstruction at the aqueduct of Sylvius or at the foramina of Magendie and Luschka, and that the cerebellum might obstruct the cerebrospinal fluid circulation by herniation through the tentorial notch. Dr. Cameron had also shown that venous congestion over the malformation might be followed by arachnoiditis leading to the late development of hydrocephalus.

Operative Procedures

Various operative procedures had been used in the 105 cases, went on Mr. Macnab, beginning in 1929 with bilateral ligation of the common carotid arteries with the object of reducing the rate of C.S.F. secretion. Neither this nor diathermy of the choroid plexuses caused any improvement. McNickle's blind third ventriculostomy for aqueduct stenosis had proved unsatisfactory, as had also a similar open operation. Ventriculo-pharyngostomy, by the insertion of a polythene tube into the temporal horn of the lateral ventricle and drainage into the aditus of the mastoid antrum, produced arrest in six out of fifteen cases, but eight cases had died some months after operation.

In lumbar myelomeningocele, drainage of the sac into the peritoneal cavity through a polythene tube was unsuccessful because of loculation inside the sac. A polythene tube passed into the spinal canal above the sac and threaded into the ureter produced some variation in tension in the sac, but two cases had died in uraemia some months after operation. A modification in which the kidney was removed and the polythene tube passed direct into the ureter allowed drainage to take place when the cerebrospinal pressure was high, but eventually blockage or reflux infection occurred.

Drainage by polythene tube from the temporal horn of the lateral ventricle into the transverse sinus had proved unsuccessful in most of the cases so treated, as had also drainage of the ventricle into the peritoneal cavity or the ureter.

New Drainage Device

The current method of treatment, said Mr. Macnab, was drainage of the lateral ventricle directly into the subarachnoid space by the use of a double nylon disk lying in the subarachnoid space. From the disk led a tube which coiled into a spiral after its introduction into the ventricle. This apparatus had been devised by Mr. D. M. Forrest, registrar at the Westminster Children's Hospital. Sixteen cases had been operated on, and at the end of three months they showed a big drop in ventricular pressure, but two post-meningitic cases were not arrested.

In the discussion which followed, Dr. J. E. SCARFF (New York) said that he thought that tension of the anterior fontanelle was the most useful sign of developing hydrocephalus. If there was no obstruction the level of the fontanelle should slowly fall if the child were held up by supporting it under the armpits. In respect to surgical measures, he was using the operation of opening the floor of the third ventricle, as described by Dandy; out of 34 cases 15% had died at operation, in 30% the operative results were unsatisfactory, and 54% had returned to normal.

Mr. A. N. GUTHKELCH (Manchester) said that he had seen 160 cases in seven years. He had operated upon 90. Twenty were too severe, 20 too mild, and 30 (all associated with myelomeningocele) were complicated by complete paraplegia. In cases of internal obstruction, especially anomalies of the iter of Sylvius, he had used Torkildsen's operation for draining the ventricle into the cisterna magna with good results. In communicating hydrocephalus he had had 12 successes for periods of up to 18 months with spino-peritoneal drainage. Spino-ureteric drainage had been as successful in relieving pressure, but there was a morbidity from chloride loss and urinary infection.

Mr. DENIS BROWNE (London) discussed his theory of the production of the Arnold-Chiari malformation by intra-uterine compression.

Mr. D. M. FORREST (London) then demonstrated the disk he had devised and which was being used by Mr. Macnab for draining the ventricle.

Necropsy Evidence

Dr. A. H. CAMERON (Sheffield) described his necropsy findings on 42 cases of hydrocephalus, of which 23 had been investigated at the Hospital for Sick Children, Great Ormond Street, whilst he was Hydrocephalus Research Fellow there. Post-inflammatory stenosis of the aqueduct

was present in seven cases with spina bifida, four cases of post-haemorrhagic hydrocephalus, and two cases of meningo-encephalitis. Congenital stenosis was present in one case with spina bifida and one case with encephalocele. Forking was present in five cases, all with spina bifida; in two of these there was superadded inflammatory stenosis, and in one of the other three the aqueduct, though forked, was not abnormally narrow. Congenital stenosis or forking was not found in any of the cases without spina bifida or encephalocele.

There was conclusive evidence that the spina bifida lesion was in each case a myelocoele. In the six neonatal cases dying within two weeks of birth the cord tissue presented on the surface of the sac as an unclosed neural groove; this was covered over by fibrogranulation tissue in the four cases dying within the first two months of life; and in the remainder it was in much the same superficial position but covered over by fibrous scar-tissue and squamous epithelium. In the cases of spina bifida there was a high incidence of diastematomyelia, rib deformities, deformities of the vertebral column underlying the sac and at higher levels, and of congenital abnormalities of the urogenital tract. This was considered to be the result of inhibition of Hensen's node during early embryonic life. Attention was drawn to the similarities between spina bifida in the human and experimentally induced spina bifida in amphibia.

Three cases of duodenal ulceration, all with gross internal haemorrhage, were encountered. In each case there was a suppurative inflammation of the meninges and ventricular lining involving the attenuated floor of the third ventricle. This was considered to support the neurogenic hypothesis developed by Harvey Cushing.

LOCAL MEDICAL SOCIETIES**Devon and Exeter Medico-Chirurgical Society**

It was salutary to remember that doctors were unnecessary, said Dr. FRANGCON ROBERTS when addressing the Devon and Exeter Medico-Chirurgical Society on April 14. He was speaking on the historical relation between preventive and curative medicine. Many civilizations had flourished without doctors, he said. What had influenced population growth was not medical progress but food and epidemics. Since 1801 the population of Britain had increased fivefold, and thirty-fold since Domesday. From the dim past to the nineteenth century the birth rate had been high, about 35-40 per thousand, but the death rate was only slightly lower, so that only two children per family could be expected to survive. In the fifteenth century the towns became graveyards, and the country areas only a little less so. The Great Plague was not much greater than some previous epidemics; for some obscure reason it was the last. London's population was constantly recruited from the country, but had the plague victims remained in the country they would have died, just as inevitably, of starvation. Eighteenth-century enterprise caused the growth of towns, more food production, and increased population. But sanitation was still bad. Civil engineering was not understood and Roman teaching had been forgotten. The fall in the death rate from 35 per thousand in 1750 to 20.5 in 1815 was not due to medical progress. Vaccination and improved midwifery—due to the decline in rickets owing to better feeding as much as to Smellie's work—were the only purely medical factors contributing to this improvement. Much more was it due to increased cleanliness and sobriety. The industrial revolution was accompanied by an agricultural revolution as a result of which beasts could be fattened and kept throughout the year and winter milk became available. Only recently had curative medicine begun to reinforce preventive medicine, thus creating an entirely new kind of civilization in which, medically speaking, the individual had come into his own. Living longer, he experienced more diseases, many of which required expensive investigation and treatment; hence the great and increasing cost of the Health Service, which must be paid for by the labours of the community, not assumed as a right or a gift from heaven.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Youth Looks at General Practice

SIR,—The article "Youth Looks at General Practice," by Dr. C. P. D. Grant (*Journal*, April 30, p. 1049), should be read by every medical practitioner and senior medical student, for it expresses the views of the majority of young general practitioners. In a short space Dr. Grant reviews comprehensively the fears, problems, hopes, and subsequent thrill of success that result from the efforts of the general practitioner. I should like to stress several of his points and elaborate them.

It is true that many of us on qualifying set as our ideal a specialty and rather unwillingly later turn to general practice as the permanent sphere of our work. Having arrived in general practice it is found that we are lacking in many of the essentials which are necessary to make a success of the job. We do not know what measles is like, and have never seen a patient suffering from diphtheria. In fact, many of us have never even seen a sore throat; and we certainly have never tried to treat one before. Neither do we appreciate the differences in approach which are necessary in the surgery and home, as compared to the hospital. We have not access to white cell counts and endless x-rays to aid our diagnosis. We have to diagnose perforated ulcers immediately after perforation and not six hours later, as the hospital staff can do.

These defects show a grave lack of foresight in our medical education which is partly administrative and partly due to the teaching clinician. Those who arrange our curriculum and timetables have not yet fully appreciated the ever-widening gulf between hospital practice and general practice, which has become so pronounced since the end of the war. Our teaching clinicians are composed more and more of younger men who, though brilliant in their own sphere, have little, if any, personal experience of general practice. As a result, they do not know what the medical student needs to be taught. The uses of cortisone and intravenous terramycin are of no great importance to the general practitioner; but which student has been taught how to treat influenza?

Learning the job takes time, but if we are willing and humble a great deal can be learnt quickly. Like Dr. Grant, I have had to learn to try to control a temper which I had not realized existed. But we must learn to endure fools; and also eccentric hospital consultants. There are consultants who will only do domiciliary visits on a Sunday afternoon, and those who will not do them outside a town except under pressure. These are a minority, granted, but one cannot always do without their services. The majority fortunately are on extremely good terms with the general practitioner and are only too willing to help at any time.

The greatest satisfaction comes from being accepted as a family doctor, and as such I consider it is my duty to provide full maternity services to all my patients who request such services; and the majority prefer their own doctor to the clinics. I am glad we have no regulation in force in this part of the world like there is in Glasgow controlling admission to maternity beds. Here the general practitioner has equal access to beds as do the local authority clinics and those who attend the hospital clinics entirely. It seems to me that the local authority clinics for maternity care have largely outworn their usefulness in many areas, and could be dispensed with or curtailed. As Dr. Grant says, it is the general practitioner who has to deal with the antenatal emergencies, and not the clinic.

Finally, let us realize that the patients themselves are mostly considerate and appreciative, often out of all pro-

portion to the services rendered to them. But a word of advice to those who have not yet settled in practice—get out of the seaside resorts and wealthy residential areas, and practise in an honest-to-goodness working-class area, where there is more work, more appreciation, and more satisfaction to be gained.—I am, etc.,

Rossington, Doncaster.

G. F. G. MARSHALL.

Clinical Staging of Cancer of the Breast

SIR,—Mr. Michael Harmer's letter (*Journal*, March 26, p. 790) is timely in calling attention to the need for a method of staging breast cancer which is recognized internationally. Many methods of treatment are now being practised, and it is therefore important to be able to compare the results from different centres. At present, there are at least ten different methods of staging the disease, which makes a comparison between results difficult and often impossible, and has prevented a proper evaluation of some of the results published in the past. The need for an international method of staging breast cancer such as exists for cancer of the cervix is well recognized, and the problem of finding a method acceptable to the majority of workers has already been discussed at several cancer congresses. If a simple method of staging cannot be agreed upon, it would still be possible to present the results in such a way as to enable the work of different centres to be compared.

The features which influence the prognosis and on which most methods of staging are based are the fixation of the primary tumour to skin, pectoralis major, and chest wall; the presence of enlarged axillary nodes and their fixation; the presence of supraclavicular nodes and distant metastases. Cases would be placed into various groups according to which of these structures was involved at the first clinical examination. If distant metastases were present, however, further subgrouping according to the local condition of the primary tumour would seem unnecessary. In the same way, one group would suffice for cases having supraclavicular node involvement and one group for cases with fixed axillary nodes. For the less advanced disease, a number of groups would be required, depending on the state of the primary tumour and the axillary nodes. For example, a suggested arrangement of groups might be:

- Visceral Metastases Present:
Group A.
No Visceral Metastases, Supraclavicular Nodes Present:
Group B.
No Visceral Metastases, no Supraclavicular Nodes:
Group C. Fixed axillary nodes.
Group D. Mobile axillary nodes—primary fixed to chest wall.
Group E. " " " —primary fixed to pectoralis major.
Group F. " " " —primary fixed to skin.
Group G. " " " —primary mobile.
Group H. No axillary nodes—primary fixed to chest wall.
Group I. " " " —primary fixed to pectoralis major.
Group J. " " " —primary fixed to skin.
Group K. " " " —primary mobile.

Other groups might have to be added to include certain clinical features considered to be of importance in prognosis such as overlying skin nodules, *peau d'orange*, etc. Of necessity, the number of groups would be rather large and this would mean that only a few cases would be included in some groups. When results were being compared, however, it is likely that several groups would be considered together, and the small numbers in some groups would therefore not be a disadvantage. Individual groups could be rearranged according to any method of staging, and it would thus be possible not only to compare the results published by different workers but also to make a comparison with previously published figures where the method of staging was known.—I am, etc.,

London, W. 12.

ROBERT MORRISON.

Carcinoma of Bronchus and Pulmonary Tuberculosis

SIR,—I was very interested to read Dr. A. Sakula's article (*Journal*, March 26, p. 759) on this subject. He is quite right in stating that this combined condition is not uncommon. During the years 1951–4 I have seen nine cases, all male, occurring in Birkenhead and Wallasey—a total population of 244,000—in which the adult male pulmonary cases on the tuberculosis register at the end of the four years in question were: 1951, 985; 1952, 937; 1953, 1,027; 1954, 1,115; and the cases of carcinoma occurring in the lung in men were: 1951, 43; 1952, 50; 1953, 49; 1954, 54. I realize that the total number of cases involved cannot possibly be statistically significant, but I feel that these background figures are worth recording.

In addition to these cases, I have seen two other cases during this period in which it was quite likely that the same two conditions coexisted, but the proof is not sufficient to record them as definite. All but one of the cases have been proved histologically or by post-mortem examination, and in the other the x-ray and clinical evidence was such as to make the diagnosis certain. Two cases did not show any tubercle bacilli in the sputum, but the laryngeal biopsy in one and the tuberculous epididymo-orchitis in the other indicated that the infiltration in the lungs was definitely tuberculous. I have not the exact details of the smoking habits of all the patients, but they all certainly smoked, and at least four of them were heavy smokers. The site of the carcinoma did not appear to be related in any way to the site of the tuberculosis. In six cases the carcinoma appeared to supervene on established pulmonary tuberculosis, while in three others the two conditions appeared to occur more or less simultaneously.

As we go on keeping our patients with active pulmonary tuberculosis alive, so, I think, we must be on the constant look out for a carcinoma supervening on the pulmonary tuberculosis, though many cases seem to be the sort in which it is unlikely there will be much in the way of successful treatment, partly because of their age and partly because of the rather extensive nature of the tuberculosis. If one of my cases had been diagnosed earlier, he might possibly have been treatable by pneumonectomy, and so I think it is important that we should bear the combined diagnosis in mind should a case of pulmonary tuberculosis fail to respond to treatment within the first three months. The other important point is that any small rounded nodule appearing in routine serial x-ray follow-up of patients with pulmonary tuberculosis should be regarded as a potential carcinoma, and, should the local chest condition permit it, early resection should be seriously considered.

I should like to acknowledge the help of the pathologists who carried out the post-mortem and histological examinations; of Mr. Ronald Edwards, who carried out the bronchoscopies; and of Dr. Fulton, medical director of the Liverpool Radium Institute, who supplied the figures for the incidence of carcinoma of the lung in the area.—I am, etc.,

Liverpool, 1.

DAVID L. CALDWELL.

Natural Childbirth

SIR,—Although at one time I was an ardent follower of Dr. Dick Read I came to feel that for a function that was meant to be "natural" elaborate instruction and exercises in class twice a week and alone twice a day seemed unnecessary. I developed a routine in practice that seemed satisfactory. At the first visit I gave a little explanatory talk on pregnancy and labour accompanied by diagrams on the blotter, and explained a simple exercise for the abdominal muscles (this is more diligently practised if it is explained that it will help the figure return to normal after the baby arrives). At about 36 weeks I gave a slightly more detailed description of labour and the gas and air machine. I tried to be present very early in labour to show the woman how to put into practice what I had told her about relaxing. I then visited her frequently to keep up

her morale, and towards the end of the first stage stayed. Relaxation achieved in this way is just as good as that much practised beforehand, and apprehension is less. After labour I gave further exercises for the abdominal muscles and for the perineum. I have never used exercises designed to increase pelvic capacity during pregnancy. They may add to the prevalent low backache due to sacro-iliac strain.

It is a mistake to tell a primipara that labour should be painless. In animals, where it is all perfectly natural, first labours appear to be accompanied by considerable pain (cats and cows). With complete relaxation I fail to see why the end of the first stage should be painful, as your correspondents seem to think. I personally have never found it so, but I think the final stretching of the perineum as the head crowns with a first baby is nearly always painful. It is for this that the gas and air is invaluable. It need not cause lack of co-ordination with subsequent loss of control as stated by Mrs. Alison Duddington (*Journal*, April 16, p. 971). It will do this if it is not started till the woman is distressed and not in a mood to use it calmly. She should be taught to use it in the painless contractions at the beginning of the second stage; it will then prove invaluable both to the woman in relief from pain and to the attendant in increased co-operation from a calm patient at the end. When properly used it causes no clouding of consciousness.

One thing that is not fully realized is that this type of instruction can only be given to patients willing to receive it. The majority of women are much too shy of these matters to attend classes or even tolerate private instruction. They prefer to keep it all wrapped up in mystery and old wives' tales. The beginning of a first pregnancy is the wrong time to radically alter an outlook, and most women will not take kindly to a doctor who tramples on her prejudices at this time. Much might be done by health education to change the attitude of young people before they start on their families.—I am, etc.,

Wednesbury.

HAZEL B. BAKER.

SIR,—As another doctor's wife whose 3-weeks-old daughter was born in hospital, I should like to comment upon Mrs. Constance Lynn's letter (*Journal*, April 2, p. 851). While in the maternity ward I was struck by the great difference in behaviour and attitude of mind between the mothers who had attended classes and those who hadn't, and which affected at least the first part of their labour. I remember in particular one woman who confided in me her absolute dread of being wheeled to the labour ward—she lay in bed tense with fear and not through the pain of contractions. I thought then that if only she had attended the voluntary lectures and classes and visited the labour ward she would have realized there was nothing to be afraid of. Was it only coincidence, I wonder, that eventually she had a caesarean section, as labour was not progressing satisfactorily?

I am sure, however, that understanding the natural process of labour is as beneficial as exercises and relaxation. A woman is much more likely to remain co-operative—particularly towards the end of the first stage when relaxation is very hard—if she understands what is happening. As to my own application of exercises and relaxation, I did find the latter helpful, although I found it impossible to maintain complete relaxation towards the end of the first stage.—I am, etc.,

London, S.W.11.

RACHEL LITTLEWOOD.

Salk Vaccine

SIR,—The Salk anti-poliomyelitis vaccine is prepared from monkey tissue cultures. Is it certain that injection of this preparation will not produce rhesus antibodies when injected into susceptible human subjects, most especially those already sensitized?—I am, etc.,

London, S.W.1.

J. G. HUMBLE.*

The Aftermath of Hysterectomy

SIR,—The letter of Dr. Winifred Coppard (*Journal*, April 2, p. 852) raises two separate issues. She suggests that gynaecologists may advise the performance of hysterectomy without ascertaining that their patients appreciate what that operation involves. This failure to inform the patient is always reprehensible, although it may sometimes be difficult to give an elementary lecture in the anatomy of the genital tract to a patient whose mind is hopelessly disoriented by hearing the word "operation."

The second implication is that patients may not be warned in advance of the changes (anatomical, hormonal, psychic, and domestic) that may follow in the wake of that operation. The reason that this warning is not given lies surely in the extreme variation of individual response and the difficulty in assessing how far that response is functional or organic. It is common experience that symptoms of the climacteric will rapidly occur in many women from whom both ovaries have been removed, yet in some cases there will be no such symptoms and a vaginal smear will show evidence of oestrogen activity. Conversely, failure of ovarian function may be established within three years in a significant percentage of women in whom one or both ovaries have been retained. The age of the patient and the operative technique may both be important.

The follow-up of these cases is not an easy matter, for the personality of the investigator may easily cause symptoms to be suppressed or exaggerated. The attitude of the surgeon before operation and during convalescence is also of great importance, and the conservative operator who rarely removes an ovary will get wonderful results from the assurance that "the womb is of no value, but of course the ovaries which make you womanly will be saved." It must be admitted that the radiotherapist can do an equally good line with his remark, "Just a small dose of rays to damp things down, and of course nothing need be removed." It is, however, my personal opinion that, with careful pre-operative reassurance, early return to normal domestic life, including intercourse, and an operation that preserves the maximum ovarian function, any unpleasant aftermath is extremely rare; when it does occur it will usually be in a patient whose operation has been occasioned by a psychosomatic disorder.—I am, etc.,

Birmingham

W. G. MILLS.

SIR,—Although one agrees with Mr. V. B. Green-Armytage's contention (*Journal*, April 16, p. 971) that disastrous results may follow the total ablation of both ovaries when performing a hysterectomy for non-malignant disease of the uterus such as fibroids, one cannot agree with his suggestion that the same results may follow treatment by irradiation.

In reviewing my own 990 cases¹ of metropathia haemorrhagica, fibrosis uteri, and fibromyomata of the uterus, I find that I performed myomectomy or hysterectomy in 502 cases and irradiation in 488—namely, deep x-ray therapy in 314 and radium treatment in 174. I reserved irradiation for all cases of metropathia, and x-ray therapy for metropathia and fibroid uteri not larger than a four-month pregnancy where the fibroid was interstitial and not undergoing degeneration, there was no other pelvic abnormality, and malignancy was not suspected.² Owing to the war I had to treat some cases of metropathia with radium for which otherwise I should have preferred x-ray therapy. The latter can now be done in one sitting lasting 64 minutes, and is, in my opinion, an ideal treatment for patients over the age of 40–45, for one can guarantee a permanent amenorrhoea and a reduction in the size of the uterus to one-third its original size, thus eliminating pressure symptoms. According to my follow up there is no loss of libido and no psychological disturbance.³ In younger patients undergoing x-ray treatment the amenorrhoea lasts only about two years, and in two of my cases the patients later produced healthy babies.

In the case of radium treatment it is difficult to believe that the usual intrauterine dose could have any effect on the ovaries, considering their distance from the radium and the thickness of the uterine wall. I certainly have not encountered disastrous results following irradiation, such as have recently been described in your columns following the total ablation of both ovaries, and the consequent break-up of hitherto happy marriages.—I am, etc.,

London, N.W.8.

Chlorpromazine for Mental Hospital Patients

SIR,—It is always gratifying to hear of psychiatrists in mental hospitals taking an interest in those of their patients who have been ill for a long time. One cannot conceive any treatment, provided it does not produce irreversible structural damage, failing to be of benefit to these patients, because it would mean that during the period of treatment they will receive the observation and interest of the psychiatrist and his nurses, which they otherwise generally fail to receive. One has little doubt that chlorpromazine has indeed some effect in psychiatric illness, but one cannot believe that anyone will be favourably impressed by the accounts of it given in the *Journal* of April 9 by Dr. J. Lomas (p. 879) and Dr. C. P. Seager (p. 882). These two articles reveal what would be a quite astonishing state of affairs were it not so widespread. Those of your readers who are not psychiatrists should realize that the state of so-called improvement produced in the patients in these two hospitals which the authors allege was due to the drug was a state less good than that which can easily be produced by nothing more dramatic or expensive than a liberal regime.

One does not wish to say the drugs should not be tried out, but one cannot emphasize sufficiently that until psychiatrists are aware of the natural course of the diseases which they treat they should beware of attributing improvement to the drugs they are employing. Patients described in these articles have improved concurrently with the administration of chlorpromazine, but their final state is not as good as that found in many hospitals in this country who are without this drug.

The nursing problems which one of the authors describes are, one thinks, man-made, and if these patients were treated liberally then they would show an even greater improvement than that which he ascribes to the drug he employs.—I am, etc.,

Wallerby, E. Yorks.

J. A. R. BICKFORD.

Toxicity of Chlorpromazine

SIR,—I read with interest Dr. J. R. Tasker's paper on a case of fatal agranulocytosis (*Journal*, April 16, p. 950). Agranulocytosis is a complication of chlorpromazine that is not widely known, and, with the increasing use of this drug in general practice and other fields, it certainly must join the ranks of such drugs as thiouracil and phenylbutazone as a potential inhibitor of leucopoiesis, so that the possibility may be borne in mind (especially during the sixth week of treatment).

On referring to the manufacturer's booklet on chlorpromazine (first edition, undated like most of these booklets unfortunately are) I find that minor variations in the white cell count, either way, have been noted but "there has been no evidence of depression of leucopoiesis." The sex incidence of agranulocytosis attributable to chlorpromazine is interesting, although not altogether unexpected, as agranulocytosis from all causes is said to be two or three times more frequently encountered in females than in males.¹ Amidopyrine was at one time the outstanding toxic or sensitizing agent, and the inclusion of this drug (in the past) in pain-relieving tablets may, I suppose, partly account for the predominance of the disease in women. The mortality

rate is high, being in the region of 70% to 90%,¹ and it is therefore encouraging to know that three out of the four cases mentioned by Dr. Tasker recovered, in spite of their age (when leucopoiesis in any case is not at its best). Antibiotics were given to them all as prophylactic treatment; the three that recovered also received either cortisone, blood transfusion, or a combination of blood transfusion and folic acid (other lines of treatment suggested in the textbooks are: "pentnucleotide," leucocytic cream, and pyridoxine). As Dr. Tasker only mentions antibiotic treatment in his case, and as Dr. J. Lomas (*Journal*, August 7, 1954, p. 358) treated his patient purely on penicillin for ten days before resorting to cortisone, I wonder if there is any contra-indication to carrying out these "curative" methods, such as blood transfusion, immediately agranulocytosis is diagnosed?

It is wise to heed Dr. Tasker's warning that evidence of sensitivity to chlorpromazine, such as fever, jaundice, and skin eruptions during the early weeks of treatment, should be treated with respect, and should call for regular blood counts, especially in the light of the fatal case of jaundice reported by Dr. R. H. Boardman (*Journal*, September 4, 1954, p. 579), be this toxic or obstructive (see the letter by Drs. J. G. Macarthur and B. Isaacs, *Journal*, September 25, 1954, p. 754). In your leading article on September 4 (p. 581) you advise that if big doses are to be used a liver function test should be performed beforehand and the urine tested for bile while treatment goes on. Pallor of faeces must also be a warning sign. In a further leading article on chlorpromazine (*Journal*, February 5, p. 338) you conclude that as the effects of this drug are prolonged and for the most part irreversible, together with evidence of toxic action on the liver, great caution must be exercised in its use. In Dr. Tasker's article we have yet another reason for caution.

I doubt the advisability of using it for treating children suffering from intractable vomiting following whooping-cough (Dr. Howard Reeve, *Journal*, April 23, p. 1034), especially when ketosis and dehydration were probably accompanied by some impairment of liver function. With so many new drugs of considerable potency and toxicity available, it will be wise, especially for the general practitioner, to exercise great care and discrimination in using them, and, until we have better knowledge of their more remote effects, to confine their use to a carefully selected series in which constant supervision is possible.—I am, etc.,

Penygroes, N. Wales.

REFERENCE

¹ Wilkinson, J., in *British Encyclopaedia of Medical Practice*, vol. 1, p. 261. London.

SIR,—I was interested to read the account of chlorpromazine jaundice by Dr. A. G. W. Whitfield (*Journal*, March 26, p. 784). I have recently had a similar case.

A housewife aged 74 was admitted to hospital on February 16, 1954, with mental confusion and loss of memory. In October, 1954, she became restless and agitated. Chlorpromazine (200 mg. daily) was started on November 25, the dosage being increased to 300 mg. daily on December 2. Since admission she had vomited small quantities of food from time to time, but on December 6 copious vomiting began and the chlorpromazine was discontinued. On December 9 jaundice was first noticed. The jaundice steadily increased. It was accompanied by pale stools and bile in the urine. Her general condition deteriorated progressively and she died on January 25, 1955.

In brief, the post-mortem findings were as follows: external examination: thin, deeply jaundiced, with slight oedema of the ankles; respiratory system: lungs congested with oedematous lower lobes; cardiovascular system: normal, apart from a flabby myocardium and some old thickening of the mitral valve; abdomen: liver atrophic (880 g.) and firm, surface bile-stained with a fine nutmeg surface; gall-bladder shrunken; biliary tracts all free of obstruction; other viscera not significantly abnormal; central nervous system: C.S.F. jaundiced, brain rather atrophic with area of softening 2 cm. in diameter in the right temporal lobe.

Histologically, the liver showed severe centrilobular degeneration of the parenchymal cells with well-marked fatty change and deposition of bile. The appearance suggested a toxic change superimposed on mild chronic congestion. In sections of the myocardium there was some hypertrophy of the muscle fibres and a little interstitial fibrosis.

In common with other cases reported the clinical picture was one of obstructive jaundice, and the pattern of the liver function tests carried out supported this conclusion. The post-mortem findings suggested that the liver had already suffered mild damage as a result of anoxaemia due to heart failure. In life heart failure had not been apparent clinically, but her extremely restless condition made proper examination difficult. The total dosage of chlorpromazine (2.6 g.) was small, but the initial dosage (200 mg. daily) probably rather high. This is the first case of jaundice in over 100 cases treated with chlorpromazine by the present writer. Although a valuable drug in the treatment of certain psychiatric disorders, it should not be used unless definitely indicated and is probably dangerous in the presence of any liver damage already present.

I would like to thank Dr. J. O. P. Edgumbe for the pathological reports.—I am, etc.,

Exeter.

B. V. EARLE.

Cyst Formation Following Hernia Repair

SIR,—I was interested in the article by Mr. A. G. Rutter (*Journal*, April 16, p. 951) on the formation of a cyst following dermal implant repair of a hernia. Actually, in our experience at the Birmingham General Hospital this is more common than his article would suggest. We have now seen half a dozen of these, one of them five inches in length. Another contained large amounts of golden hair. Another complication we have observed is complete disappearance of the grafts. We have now completely abandoned the operation owing to these complications, and also to the fact that sepsis is not an infrequent occurrence. All these complications are, of course, not surprising in view of the completely unphysiological nature of the operation.—I am, etc.,

Birmingham, 4.

G. T. WATTS.

Chicken-pox Quarantine

SIR,—Dr. Neil McDougall's letter (*Journal*, April 23, p. 1030) is interesting. In 1922 a patient aged 55 paid several visits to his brother, who had herpes zoster in a severe form. My patient developed herpes. His daughter, living with her parents and near full term in her third pregnancy, developed chicken-pox. Three days after the appearance of the rash she gave birth to a healthy boy, who developed the rash of chicken-pox at the age of 14 days. Mother and son did very well.

In the case of a mother suffering from small-pox at her confinement, the infant usually has the disease at the same stage as the mother.—I am, etc.,

London, S.W.12.

S. G. ASKEY.

SIR,—I was surprised to read the suggestion in Dr. G. E. Breen's letter (*Journal*, April 23, p. 1030) that an attack of chicken-pox might be beneficial in protecting the patient from a subsequent attack of herpes ophthalmicus with concomitant iritis. Surely this view is contrary to observed fact. Thus, McNair Scott,¹ in a full discussion of the association of chicken-pox with herpes zoster, states that "it is very common for a person with herpes zoster to have a previous history of chicken-pox; about 70% of cases were found to have such a history in a recent survey of epidemic diseases in schools." In fact the author suggests the hypothesis that herpes zoster is a response of an immune person to an overwhelming dose of varicella-zoster virus. Likewise, Ker² states that "it is undoubtedly the fact that many adult patients suffering from herpes zoster are able to give a definite history of chicken-pox in childhood." It would seem more germane to the argument concerning the quarantine of chicken-pox to point out that exposure to chicken-pox can in an adult result in herpes ophthalmicus with risk of damage to the eye.

I would support Dr. Breen's statement that severe complications of chicken-pox do, exceptionally, occur. Besides

encephalitis, I have also seen as complications staphylococcal septicaemia, a gangrenous lesion of the anterior abdominal wall giving rise to peritonitis, and a few severe cases of pneumonia. I also know of a colleague who had a case in which perforation of the oesophagus occurred with fatal results. Even uncomplicated chicken-pox in the adult is generally quite an unpleasant experience, and in the female there is the risk of a residual facial scar being regarded as a disfigurement. I feel, therefore, that the doctor advocating indiscriminate and avoidable exposure to chicken-pox might ultimately find himself in difficulties.—I am, etc.,

Croydon.

J. J. LINEHAN.

Corrosive Poisoning

SIR,—The article on corrosive poisoning (*Journal*, April 16, p. 962) cannot pass without comment. Under "Chemical Burns of the Skin," it is said: "These are usually due to strong acid or alkali spilled or splashed at work. They are seldom severe, as the substance is easily washed off." My criticism is directed only to the statement so far as it relates to sodium hydrate, commonly known as caustic soda, of which I have had many years' experience, and I have to say that burns from this cause may be very severe and that the substance is not easily washed off.

In 1930 at the alkali works with which I became connected there were 26 men off work with caustic burns. The treatment in vogue was copious washing with water and then application of bicarbonate of soda. The result was a burn which looked like an inlay of black leather in the skin; this took several weeks to heal, the gangrenous skin having to separate, leaving a granulating area, slow to heal. There is a latent period of 20 to 30 seconds after the contact of the caustic with the skin. If within this time a stream of 5% solution of ammonium chloride is directed on to the affected skin, no burn will take place: so that wherever there is a caustic soda risk that solution ought to be at hand for instant use. Caustic burns of the skin are almost unknown at the present day at these works, although the exposure is greater than it was then.

In the case of splashes in the eye the results are very serious with inadequate treatment: symblepharon, ectropion, intropion, corneal ulcer, corneal opacity, even loss of vision. All these have been abolished. I dare not trespass any further on your tolerance. The way that these eye risks were abolished was described in the *Journal* of June 19, 1943.—I am, etc.,

Bunbury, Cheshire.

HERBERT TERRY.

Agricultural Pesticides

SIR,—I was surprised to see aldrin and dieldrin in Dr. E. F. Edson's paper (*Journal*, April 2, p. 841) under the "Comparatively Safe" heading. These compounds were introduced to Britain some four or five years ago, and Messrs. Shell Chemicals Ltd. issued special instructions to insecticide manufacturers regarding the handling of aldrin and dieldrin in the production of typical insecticide mixtures—sprays, powders, and the like. The oral toxicity of dieldrin was quoted as eight times that of D.D.T. However, it appears that aldrin and dieldrin can be absorbed through the skin to a much greater extent than D.D.T., and that it is dangerous to walk across a floor carrying the dust of these chemicals, as the shoe soles would become contaminated and ultimately lead to absorption into the feet. Masks and special washable clothing—including rubber footwear—would have to be worn by workers.

While recognizing that preparations containing these compounds in dilute form may not be nearly as dangerous as the pure substances, considerable risk appears to attach to aldrin and dieldrin. The control of insects resistant to

D.D.T. has led to the introduction of chemicals more and more toxic to human beings, the deadliest being the organic phosphorus compounds. Aldrin and its companion are not comparable with the latter, but are nerve poisons and could probably lead to chronic poisoning from contaminated clothing unless the worker at least uses rubber gloves, apron, and boots, and washes these thoroughly after use.—I am, etc.,

Walton-on-Thames.

A. F. MCK. JACKSON.

Nocturnal Enuresis

SIR,—I have for some time past treated all cases of non-organic nocturnal enuresis by suggestive therapy to the child and varying doses of amphetamine. I have insisted on the children drinking not only their usual drinks but greatly increased quantities irrespective of the nearness to bedtime. Explanation is given to the child and the parents that the enuresis is a failure on the part of the bladder of remembering how much fluid it can take during the day when volition is brought into play. By its ability to hold urine for longer periods and by increasing amounts during the day does the child relearn control by night. The amphetamine in the first few nights of treatment keeps the child from sleeping and sends the child on many "excursions," increasing the child's confidence that at last it can be trusted at night.

I am unable to claim 100% cures as do the advocates of conditioning, but find the results excellent and certainly better than when the fluid intake is restricted. The child is more co-operative and helpful, feeling "grown up" because he is trusted and treated normally. I put forward this letter not to establish any new theory or more modern concept of treatment of enuresis but to remove ancient prejudices and injunctions not only from medical practice but from medical textbooks.—I am, etc.,

Sidcup, Kent.

L. A. NICHOLS.

E.C.T. in Pregnancy

SIR,—With reference to the annotation on E.C.T. in pregnancy (*Journal*, April 16, p. 958) we would like to confirm the safety of this procedure.

During the last seven years we have successfully administered E.C.T. in 10 cases of pregnancy with no ill effects. The pregnancies have been between 3 and 8½ months' gestation. We do, however, deprecate the use of anaesthetics and muscle relaxants in these cases, as they involve an additional complication and risk. They are unnecessary when the new ectonus technique of E.C.T. is used, in which there is no sudden muscle contraction, and the clonic movements are eliminated. With the ectonus technique we do not consider any stage of pregnancy a contraindication to E.C.T.—We are, etc.,

Speaking Up

SIR,—Your correspondents blamed only the speakers at meetings for lack of intelligibility. The acoustic properties of lecture-rooms, often quite atrocious, should be also taken into account. Many amplification systems, installed to improve acoustics, are ineffective, or make things worse by increasing the effects of reverberation. The microphone provided for the speaker is usually strongly directional, and as soon as the lecturer turns his head a little (for instance, when trying to point out certain things on the blackboard or screen) amplification ceases, and intelligibility is reduced to the minimum. Also one must consider that a large proportion of the audience at medical meetings consists of elderly gentlemen, and a good number of them already suffer from more or less impaired hearing for high frequencies. Consequently their discrimination of speech in unfavourable circumstances is reduced. This is made worse when the lecture is read, because the audience is then deprived of a valuable aid to intelligibility—that is,

lip-reading. One should not deliver a lecture in a darkened room, and the lecturer should be positioned in a favourable light and favourable position from the point of view of the audience, so that listeners should be able to lip-read as much as possible.

Undoubtedly many speakers could improve their technique. Some would benefit from a little rehearsal with the aid of a tape recorder. Many would get such a shock from hearing a record of their own speech that they would change their mind and decide not to deliver the lecture. This is of course not necessary. A little practice could make a great difference. For instance, the lecturer could practise keeping his voice as low as possible. The higher the pitch of the voice the smaller the degree of intelligibility. Excitement, which is difficult to suppress, causes tension of the vocal cords and this raises the pitch of the voice. Practice can lessen this unpleasant effect.

Speakers who have doubts about their voice and intelligibility of their speech should not hesitate to take professional advice. For instance, speech therapists, employed in so many hospitals, could be very helpful, and it should not be below the dignity of the lecturer to ask for such advice. Perhaps some experts could produce a little booklet for medical speakers on the technique of delivering a scientific lecture.—I am, etc.,

London, W.C.1.

An Occupational Hazard

SIR,—During the past year in casualty I have come across the following similar cases—which might be described as an occupational hazard. Each was a healthy young man in the butchery trade, presenting with a $\frac{1}{4}$ -1 in. (6.4 mm.-2.5 cm.) long stab wound of right groin over the femoral canal, and the wounds lying in a transverse direction. All the patients were right-handed, and each stated they were boning frozen meat when the knife accidentally slipped through a part of the meat which had thawed out. The first case was in a 29-year-old butcher, who was brought in moribund although still just conscious. He had a 1 in. (2.5 cm.) stab wound over the right femoral canal. It was not bleeding when I saw him, but he had obviously lost pints of blood. An intravenous drip was put up immediately, but after 10 minutes, when only $\frac{1}{4}$ pint (0.2 l.) of blood had gone into the patient, he began to bleed from the wound again, and collapsed and died in one minute. A post-mortem examination was not carried out, but I feel that as the wound measured exactly the same as the widest part of the 4-in. (10.2-cm.) long knife—that is, 1 in. (2.5 cm.) at the hilt—the knife probably penetrated the abdominal aorta. The other three cases were more fortunate in that the femoral vein was cut on one occasion, and only the skin and superficial tissue in the remaining two. All three were sutured after the bleeding vessels had been ligated, and made an uneventful recovery.

A master butcher present at the inquest on the first case stated that this was not the first fatal case he had come across. Still no protective clothing or shield fixed to the near edge of the table is yet adopted in this dangerous occupation.—I am, etc.,

Nottingham.

EDITH FAULKNER.

Swallowed Hair-grips

SIR,—During recent weeks several articles and letters have been written concerning the fate of swallowed "kirbigrips." Opinions appear to be divided as to the treatment, particularly in small children. In the last week we have had to deal with such a case. The method used differed from those already described in the recent *British Medical Journals*, and is therefore being reported.

A small girl, aged 12 months, was admitted to the ward having swallowed a kirbigrip five hours previously. X-rays taken on admission and during the following week showed that it had not passed from the stomach. The child remained quite well. On the seventh day a James's magnetic tube (similar to a Ryle tube with a magnet being substituted for the usual metal tip) was

passed through the mouth into an empty stomach. Under x-ray screening the grip was seen to become attached to the magnet. After several attempts it was manoeuvred through the cardia and drawn into the oesophagus. Then the child was held upside down, and after gentle traction the kirbigrip was felt in the laryngopharynx and removed digitally. No anaesthetic was given. The whole procedure lasted 30 minutes. The child recovered rapidly, and was discharged after 24 hours' observation. She suffered no ill effects.

This is a simple way of removing a potentially dangerous object from the stomach without adding the hazards of surgical intervention. Perhaps we were lucky. It would be of interest to know if others have tried this method and have any improvements to suggest.—I am, etc.,

Old Windsor.

MARGARET S. I. WILLIAMS.

Psychosomatic Appendicitis?

SIR,—I have read the annotation on "Psychosomatic Appendicitis?" (*Journal*, April 16, p. 960) with great interest. The suggestion was made that "perhaps the answer will be found when surgeons take psychosomatic histories from all their patients." I do not think this is a very practical suggestion—everyone knows that surgeons' notes on patients are necessarily brief, by reason of the comparatively large number of patients they see in a very short period.

I would be interested to know whether the writer of this annotation excludes so-called obstructive or recurrent appendicular colic. Superadded muscular spasm induced by overaction of the sympathetic would account for these recurrent attacks of pain far more than in the case of acute appendicitis, which is a pathological phenomenon. The fact that countless appendices which have been removed show no pathological lesion seems to me to support the psychosomatic theory.

It might interest readers to know I have had recurrent attacks of mild appendicular colic, which only occurs when I am driving a car and when I am under certain tension. For example, while driving to Edinburgh to sit an examination, I was seized with sharp stabbing pain localized to the right iliac fossa, which disappeared as rapidly as it came when I reached my destination. Whenever these attacks occur, I anxiously wonder if it will be necessary for me to have an operation.

One wonders if the condition is allied to "spastic colon." Perhaps a drug such as chlorpromazine would be indicated.—I am, etc.,

Halifax.

J. W. WESTON.

"Half-minute" Thermometers

SIR,—I recently purchased a "half-minute" clinical thermometer of reputable manufacture which takes a full five minutes to register. Would it not be possible for thermometers to have issued with them not only a certificate of accuracy but also a certificate of time?—I am, etc.,

London, W.1.

PETER GILBERT.

Anonymous Anaesthetists

SIR,—At the end of his most interesting account of "Recovery after Penetrating Wound of the Heart" (*Journal*, April 16, p. 952), Dr. R. W. Lawrie thanks "Mr. P. W. Bleasdale for permission to publish this case; also the anaesthetist, without whom the operation would have been impossible." Dr. Lawrie's tribute is just, because it is largely due to the advances in anaesthesia and the co-operation of the anaesthetists that a modern surgical procedure such as he describes can now be carried out. Anaesthetists are modest men, and not so much in the limelight as surgeons; but credit should be given where credit is due. Could Dr. Lawrie take off therefore the mask of anonymity and let us have the name of his anaesthetist, so that we can congratulate him, as well as his colleagues, on their brilliant success?—I am, etc.,

Edinburgh.

JAMES A. ROSS.

Obituary

EGBERT MORLAND, M.D., F.R.C.P., F.R.C.S.

Dr. E. G. Morland, formerly Editor of the *Lancet*, died on April 26 in a nursing-home at York, aged 80 years.

Egbert Coleby Morland, fifth son of the fourteen children of Charles Coleby Morland, J.P., was born on September 3, 1874, at Croydon, and was educated first at the Whitgift School there and later at the Friends' School at Bootham, York. As a schoolboy he was

something of an infant prodigy, showing an equal facility for languages and science. It was said that at the age of 14, his brother Harold, a recent senior wrangler, was the only member of the staff capable of teaching him mathematics; be that as it may, he left school with the Gilchrist Scholarship in the London matriculation examination too young to start the study of medicine. Proceeding to Owens College, Manchester, he took the London B.Sc. in biology, with first-class honours, in 1893. Still only 19 years of age, he started on his medical career at St. Bartholomew's Hospital, to which he won an entrance scholarship. He qualified in 1897 and graduated M.B. in the following year, winning the gold medal in physiology. Then followed a series of house appointments and a tendency to specialize in

diseases of the eye, but his ambitions were frustrated by a severe haemoptysis and a long period of treatment in Switzerland. The severity of the catastrophe was mitigated by the loyalty of his fiancée, Mary Latchmore, who insisted on marrying the patient (in 1903) and devotedly nursed him back to health.

Egbert Morland's constitution was too frail and his tuberculosis too severe for him to return to specialist training and practice in London. He therefore decided to remain in Switzerland and to specialize in tuberculosis. That decision involved going back to school at Schiers College in the valley below Davos to pass the Swiss matriculation examination. A period of medical study at Berne under Kocher and Sahli ended with the acquisition in 1907 of the M.D., and, more important, the Federal Diploma, which gave him the right to practise in Switzerland. It was at about this time that Egbert Morland, with his architect brother, Geoffrey, entered the competition for the design and equipment of the King Edward VII Sanatorium for Consumption at Midhurst. Their essay was awarded the second prize, and some of their suggested features were incorporated in the final plan.

At that time the climatic treatment of tuberculosis was at its zenith and Davos was its Mecca, but in that centre competition from English and Swiss colleagues was sufficiently severe to make the prospects of a newcomer uncertain and arduous. After much consideration Egbert Morland decided to settle at Arosa, then a comparatively small resort separated from the railhead at Chur by a six-hour coach or sleigh drive. The choice was a good one, as the high altitude (6,000 feet) and its sheltered, sunny position soon made Arosa one of the leading centres in the Alps. A small sanatorium, the Villa Gentiana, was acquired, and the number of patients living in hotels and pensions grew so rapidly that Morland was soon overworked during the winter season. In an Alpine resort summers are always slack, and so he found time to write several original articles, and, in conjunction with the late Dr. Clive Riviere, an excellent little book on *Tuberculin Treatment*, which was so clearly written and so moderate in its claims that it remained the most reliable textbook on the subject for as long as tuberculin continued to be used as a therapeutic agent. Artificial pneumothorax was only just becoming established at that time, and Morland, although he never used it extensively, was one of the first British doctors to practise that form of treatment.

Morland took no part in winter sports and had no interest in mountain climbing; but he was a great walker, and his extensive knowledge of Alpine flowers, animals, people, and history made him a delightful companion. During the summer months he would take his turn to deputize for Swiss colleagues who looked after the population of the surrounding villages, some of which were very isolated and could be reached on foot only after five or six hours' walking. The villagers were too considerate to send so far for a doctor for normal events such as birth and death, and it was only the mysterious illness that called for a doctor's visit. Morland always considered his most profitable consultation to have been one involving ten hours' walking, a history taken from a small boy in a dialect which taxed Morland's linguistic powers to the utmost, a diagnosis (subsequently confirmed by the patient) of unripe apples, and a fee of two francs.

In 1914 the railway, which had taken several years to build, was completed, but by the time the first train had arrived war had broken out and the flow of British patients had stopped abruptly. By 1915 there was virtually no practice left, and Morland had no option but to return to England to try to make a living by private consulting practice, helped by the writing of occasional articles for the medical press. The latter

activity brought him into contact with Dr. (later Sir) Squire Sprigge, who liked his literary style, and it was not long before he received an invitation to become assistant editor of the *Lancet*, a post he held from 1915 until he succeeded Sir Squire Sprigge as editor in 1937 at the age of 63. Morland soon made his mark as a medical journalist; by vigorous pruning of all unnecessary words and by careful polishing he achieved a lucid, apparently effortless style in which no word was wasted. The somewhat austere effect of his prose contrasted with the frequently Puckish, almost Chestertonian, context of many of his leading articles. His private correspondence was almost confined to the postcard, a scanty plot on which he contrived to cultivate both substance and wit.

In 1936 Morland was elected a Fellow of the Royal College of Surgeons, and in 1941 a Fellow of the Royal College of Physicians. The field of medicine now covered by the term social medicine always interested him, particularly the problems of old age, and he served as vice-president of the Section of Medical Sociology at the Annual Meeting of the B.M.A. at Plymouth in 1938. He retired from the editorial chair of the *Lancet* in 1944 and went to live near his married daughter and her young family in the Yorkshire Pennines, where he combined free-lance journalism with gardening. His later years were saddened by the loss of his wife, who died suddenly in 1948, and shortly afterwards by blindness, which became almost complete, and by a fractured femur. He remained mentally alert, however, and derived much consolation from the wireless, especially from the Third Programme.

Egbert Morland was born a Friend, and was throughout his life an active member of the Society. He was one of the founders of the Quaker Medical Society, which came into being shortly after the war of 1914-18. Unlike many Quakers, he was fond of music and the visual arts, and it was characteristic of him in his later years that he made a weekly practice of brightening the austere seventeenth-century Meeting House at Wooldale with flowers from his garden.

We are indebted to our colleagues on the staff of the *Lancet* for the following composite pen picture of their former chief:

One week in February, 1915, when the *Lancet* was going to press, its editor, Squire Sprigge, stopped the printing machines so that he could include a summary of a German pamphlet describing the food resources of the German nation. This uninvited article, which had come unexpectedly from Switzerland, was Egbert Morland's introduction to the *Lancet* editorial circle. At once intrusive and appropriate, it was not uncharacteristic. Lucid, accurate, and highly topical, it arrived at an awkward moment and yet was too important to be ignored. For the first time the *Lancet* was exposed to Morland's sense for exciting news or significant principles hidden behind an apparently dull collection of facts and figures, printed perhaps in small type in a foreign language. Later in 1915, on his way through London after a tour of duty with a Friends' relief unit on the Marne, he dropped in at the *Lancet* offices on the corner of the Strand and Bedford Street. Dr. Sprigge, who was short-handed, suggested that he should "stay and help." What began as a casual afternoon call endured as an association of over 30 years.

Morland's career had been twice checked—once by illness and again by war—but in the *Lancet* office he found congenial scope for his talents. His experience as a clinician, his interest in tuberculosis, his concern for the new science of social medicine, his facility for languages, and his knowledge of Europe were all assets to the journal. His lack

of journalistic experience mattered less than might have been expected, for it was his set technique to tackle even the familiar by unfamiliar methods. He had not been long at the *Lancet* before problems of printing, make-up, and editorial administration had captured his interest and engaged his ingenuity. For the arrangement and selection of illustrations he had both skill and taste, and even as editor he occasionally indulged his enjoyment of his craftsman's aptitude. The *Lancet* traditions held in bounds the overzealousness and exaggeration which were the reverse of his brilliance and driving power. If Morland got things done, Sprigge was able to restrain him from overdoing things. And if this restraint sometimes irked Morland, who had after all started a new career in middle age, he soon found in the editorship of *Maternity and Child Welfare*, to which he was appointed in 1917, an opportunity to try his independent wings.

As the years between the two wars passed, the staff and scope of the *Lancet* broadened. But when, in 1937, Dr. Morland succeeded Sir Squire Sprigge, a dubious peace was already giving way to an uncertain war, and he had had little time to settle in the editorial chair before the *Lancet* was evacuated to Aylesbury in 1939.

For the next five years he edited the journal from what he called his "pocket office" in an old-fashioned dwelling-house in Temple Street, and lived "above the shop." If he regretted the limitations imposed on his work by war he never said so. Instead of repining for the opportunities and contacts of London, he joined with zest in the busy life of a market town. He quickly made friends with the local hospitals and doctors; he attended the meetings of local societies; and he took a benevolent interest in civic problems. Being Morland, he could not live a country life without dressing for the part; and his highly individual version of the formal clothes of an editor-about-town now gave way to rough tweeds, a beret, and, latterly, even a beard.

As the war went on it became clear that, though Aylesbury itself was nowhere in particular, it was on the way to several other places; and people began to drop in at the *Lancet* office. It might be an Oxford don, a Cambridge professor, a general in battle-dress, an admiral in gold braid, an American colonel, or a Quaker neighbour with a basket of apples from a Buckinghamshire orchard. Morland offered them all the same sincere if astringent welcome, and they all found his conversation stimulating if sometimes puzzling; for his passion for lucidity was sporadic and always stopped short at print. To the reader he was usually considerate; but his correspondents and callers had to fend for themselves. On a postcard—in his view the ideal vehicle for correspondence—he was oracular, and in conversation cryptic. But what he said, and didn't say, was usually worth pondering. As one of his staff once pointed out:

"He seldom asked a question directly or answered one comprehensibly, but by a series of hints, sniffs, and silences spurred others into spirited performances, which he managed by only the lightest of guiding reins. He was not only a good journalist, but a cause of journalism in others."

E.C.-J., who so largely shared the anxieties and difficulties of the war years with him, also found him a congenial chief.

"Egbert Morland was nearly the ideal editor for the newcomer to journalism. He could assess in an instant the shadowy ideas that keep floating up when one lacks confidence and experience, and if one of them seemed potentially valuable he would imperceptibly add the deft touches it needed and guide one's hand so tactfully that one forgot how much of the finished article was a result of his skill."

"His conversation was unique. Strangers often found it incomprehensible, for he assumed that his hearers' lines

of thought must run parallel with his own. After five minutes' silence he would break in with a terse comment that seemed wholly irrelevant except to his intimates who had learnt the technique—to link it not with the last remark made but with Egbert's own last contribution to the conversation, which had been exercising his astute mind ever since.

"On tuberculosis and child welfare he was an authority—and on these subjects he could write and speak with brilliant originality. In other branches of medicine he may have seemed to take disproportionately little interest; yet when brought a newly written paper to judge nobody would grasp its significance more quickly and accurately, and few could spot snags and fallacies in its conclusions so surely and certainly."

In the later years of the war Morland's disabilities forced him to leave an increasing amount of routine to his staff; and when at the end of 1944 the editorial office was moved back to London he felt free to remain behind in active retirement.

D. T. BARRY, M.D., D.Sc., F.R.C.S.

The death occurred in London on April 15, after a short illness, of Professor D. T. Barry, for 35 years professor of physiology at Queen's (now University) College, Cork. He was 84 years of age.

David Thomas Barry was born at Ballyannahan, Co. Cork, in 1870. He received his medical education at Queen's College, Cork, and graduated M.B., B.Ch. at the old Royal University of Ireland in 1894. He then spent some years in general practice in England, and took the D.P.H. of Liverpool University in 1904, having proceeded to the M.D. in the previous year. It was about this time that he decided to return to the study of physiology, and he spent some years in London, working with Starling, and at the Universities of Berlin and Heidelberg.

Barry obtained the Fellowship of the Royal College of Surgeons of England in 1907, and in the same year was appointed to the newly created chair of physiology at Queen's College, Cork, a position he was to fill until 1942, when he retired as emeritus professor. One of the first tasks in his new appointment was to create a separate department of physiology, which, up to 1907, had been linked with anatomy, and within a few years he had the satisfaction of seeing a physiological laboratory established and in use. Later a histological laboratory was added, and this was soon followed by the provision of similar accommodation for biochemistry and experimental physiology. When he retired Barry estimated that during the 35 years he was professor at Cork over 2,000 students had passed through his hands. In him they had a teacher who was also an enthusiastic investigator: his inspiration turned the thoughts and endeavours of many of his pupils to original research. As one of his colleagues wrote of him some years ago: "To hear him talk about the central nervous system, to watch him draw cross-sections of the brain and cord at various levels, to see him doing heart-lung perfusions, demonstrating the electrocardiograph, and illustrating the action of curare—in 1917—was to be given a preview of the influence of applied physiology on the clinical practice of the 1930's and 1940's. Barry was a forthright teacher, as all great teachers are. Someone said of him that he spoke English quite as well as he did French; the remark was meant to imply Barry's many contacts with the French school of physiology."

Barry was deeply influenced by the teachings of Claude Bernard, and after the first world war paid frequent visits to France and carried out research with Gley at the Collège de France in Paris, at the Sorbonne, with A. and B. Chauchard, and with the Lapiques at the Institut Marey and at the Laboratoires Maritimes de Dinard. He was appointed a Chevalier of the Legion of Honour in 1928 in recognition of this work.

His writings, numbering over 50 papers, appeared in the *Journal of Physiology* and other journals, and, while he covered a wide range of subjects in these communications, he wrote frequently on heart perfusion and electrocardiography. He also translated and condensed numerous papers for *Physiological Abstracts*. For many years he was an external examiner in physiology, in particular for the colleges of veterinary surgeons. In 1918 the National University of Ireland conferred on him the honorary degree of D.Sc.; he was a member of the Senate of the University from 1915 to 1919. He is survived by his widow, formerly Mlle. Marie Yvonne Boiret, whom he married in 1908, and two sons, Claude Thomas Barry, an anaesthetist, and Declan René Barry, a pathologist.

Dr. E. F. McCARTHY writes: The announcement of Professor Barry's death must have aroused vivid memories in the minds of the many Cork doctors who were privileged to be his students. A surgeon with the best qualifications, he was appointed to the chair of physiology in Cork in 1909 during the presidency of Sir Bertram Windle. He was a worker in Starling's laboratory before this, and his subsequent development was greatly influenced by his training in University College, London. His interests ranged widely in the field of physiology, as the titles of his papers in the British and French physiological literature show, but he was mainly concerned with the cardiovascular and respiratory systems. During his long tenure of the chair in Cork he published continuously. His family connexions with Paris induced him to spend his holidays there, where he worked with different French physiologists and where he was well known and very friendly with such scientists as Lapicque. French art and history attracted him strongly, and he was known to lecture and write very competently on such diverse subjects as the Valois monarchs and pointillism. His command of the French language was quite remarkable, and physiologists in general are familiar with his many excellent abstracts of French scientific literature. Professor Barry was a most conscientious and up-to-date teacher who was more conversant with current physiological literature than most physiologists. A strictly self-disciplined and hard worker, his example has a very salutary effect on his students, who greatly respected his detachment, fairness, and personal dignity and the fact that he treated them as grown-up individuals with a fully developed sense of responsibility. His apparent aloofness frequently hid a deep concern for their welfare and a respect and liking for their qualities, of which they can have had little awareness.

D. W. HOODLESS, O.B.E., B.Sc., L.M.S.S.A.

We record with regret the death on April 15 of Dr. D. W. Hoodless, who for over forty years was a much-loved figure in Fiji, where he rendered invaluable service first as a teacher and later as principal of the Central Medical School at Suva. He and Mrs. Hoodless were on holiday in England when he was taken ill and admitted to Addenbrooke's Hospital, Cambridge, where he died at the age of 67.

David Winn Hoodless was born at Walkeringham, Nottinghamshire, on May 16, 1887, and was educated at Sheffield and at King's College, London, graduating

B.Sc. with honours at London University in 1910. He went to Fiji in 1912 as headmaster of the first provincial school for native boys, and later he was appointed headmaster of Queen Victoria School. From 1919 to 1921 he studied medicine at Charing Cross Hospital, but went back to Fiji to become, first, inspector of schools, and then director of education. Resuming his medical studies in England in 1928, while on two years' leave, he again returned to Fiji to become the first principal of the Central Medical School for South Pacific natives, which was opened in 1930. Five years later, when he was well into middle age, he qualified in medicine by taking the diploma of L.M.S.S.A., illness having prevented him from taking the final examinations in 1929. Since 1953 he had been *The Times* correspondent in Fiji.

As principal of the medical school Hoodless helped hundreds of natives of the South-west Pacific territories administered by five Colonial powers to embark on careers useful to their home communities, where they provided a medical service which would have been beyond the means of their respective governments if all posts had been filled by European practitioners. His work in Fiji was always in great part with the Fijian, for whom he had a real affection. He was honorary secretary of the Fiji Branch of the British Medical Association from 1937 to 1940 and president of the Branch from 1941 to 1943. Retiring from the post of principal in January, 1947, he was appointed O.B.E. in the Birthday Honours of that year. He was also an Associate of King's College, London. He leaves a widow, formerly Miss Hilda J. Adlington, of New Zealand, whom he married in 1923, and one daughter, to whom the deep sympathy of all his friends is extended.

A colleague writes: Throughout the island territories of the South-west Pacific, as in a much wider field, the name of Hoodless was well known as the principal of the Central Medical School in Suva, a post he had held for 16 years and from which he retired in 1947. By his death many hundreds of graduates from this well-known school have lost a real friend and a personal adviser. They, and the peoples of the South Pacific generally, owe him a very great debt because he was a teacher to whom family problems and the guidance of youth through the inevitable difficulties of adolescence were as real, or more so, than mere academic learning. The Central Medical School in Fiji draws its students from many groups of islands, and the personal friendship he extended to them all during the formative years of their lives, and while they were in surroundings strange to many of them, had a lasting effect on their character, and it is to his guidance and teaching that the high professional standard and traditions of the assistant-medical-practitioner system in the South Pacific is largely due. Apart from his professional work, Hoodless was a man with many human interests. He had an intimate knowledge of the Fijian language, and of Polynesian and Melanesian customs, and he had a multitude of friends among all races and all strata of society, by all of whom his passing will be deeply mourned.

Dr. J. C. PEARCE, who practised in Norfolk and was well known for his keen interest in local affairs as well as for his work for the B.M.A., died suddenly in a Norwich nursing-home on March 31, nine days after his 73rd birthday. John Cuthbert Pearce was the younger son of Canon R. J. Pearce, vicar of Bedlington, Northumberland, and honorary canon and rural dean of Newcastle. He was educated at Durham School, where he was King's Scholar, Durham University, and the College of Medicine, Newcastle-upon-Tyne, graduating M.B., B.S. in 1906. Two years later he

proceeded to the M.D., being awarded the gold medal for his thesis. After graduation he held the appointments of assistant demonstrator of anatomy and physiology in the Durham College of Medicine, and assistant medical officer at St. Marylebone Infirmary. Subsequently he went into general practice as assistant to Mr. William Robinson at Sunderland, and was appointed honorary assistant physician to the Royal Infirmary and honorary assistant surgeon to the Sunderland and Durham County Eye Infirmary. In 1912 he entered into partnership with the late Dr. A. L. Vaughan, who died on the 28th of last month, at Diss, Norfolk, where he soon identified himself with the life of the community, and where he lived and worked for the next 43 years, except for his period of service in the first world war. Attaining the rank of captain in the R.A.M.C., he was first attached to the King's Own Yorkshire Light Infantry, and was wounded while serving in the line, and later worked in a Red Cross hospital, being awarded the Red Cross medal. After the war he became more and more absorbed in local affairs. Elected to the Norfolk County Council in 1922, he remained a member until 1930, and four years later he became chairman of the Diss Urban District Council, being also chairman of the governors of the local secondary school and of the county ambulance committee. He gave a good deal of his spare time, such as it was, to further the work of the British Medical Association. Chairman of the East Norfolk Division in 1946-7, he was a member of the old Insurance Acts Committee and its successor, the General Medical Services Committee, from 1943 to 1951, and of the Rural Practitioners Subcommittee over the same period. Another committee on which he served was the Central Medical War Committee, from 1944 to 1950. He was also a member of the Council of the B.M.A. for two sessions from 1948 to 1950. For some years he was a member of the local panel committee and, after the inception of the National Health Service, of the Norfolk Executive Council and the local medical committee. Until about a year ago he was a member of the Medical Practices Committee. Between 1920 and 1930 he was chairman of the Diss branch of the South Norfolk Unionist Association. A keen and active member of the Manchester Unity of Independent Oddfellows for about 30 years, he was a past provincial grand master of the Bury St. Edmunds district. He often deplored the fact that the ideals of the friendly societies were disappearing under the impact of organized charity and the welfare state. He was also a justice of the peace and deputy chairman of the Diss bench. A keen golfer, he was responsible for the revival of the Diss club after the first world war, and presented the club with its first cup when he was captain in 1925, winning the trophy himself three years later. Dr. Pearce believed in service to his fellow men and in the ideals of practical Christianity, which found further expression in his work for the British and Foreign Bible Society. He leaves a widow, formerly Miss Victoria Helen Bisset, whom he married in 1909, and one son, Dr. Ian C. B. Pearce.

Dr. J. A. PRIDHAM writes: The sudden death of Dr. J. C. Pearce has removed from the profession a fine example of the best type of general practitioner. He was a good doctor held in high regard and indeed affection by his patients, and greatly respected by his medical colleagues. Though he had a busy practice he found time for a multitude of activities of service to the community in which he lived, and to help the organized medical profession both locally and nationally. Those who had the privilege of his friendship knew him to have a fine sense of humour, and his conversation was illumined with wit. His courtesy and consideration were a part of the man. Perhaps his character can be summed up by saying that he was, in the best sense of the word, a gentleman. Last year, when he left the Medical Practices Committee, of which he had been a member since 1948, his colleagues gave him a farewell luncheon to show their appreciation of one whom they would always remember with esteem and affection. March 31 saw the end of a life of service.

Medical Notes in Parliament

BAN ON HEROIN

The manufacture and export of heroin will not be permitted after December 31, 1955, except for small quantities for purely scientific purposes. The Government's decision to this effect was announced in the House of Lords on April 28 by Lord MANCROFT, Under Secretary, Home Office. He said that, as adequate supplies had hitherto been manufactured in this country, imports had not been authorized for many years. It was intended to maintain the ban on importation.

The Government had taken the decision to give effect to a resolution adopted by the U.N. Economic and Social Council at its 18th session urging that all governments should prohibit the manufacture, export, and import of the drug, except for scientific purposes. The advice of the appropriate statutory advisory bodies had been taken.

Viscount ELIBANK said that Dr. Arthur Douthwaite, senior physician at Guy's Hospital, had stated in the *British Medical Journal* (April 9, p. 907) that the banning of this pain-killing drug was an astonishing move that would inflict much hardship on a multitude of patients. One of the best-known physicians in Edinburgh, Dr. A. B. Flett, had also written to him saying it was iniquitous that this most useful and often necessary drug should be banned. Lord MANCROFT said the Government was aware of these opinions. On the other hand, adequate supplies of a perfectly good substitute were now available. The purpose of the Government's action was to facilitate the world-wide banning of the traffic in this extremely dangerous drug. They had taken the opinion of the statutory bodies they were under obligation to consult—the Central Health Services Council, the standing medical advisory committee, and the appropriate bodies in Scotland and Northern Ireland. The Government could not do more than follow the technical advice and guidance given by them.

Viscount ELIBANK said it appeared from the information given to him that there was no satisfactory substitute for the drug. Lord HADEN-GUEST asked whether it was not a fact that the whole medical profession, so far as could be ascertained, was behind the order. Lord MANCROFT replied that that was the information available to him. The vast weight of evidence was in favour of the move.

Treatment at Broadmoor

Mr. T. DRIEBERG (Maldon, Lab.) asked the Home Secretary if he was aware that a medical report by the Principal Medical Officer of Brixton Prison, dated February 14, 1953, stated that a prisoner (whose name has been given) was sane and fit to stand trial on a charge of attempting to murder his wife, and recommended him as suitable for voluntary treatment in a mental hospital; that, at his trial five days later, this man was found guilty but insane, and ordered to be detained during Her Majesty's pleasure, and that he was still detained at Broadmoor, where his wife and other relatives had found him in apparently normal health; and if, in these circumstances, he would allow an independent medical examination of this patient.

Major G. LLOYD-GEORGE, replying on April 28, stated that the responsibility for deciding when a Broadmoor patient was fit to be transferred or discharged rested on the Home Secretary; and his predecessors and he had consistently taken the view that the expert staff of psychiatrists at Broadmoor, who had the patient under constant observation, were in a better position than an outside doctor to advise the Home Secretary on the patient's mental state and future prospects. The answer was, therefore, "No."

Mr. DRIEBERG said that Dr. Mathieson, of Brixton, had also said that the man was suffering simply from a mild anxiety neurosis, which should yield to psychiatric treat-

ment, but since he had been in Broadmoor he had had no such treatment. It was obviously impossible for the efficient and conscientious staff at Broadmoor to give proper psychiatric treatment to the large number of patients with whom they had to deal. In these circumstances, would the Home Secretary consider getting an independent opinion or transferring the man to a mental hospital, where he could be treated? Major LLOYD-GEORGE said he was aware of the opinion Mr. Driberg had referred to, and he had gone into the case himself with great care. On the information he had he did not think anything could be done, but he was prepared to look at the matter again.

Tuberculosis in Malaya

Mr. H. HOPKINSON, Minister of State for Colonial Affairs, in a statement on April 26 about the incidence and treatment of tuberculosis in Malaya, said that no detailed survey on a sufficiently large and representative section of the population had been carried out, and an accurate guess was further hampered by the fact that many deaths were certified by non-medical persons, and no clear indication could be obtained from the figures given as death from tuberculosis. Local surveys on specially selected groups had disclosed an incidence of between 5 and 6 active cases of pulmonary tuberculosis per 1,000. It was considered that, if a survey were taken of all sections of the community, the figure would be somewhat higher. The new Lady Templer Tuberculosis Hospital was expected to be opened this year and would provide further beds for treatment of cases that were likely to improve. It would also provide an opportunity for research work into this disease in Malaya.

Food Hygiene Council Formed

The membership of the Food Hygiene Advisory Council has been completed, and was announced by the MINISTER OF AGRICULTURE, FISHERIES, AND FOOD on May 2. The chairman is Lord Strang, and the 17 members are:

Mr. S. W. Barnes, secretary to Board of Governors, King's College Hospital; Hon. Daphne Courthope, councillor, Battle Rural District Council; Mr. H. Crane, national industrial officer, National Union of General and Municipal Workers; Mrs. J. H. Engwell, Alderman of Barking Borough Council; Mr. C. W. Fulker, secretary, Parliamentary Committee, Co-operative Union Ltd.; Mr. J. Fuller, principal, Catering Department, Battersea Polytechnic; Mr. C. Leslie Gillitt, past president, National Federation of Grocers' and Provision Dealers' Associations; Dame Florence Hancock, member, General Council, T.U.C.; Mr. J. D. Hiscock, assistant general secretary, Union of Shop, Distributive and Allied Workers; Alderman F. J. Jackson, chairman, Clean Food Guild, Leicester; Miss A. Lumby, chairman, Food Hygiene Committee of Women's Group on Public Welfare; Mr. K. McCullum, director of Trust Houses, Ltd.; Sir Frank Shires, past president, Food Manufacturers' Federation; Sir Harry Sinderson, county director for Sussex of the St. John Ambulance Association; Mr. G. Squire, past president, National Federation of Meat Traders' Associations; Mrs. James Tweed, chairman, House Committee, St. James' Hospital, Balham; Mr. D. T. Williams, Alderman of Cardiff Borough Council.

The Salk Vaccine

Mr. ERIC FLETCHER (Islington, East, Lab.) asked the Minister of Health for a further statement about poliomyelitis vaccine in view of the decision taken in the United States to suspend all injections of Salk vaccine made by the Cutter Laboratories. Mr. IAN MACLEOD stated on May 2 that he was aware of the Press reports of action by the American authorities. A small field trial was being carried out by the Medical Research Council. All vaccine used in this trial, whether imported or manufactured here, would first have been the subject of rigorous tests by the M.R.C. Plans for large-scale immunization were dependent on the Minister of Health being satisfied, so far as was humanly possible as a result of these tests and trials, that the vaccine to be used was both efficient and free from danger.

Mr. FLETCHER asked whether any supplies of Salk vaccine from the Cutter Laboratories had been received in this country, and whether the Minister was satisfied that all

possible information from the United States would be received to enable the Ministry's experiments to be continued. Mr. MACLEOD said that no Cutter vaccine had been received in this country. The Ministry was in close touch with the American authorities on all aspects of the problem.

Mr. R. W. SORESEN (Leyton, Lab.) asked whether the Minister had yet had information from America or elsewhere about the cause of the deleterious effect of what might be a very beneficial vaccine and whether, when he was assured that no further deleterious effect was likely to arise, progress would be made in distributing the vaccine. Mr. MACLEOD said he had no information so far beyond the Press reports. As soon as the Ministry was absolutely satisfied that the vaccines were safe as they could humanly be made there would be no delay in going ahead.

Lists of Patients for Voting

Mrs. B. CASTLE (Blackburn, East, Lab.) asked the Minister of Health whether he was aware that political party organizations were asking doctors for lists of patients for the purpose of the postal vote at the General Election; and if he would instruct N.H.S. doctors to refuse to give this information in respect of N.H.S. patients.

Miss PAT HORNSBY-SMITH stated that the Minister was certainly not aware of any such arrangements, and if Mrs. Castle would supply the Minister with the evidence she had he would investigate. The vote was secret, and in an individual capacity it was certainly helpful to see that as many people as possible voted.

Mr. HERBERT MORRISON (Lewisham, South, Lab.) asked for an assurance that neither directly nor indirectly would those associated with the Health Service co-operate with any political party association in the forthcoming General Election. There was the strongest impression in the last election that such malpractices did take place.

Miss HORNSBY-SMITH gave an assurance that the Health Service would not be used that way. Mr. MORRISON asked if, in view of the allegations, the Minister would make a statement later in the week. Mr. IAIN MACLEOD said he would look into it at once. Whether he made a statement depended on what he found.

Medico-Legal

DEATH FROM CHLORAMPHENICOL

A death from aplastic anaemia due to chloramphenicol was the subject of an inquest before Dr. H. N. Stafford, coroner, at Hammersmith on March 21. The patient, a 5-year-old girl, developed bronchitis in April, 1954, and her medical attendant, Dr. F. T. F. Lutter, prescribed "chloromycetin" in a dosage of "one teaspoonful three times a day." She was on this dosage for about three days, and the bronchitis cleared up very quickly. On November 24 the child was again brought to her doctor. She had a rash on her face and legs, not purpuric, and enlarged tonsils. The doctor thought it might be a toxic rash. He did not connect it with the administration of chloramphenicol. Later a blood count was taken, and on December 1 the child was admitted to the Victoria Hospital for Children, Tite Street, Chelsea, with a diagnosis of aplastic anaemia. Treatment by blood transfusion was without avail, and the patient died on March 3, 1955. Dr. F. E. Camps, consultant pathologist, conducted the post-mortem examination and confirmed the cause of death as aplastic anaemia. This condition, he said, was an extremely rare complication following the use of chloramphenicol, and he observed that the drug ought to be used with discretion. He did not think a doctor could forecast the condition, and blood counts were not practicable in every case. The coroner recorded a verdict of death from misadventure.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending April 16 (No. 15) and corresponding week 1954.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenzal pneumonia.

§ Includes puerperal pyrexia.

Vital Statistics

Infectious Diseases

In England and Wales during the week ending April 16 the largest rises in the number of notifications of infectious diseases were 6,136 for measles, from 26,833 to 32,969, and 164 for whooping-cough, from 1,310 to 1,474, and the largest falls were 263 for dysentery, from 1,454 to 1,191, 68 for scarlet fever, from 665 to 597, and 68 for acute pneumonia, from 872 to 804.

The number of notifications of measles was the largest in any week since this disease was made notifiable. The largest increases during the week were 892 in Middlesex, from 1,705 to 2,597, 518 in Surrey, from 952 to 1,470, 480 in Essex, from 1,689 to 2,169, 423 in Southampton County, from 553 to 976, 404 in Kent, from 848 to 1,252, 366 in Warwickshire, from 3,199 to 3,565, 328 in Leicestershire, from 280 to 608, 275 in Lancashire, from 1,298 to 1,573, 263 in Buckinghamshire, from 389 to 652, 260 in Cheshire, from 574 to 834, 239 in Sussex, from 205 to 444, and 202 in London, from 3,089 to 3,291, and the largest exceptions to the general rise were decreases of 139 in Nottinghamshire, from 881 to 742, and 81 in Yorkshire West Riding, from 3,807 to 3,726. Only small variations occurred in the local trends of scarlet fever and whooping-cough. 7 cases of diphtheria were notified, being 2 more than in the preceding week.

20 cases of acute poliomyelitis were notified; these were 11 more for paralytic and 2 more for non-paralytic cases than in the preceding week. The largest returns were Lancashire 4, Yorkshire West Riding 3 (Leeds C.B. 2).

The largest centres of dysentery were Lancashire 451 (Oldham C.B. 81, Manchester C.B. 55, Blackburn C.B. 52, Blackpool C.B. 43, Liverpool C.B. 30, Royton U.D. 27, Chadderton U.D. 25, Whiston R.D. 18, Leyland U.D. 12, Stretford M.B. 11, Salford C.B. 10, Middleton M.B. 10), Durham 193 (Easington R.D. 89, South Shields C.B. 30, Seaham U.D. 26, Gateshead C.B. 21), London 87 (Hackney 35, Southwark 10), Yorkshire West Riding 85 (Pontefract M.B. 43, Castleford U.D. 14, Leeds C.B. 13), Northumberland 50 (Bedlingtonshire U.D. 16), Surrey 49 (Banstead U.D. 26), Leicestershire 40 (Leicester C.B. 27), Norfolk 31 (Ipswich C.B. 16), Glamorganshire 29 (Cowbridge R.D. 24), Cheshire 20 (Stockport C.B. 16), and Yorkshire North Riding (Middlesbrough C.B. 19).

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in March was 114, compared with 117 (revised figure) in the previous month and 118 in March, 1954.

The numbers of cases of industrial diseases in the United Kingdom reported during March, 1955, were as follows: lead-poisoning 8, compressed air illness 2, anthrax 3, epitheliomatous ulceration 13, chrome ulceration 16; total 42. There was 1 death due to compressed air illness.—*Ministry of Labour Gazette*, April, 1955.

Week Ending April 23

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 467, whooping-cough 1,658, diphtheria 14, measles 28,425, acute pneumonia 688, acute poliomyelitis 6, dysentery 1,053, paratyphoid 15, and typhoid fever 3.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the nine years 1946-54 (influenza, 1952-4) are shown thus -----, the figures for 1955 thus ———. Except for the curves

showing notifications in 1955, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Medical News

British Trial of Poliomyelitis Vaccine.—Preparations for the British trial of poliomyelitis vaccine (see *Journal*, April 30, p. 1103) are continuing pending further information from America about the cases of poliomyelitis in children inoculated with Salk vaccine. In a Press statement on May 4 the Medical Research Council stated that a member of the Council's staff was proceeding immediately to the U.S.A. to obtain first-hand information. This should be available before the routine safety tests on the present batches of vaccine in Britain are completed, and therefore before the proposed British trial is due to begin. A dispatch from the New York correspondent of *The Times*, dated May 1, states that 29 cases of poliomyelitis occurred last week in the United States in persons inoculated with Salk vaccine, all but three of whom had received the vaccine prepared by the Cutter laboratories of Berkeley, California. As a result, the use of the Cutter vaccine has been banned and California has suspended its inoculation programme until the investigation of the cases is complete. The possible causes of the American setback are discussed elsewhere in the *Journal* (p. 1144). Meanwhile in Britain negotiations continue with the Government of India to relax the ban on the export of monkeys. The M.R.C. has also sent a member of its staff, Dr. F. KINGSLEY SANDERS, to the M.R.C. field station at Fajara in the Gambia to investigate the possibility of arranging regular supplies of monkey kidneys from there. The financial implications of the American demand for the Salk vaccine have been agitating Wall Street, according to reports of an article in the *New York Post*. This source says that the American firms producing the vaccine are expected to make \$20m. profit this year, and is quoted as saying, "Sharp-eyed investors already have made an impressive killing on the vaccine." The report adds that Dr. Salk draws no royalties.

Edinburgh Medical Exhibition.—Declaring open the "Edinburgh Medical Exhibition" at the Assembly Rooms, Edinburgh, on April 25, Professor D. M. DUNLOP reminded his audience that the remarkable therapeutic advances of the past 50 years had been largely due to the close co-operation between the medical profession and the pharmaceutical industry. Not only had the industry developed the fundamental discoveries of university research workers such as Ehrlich, Minot, and Fleming, but it had itself contributed many discoveries such as cyanocobalamin and the new anti-malarials. Professor Dunlop complimented the industry on marketing drugs which are amongst the lowest-priced in Europe, despite rising wages, the increased cost of plant and buildings, and an annual expenditure on research estimated to exceed £3m. Too rigid a bureaucratic control on the price of drugs might prove disastrous to the pursuit of pharmaceutical research and to the industry's exports, which had increased in value from under £2m. in 1938 to over £33m. in 1954. The manufacturers of "ethical" products, continued Professor Dunlop, had through their advertising an influence on medical practice much more potent than that of "the bleatings of professors of therapeutics." Such an influence carried with it great responsibilities. It was not particularly ethical, he thought, to market, for example, expensive tonics, capsules of the vitamin-B complex in a country where beriberi and pellagra are practically unknown, and polyglandular pills. The last was a return to the medicine of savages "who believe that if you eat the heart of a lion you will grow strong." Professor Dunlop concluded by declaring it a privilege to open an exhibition of great interest and educational value, an expression of the splendour of modern therapeutic advance.

Bart's Linear Accelerator.—Last October we reported the completion of the Mullard 15 million volt linear accelerator

at St. Bartholomew's Hospital, London (see *Journal* of October 2, 1954, p. 819). On April 27 the accelerator was officially inaugurated by the DUKE OF GLOUCESTER, president of the hospital. The machine, costing over £50,000 and paid for from the hospital's endowment funds, with its combination of high energy and high intensity of radiation is the most powerful therapeutic apparatus to be installed in any hospital in Britain. The accelerator will be used primarily for fundamental research on the action of radiations on living tissue, and secondly for treatment. For the latter, besides high energy x rays, the machine can produce electrons and also, by bombarding uranium, neutrons. It is proposed to investigate the possibilities of both electron and neutron therapy. Electron therapy has the advantage of limited penetration (about 3 in.—7.6 cm.), while neutron therapy may differ entirely from conventional x-ray therapy. For the present, the accelerator is being housed near the physics department under the direction of Professor J. ROTBLAT.

Dr. G. W. Corner, director of the department of embryology at the Carnegie Institute of Washington, has been elected a Foreign Member of the Royal Society "for his work on the endocrine control of gestation, and especially on the function of the corpus luteum in mammals."

Royal College of Surgeons.—At the Council meeting on April 21 Mr. WILLIAM DOOLIN (Dublin) and Professor ROBERT JANES (Toronto) were admitted Honorary Fellows, and Professor G. J. CUNNINGHAM (London) Sir William Collins Professor of Human and Comparative Pathology and Conservator of the Pathological Museum. *Jacksonian Prize.*—Last year's prize was awarded to Mr. CECIL W. D. LEWIS (Cardiff) and a certificate of honourable mention to Dr. OLIVER C. LLOYD (Bristol) for their essays on "Melanomas and Melanosis." The subject for the 1956 prize will be "Portal Hypertension." *John Hunter Medal and Triennial Prize.*—These were awarded to Professor STEPHEN L. BAKER (Manchester) "for his outstanding contributions to the study of bone structure and disease." *Mitchiner Medal.*—The 1955 medal was awarded to Colonel W. R. M. DREW, late R.A.M.C., "for his distinguished contributions to medicine in the Army, with special relation to the teaching of tropical medicine."

Jessie Macgregor Prize.—The Royal College of Physicians of Edinburgh announces that an award of the Dr. Jessie Macgregor Prize for Medical Women (value £75) will be made in July to the applicant presenting "the best record of original work in the science of medicine." Applicants must be medical graduates of Edinburgh University or holders of the Scottish Triple Qualification, and applications, marked "Dr. Jessie Macgregor Prize," must reach the Convener of Trustees, Royal College of Physicians of Edinburgh, 9, Queen Street, Edinburgh, 2, not later than June 30.

Clinical Evening for G.P.s.—The London Hospital held its second clinical evening for local general practitioners on April 27, when cases were demonstrated by members of the medical and surgical staff. A large number of practitioners took advantage of the opportunity to meet their hospital colleagues and attend the clinical demonstrations. Light refreshments were provided beforehand. The evening was an obvious success: as a member of the staff put it, "I don't know why we didn't do this years ago." The guest practitioners, for their part, were clearly most appreciative of the teaching hospital's gesture.

Agricultural Pesticides.—The spraying season is now in full swing. An article describing the toxic hazards of the more dangerous selective weed-killers and insecticides was printed in the *Journal* of April 2 (p. 841). Treatment was fully discussed and an appendix stated where samples of oxalated blood should be sent for D.N.C. and cholinesterase estimations, and gave technical details of their collection. In addition to certain named laboratories in Lewisham, Portsmouth, Peterborough, and Worcester, specimens may be

sent to the hospital laboratory normally used for pathological tests of any kind.

British Association of Physical Medicine.—The following officers for 1955-6 were elected at the annual meeting on April 23: *President*, LORD HORDER; *vice-president*, Dr. W. S. TEGNER; *hon. treasurer*, Dr. A. C. BOYLE; *hon. secretary*, Dr. G. O. STOREY; *hon. editor*, Dr. H. A. BURT.

COMING EVENTS

Society for Endocrinology.—Dr. A. LACASSAGNE (Paris) will lecture on "Endocrine Factors Concerned in the Genesis of Experimental Mammary Carcinoma" at the Royal Society of Medicine, May 24, at 5 p.m. Non-members welcomed. Admission free, without ticket.

Institute of Hospital Administrators.—Annual Conference at the Caxton Hall, Westminster, May 12-14. Details from the secretary of the Institute, 75, Portland Place, London, W.1.

Society for Applied Bacteriology.—Summer conference and annual meeting at Cambridge, July 4-6, open to non-members. Symposium on "Food Microbiology and Public Health." Details from Mr. G. SYKES, Boots Pure Drug Co., Ltd., Microbiology Division, Nottingham.

NEW ISSUES

Medical and Biological Illustration.—The next issue (Vol. 5, No. 2) is now available. The contents include:

DIRECT KINERADIOGRAPHY ON 35 MM. FILM AND ONE APPLICATION IN BIOLOGICAL RESEARCH. P. Thevenard.
CAMERA LUCIDA TRACINGS IN MEDICAL RESEARCH. S. Enzel.
THE PHOTOGRAPHY OF GROSS SPECIMENS WITH FLUORESCENT LIGHTING. T. N. Salthouse.
A NEW MUSEUM OF CARDIAC PATHOLOGY. Reginald Hudson.
THE CYCLOSTEREOSCOPE. Francois Savoye.
A SIMPLE LIGHT INTEGRATING METER FOR USE WITH FLASH TUBES. R. D. Moore.
EQUIPMENT AND METHODS.

Issued quarterly: annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, May 9

EDINBURGH UNIVERSITY.—At West Lecture Theatre, University New Buildings, 5 p.m., Dr. D. J. Guthrie: Medicine Becomes Anatomical.
INSTITUTE OF CARDIOLOGY.—9.30 a.m., Sir John Parkinson: Diseases of the Aorta.
LONDON UNIVERSITY.—At Wright-Fleming Institute Lecture Theatre, St. Mary's Hospital Medical School, 5 p.m., special university lecture in medicine by Professor F. D. Moore (Harvard): Endocrinology and Metabolism in Surgical Care: (1) Metabolic Observations.
MEDICAL SOCIETY OF LONDON.—8.30 p.m., second general meeting: 8.45 p.m., Annual Oration by Dr. Macdonald Critchley: Verbal Symbols in Thought.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. R. I. S. Bayliss: Infantism and Dwarfism.
ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Dr. DeWitt H. Smith: Ballistocardiography.

Tuesday, May 10

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. G. C. Wells: Disorders in Pigmentation.
LONDON UNIVERSITY.—At King's College, 5.30 p.m., special university lecture in biophysics and microbiology by Dr. Harriett Ephrussi-Taylor (Paris): Induced Transformations of Bacteria: The Nature of Transformation and the Factors Involved.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Arnold Demonstration by Dr. H. J. Hoffmann: Innervation of Voluntary Muscle.
ST. ANDREWS UNIVERSITY.—At Department of Medicine, Queen's College, Dundee, 2.30 p.m., discussion to be opened by Mr. A. Logan, Dr. R. D. Marquis, and Professor D. M. Douglas: Consideration of Aortic Stenosis and its Surgical Treatment.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C.1, 5.15 p.m., Cushny Memorial Lecture by Dr. Mary Pickford: Antidiuresis.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., neurological demonstration by Dr. T. Rowland Hill.
WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY.—5 p.m., Almroth Wright Lecture by Dr. D. A. Long: Response of the Host to Bacterial Infection.

Wednesday, May 11

BIRMINGHAM UNIVERSITY: FACULTY OF MEDICINE.—At Large Anatomy Theatre, 4 p.m., Leonard Parsons Memorial Lecture by Professor Wilfrid Gaisford: Protection of Infants Against Tuberculosis.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Pathogenesis of Fungous Infections of the Skin.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. F. P. Lee Lander: Prognosis in Bronchiectasis.

LONDON UNIVERSITY.—(1) At Wright-Fleming Institute Lecture Theatre, St. Mary's Hospital Medical School, 5 p.m., special university lecture in medicine by Professor F. D. Moore (Harvard): Endocrinology and Metabolism in Surgical Care: Application in Daily Care. (2) At King's College, 5.30 p.m., special university lecture in biophysics and microbiology by Dr. Harriett Ephrussi-Taylor (Paris): Induced Transformations of Bacteria: Kinetic Study of the Transformation Process.
MEDICAL RESEARCH COUNCIL.—At National Institute for Medical Research, The Ridgeway, Mill Hill, N.W.1, 5 p.m., Dr. Emil L. Smith (University of Utah): Chemistry of Antibodies and Gamma Globulins.
MIDDLESEX COUNTY MEDICAL SOCIETY.—At Harefield Hospital, 3 p.m., Mr. T. Holmes Sellers: Cardiac Surgery To-day; Dr. E. Idris Jones: Emphysema and Bronchiectasis; Mr. J. W. Jackson: Modified Thoracoplasty.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Professor G. Payling Wright: General Pathology of Tuberculosis (II).

Thursday, May 12

ALFRED ADLER MEDICAL SOCIETY.—At 11, Chandos Street, W.1, 8 p.m., Dr. W. P. Berrington: Fugue States.
BIRMINGHAM UNIVERSITY: FACULTY OF MEDICINE.—At Large Anatomy Theatre, 4 p.m., Leonard Parsons Memorial Lecture by Professor Wilfrid Gaisford: Protection of Infants Against Tuberculosis.
DUBLIN UNIVERSITY: SCHOOL OF PHYSIC, TRINITY COLLEGE.—At Physiology Theatre, 4.30 p.m., John Mallet Purser Lecture by Professor G. R. Cameron, F.R.S.: New Fields in Cell Pathology.
EDINBURGH UNIVERSITY.—At West Lecture Theatre, University New Buildings, 5 p.m., Dr. D. J. Guthrie: Classic Literature of Medicine.
HOSYMAN GILLESPIE LECTURE.—At University New Buildings, Edinburgh, 5 p.m., Mr. G. H. Macnab: Malescent of the Testicle.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. O. Oliver: Antibiotics.
LONDON UNIVERSITY.—At King's College, 5.15 p.m., Halliburton Lecture by Professor Irino Spadolini (Florence): Effects of the Acetylcholinesterase System on the Heart.
NUFFIELD ORTHOPAEDIC CENTRE.—At Wingfield-Morris Orthopaedic Hospital, 8.30 p.m., Dr. A. B. Kinnier Wilson: New Approach to Respiratory Poliomyelitis.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. C. L. Cope: Cortisone and A.C.T.H.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor R. V. Cooke: Advanced Carcinoma of the Colon, with particular reference to the Inflammatory Factor.
ROYAL SOCIETY.—4.30 p.m., film illustrating research activities of Istituto Superiore di Sanità, Rome, with introductory address by Director-General, Professor D. Marotta, followed by talk by Professor E. B. Chain, F.R.S.: Some Recent Advances in Carbohydrate Metabolism.
ST. ANDREWS UNIVERSITY.—At Physiology Department, Medical School, Small's Wynd, Dundee, 5 p.m., Dr. H. Payling Wright: Thrombosis and Some Less Recognized Aspects of Anticoagulant Therapy.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., postgraduate demonstration in Psychiatry.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.—At Physiology Theatre, Gower Street, W.C.1, 4.45 p.m., Professor Emil L. Smith (University of Utah): Mode of Action of Proteolytic Enzymes.

Friday, May 13

HARVEY SOCIETY OF LONDON.—At Royal College of Surgeons of England, 8.15 p.m., Buckton Browne Dinner.
● INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. B. F. Russell.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., clinical demonstration by Dr. J. G. Scadding.
INSTITUTE OF LARYNGOLOGY AND OTOLARYNGOLOGY.—3.30 p.m., Mr. A. R. Dingley: Tonsillectomy in Children and Adults.
LONDON UNIVERSITY.—At King's College, 5.30 p.m., special university lecture in biophysics and microbiology by Dr. Harriett Ephrussi-Taylor (Paris): Induced Transformations of Bacteria: Confrontation of Genetic and Physico-chemical Data.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. J. H. Middlemiss: Radiology of the Acute Abdomen.
ST. ANDREWS UNIVERSITY.—At Department of Medicine, Queen's College, Dundee, 2.30 p.m., discussion to be opened by Professor E. J. Wayne and Dr. C. Pickard: Angiocardiography in Congenital Heart Disease.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Sir Heneage Ogilvie: Shock (with coloured film and sound track).
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C.1, 5.15 p.m., Cushny Memorial Lecture by Dr. L. E. Bayliss: Process of Secretion.
WHITTINGTON HOSPITAL.—At St. Mary's Wing (Ward D.6), 5.15 p.m., clinical pathological conference. Dr. C. G. Whiteside: Aortography in Urology.

Saturday, May 14

BIOCHEMICAL SOCIETY.—At Reading University, 11 a.m., scientific papers.
CAMBRIDGE UNIVERSITY MEDICAL SCHOOL.—10.30 a.m., Symposium: Paediatrics.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Campbell.—On April 14, 1955, at Harbour Breton, Newfoundland, to Dr. Margaret (formerly Kennedy), wife of Dr. Ronald W. Campbell, a son—David Alexander Young.
Ellison.—On April 10, 1955, to Jean, wife of Dr. Stanley Ellison, of 79, Fortnum Green Road, London, N.W.1, a sister for Beverly.
Luntz.—On April 25, 1955, at Sorrento Maternity Hospital, Birmingham, to Pamela, wife of George Richard William Neal Luntz, M.R.C.P., a daughter—Verity Anne.
McCracken.—On April 28, 1955, at St. Mary's Hospital, Manchester, to Dr. Margaret (formerly Laycock) and Dr. Dermot McCracken, a son—James Justin.

DEATHS

Sankey.—On April 6, 1955, at 16, Crick Road, Oxford, Richard Harvey Sankey, M.B., B.Ch., F.F.R., aged 80.
Shafto.—On April 12, 1955, at Edinburgh, William Alexander Shafto, M.D., D.P.H., of Craigdarroch, Bo'ness, West Lothian.
Young.—On April 3, 1955, at his home, Sandrock Cottage, Westcott, near Dorking, Surrey, William Arthur Young, M.B., B.S., D.T.M.&H., formerly of Singapore, and Perth, Western Australia.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Inoculations and Poliomyelitis

Q.—What is thought to be the mechanism by which certain inoculations predispose to the development of paralytic poliomyelitis? Is it due to a direct transfer of virus during the inoculation procedure, similar to a streptococcal cellulitis following inoculation, or is there some other mechanism?

A.—Firstly, there is no evidence to support the view that poliomyelitis virus is transferred to the tissues from needle or syringe during the inoculation of whatever prophylactic or other substance is being injected. The evidence rather indicates that virus already present in the host is activated and localized by tissue trauma. It is known, for example, that the performance of tonsillectomies in an area where poliomyelitis is prevalent may be followed by cases of bulbar poliomyelitis, and that excessive exercise and fatigue of certain muscle groups may be associated with paralytic poliomyelitis in these muscles. The injection of a substance likely to cause local tissue trauma and reaction—and this is most common with alum-containing prophylactics—may for the same reason help to localize poliomyelitis virus, already present in the host, to the motor cells of the central nervous system associated with the traumatized area. Therefore the intramuscular injection of prophylactics likely to cause some degree of local reaction may have to be temporarily discontinued in an area where poliomyelitis has become prevalent.

Neurological Effects of Chronic Carbon Monoxide Poisoning

Q.—I have a patient who has been diagnosed as suffering from disseminated sclerosis. For a long time prior to and during the early part of his illness he was employed at a gas works, and several doctors have expressed the opinion that chronic carbon monoxide poisoning might have initiated the disease. Another person working in the same place for a time exhibited, broadly speaking, the same symptoms. Is it thought that continual exposure to carbon monoxide can ultimately produce sclerotic lesions in the nervous system, and, if so, where are references to be found in medical literature?

A.—There is no evidence that chronic carbon monoxide poisoning can lead either to the clinical manifestations or to the histological changes of disseminated sclerosis. From experimental data it appears that the chronic stages of degeneration are of the same order and situation as those found in acute poisoning, and principally affect the neurones of the cerebral cortex and corpus striatum. While variable degrees of Parkinsonism may be observed clinically, a wide variety of minor neurological disturbances have also been recorded in numerous reports. These, and a detailed personal investigation into the problem of chronic carbon monoxide poisoning as an industrial hazard, have been published as a monograph by Aage Grut (Copenhagen, 1949). Two cases in which cerebral subcortical myelinopathy was attributed to carbon monoxide poisoning have been reported also by Hsü and Ch'eng.¹ Since the lesions here involved the white matter these cases are of greater interest in relation to the present query. But neither the histology nor the recorded neurological disturbances in these two subjects suggest any affinity with disseminated sclerosis. It seems most likely that the cases mentioned in the question were coincidental.

Dreams

Q.—What is the cause of excessive dreaming? Can any treatment be given to prevent it? Is it true that dreaming occurs in the penultimate seconds of sleep? A patient of mine, aged 28, is pregnant for the second time. She has always had vivid dreams, but during her first pregnancy, and so far during her second, she has dreamt every night, and her dreams have been of such startling reality and apparently of such great length that she wakes up unrefreshed from her night's sleep. There is no evidence of any psychiatric abnormality.

A.—Excessive dreaming—that is, dreaming more than is customary for a particular individual—comes from unconscious—that is, unrecognized—emotional stress. The already vivid dreams of this patient may well have been intensified in consequence of emotions associated with her pregnancy. Dreams are the experience of everyone and are not symptoms of a disorder. Their vehemence can best be modified by discussing them with a psychotherapist, as the appreciation of a dream's significance renders its repetition unlikely. Dream activity can be reduced and often eliminated by the use of hypnotics.

There is no evidence that dreaming always occurs just before waking. Thus sleep-walkers and talkers may subside into tranquil slumber without waking up. Probably we dream all night, but remember only fragments; thus the train of thought during the day will often revive a forgotten dream.

Aetiology of Peptic Ulcer

Q.—What are the latest views on the aetiology of peptic ulceration?

A.—The short answer, and probably the most correct one, is that we do not know the cause of peptic ulceration. There are, however, a few clues to the aetiology which may prove to be of value.

In the first place, it is probably necessary to consider gastric ulcer and duodenal ulcer separately. Although the two types of ulcer are practically indistinguishable clinically and are treated in much the same way, and although they are found in association with one another more often than would be expected by chance, there are many reasons for thinking that their causes are not identical. Both types of ulcer are to some extent hereditary—that is to say, they occur more commonly among members of the families of ulcer subjects than in the general population—but the hereditary susceptibility is expressed relatively seldom, and the environmental factors which determine whether or not a person has an ulcer are extremely important. (See *British Medical Journal*, 1954, 2, 315.)

Recent evidence bearing out the role of heredity has been obtained by Professor Aird and his colleagues at the British Postgraduate Medical School who have shown that both types of ulcer—but perhaps more particularly duodenal ulcer—are commoner in persons of Blood Group O. This is not surprising when it is recalled that blood group substances occur in the gastro-intestinal secretions, and it is therefore understandable that they may play a part in protection against autodigestion.

The importance of environmental factors is shown by the great changes in prevalence which have taken place over the last half-century. Duodenal ulcer has become much commoner, while gastric ulcer, which was characteristically a disease of young women, is now predominantly a disease of the middle-aged.

Duodenal ulcer is rare in childhood, but when it occurs it affects both sexes equally. It begins to be common after puberty, and subsequently is four to six times commoner in men than in women. It is approximately equally distributed among all sections of the community. Duodenal ulcers nearly always occur in association with an increased amount of gastric secretion, which would appear to be the result of an increased number of oxyntic cells in the mucosa. Why there should be more oxyntic cells is not known; one theory is that they reflect a work hypertrophy,

in which the stimulating factor is a food substance or chemical added in food processing. Psychological factors are probably of less importance than was thought 10 years ago. There is no doubt that anxiety or mental conflict may exacerbate symptoms of ulcer or bring on a complication; but the evidence that a particular personality, or type of emotional stress, is the primary cause of duodenal ulcer is not impressive.

Gastric ulcer shows a less marked male preponderance and it does not become common until later—that is, until after the age of 35 years. It is rare among the wealthy and becomes increasingly common as the social scale is descended. In this its distribution is reminiscent of gastric cancer. Gastric ulcer occurs characteristically in persons whose gastric secretion is normal or diminished, but it is doubtful if it ever occurs in persons whose stomachs are persistently achlorhydric. In the light of present knowledge it may be thought of as due to "wear and tear."

Nausea after Morphine

Q.—What is the best way of dealing with nausea and vomiting following the administration of morphine for pain relief? Are nalorphine, antihistamines, or sedatives helpful?

A.—There are two ways of dealing with the nausea and vomiting. When the morphine has been given and has produced these symptoms they can be arrested by the administration of nalorphine. This will, however, abolish the analgesia also. The better method is to try a different analgesic, for there are great variations in the way they are tolerated. Amidone is rather stronger than morphine, and is given in about three-quarters the dose. Pethidine is weaker and is given in about eight times the dose. Phenadoxone (by injection) is stronger and is given in three-fifths the dose. In using analgesics the attempt should be made to find which suits the patient best: what suits one may not suit another. On the whole it seems to be true that morphine produces nausea and vomiting more often than the other analgesics mentioned. The article by P. W. Nathan¹ should be consulted.

Epidermolysis Bullosa

Q.—Would you please tell me if there is any efficient form of treatment for epidermolysis bullosa in an 8-months-old infant? The symptoms, affecting her buttocks, shoulders, back of neck and head, finger-tips, and centre of upper lip, appeared soon after birth.

A.—The baby is probably suffering from the recessive hypoplastic type of epidermolysis bullosa which appears at birth or soon after. Bullae may arise spontaneously on any part of the skin, but especially at the sites of pressure or trauma. The mucous membranes are usually affected.

The outlook is gloomy and few patients reach puberty. If they do it is possible that some improvement may take place, but it is likely that treatment with plastic surgery will be required, such as to correct the binding together of the fingers. No treatment is known which affects the condition, and this, of course, is true of most congenital defects. Cortisone is not beneficial. Antibiotics are only helpful in the treatment of secondary infection of the raw areas. It is necessary to wrap the baby in cotton-wool so that all surfaces liable to injury are protected.

Cyanosis of Lips in Acrocyanosis

Q.—Is cyanosis of the lips a common concomitant of acrocyanosis? My patient, a little girl aged 4½, shows a constant bluish tinge of her lips, summer and winter. She appears to be perfectly healthy, and, apart from the fact that she tends to suffer from acrocyanosis in the winter, shows no evidence of organic disease on clinical examination. What might be the aetiology of this condition, and what possibilities ought one to exclude?

A.—Hands and feet are dominantly affected by acrocyanosis. The condition is due to dilatation and sluggish

circulation in the small vessels and venules, and cyanosis is exaggerated in cold weather. The lips are not involved. In judging cyanosis of the lips it should be remembered that there is often some pigmentation on the outer edge of the lips, which may be deceptive. When the interior of the lip is inspected in such cases no cyanosis is seen.

Cyanosis due to congenital heart disease is accompanied by some degree of polycythaemia and finger-clubbing, and it should be remembered that the cardiac physical signs of congenital cyanotic heart disease may be minimal. Methaemoglobinemia gives a leaden hue to those parts of the skin and mucous membranes where the colour of the blood is visible. Remarkable improvements in colour may follow the oral administration of a large dose of ascorbic acid. Methaemoglobin is recognized by spectroscopic examination of the blood.

Frigidity after a Difficult Labour

Q.—A young married couple are worried by frigidity in the wife since the birth of their first child after a difficult labour. Previously the wife was passionate and achieved orgasm easily, but now, although allowing intercourse, she is not roused by it. She realizes that fear of another difficult labour may have played a part in the first few months after the birth of the baby, but that was two years ago, and she thinks that she has now got over this. The couple practise contraception with a Dutch cap, and owing to the husband being away at sea intercourse is necessarily infrequent.

A.—An organic basis for the frigidity is unlikely, although overstretching or tearing of the vagina during delivery could diminish stimulation and therefore satisfaction during coitus. However, reduction in sexual feelings after pregnancy, and especially the first pregnancy, is the experience of most women. The fact that a fundamental objective of coitus has been achieved; the awakening of mother love with some readjustment of the affections; the extra work, anxiety, and responsibility of looking after the child—all play a part. This reaction, however, is usually only temporary and clears up as the period of nervous strain passes, as physical well-being returns, and as the baby begins to show signs of independence. Two years is rather long for this mechanism to continue to operate, although in this case it may be fostered and extended by the frequent and prolonged absences of the husband. Separation means that the woman must deliberately stifle her sex feelings and learn to live without coitus. She may therefore look more and more to the child as an outlet for her emotions and affection, and this is even more likely if she has decided not to conceive again because of her previous obstetrical experience. Despite the passage of time, fear of another pregnancy must also rank high in the list of possible causes of frigidity. The woman might also have a fundamental objection to contraception, and this could arouse an inner conflict between desire for, and fear of, pregnancy. Is it not possible for the difficulty which occurred in the last pregnancy to be avoided in the next, and could the couple be reassured on this point with a hope of them then being able to take a more normal outlook on married life and the production of a family?

Treatment of Diverticulosis

Q.—What dietetic or other regime is indicated in a case of diverticulosis of the transverse colon discovered by barium follow-through? The patient was referred to the radiologist on account of occasional discomfort around the left costal margin.

A.—It is customary in cases of diverticulosis to prescribe a diet from which articles of food known to leave a high residue are excluded, the so-called non-roughage diet. Cellulose residues from green leafy vegetables and fruits, especially uncooked, wholemeal bread, and so on are the chief offenders. The absence of roughage tends to induce constipation which can to some extent be overcome by an adequate fluid intake and by the administration of plain "petrolagar emulsion" in small doses with each meal. It

must be remembered that there is no musculature in the wall of the diverticulum, so that if it becomes filled with inspissated faecal material it cannot empty itself: the colonic contents should therefore be kept, so far as possible, soft and moist.

In the absence of inflammation pain is due to the associated colonic spasm, so in an attack the administration of bowel antispasmodics is often valuable. Ordinary purges should be avoided, since they tend to increase spasm, but an occasional Studa chair colonic wash-out, say once a month, may be well worth a trial. On a simple regime such as this many cases of diverticulosis carry on for a great number of years without any serious complication arising.

Shoes for Patients with Pes Cavus

Q.—I think that those who suffer from the common condition of pes cavus are less disabled if they can obtain shoes that fit. Do you agree? If so, can you tell me of any firm that provides suitable shoes? Hand-made shoes are too expensive for most patients, and I do not think every patient is willing to get his shoes through an orthopaedic clinic. So far as I can tell the local shops can only provide shoes for "standard" feet.

A.—I entirely agree that to be comfortable with pes cavus shoes must fit. Unfortunately no firm provides suitable shoes. There are no alternatives to having hand-made shoes or surgical shoes obtained from the National Health Service.

Sometimes such people can get along with wide toe-capped shoes and a firm pad under the arch.

Sulphathiazole

Q.—According to certain publications, principally North American, sulphathiazole should not be used on account of its greater toxicity; according to others sulphathiazole is still a useful drug in many cases, as it is the most active of the sulphonamides and in certain cases the toxic effects are insignificant. What are your expert's views on this?

A.—Although sulphathiazole is a highly active sulphonamide it is a very insoluble one and is particularly likely to cause renal irritation, and even in some cases urinary suppression. Such dangers can usually be easily guarded against in temperate and cold climates, where most of the fluid output is through the kidneys, by ensuring a really adequate intake of fluid whenever sulphathiazole is given; but in warm climates, where perspiration may be excessive and where even with care the urinary output may not be adequate in febrile conditions, sulphathiazole undoubtedly possesses serious drawbacks. It is very doubtful if the more modern and much more soluble sulphonamides such as sulphadimidine are any less active than sulphathiazole.

Epilation

Q.—Which method of epilation of facial and body hair is preferable—galvanic or diathermy—and why? Should a local analgesic be used before epilation? Does the epilation leave any scarring afterwards and, if so, can it be prevented?

A.—The choice between electrolysis and diathermy is a matter of personal preference, and in the opinion of the writer, who has used both, there is really little to choose between the two. The apparatus for electrolysis is less expensive, and it is probably easier through faulty technique to cause scarring with diathermy than it is with electrolysis. For these two reasons electrolysis is perhaps preferable. Local analgesia is not usually given; some patients complain of pain, and a local analgesic is then advisable provided the area to be treated is not too large.

Of course, the object of epilation is to destroy the hair follicle permanently without the production of a scar, and the skill in treatment lies in passing the current for the right length of time and at the right intensity. When the current has passed long enough the hair will come out with very gentle traction, and there may be a slight white opacity of the skin extending for a distance of a fraction of a millimetre

around the follicle. Any area of necrosis which is wider than this is excessive and is liable to be followed by visible scarring. It is, of course, better to err on the side of under-treatment rather than over-treatment, which would result in scarring; the operator soon gets to know how long to leave the current on in the precise conditions in which he is working. A practical demonstration with the apparatus to be used would be very valuable for anybody intending to undertake this treatment for the first time.

"Cracking in the Head"

Q.—I should be grateful if you could kindly throw a little light on the following case. The patient is a rather senile lady of 77 who has a well-compensated mitral valvular disease. Her principal complaint is of a "cracking in the head" which is accompanied by a sudden severe pain and often followed by flushing of the face. She has phases when she is withdrawn and others when she is full of complaint and worrying about herself, and in the absence of physical findings I was inclined to the view that the "crackings" were neurotic in origin. However, recently both her husband and her daughter have heard the cracks, though they have not told her so. Her daughter, who is a very sensible and competent woman, likens the sound exactly to that of "knuckle cracking." The attacks occur many times a day and are very distressing.

A.—Audible cracking like knuckle cracking is almost certainly produced in a joint. Cracking in the temporomandibular joint is a very familiar phenomenon. In elderly and particularly edentulous patients the chewing movements may force the head of the mandible back on to the anterior surface of the external meatus, and pressure here may produce pain referred to the face.

Chronic Alcoholism and Fertility

Q.—What effect has chronic alcoholism on fertility? What is the mechanism for any adverse effect?

A.—It is generally accepted that chronic alcoholism can lead to male infertility by interfering with sperm production. It is most probable that the effect is a direct toxic one on the germinal epithelium, leading to partial or complete failure of spermatogenesis. Since chronic alcoholism is a good deal less frequent in women than in men, its effects on female infertility are less well recognized. It can, however, bring about amenorrhoea, either as a result of a direct toxic action on the ovaries or perhaps more likely through disturbance of the pituitary-ovarian relationship.

Correction.—The penultimate sentence in the first paragraph on p. 871 of the paper by Dr. C. D. R. Pengelly on "Pneumococcal Meningitis" (*British Medical Journal*, April 9, p. 870) should have read, "Only three recoveries occurred in 16 patients in the latter group (81% mortality)." Later on the same page the paragraph beginning "The additional therapy in Group 3 . . ." should have had the words "with chloramphenicol (orally) in two and" inserted before the words "with intrathecal streptomycin in one."

Books of "Any Questions?"—The second and third volumes of "Any Questions?" are available, price each 7s. 6d. (postage 6d.), from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller. Each contains some 200 selected expert answers, and the third volume a cumulative index to the three published books.

for seborrhoeic dermatitis patients . . .

SELSUN[®]

REGD

(Selenium Sulphide, Abbott)

controls scaling

stops itching

relieves burning

SELSUN brings prompt, welcome relief from seborrhoeic dermatitis of the scalp. Published reports covering more than 400 cases show SELSUN completely controls 92 to 95 per cent of common dandruff cases, and 81 to 87 per cent of all seborrhoeic dermatitis cases.

It relieves itching and burning symptoms after the first two or three treatments—restores the scalp to a clean, healthy condition in just four to six weeks. After that, each treatment will keep the scalp free of scales for one to four weeks.

Your patients will find SELSUN pleasant and easy to use. They just add it to their regular hair-washing routine. It rinses out easily, leaves the hair and scalp clean. There are no complicated procedures, no messy ointments, no daily rituals.

SELSUN is supplied in 2 and 4 oz. bottles with complete instructions for use.

OPPORTUNITIES FOR MEDICAL PRACTICE AT HOME AND ABROAD

BY

Sir STANLEY DAVIDSON, M.D., F.R.C.P., F.R.C.P.Ed.

Professor of Medicine, University of Edinburgh

The news that a Government committee has been set up to consider the intake of students into the medical schools has made me decide to publish certain pertinent data which were collected for a lecture entitled "Medical Research and Medical Practice at Home and Abroad." Since I have spent my life as a teacher in Scottish medical schools, it is natural that I should consider the problem under discussion mainly from the Scottish angle. Nevertheless, many of the collected data are of equal importance to the young English graduate.

I have approached this problem in the first instance by considering the composition of the class of medicine in Edinburgh graduating in 1912, the year in which I started my academic career as a medical student. Table I compares the sex distribution and country of origin of

University has occurred, as can be seen from Table I. The overseas students now take their medical degrees in their own institutions, which is as it should be, and the 175 students beginning medicine in Edinburgh every year are selected from the hundreds of applicants mainly domiciled in Great Britain, a small number of places being reserved for students living in those Colonies in which there are no medical schools. Edinburgh has always been a popular choice for English students wishing to study medicine, and in 1954 there were some 333 English applicants for entry to the medical school, of whom 63 were accepted.

I believe it is a sound policy to encourage undergraduate students in the Dominions to undertake their medical studies in their own universities and to fill our quota mainly from the long list of British applicants. In contrast to undergraduate education I believe that the British universities should cater especially for post-graduate education for students from overseas. In this respect Edinburgh has been very successful, since approximately 600 doctors per annum attend the various courses of instruction arranged by the Edinburgh Post-graduate Board. In summary, the points of particular interest in Table I are: (1) The great increase in women medical students: they now comprise approximately 25% of the class. (2) The increase of Scottish students from 40% to 70% of the class. (3) The great reduction in the number of students from Ireland, from Wales, and from overseas.

At this point it is appropriate to consider what happened to the Edinburgh medical students who qualified 40 years ago. Only a small percentage remain to practise in Scotland. What that figure was cannot be ascertained, but I doubt if it was 25% of those who qualified annually as doctors. The great majority of the students from England, the Dominions, and the Colonies who came to Edinburgh for their training returned to their native countries to undertake medical practice. Their example was followed by many Scottish medical graduates, who saw a brighter future in England and overseas than existed for them in Scotland at that time. The Indian Medical Service was a popular choice for many doctors, as were the Sudan Medical Service and the Colonial Medical Service. There appeared to be ample opportunities for every medical graduate of Scottish birth who was prepared to leave Scotland to obtain the type of work which he desired if this was not available to him in his native country.

Opportunities for Practice

Detailed consideration may now be given to the opportunities for practice available at the present time to British graduates in general and Scottish graduates in particular.

4923

TABLE I.—Numbers Graduating M.B., Ch.B. in Edinburgh in 1912 and 1952

the graduates in medicine in 1912 and in 1952 in Edinburgh. Prior to the first world war, Edinburgh was a medical centre which drew its student population not only from Great Britain but from all parts of the British Commonwealth. At that time some of the medical schools in the Dominions which are now flourishing institutions either did not exist at all or taught medical students only up to the standard of the first or second M.B. (anatomy and physiology). Accordingly large numbers of Colonial and Dominion students came to Britain for their clinical teaching and to obtain a British qualification in medicine. Scottish medical schools were frequently selected by these overseas students for their medical studies. This is perhaps not surprising, since at that time a very large number of Scottish graduates practised medicine in the Dominions and Colonies, and naturally they recommended Scottish educational facilities to potential students. When the new medical schools were created in the Dominions before and after the first world war, many professors of the faculties of medicine were Edinburgh graduates, and so it was only to be expected that Scotland's capital would be a popular choice for overseas students.

During the last 25 years a complete change in the source of origin of medical students in Edinburgh

During the past 20 years the population of Great Britain has increased by approximately 10%, while the number of doctors on the *Medical Register* has increased by no fewer than 25,594—that is, 45%. The number of persons per doctor in England has fallen from 1,250 in 1930 to 900 in 1953 and in Scotland from approximately 800 to 570 during the same period (*British Medical Journal*, 1955). Even if it were conceded that 20 years ago Great Britain was under-doctored as estimated by modern standards, such a disproportionate increase in the number of doctors compared with the increase of the population would inevitably make it much more difficult for recent medical graduates to obtain suitable posts. The position is particularly serious for Scottish graduates, for not only is the ratio of persons per doctor lower in Scotland than in England but the opportunities for entering practice in England are becoming increasingly difficult. The reason for this is clearly indicated in Table II, which shows that the output of doctors by

TABLE II.—Great Britain: Increase in Numbers of Medical Students Graduating in Selected Years

Year	England	% Increase	Scotland	% Increase	Ireland	% Increase
1934	847		471		154	
1937	1,096		593		239	
1940	1,323	56	673	43	315	105
1945	1,268		581		428	
1949	1,436		589		452	
1952	1,848	118	673	43	506	228

the four Scottish medical centres in 1952 has remained the same as it was in 1940, while the annual production of doctors in England has increased from 1,323 to 1,848 during that same period. This has resulted mainly from the expansion of the English provincial medical schools. Attention is also drawn to the great increase in production of doctors which has taken place in Ireland in recent years. The majority of these Irish graduates are unable to obtain work in their own country and accordingly seek employment in Great Britain or the Dominions and Colonies.

It is only natural that preference should be given to local graduates by regional appointment boards in England, provided that the applicants' qualifications are satisfactory. Under these circumstances the young Scottish graduate looking for work will turn his eyes to lands overseas, where so many of his predecessors made such a success of their professional careers. India, Pakistan, Burma, and Ceylon are independent nations with their own medical schools, which are being rapidly expanded so that the medical services of these countries can be staffed by their own graduates. The Indian Medical Service is no longer open to our graduates, and the Sudan Medical Service is now at an end so far as European doctors are concerned. A small number of posts in these countries are advertised from time to time by British commercial firms who want British medical officers to be responsible for the care of their employees, but the number of such posts is so small as to make no difference to the overall picture. When I was in Ceylon four years ago I was told that only three European doctors were practising medicine in Colombo, a city of 425,000 inhabitants.

TABLE III.—British Dominions: Increase in Total Number of Registered Practitioners Compared with Increase in Population (data obtained from the Dominions Offices)

Country	Year	Approximate Population in Millions		Approximate % Increase		Total No. of Registered Practitioners	% Increase	Approximate No. of Persons per Doctor

Practice in the Colonies and Dominions

With regard to the opportunities for British doctors wishing to practise in the Colonies, the medical schools in Hong Kong, Singapore, and the West Indies will presumably be able to meet the medical requirements of these regions in the near future. The University of Ibadan, Nigeria, and Makerere College, Uganda, each have flourishing medical faculties, but for a long time to come the Colonial medical services will require medical officers to carry on the excellent work being done in the African Colonies. The opportunity for private practice in Tanganyika, Uganda, and Kenya is small, since the total European population of British East Africa is only about 60,000 persons, many of whom are Civil Servants who receive free medical care. It should also be remembered that there are a large number of Indian doctors practising in these territories. Two-thirds of the European population of British East Africa is concentrated in Nairobi and the adjacent White Highlands. It is my belief that the number of doctors practising in this region already exceeds the regional requirements. This belief is equally applicable to Salisbury and Bulawayo, in Southern Rhodesia.

As the Colonies can absorb only a small proportion of the British doctors wishing to emigrate, what opportunities exist for them in the great Dominions of Australia, New Zealand, South Africa, and Canada? I have visited all these countries during the past five years, and it seemed to me that the competition for practice was extremely severe, at any rate in the big cities. This impression would appear to be fully justified by the data shown in Table III. During the past 20 years there has been a most remarkable increase in the number of practitioners registered in Australia, New Zealand, South Africa, and Canada. With the exception of Canada, this increase is out of all proportion to the increase in the size of the population that has occurred during the same period. Table IV clearly shows that the reason for this great expansion is the increase in production of doctors by the Dominion medical schools. I have not been able to obtain the figures for the total medical man-power registered in Australia, as medical registers are kept only by each State. I am informed that such registers may be somewhat inaccurate, for the same doctor may be registered in more than one State. The number of doctors registered in Victoria has risen from 2,498 in 1934 to 4,207 in 1954, while in South Australia the comparable figures are 484 and 1,202 respectively. There is ample evidence to suggest that the production of doctors in Australia by the Australian medical schools exceeds the national requirements without including the doctors of British and foreign nationality who have emigrated there in considerable numbers since the war and who will wish to continue to do so in the future.

This matter is well reviewed by Sir Hugh Poate (1953) in an article entitled "The Capacity of the Medical Profession in Australia to Absorb New Doctors." Sir Hugh calculates that the number of new graduates required annually for Australia as a whole is approximately 486. The number of Australians graduating in medicine in Australia in 1948 was 297, but by 1951 and 1952 it had reached the

huge figure of approximately 650 per annum. In addition to local graduates, some 585 doctors from Great Britain and Ireland and from foreign countries have emigrated to Australia between 1948 and 1952. There can be little doubt, therefore, that Australia is rapidly becoming over-doctored.

TABLE IV.—British Dominions: Increase in Number of Medical Students Graduating in Selected Years Compared with Increase of Population (data obtained from the "Year Book of the Universities of the Commonwealth")

Country	Year	Approximate Population in Millions		Approximate % Increase		No. of Students Graduating Annually	% Increase
		European	Non-European	European	Non-European		
South Africa	1938 1951	2.05 2.65	8.0 10.0	29	25	134 435	224
New Zealand	1936 1951		1.65 2.05		24	39 112	187
Canada	1938 1951		11.5 14.0		22	492 791	62
Australia	1934 1952		6.6 8.8		33	175 635	263

Conclusion

Sufficient has been said to make it clear that opportunities for medical practice in the Dominions and Colonies for British graduates wishing to emigrate overseas are much fewer to-day than they were 40 years ago. Owing to the overcrowding of the profession and the preference given to local graduates, it is my opinion that it would be unwise for a British graduate in medicine to proceed overseas without first having obtained a salaried appointment in a commercial firm, in a university, in a research institute, or in H.M. Overseas Service, or without having obtained a legal contract safeguarding an offer of an assistantship or partnership in private practice. It is also clear that in Great Britain at the present time the chance of becoming a consultant in hospital practice or a principal or partner in general practice is too difficult and too uncertain. In short, there seems to be an over-production of doctors both in Great Britain and in the Dominions.

Unless reasonable opportunities for employment are going to be made available to potential graduates, not only will the numbers entering medical schools fall, according to the laws of supply and demand, but so will the quality of the entrants. The Government Committee appointed to study this important problem will have to consider whether it is better to allow the laws of supply and demand to operate or whether restriction of entry to medical schools should be enforced. That the former mechanism is already operating would appear to be the case, since the number of students starting medicine in Great Britain and Ireland has declined from 2,725 in 1949–50 to 2,280 in 1953–4 (*Lancet*, 1955). On the other hand, it may be felt that the second course is preferable, as it is obviously a wasteful and expensive business to produce more doctors than are required. The question will then arise whether medical schools should be ordered to reduce their annual intake of medical students by a certain quota or whether they should merely be recommended to do so. In this connexion the problem of the excessive production of doctors by the Irish medical schools will require particular attention. Lastly, it will be necessary to decide whether any proposed reduction in intake should be proportionally the same for every medical school in Great Britain or whether medical centres with a long-established international reputation for medical education should receive special consideration.

My thanks are due to Mr. Jolley, Librarian of the Royal College of Physicians, Edinburgh, for the help he has given me in collecting the data for Tables III and IV.

DIVERSITIES OF SEX*

BY

C. N. ARMSTRONG, M.D., F.R.C.P., D.P.H.

Physician, Royal Victoria Infirmary, Newcastle-upon-Tyne,
and Queen Elizabeth and Bensham General
Hospitals, Gateshead

Diversities of sex can be divided into: (1) hermaphroditism, in which the gonads are of both sexes and the external sexual appearances may be male or female or a mixture of both; (2) pseudohermaphroditism, in which the external sexual characteristics are more or less characteristic of the sex opposite to that of the gonads; and (3) homosexuality, a state of affairs in which the libido and sexual urge is directed towards the same anatomical sex and may or may not be associated with recognizable endocrine abnormality.

Hermaphroditism

True hermaphroditism is rare: there is a separate ovary and testis, or an ovo-testis.

Case 1: Woman aged 66.—Her mother died when the patient was 8 years old. She looked after six other children and received no proper schooling. During this period she regarded herself as a woman and wore women's dress, but at the age of 18 realized there was some doubt about her sex and tried to commit suicide on this account. Subsequently she led a vagabond life doing farm work and hawking. She shaved about once a week. For some years she has been becoming progressively bald on the top of the head, after the manner of a man. In May, 1952, she was

FIG. 1

FIG. 2

FIG. 1.—Case 1. True hermaphroditism. Sex regarded as female; has lived as a female, although general appearance rather masculine. One gonad a testis; the other an ovary. Ketosteroids, 3.8 mg.
FIG. 2.—Case 1. True hermaphroditism. Scrotum on right containing a hydrocele; short phallus with hypospadias orifice on the perineum; no vagina. Testis in the right inguinal canal.

taken to a welfare institution and transferred to Bensham General Hospital for investigation.

On examination the skin and hair distribution were seen to be those of a man. She had a short stubble of beard, long unclipped hair, but central baldness (Fig. 1). The external genitalia also looked masculine, there being a well-formed scrotum on the right containing a hydrocele, a short penis with a hypospadias orifice on the perineum, and no vagina (Fig. 2). An organ in the right inguinal canal was considered to be an undescended testicle. On closer examination the skin fold on the left side appeared like a labium. The urethra opened on the perineum and there was a slight opening $\frac{1}{2}$ in. (1.9 cm.) long at the end of

*A paper read to Newcastle-upon-Tyne Obstetrical and Gynaecological Society on March 4, 1955.

the penis, but the scrotum was empty apart from the hydrocele. Urinary 17-ketosteroid estimation was 3.8 mg. per 24 hours.

Laparotomy was performed on June 20 by Mr. David Smith. There was a small uterus with broad ligament and left ovary. No right ovary could be seen. A rudimentary right tube disappeared into the inguinal canal. The gonad was removed from the right inguinal canal for section. Histological examination showed a rudimentary uterus; a Fallopian tube; an ovary with numerous corpora albicantia and calcified vessels, showing in its mesentery large clumps of interstitial cells; a testis with fibrosed seminiferous tubules and grossly increased numbers of Leydig cells. On this side there was in addition a structure which might be a tube of a ductus deferens. Unfortunately it has not been possible to obtain skin or a blood film for determination of chromosomal sex because the patient has been transferred to another hospital.

Pseudohermaphroditism

Pseudohermaphroditism, male and female, is much more common, and is a condition in which the gonads are of one type—testes or ovaries. There are two varieties of male pseudohermaphroditism.

Male Pseudohermaphroditism

(1) Cases with testes and general male external characteristics with the exception of the external genitalia: undescended testes and hypospadias.

Case 2: A girl aged 13.—This girl's mother consulted her home doctor because it was noticed that the child had enlarged genitalia.

Otherwise she was very healthy, a good scholar, active, and good at games.

On examination she was tall for her age and thin, with a deep voice; pubic hair was present (Fig. 3) and the clitoris was enlarged. A swelling in the right inguinal region felt like a testis. She had an infantile vagina with no evidence of cervix or uterus; no breast development. Urinary 17-ketosteroid estimation, 9.6 mg. per 24 hours.

Laparotomy was carried out by Professor Bentley. The right inguinal canal was opened, and what appeared to be a normal testicle for a child of this age was delivered; a biopsy specimen was taken: on microscopy the testicle tissue looked normal. The inguinal canal was then closed. A midline subumbilical incision was made and the pelvis explored. There was no evidence of any rudimentary female viscera. The midline incision was then closed in layers without drainage.

Histologically the specimen was morphologically testis, with well-formed tubules and considerable aggregation of interstitial cells. There was no evident spermatogenesis. The results of the operation suggested, therefore, that this child was essentially a male.

A plastic operation was carried out by Mr. Fenton Braithwaite and the patient has assumed the male sex very successfully.

(2) These are cases with external female characteristics and absence of internal female organs, and in which the gonads are testes and the chromosomal sex is male. This type of male pseudohermaphroditism is commonly mistaken for female, but should always be suspected in a female of adult age who has never menstruated, has no pubic hair, and is without signs of hypopituitarism. Cases have been published by Armstrong (1953) and Beatty, Champ, and Swyer (1953).

Case 3: Girl aged 17.—This patient was referred to hospital on April 22, 1952, because she had never menstruated. She was a twin—the other twin died *in utero*. There was a family history of late menarche. She was of normal stature with well-developed breasts and a normal head of hair. There was no axillary or pubic hair, and her skin was generally somewhat hairless (Fig. 4). The vulva was infantile but otherwise appeared normal. The vagina was only $\frac{1}{4}$ in. (1.3 cm.) in length. On rectal examination no internal female organs were palpated. No abnormal signs were found in the heart, lungs, abdomen, and central nervous system; blood pressure 130/90; urine normal; x-ray examination of sella turcica, normal; urinary 17-ketosteroid estimation, 8.9 mg. per 24 hours.

She had the mental attitude of a girl. Socially and occupationally, the adaptation is that of a girl of 17 of rather above average intelligence. Sexually she is a little immature, but her inclinations are entirely female. She has had girl's toys, has female daydreams, reads love stories, and identifies herself with

FIG. 4

FIG. 5

FIG. 4.—Case 3. Male pseudohermaphroditism. "Girl" aged 17: external feminine characteristics; breasts developed, no pubic hair, infantile female vulva. Gonads undescended testes; no female internal organs and no vagina. Chromosomal sex, male. Ketosteroids, 8.9 mg. Oestrogen excretion in urine: oestriol 2 μ g., oestrone 2.4 μ g., and oestradiol 0.5 μ g., which are at male level. **FIG. 5.**—Case 3. Drawing showing appearance of pelvic organs at laparotomy: undescended testes and no female organs.

female fictional and film characters; she hopes to marry and is fond of babies.

At laparotomy there was no uterus, but a broad fold of peritoneum ran across the pelvis in the corresponding position. On the left side, lying on the psoas muscle, was a gonad anatomically resembling a testis. On the right side a similar structure was found, but more inferiorly placed so that it was lying right at the internal ring (Fig. 5). The arrangement was quite consistent with undescended testes. Both inguinal regions were bimanually palpated and no swelling was noted in either groin. The broad fold of peritoneum running across the pelvis is the transverse pelvic fold, a remnant of the uro-rectal septum or genital fold, and its attachment to inguinal fold (gubernaculum) appears almost ligamentous and may well have been a factor in checking the descent of the testis. Such an attachment as this occurs in the female from the lateral aspect of the body of the uterus to the ovary, to form the ligament of the ovary.

Material from each gonad was identical histologically and consisted of testicular tissue. There were numerous immature seminiferous tubules which showed no evidence of spermatogenesis. Numerous and increased numbers of interstitial cells were present.

17-Ketosteroid fractionation carried out by Professor Charles H. Gray gave the following results. Total excretion of 17-ketosteroids, 8.8 mg. a day. The 17-ketosteroids could be separated into eight fractions, as follows:

I	Containing mainly artefacts of fraction	19%
II	Transdehydroisoandrosterone	0%
III	Containing mainly androsterone	13%
IV	" " acetocholanolone	18%
V	" " " "	33%
VI	" " 11-oxygenated 17-ketosteroids	11%
VII	" " unknown artefacts	0%
VIII	" " " "	6%

This fractionation is within normal limits.

Adrenocortical Steroid Analysis (all figures in μ g. per 24 hours)

	Δ^4 -3-Ketosteroids			Reducing Steroids		
	Free			Glucuronide-conjugated		
	Comp. E	Comp. F	Comp. X ₄	Comp. X ₅	Tetrahydro-Comp. E	Unidentified Comps
Normal range:	20	20	60	80	1,200	240
Male	20-200	10-80	20-120	0-200	240-3,000	0-1,500
Female	30-110	10-120	10-320	10-4,000	160-4,000	0-2,200

X₄ and X₅ are unidentified Δ^4 -3-ketosteroids with R_F values of 0.24 and 0.39 in benzene:50% methanol system. Excretion of free compound E of 20 μ g. a day is within normal limits for males.

Dr. J. E. Gray was of the opinion that the chromosome content of the skin was male.

Professor G. F. Marrian estimated the oestrogen excretion in the urine, and reported the following results:

	1st Week	2nd Week
Oestriol	2.0 μ g.	1.6 μ g.
Oestrone	2.4 "	3.1 "
Oestradiol	0.5 "	1.4 "

These figures are at male level.

The patient whose case was reported by Beatty *et al.* (1953) was admitted to the Royal Victoria Infirmary on December 1, 1954, as an emergency under my care because of haematemesis. Dr. G. I. M. Swyer reported on the oestrogens as follows: oestriol, 2.1 μ g. in 24 hours; oestrone, 1.5 μ g.; oestradiol, 2.6 μ g. This patient intends to marry in the near future.

In both these cases the oestrogen excretion in the urine is at the male level, which suggests enhanced response of target organ to oestrogen or that there is another oestrogen not yet determined.

Female Pseudohermaphroditism

Female pseudohermaphroditism is a condition in which the gonads are ovaries, the chromosomal sex is female, but the external appearance is more or less masculine. Usually there is lack of breast development, with a male type of hair distribution, and the clitoris is enlarged to a degree which resembles a penis but micturition is feminine in type. The condition either is of genetic determination or is due to adrenal hypersecretion, starting in foetal life. These subjects are seldom brought up as boys, and such a case is reported here.

FIG. 6

FIG. 6.—Case 4. Female pseudohermaphroditism. "Boy" aged 16; external genitalia: phallus with appearance of a penis, and urethral opening on the ventral surface. In perineum, two sinuses, from one of which menstrual bleeding occurred. Ketosteroids, 6.3 mg. **FIG. 7.**—Female pseudohermaphroditism. Photograph shows appearance of external genitalia.

FIG. 7

FIG. 8.—Case 4. Female pseudohermaphroditism. Drawing illustrating pelvis at laparotomy; uterus and ovaries present; no male organs.

surface (Fig. 7). In the perineum there were two sinuses, from one of which periodic bleeding occurred. Lipiodol injection showed it to have a connexion with the urethra. Ketosteroids were 6.3 mg. per 24 hours.

Laparotomy, carried out by Mr. D. J. Tibbs, revealed a normal adolescent uterus which connected by a rudimentary vaginal canal with the perineal sinus (Fig. 8). Gonads were present in the position of normal ovaries. Biopsy showed them both to contain ovarian tissue histologically. Fallopian tubes were malformed.

This patient has refused to assume female sex.

The more common type of female pseudohermaphroditism has enlarged clitoris, male type of hair distribution, no breast development, and non-establishment of menstruation. These cases of adreno-genital syndrome respond to treatment with cortisone.

FIG. 9

FIG. 9.—Case 5. Female pseudohermaphroditism. Girl aged 14. Enlarged clitoris; thick pubic hair, no breast development and no menstruation. Ketosteroids, 23.0 mg. Since above photograph was taken has been treated with cortisone: ketosteroids have dropped to 6 mg., breasts have developed, and menstruation established. **FIG. 10.**—Case 5. Female pseudohermaphroditism. Photograph showing enlarged clitoris.

FIG. 10

Case 5: Girl aged 14.—This patient was referred to me at 11 years of age with the complaint that she was changing her sex. The history was that at 1 year the clitoris was found to be enlarged and at 2½ years pubic hair began to grow. At 4 years laparotomy had demonstrated a normal uterus and ovaries, with histological confirmation. Examination confirmed the presence of a small vagina and separate urethral passage (Fig. 9). The urethral opening is set very far back (Fig. 10). Ketosteroids were 23 mg. The condition in this case was considered to be adrenal hyperplasia. She has continued to be successfully treated with cortisone: the breasts have developed and menstruation has been established.

Homosexuality

In both sexes there are two types, active homosexuals and the passive homosexuals—the active assuming the male role and the passive the female role. It is as yet indefinite whether homosexuality—the libido, emotional attraction to another individual, and urge of sexual expression being to a member of the same sex—is inborn and of genetic determination or due to acquired environmental psychological factors. Because of the law in regard to homosexuality in males, research into this problem is urgent. The only contribution I have to make is that recently I have had several passive male homosexuals referred to me for an endocrine opinion, and in each instance I have been able to recognize certain female characteristics.

Case 6: Man aged 22.—This patient was referred to me at Royal Victoria Infirmary in September, 1954. He had previously been admitted to the Department of Psychological Medicine, where it was thought that little could be done to help him. He volunteered the information that he was of the opinion that from very early childhood he had had female tendencies and female habits, and at the age of 13 a neighbour had had homosexual activities with him. Later he used to be called a "cissy." He joined the Royal Navy for his National Service at 18 and was immediately recognized by active homosexuals, which led to frequent physical homosexual practices taking place to a degree which eventually led to his seeking the advice of the padre, who recommended his discharge from the Navy. Since leaving the

FIG. 11

FIG. 12

Fig. 11.—Case 6. Passive male homosexual, aged 22. Somewhat general feminine appearance and contours; deficient beard—can go without shaving for two weeks without being noticeable; level pubic hair; well-developed genitalia; ketosteroids high normal, 22.2 mg.; and high sperm count, 110 millions per ml. **Fig. 12.**—Case 7. Passive male homosexual, aged 17. Rather eunuchoid appearance with feminine voice, small penis, level pubic hair, scanty axillary hair, and no facial hair—he does not shave. Ketosteroids, 8.5 mg.

Royal Navy homosexual intercourse has continued, and he sought the advice of his doctor, who referred him to hospital at the age of 22.

On examination his general appearance had undoubtedly certain feminine characteristics in general contour (Fig. 11). His head hair was male pattern in distribution, but his beard was deficient, and he required to shave only once in three days, and can go as long as two weeks without it being hardly noticeable. Pubic hair was level. Genitalia were well developed. There was no gynaecomastia. Legs were of feminine contour. Urinary 17-ketosteroids were 22.2 mg. per 24 hours. Semen analysis: count, 110,000,000 spermatozoa per ml.; 90% of the normal spermatozoa highly motile and normal in appearance.

There are undoubted feminine endocrine features in this case, together with a high urinary 17-ketosteroid excretion and a high sperm count.

Case 7: Youth aged 17.—This patient wrote direct to me, and the following is an extract from his letter. "I have seen my doctor because ever since I was young I have always felt like a girl and I've always wanted to show I am one. I played with dolls and girls instead of boys. I detest boys' games, but have loved to play girls' games. I love girls' clothes and look into every clothes shop in town. I am now nearly 18, and for just over a year I have been in love with a man, and it grows more sincere as the months go by. I love little children, and some day hope to have some of my own; but I don't want to be a father—a mother is more in my line. I think like a girl, act like one. I've been told I look and try to dress like one; of course I do—anything that makes me look feminine I'll wear. I blush when a handsome man looks at me, and am embarrassed when they start talking about male subjects. My mother and family know about this; I thought it best to tell them. Well, my doctor sent me to a psychiatrist, who asked me everything. She sent me to another; after going five times he sent me to another, who asked the same questions as the others. It started all over again, but none of them have done anything for me; the last one said if I go on like this I will be a homosexual, yet I have done nothing sexual or ever suggested doing it."

On examination he was tall, slender in build and contours, with a rather feminine voice and small penis; testes were descended, pubic hair was level; axillary hair was scanty, and facial hair was absent—he does not shave. Head hair was of male pattern but worn rather long. Urinary 17-ketosteroids were 8.5 mg. per 24 hours. X-ray examination of the sella turcica showed nothing abnormal. Semen analysis:—Wet film: The majority of the spermatozoa were actively motile, but several abnormal and immature forms were seen; no pus cells, red blood cells, or crystals present. Count, 21,200,000 per ml. Stained film. Approximately 60% of the spermatozoa showed no morphological abnormalities, but the remaining 40% showed immaturity—swollen or pyknotic heads or other aberrations. There are also an excessive number of spermatids and spermatocytes.

This case is of interest because the patient has always felt that his outlook was female. He has never had any physical homosexual contacts, and there are features—small genitalia, level pubic hair, and absence of beard—that would suggest masculine deficiency amounting to eunuchoidism.

The general form, contours, and appearance, together with deficiency of male type of hair, are easily recognizable in these cases. The ketosteroid excretion in Case 6 is high and in Case 7 low.

Discussion

I should like to draw attention to the fact that there is as yet no precise definition in law or in medicine of what really constitutes male or female sex. I have expressed the opinion (Armstrong, 1953) that the legal sex of an individual is the anatomical structure of the gonads irrespective of the external appearance or social or sexual inclinations. Although most legal authorities would accept this, it is not in fact a true legal definition (*British Medical Journal*, 1954). So far the law has never defined sex, which is extraordinary in view of the homosexual laws in this country, and it is sometimes very difficult to say to which sex an individual belongs. Histological examination of the skin and of the polymorphs will reveal the chromosomal sex of the individual, which corresponds to the gonad sex, but this is not definite proof of the genetic sex. With the exception of the cases of female pseudohermaphroditism the hormone secretion estimations are not what one would have expected.

In Case 3 and in Dr. Swyer's case the oestrogen excretion in the urine is male level, which suggests enhanced response of the target organ to oestrogen or that there is another oestrogen not yet determined. In one of the female-role homosexuals with some signs of feminization the ketosteroid excretion and the sperm count are high. All of this goes to suggest that external sexual characteristics are dependent upon factors other than the level of hormone secretion.

It is obvious from the cases illustrated that it is sometimes not easy to draw a hard-and-fast line between the sexes and define exactly to which sex an individual belongs. In Case 3 the gonads are male and the chromosomal sex is male, and this patient might have a good case in claiming sex as male if the question of legacy, etc., in law arose, but would hardly be likely to be prosecuted for practising female-role intercourse with a male. On the other hand, Case 6 would be liable to be prosecuted, although I submit there are endocrine signs present suggesting a mild degree of feminization: such signs might pass unrecognized by the normal individual, but they are recognized amazingly easily by active male homosexuals. Such passive homosexuals have told me that at boarding school and in the Forces they are pestered by active male homosexuals, even by those they dislike and to whom they give no encouragement. One boy knew all his life that his outlook was female, but he had high moral principles and managed to steer himself through his public school life without physical contact in spite of the fact that he was attacked by the active homosexuals and his life made miserable. These active homosexuals were able to recognize what to me was not clinically obvious, yet I was interested to find that androgen excretion was low in this particular case. There is no doubt that active male homosexuals recognize passive male homosexuals by some means unknown. Is there a sixth sense?

In my experience these passive male homosexuals have really known all their lives that their outlook is female, and if when young they are subjected to interference by adult males this experience is not the initiating cause although often blamed as such.

It seems to me extremely likely that these homosexual characteristics are inborn and of genetic determination; this is supported by the research carried out by Kallmann (1952) on identical twins—both homosexual, although brought up in totally different environments. If this is so, psychoanalysis is a waste of time.

Active male homosexuals may be a different problem: I have had insufficient experience on which to express an opinion.

If passive (female-role) male homosexuality is of genetic determination it is open to consideration whether homosexuals should be subject to prosecution for physical expression of an inborn and genetic characteristic, an urge so strong that some individuals are unable to control it. In spite of the legal attitude towards homosexuality, society regards it as quite in order for a boy visiting a respectable household to have to occupy the same bedroom or even the same bed as the son of the house, for boys' boarding schools to sleep several boys in the same room, for hotels to accommodate two men in the same bedroom, or for British Railways to put two men alone in the same sleeper. The natural sexual urge must obviously be very strong: persons will go through fire and water and put themselves to all manner of hardships to achieve gratification. Nature has to make the instinctive urge strong or the human race would die out. The perverted urge may be no less strong. This is a legal problem, as also is the definition of sex. The medical profession also has a problem in its attitude to these diversities of sex. I think, so far as Cases 2 and 4 are concerned, it should be our duty as medical practitioners to repair physical abnormality and advise the patient to assume his or her true sex.

Case 3 is more difficult; it is obvious that it would be impossible to make the external appearances male. My advice would be to leave alone. I would not advise a plastic

vagina and be party to promoting relationships or a marriage which may well end in disaster. I do not consider the medical profession should further pathology. For the same reason I should consider it also wrong for physicians and surgeons to administer hormones and carry out plastic operations on homosexuals with the object of making homosexual transvestists appear more like the opposite sex—converting males into pseudofemales and females into pseudomales.

Summary

Diversities of sex are divided into hermaphroditism, pseudohermaphroditism, and homosexuality, and cases are described illustrating the different types. Attention is drawn to the fact that sex of gonads, chromosomal sex, and hormone excretion may not correspond to the external physical appearances. Passive (female-role) male homosexuals may present certain physical feminine characteristics and, whether this is obvious or not, active (male-role) male homosexuals can readily recognize female-role homosexuals. It is suggested that passive male homosexuality is of physical origin rather than due to psychological environmental circumstances. There is no definition of what constitutes male or female sex in medicine or in law.

The problem of what should be the attitude of the medical profession to this problem is discussed. The opinion is expressed that in cases of pseudohermaphroditism in which the patient's sex is anatomically obvious, with corresponding external characteristics excepting minor abnormality, treatment should be by hormones or plastic surgery and the patient assume the correct sex, but in all other cases of pseudohermaphroditism or homosexuality the medical profession should leave alone and not administer hormones and carry out plastic operations to further an already pathological condition.

I should like to thank Professor Charles Gray for the adrenocortical steroid analysis and Professor Marrian for estimating the oestrogen excretion in Case 3; Dr. J. E. Gray for determining the chromosomal sex; my surgical colleagues, Professor F. H. Bentley, Mr. David Smith, Mr. D. J. Tibbs, and Mr. Fenton Braithwaite, for their help; Professor Alexander Kennedy and Dr. Robert Orton for the psychological investigation of some of the cases; Dr. D. W. R. Ashby for asking me to see Case 1 when under his care; Mr. C. J. Duncan for the photographs; and Mr. D. P. Hammersley for the drawings.

The possibility of using sulphate-reducing bacteria for the production of hydrogen sulphide, and hence sulphur, is being studied at the Chemistry Research Laboratory of the Department of Scientific and Industrial Research (*Chemistry Research 1954*, H.M.S.O., London). Significant progress has been made, but industrial application is unlikely to be economically attractive under existing conditions. However, the method might well be useful should there be the threat of another sulphur shortage. Sewage sludge is the most promising raw material for sulphide production that has been examined. Three problems have been investigated during the year—the rate of sulphide production in sulphated sludges, the inhibition of methane production, and the possible use of two reactors producing methane and sulphide separately to give a gas mixture from which sulphur could be recovered. Experiments indicate that under certain conditions it may be possible to produce both methane and hydrogen sulphide simultaneously from raw sludge.

TUBERCULIN-TESTING OF A SCHOOL POPULATION (MUSSELBURGH, 1953)

BY

Formerly Area Tuberculosis Physician, East Fortune Hospital, N. Berwick.

In recent years the results of tuberculin surveys in England and Wales have been published, and have shown differing degrees of tuberculous infection in different areas of these countries.

The unenviable post-war record of tuberculosis in Scotland is well known. Even after the belated downward trend in mortality had occurred, the notifications continued to increase, a trend which still persists. In view of this alarming situation, it seemed to us that a survey of tuberculin sensitivity in a Scottish area was overdue. It was thought possible that such a survey might show significant differences from the English and Welsh ones, and might conceivably shed some light on the perplexing problem of why the Scottish notification rate has remained proportionately high. No survey of this type has been published from Scotland, and the need to rectify this situation seemed to us to have some urgency, as it is obvious that the impending use of B.C.G. on a wider scale in school-leavers and in tuberculosis contacts will rapidly obscure the true picture of natural tuberculin sensitivity.

Musselburgh can be taken to be a representative Scottish burgh, with a population, including the surrounding area, of 21,800. It lies near Edinburgh, and, while there is a good deal of daily migration to this city, this is not so great as it might be, because there is adequate scope for employment in the town itself. In no sense can it be regarded as merely a dormitory for Edinburgh.

It is not thought that milk-borne bovine tuberculous infection has influenced our results to any great extent. The milk supply has been almost entirely heat-treated for the past ten years, and for some years before that the bulk of the milk sold in the town was retailed from a few dairies which employed heat treatment.

Housing in Musselburgh had been unsatisfactory until the last five or six years, since when much has been done to rehouse the overcrowded slum and tenement dwellers. The housing conditions can be taken to represent a typical picture of Scottish urban life, where overcrowding and poor conditions are commoner and more severe problems than in England.

Methods Used in the Survey

Propaganda was thought to be of great importance in order to secure the co-operation of the parents of the schoolchildren. The local newspaper generously gave space to the subject, and for several weeks before the campaign began articles were published explaining the objects of the scheme and describing the performance of the tests. Various organizations, town council, churches, and political clubs gave valuable support. All

the general practitioners were informed of the plan and asked to lend their weight to it.

Each schoolchild was given a leaflet to take home. This explained the tests and contained a consent form which the parent was requested to sign. If consent was not given at the earliest opportunity the child involved was shown the test being carried out and asked to tell his parents how simple it seemed. Thereafter, remarkably few parents withheld their sanction.

The positive reactors were x-rayed by the mass radiography unit at school, or in near-by convenient centres. The negative reactors who were within two years of school-leaving age were offered B.C.G. vaccination.

The positive reactors were given letters of explanation to their parents. In these, the significance of the positive test was briefly explained and the parent was given an appointment for interview. This interview was conducted by one of the doctors or by a health visitor, and details were obtained of the child's previous health, the housing conditions, and the home contacts, with their ages and occupations. Time-tables of available x-ray sessions in the town were given to the representatives of the family, and they were asked to try to ensure that all the people in the house were x-rayed. The response to the invitation to be interviewed was astonishing: 95% of those invited were seen and questioned. The response to the invitation to be x-rayed was less impressive, partly because not enough sessions of the mass unit could be secured at hours which did not clash with work.

Skin Tests Employed

The first test was a modified tuberculin jelly test. The skin between the scapulae was cleansed with acetone, six light strokes with flourpaper were given, and the jelly was applied in the form of a T. Control jelly was applied near by and the whole area was then covered by adhesive, which was removed at 48 hours (Dick, 1950). The test was finally read on the fifth day (Lendrum, 1951).

The criteria for acceptance of a test as positive were: (1) erythema and/or induration in the shape of the original application; (2) at least six papules or vesicles in the shape of the original application; and (3) no reaction at the site of application of the control jelly.

In negative reactors to this test a Mantoux test was carried out on the skin of the forearm, using 0.1 ml. of 1 in 100 old tuberculin (1 mg. O.T.). The test was read on the third day, which is thought to exclude some false-positive reactions seen if the tests are read on the second day. The criterion used for a positive reaction was palpable induration 5 mm. or more in diameter.

All the tests were performed and read by a small team of doctors and one experienced tuberculosis health visitor. Where any doubt existed in the interpretation of these tests, consultation between several observers took place.

Statistical Criteria.—Differences are not held to be significant if they are less than three times the standard error of the difference.

An Analysis of the Completeness of the Survey

An attempt was made to determine the tuberculin sensitivity of every schoolchild between the ages of 5 and 15 years in the local authority schools of the Musselburgh area.

Table I examines the success of this attempt by age groups and sets out the lapses by cause. The three age groups chosen correspond as nearly as possible to the three types of school: infants 5 to 7, primary scholars 8 to 11, and secondary scholars 12 to 15.

The total number of children tested (3,282) is 98.2% of the 3,342 children whose parents consented to testing (93.5%

of all the children on the school rolls). This compares favourably with the figures for the Calder Valley (Keidan *et al.*, 1952) and the Rhondda Fach (Jarman, 1953) surveys. The figures for these surveys are set alongside those for Musselburgh in Table II.

In the Rhondda Fach Jarman (1953) found that most of the lapses occurred in the younger age groups. He thought that "the refusal of parents to have their children skin-tested is mainly determined by the age of the child." Our experience on this point is quite strikingly different from his, and to bring this out the Musselburgh figures have been superimposed on Jarman's graphs (Fig. 1).

Effect of Previous Tuberculosis Prevention Work on the Present Survey.—Of the children who were found to be tuberculin-positive during the survey, 101 (64 males and

TABLE I.—Acceptances and Lapses in Musselburgh Schoolchildren by Age Groups

Group	Age*	Total No. on School Rolls	No. Completing the Tests	No. of Lapses, with Reasons			
				Consent Withheld	Absent from All Tests	Consent Received but Test Incomplete	
						1st Test Not Read	1st Test Neg. 2nd Test Not Read
Infants ..	5-7	1,097	1,004	59	18	7	9
Primary scholars	8-11	1,349	1,257	59	23	6	4
Secondary scholars	12-15	1,064	1,021	35	8	0	0
All groups		3,510	3,282	153	49	13	13

* Age is here reckoned as the age of the child on the day of the administration of the first test or, where no tests were given, on the day when the first test was performed on the child's classmates.

TABLE II.—Response of Schoolchildren in Three Different Tuberculin Surveys

Area	% on School Rolls Who Completed Tests	% Present at First Test Who Completed Tests	% Whose Parents Consented Who Completed Tests
Calder Valley ..	85	Not recorded	95.6
Rhondda Fach ..	71.9	76.0*	85.1*
Musselburgh ..	93.5	95.4	98.2

* These percentages are calculated from the published figures 3,410 of 4,484 and 3,410 of 4,004 respectively.

Total	1,645	598	36.4	1,536	530	34.5

37 females) were known to have been tuberculin-negative when seen as contacts and to have converted to positive after B.C.G. vaccination. Since we cannot estimate how many of these children would have become positive without B.C.G. vaccination they are excluded from the main analysis of results. The difference this makes to the percentage who were positive was fairly evenly distributed over the age groups.*

Results of the Tuberculin Tests

The results of the tests are considered by year of age in three different ways: first by sex, then as a whole and in comparison with other areas surveyed, and finally to compare two districts within our own survey area.

(a) Sex Variations in the Tuberculin-positive Rates by Year of Age

The sex variations are graphically represented in Fig. 2, and are set out in Table III. There is no significant difference between the percentage positive in the two sexes for all ages. Taking the ages individually it will be seen that the rates correspond very closely up to the age of 10. Thereafter the differences are in some cases greater, but only at two points do these differences approach significance—at 11 years $t=2.6$ and, again, at 14 years $t=2.6$ —but these differences are in opposite directions and we attach no importance to them.

Our results here correspond quite closely with the findings of the National Survey of the Medical Research Council (1952).

*This can be seen by comparing the total percentage positive in each year group in Fig. 4 with the percentages positive for Musselburgh in Table IV. In Fig. 4 the calculations are based on the inclusive figures, which include the 101 children who had had B.C.G. These children were excluded from the figures used for Table IV.

(b) Variations in Tuberculin-positive Rates by Year of Age in Musselburgh and Three Other Areas

In Musselburgh the ages of the 3,181 children tested varied from 5 to 15 years old. From 5 to 14 years the age groups are reasonably comparable so far as numbers are concerned, and only the 13-year group at 245 falls below the standard of "250 persons at each year of age" recommended by the M.R.C. (1952). The 15-year group contains only 98 children, and is relatively much smaller. This is explained by the fact that most children in Musselburgh leave school at the end of the term in which they reach their 15th birthday.

Of the 3,181 Musselburgh schoolchildren tested, 1,128 were tuberculin-positive and 2,053 tuberculin-negative. This 35.5% tuberculin-positive rate compares with 27.7% for the whole of England and Wales, 24.0% for the Rhondda Fach, and 39.0% for Calder Valley.

The Calder Valley results differ from ours and the other two in that children negative to the first test and failing to attend for the reading of the second test were counted as negative. If, as is done in the other surveys, these children are excluded so that the remaining population at risk can be related to the number definitely positive the overall tuberculin-positive rate for the Calder Valley recalculated from the published figure is 40.9%.

The results of the Musselburgh survey are set out in Table IV by age and the results of the other surveys put alongside for comparison. These are also illustrated in Fig. 3.

FIG. 3.—Tuberculin-positive rates of Musselburgh schoolchildren compared with those of other areas.

An examination of these figures and graphs shows that Musselburgh differs from the others in three respects. (1) The starting-point (26.3%) is higher than in any of the other areas. In the Calder Valley, which has the next highest starting-point (19.7%), the high initial figure was attributed to milk infection. In Musselburgh the milk is all "designated" milk* and we assume that we are dealing almost entirely with human tuberculosis. (2) The amplitude (26.3% to 50.0%) is smaller than in the other areas. (3) The rise with age occurs in stages in Musselburgh, whereas in the other areas the rise year by year tends to occur more smoothly.

In Musselburgh there would appear to be three quite distinct stages, 5 to 8, 9 to 11, and 12 to 15. Within each group there is no significant difference between the percentage positives from year to year (t is less than 1 in all

*Musselburgh is a "designated area." Most of the milk is "pasteurized," some is "tuberculin-tested," and a small amount is "certified."

TABLE IV.—Variations in Tuberculin-positive Rates by Year of Age in Musselburgh, England and Wales, Rhondda Fach, and Calder Valley

Age	No. Tested	Musselburgh		% Positive in Other Areas		
		No.	%	England and Wales (M.R.C.)	Calder Valley	Rhondda Fach
5	316	83	26.3	14.5	19.7	9.1
6	365	96	26.3	15.8	22.5	11.9
7	292	76	26.0	19.9	27.1	16.1
8	298	80	26.8	22.6	32.5	11.8
9	303	103	34.0	26.6	40.0	23.1
10	335	114	34.0	32.1	45.0	27.0
11	283	107	37.8	34.5	44.0	29.1
12	341	161	47.2	38.5	46.6	32.3
13	245	118	48.2	40.9	55.5	35.7
14	305	141	46.2	43.9	58.7	41.8
15	98	49	50.0	51.5	67.7	39.7
Total	3,181	1,128	35.5	27.7	39.0	24.0

TABLE V.—Tuberculin-positive Rates in Musselburgh Schoolchildren in Three Age Groups

Age Group	No. Tested	Tuberculin-positive			Value of t
		No.	%	S.E.	
5-8	1,271	335	26.36	± 1.24	—
9-11	921	324	35.18	± 1.57	4.41
12-15	989	469	47.42	± 1.61	5.48

cases), while between the groups the differences are well marked and are significant.

It may be worthy of comment that in the Rhondda Fach the results in the 5 to 8 group seem to form a consistent group, although in the later years the Rhondda Fach pattern conforms more to that of the other areas, where the percentage positive rate rises steadily from year to year.

The three age groups representing the rising stages in the tuberculin-positive rates correspond fairly nearly to the scholastic grouping into infant, primary, and secondary scholars (5 to 7, 8 to 11, and 12 to 15), only the one year, 8, being displaced into the younger age group. Table V sets out this grouping and gives the t values for the difference between the infant and primary and between the primary and secondary scholars.

(c) Variations in the Tuberculin-positive Rates by Year of Age in Two Districts Within the Surveyed Area

In an attempt to relate tuberculin-positive rates in schoolchildren to environment certain data relating to social conditions were obtained. These may be fully examined at a later date. It is, however, possible now to compare the results in two quite distinct districts of our survey area—namely, the mining villages of Wallyford and Whitecraig on the one hand and the town of Musselburgh itself on the other.

In Wallyford and Whitecraig 85% of the houses are of recent construction. They are local authority houses of three or more rooms, laid out according to modern housing standards, and having a bathroom and proper sanitary accommodation for each house.

Housing in Musselburgh is in sharp contrast to Wallyford and Whitecraig. Musselburgh Town Council has its new housing schemes, but most of the houses in Musselburgh are still old. Some fall below accepted housing standards; many houses are of one or two rooms, and there are tenements which have no baths and in which the sanitary accommodation is shared. In addition to the unsatisfactory nature of the actual houses, parts of the town are congested and the houses are cramped together. The two districts have a common milk supply.

Of the children tested 2,442 were from the town of Musselburgh and 739 from Wallyford and Whitecraig. Of the town children 37.7% ± 0.98 were tuberculin-positive, and of the village children 27.9% ± 1.65 . This is a significant difference ($t=5.2$).

The results by year of age in the two areas separately are set out in Table VI.

TABLE VI.—Comparison of Tuberculin-positive Rates in the Town of Musselburgh with Those in the Neighbouring Villages—by Year of Age

Age	No. Tested	Town		Villages		
		Tub. Pos.		No. Tested	Tub. Pos.	
		No.	%		No.	%
5	248	70	28.2	68	13	19.1
6	298	81	27.2	67	15	22.4
7	221	62	28.1	71	14	19.4
8	226	68	30.1	72	12	16.7
9	219	81	37.0	84	22	26.2
10	258	94	36.4	77	20	26.0
11	226	91	40.3	57	16	28.1
12	254	128	50.4	87	33	37.9
13	190	91	47.9	55	27	49.1
14	218	113	51.8	87	28	32.2
15	84	43	51.2	14	6	42.9
Total	2,442	922	37.7	739	206	27.9

Relationship Between the Jelly Test and the Mantoux Test

The jelly test is simple to administer and was used as a screen before giving the 100 T.U. Mantoux test. The alternative would be to use a preliminary Mantoux test of 1 T.U. or 10 T.U. The advantage of the jelly test as the first test is that it is easier to secure the co-operation of both parents and children when no initial needle-prick is involved and where at most there will, for the complete test, be only one needle-prick.

Objections to the use of the jelly test have been made because its reliability was said to vary with the age of the child. It was thought that because younger children have clearer skins the test is easier to read in them than in older children who may have a tendency towards acne.

On the other hand, the test has sometimes been described as inconclusive in younger children because of a larger number of non-specific reactions. We feel that by reading the test on the fifth day this risk was reduced to a minimum.

Our experience with the test bears this out. Fig. 4 shows the percentage positive for each year of age divided into "jelly-positive" and "additional" positive discovered by the Mantoux 100 T.U. test. The parallelism between the two sets of readings is quite striking and shows no consistent variation with age.

Jelly-test Results in Musselburgh Compared with those in Wallyford and Whitecraig

In the M.R.C. survey of England and Wales the jelly test gave a higher proportion of the total positives in the rural children. This was attributed to repeated reinfection from milk.

In our survey area there is no difference between the milk supply of Musselburgh on the one hand and Wallyford and Whitecraig on the other, and there is no significant difference between the percentage of total positives detected by the jelly test in the two districts (83.2% ± 1.2 in Musselburgh and 79.8% ± 2.1 in Wallyford and Whitecraig).

Our experience where there is no difference in the milk supplies and no difference in the proportion detected by jelly would seem to be a reasonable corollary to the M.R.C. findings.

Tuberculin Testing of Schoolchildren as a Case-finding Measure

Of the positive reactors in the schoolchildren 95.8% were x-rayed by the mobile mass radiography

unit visiting the schools. Six children were subsequently notified as having active pulmonary tuberculosis and three others remain under observation because of minimal radiological abnormalities. (Rate of confirmed cases 5.5 per 1,000.)

The contacts of the children with positive reactions were offered x-ray examination, and of those who came forward five were found to have abnormalities warranting notification. Six other cases have been placed under observation. Quite a number of other people availed themselves of the chance to be x-rayed while the units were in the district. Five other cases were notified from this group and six have been put on the observation list. Thus a total of 10 adult cases of tuberculosis were discovered among the contact group and the casual group, giving a rate of 2.5 cases per 1,000 x-rayed.

Discussion

As was hoped, the results in this survey provide an interesting comparison with recent surveys from England and Wales. It is fairly safe to make these comparisons because the tests used were similar. The accuracy and reliability of the tuberculin jelly test have recently been questioned, and we are well aware that it is by no means satisfactory in all respects. By adhering strictly to our criteria for reading a test as positive and by carrying out an intradermal test where any doubt existed, we feel that we have enhanced the validity of our results. Fig. 4 shows that the proportion at each age positive only to the intradermal test is constant at all ages, and this is additional evidence that our reading of the tests has been consistent. By reading the jelly test on the fifth day, we think that we have reduced the likelihood of false-positive readings, and our results are therefore at least as reliable as surveys in which this test was read at an earlier stage. It is now our view that the jelly test gives a sufficient number of doubtful readings to lead us to recommend that its use be avoided where the main purpose is scientific accuracy. On the other hand, for such purposes as the tuberculin-testing of young children where the acceptance rate might be adversely affected by the necessity for injection, we still feel that the jelly test has considerable advantages, especially when used by experienced observers. More recent experience suggests that a suitable compromise is available in the Heaf multipuncture test (Heaf, 1951).

Completeness and Losses

It will be seen from Table I and Fig. 1 that a very high consent rate was obtained to the performance of the tests, and a very high proportion of the children completed them.

FIG. 4.—Musselburgh children. Percentage tuberculin-positive at each stage. The shaded area represents the percentage of children in that age group who were positive to the jelly test. The unshaded area represents the percentage negative to jelly test but positive to Mantoux test (1 mg. old tuberculin). The total percentage positive is given at top of each rectangle. The reasons given for excluding the 101 children who had had B.C.G. are not relevant to the subject matter of this chart. The percentages shown here are therefore calculated from the results of tests on all the children examined in each age group—a total for all age groups of 3,282.

This satisfactory response is ascribed to the harmonious co-operation of the public health staff and the hospital and clinic staff. In particular the availability of the facilities of the school health service gave us an instrument already geared for this type of work, and the cordial co-operation of the director of education, headmasters, schoolteachers, and school nurses did a great deal to secure the trust and co-operation of the parents. Other helpful influences were the support of the general practitioners, the town council, and local youth clubs. This survey demonstrates that practically complete acceptance of a public health or preventive measure can be carried out by the enthusiastic co-operation of all the interested authorities, when enlightened propaganda has paved the way. It is probable that this is one of the most important lessons to be drawn from the survey—that large surveys can be made acceptable to the general public by painstaking preparation and using only existing machinery and staff.

Comparison with Other Surveys

Several interesting points arise in the comparison of our results with other surveys. The average number positive at all ages (5 to 15) in Musselburgh was 35.5%, with no significant sex differences. The comparable figure for England and Wales was 27.7% (M.R.C., 1952).

The graphs giving the percentage of positives with increasing age show that in Musselburgh the graph starts at a singularly high level when compared with the National Tuberculin Survey, and yet it ends at the same level at age 15. Thus in Musselburgh 26.3% were positive at 5 years, and yet this only goes up to 50% at age 15 years, whereas in the Calder Valley the comparable figures are 19.7% and 67.7%. These figures suggest that children in the 5 to 8 age group in Musselburgh have been exposed in an unusual degree to tuberculous infection. Could this be a reflection on the post-war increase in respiratory tuberculosis in Scotland? It may be that the children who were tiny in the peak years 1945 to 1949 would be most affected by this phenomenon, since they were mainly the children of young adults on whom the brunt of the increase fell.

One interesting feature is the comparison between the positive rates at different ages in the areas we have designated urban and rural. There was a significantly lower level of positives at all ages in the rural population. We feel that milk supplies cannot be held responsible for this difference, because in both areas practically all milk comes from the same sources. It is conceivable that the main cause for this difference is to be found in the fact that almost all the families designated rural lived in relatively new houses. There is, however, no evidence that overcrowding was any less severe or less frequent in the rural families than in the urban, but there is no doubt that the building sites were much less overcrowded, giving the children more scope for playing-spaces. Also the newer houses were of a very much higher structural standard and much better from the point of view of sanitation, lighting, and ventilation. Likewise, none of the new buildings had common entries and none had shared sanitary facilities.

The fact that 50% of children of school-leaving age had negative reactions is support for the B.C.G. vaccination of this group, and it is satisfactory to note that such a scheme has since started.

Examination of Contacts of Tuberculin-Positive Schoolchildren as a Case-finding Measure

As regards the efficacy of this type of survey as a case-finding manoeuvre, it is apparent from our figures that six cases of active tuberculosis were found among the schoolchildren. This was a valuable diagnostic procedure. Most of these cases would, however, have been detected by the school-leavers' B.C.G. campaign now in action, since they nearly all occurred in the older children.

It is, however, equally apparent that the examination of home contacts of children with positive reactions was not a very useful way of finding cases, since only five notifica-

tions resulted. It is advisable to remember that the amount of work expended on detecting these five cases was very considerable. It is indeed a fact that an equal number of cases came to light through x-ray examination of the general public, who came to the units simply because they had heard they were in the district. In this way five notifiable cases were detected. While we cannot claim that these five cases were diagnosed as a direct result of our survey, yet our propaganda undoubtedly had an effect in bringing them to the x-ray unit.

Summary

In Musselburgh 3,282 children between the ages of 5 and 15 years were tested for sensitivity to tuberculin. This figure represented 93.5% of the total school population. Consent had been obtained for the testing of 98.2% of all the children.

Of the youngest group 26.3% were positive, and of the 15 years age group 50% were positive.

Six cases of active pulmonary tuberculosis were found in the schoolchildren and five cases among the home contacts of the children with positive reactions. Thus examination of contacts of these children with positive reactions did not seem to be a very good case-finding measure.

We are greatly indebted to Dr. John Riddell, Medical Officer of Health for the County of Midlothian, for his co-operation and advice at every stage of this survey and for his permission to publish the material here presented. The Secretary of State for Scotland, on the recommendation of the Advisory Committee for Medical Research, made us a grant which we gratefully acknowledge. The grant covered the modest costs of the survey that are not covered by the normal Health Services—this included the employment of one extra female clerk. For the office work we would particularly like to thank Mr. B. Murray, Tuberculosis Clerk for the Midlothian Health Department, whose untiring energy did much to keep the clerical work abreast of the field work. To the Director of Education and his staff, the Nursing Supervisor and her staff, to general practitioners and clergy, members of the Town Council, and many members of the general public who helped in various ways our thanks are also due.

In the latest annual review of the Rockefeller Foundation's programme, Mr. DEAN RUSK, the president, has this to say about the Congressional investigation of tax-exempt foundations last August. "If the Congress determines that it wishes a special Committee to look into tax exemption problems, our view is that we have an obligation to co-operate by furnishing the information desired. Unfortunately, that is not the end of the matter; the validity of the investigative process is affected by the sense of responsibility with which it is used. Repetitious investigation imposes unnecessary burdens upon those under scrutiny and adds little, if anything, to the information of the Congress. Investigations which are basically accusatory in character may, in the absence of great care, exceed the proper role of legislative investigation and infringe the established rights and privileges of those being investigated. Charges loosely framed or unsupported by facts offer no ascertainable issues on which to make reply and yet may damage reputable citizens and institutions. If fact-finding is distorted by partisan considerations, innocent bystanders are injured in the fray. If the same individuals act in both accusatory and adjudicative roles, injustice is the almost inevitable result. That the Congress itself is concerned about investigative procedures is a hopeful sign that common sense and the traditional concepts of government by law will be sustained."

VAGOTOMY WITH GASTRO-ENTEROSTOMY FOR DUODENAL ULCER

BY

M. J. BENNETT-JONES, Ch.M., F.R.C.S.

Surgeon, United Liverpool Hospitals; Surgeon, St. Helens Hospital

AND

S. O'DOMHNAILL, M.Ch., F.R.C.S.

Surgical Registrar, St. Helens Hospital

In the past few years there has been increasing agreement that a Billroth I partial gastrectomy alone is the most satisfactory surgical treatment for chronic gastric ulcer which is not associated with a duodenal ulcer or a high acid curve, and that this operation in a modified form can be used for ulcers very high up on the lesser curvature of the stomach. Only when the ulcer is high and posterior, adjacent to the oesophagus, is it necessary to use a transthoracic approach and perform an upper partial gastrectomy. For the more common case of duodenal ulcer, with its wider age incidence, which fails to respond to medical treatment there is much less agreement. Some surgeons—for example, Ogilvie (1953)—would not, in the absence of complications, advise an operation below the age of 40, but there are many cases in which a dangerous and incapacitating illness had started at least 20 years previously. It has been found impossible to be completely successful, by removing enough stomach to prevent further ulceration, without producing disturbances due to an insufficient organ. A subtotal gastrectomy cures duodenal ulcer, with only about 2% of proved recurrences, but about 10% of cases subsequently suffer from unpleasant symptoms and nutritional defects which at least make one hesitate to advise a high gastrectomy for young patients. There is much truth in Napoleon's saying that an army marches on its stomach.

Since 1948 one of us has submitted 269 cases of duodenal ulcer to vagotomy. It was quickly realized that if vagotomy was performed alone the result was usually unsatisfactory owing to gastric retention. Ulcer pain was relieved, but this was replaced by foul eructations, diarrhoea, and loss of weight. A barium-meal x-ray examination often showed a large 24-hour gastric residue even though the patients had no stenosis of the duodenum at the time of the vagotomy. The earlier a gastro-enterostomy is performed on these patients the better will be the permanent result. It was then decided to try vagotomy combined with posterior gastro-jejunostomy. Schindler (1937), from gastroscopic observations, found that a gastro-jejunostomy was more satisfactory if placed as near the pylorus as possible. It was considered even more important to drain the lowest part of the stomach when atonic following vagotomy. Incidentally, a low posterior gastro-jejunostomy is more easily converted to any form of partial gastrectomy than a high vertical one, should this prove necessary.

The vagotomy was always performed through the abdomen after mobilizing the left lobe of the liver. This latter procedure makes the operation easier, safer, and more certain. We also consider that Somervell clamps, which are non-crushing and yet non-slipping, contribute to the absence of complications in both gastro-jeuno-

stomy and partial gastrectomy. Convalescence is usually uneventful: most of the patients can dispense with the Ryle tube in 48 hours. A post-operative chest complication was the commonest cause of a delay in recovery, but many of the patients suffered from chronic bronchitis. The operation is very safe; only one patient died in the post-operative period: a week after his operation he developed bronchopneumonia during the onset of a severe influenza epidemic. He died 48 hours later, and a post-mortem examination confirmed the diagnosis, but no cause for his death was found in the abdomen.

According to Johnson and Orr (1953), G. Crile, jun., and his colleagues have used this operation over 400 times, with a mortality less than $\frac{1}{2}\%$. His recurrence rate was 6%, but this was regarded as better than radical gastrectomy, with an operative mortality of 4% and a recurrence rate of 1%. Series of gastrectomies have been performed with a mortality under 2% (Tanner, 1954), but Johnson and Orr found a 4% mortality in a collected series of 3,000 post-war gastrectomies.

Illingworth (1953) has drawn attention to the comments of Jordan (1952) in her exhaustive report for the American Gastroenterological Association on the various surgical procedures. She compared the results of 842 cases of gastric resection with 633 cases of vagotomy plus gastro-jejunostomy (see Table):

Gastric Resection Compared with Vagotomy plus Gastro-jejunostomy

	Gastric Resection	Vagotomy + Gastro-jejunostomy
No. of cases	842	633
Primary mortality	3%	1.3%
Recurrent ulceration	1.7%	2.7%
Freedom from symptoms, return to work, and absence of post-operative haemorrhage	86.4%	78.8%

In this country, Pollock (1952) has reviewed 1,524 cases of vagotomy used alone and with other procedures. He found 12% of unsatisfactory results in a collected series of 511 cases of vagotomy combined with gastro-jejunostomy: 8% had recurrent ulcer pain, but in only 1% was there a proved recurrence. The follow-up, however, was for more than three years in only 7%. Hand and Patey (1953) have been disappointed in their results of vagotomy, but they combined it with gastro-jejunostomy in only eight cases, with one relapse. They combined vagotomy with hemi-gastrectomy in 17 cases and no recurrence of ulceration has occurred so far.

Late Results

Tanner (1954) has stated that no definite conclusions can be drawn from anything less than a five-year follow-up for an operation performed for peptic ulcer. We agree with that policy, but it becomes progressively more difficult to trace old patients, and an increasing number will die of unrelated diseases. We therefore decided to examine and fill in a questionnaire for all those patients who had been operated on between six and four years previously. Ninety-five patients were in this category, and with persistence it has been possible to follow up all of them.

Five male patients had died in the intervening years. The deaths were due to carcinoma of the bronchus, coronary thrombosis, influenza, and intestinal obstruction with a lung abscess due to peritonitis from appendicitis in earlier life. These four patients were apparently cured of their duodenal ulcer, which gave no further symptoms; three of them died in hospital, and a post-mortem examination revealed no active ulcer. The fifth non-survivor was an early case: a man aged 67, who had a gastro-jejunostomy 10 months after his vagotomy, at first progressed favourably, with gain in weight. Later he developed pain in the left iliac fossa, with radiological evidence of extensive

diverticulitis. A rapidly progressive psychosis caused his death in a mental hospital. There was never any definite evidence that this man's later abdominal symptoms were due to his duodenal ulcer or to the surgical treatment. It has, however, been found by others that, if the "drainage" operation on the stomach is not performed at the time of the vagotomy, symptoms presumably due to gastritis are more likely to occur.

Seven of the 95 patients developed symptoms of recurrent ulceration—six had recurrent pain, while one developed melaena; all these were submitted to a further operation. It is noteworthy that in two of these cases, both early ones, the operation notes stated that the vagotomy was probably incomplete. An insulin test meal confirmed the incompleteness of the vagotomy. A further four patients had slight attacks of pain, probably due to recurrent ulceration. One of these had a small haematemesis, so there was no doubt about the presence of at least a temporary ulcer in this case.

We are very pleased with the result in the remaining 79 cases with no history of recurrent ulceration. Some of them, especially the older ones, have other diseases, with chronic bronchitis heading the list, which are not directly related to the duodenal ulcer. The majority have no symptoms whatsoever, and all display no nutritional defect. It is usual for the patient to retain his or her occupation, or even to obtain a better and more strenuous one, without losing weight. One young man has resumed playing Rugby football, which is not usual after a high partial gastrectomy. Serious diarrhoea was seen only after vagotomy without a "drainage" operation. Constipation is common among patients with duodenal ulcer who are chosen for operation chiefly because they are eating so little: a return to a normal daily evacuation was the most common post-operative result. It has already been recorded that an afferent-loop syndrome is rare after this operation compared with a high Polya partial gastrectomy (Wells and MacPhee, 1952). It was more likely to occur if vagotomy was performed on a patient who already had a high rather than a low gastro-jejunostomy.

Secondary Operations on the 4- to 6-year-old Cases

It is appropriate here to discuss the fate of the 7 patients of the 95 who were submitted to further operative procedures for recurrent symptoms. The two cases in which the vagotomy was incomplete were submitted to a Polya partial gastrectomy. The result was excellent in one patient and fairly good in the other, who has some dumping and occasional vomiting. Removal of the pyloric antrum below the stoma, with closure of the duodenum, was performed in four cases, with a satisfactory result in two. The two failures were both in women, who complained of symptoms suggesting an afferent-loop syndrome. A Billroth I conversion of both of these unsuccessful pylorotomies has resulted in cure of one, but it failed to relieve the other of attacks of pain and vomiting. With these symptoms she still looks well and has not lost weight. In spite of cancer-phobia and an unsuccessful second marriage, it is thought that her symptoms are genuine. Professor Wells has recently converted her gastrectomy to the Roux-en-Y type, so we await the final result with interest.

Findings at the Secondary Operations

So far as we know, no case of perforated ulcer has occurred in the 240 cases after the operation of vagotomy and gastro-jejunostomy. Out of this total, 17 patients have undergone a secondary operation with no mortality. No jejunal ulcer was seen and a stomal ulcer was found in only two cases. One of these followed incomplete vagotomy performed on a patient who had already had an operation for a perforated duodenal ulcer, and a subsequent posterior and an anterior gastro-jejunostomy performed by various surgeons. A partial gastrectomy had been contemplated on two of these occasions, but the extensive peritoneal adhesions dating from the perforation had caused each surgeon to

retreat from his original plan. After partial gastrectomy, finally performed with great difficulty, and a convalescence marred by jaundice due to incompatible blood transfusion, the patient made a good recovery. He has now been working at the coalface for some years, with no dyspepsia.

In those cases with symptoms—for example, haematemesis—suggestive or conclusive of recurrent ulcer the original duodenal ulcer appeared to be the cause, but at the second operation the oedema and crater had always disappeared; in fact, the ulcer seemed to be healed. A recurrent gastric ulcer has been found on only one occasion. This patient, a young woman, had already had two perforated duodenal ulcer closures when submitted to vagotomy and gastro-jejunostomy. A Billroth I partial gastrectomy has now apparently cured her. It is interesting that a fractional test meal examination just before her third operation showed a low acid curve, so it is possible that her gastric ulcer either was missed at this time or was too small to feel.

Type of Secondary Operation

Nine of the earlier failures of vagotomy with gastro-jejunostomy were submitted to either pylorotomy or a Polya partial gastrectomy, just over half the stomach being removed if there was evidence that the vagotomy was incomplete. Two of these cases, already mentioned, have been converted to Billroth I anastomoses. In addition eight further cases have been converted to a Billroth I partial gastrectomy, all with an excellent result. This means that there has been only one failure out of 15 secondary cases, and even this case might be finally cured.

A peritoneal adhesion occluding the efferent loop of the gastro-jejunostomy once made it necessary to reopen the abdomen 10 days later: no further trouble occurred in this case.

Jaundice due to a large duodenal ulcer is rare. Three such cases have been encountered, requiring in addition cholecystenterostomy: two of these have been successful, one for six years, but the third later developed fatal ascending cholangitis due to stenosis of the biliary anastomosis.

Discussion

Vagotomy, including attempted vagotomy, combined with a low gastro-jejunostomy, has given a very satisfactory result for duodenal ulcer, lasting between four and six years in 88%. The operation is very safe and has not caused any reactivation of phthisis in four patients with major quiescent lung lesions. A secondary operation was required in 7.4%, and a Billroth I conversion has been found to be the most satisfactory way to relieve the failures, which are not all due to recurrent ulceration. In view of the further 5% of patients with slight symptoms who must be regarded as unstable, and the success obtained with a Billroth I conversion, it was obvious that we should try vagotomy combined with a Billroth I resection as a primary operation wherever possible. This has now been done in 30 cases. At first only those with a wide duodenum were regarded as suitable. The operation is now considered possible in all cases (Schmitz *et al.*, 1954) by splitting the anterior wall of the duodenum. There has been no mortality so far, but we feel that in poor-risk patients, especially if there is a large oedematous ulcer, it may still be wiser to perform vagotomy with gastro-jejunostomy, which allows a Billroth I resection later if necessary, when the duodenum will take more kindly to sutures.

The immediate post-operative recovery has been satisfactory apart from two cases which had excessive intra-gastric bleeding. One of them had to be reopened 10 hours later, when a bleeding artery was found near the lesser curvature of the stomach. The whole anastomosis was resutured and the patient made a good recovery. The early results after leaving hospital, including gain in weight, appear satisfactory, but a few years must elapse before they can be truly assessed. Wells and MacPhee (1954) and R. Welbourn (1954, personal communication), by different

routes, have come to the same conclusion—that vagotomy and Billroth I resection should be tried further. Vagotomy and limited partial gastrectomy has been very successful in the hands of Johnson and Orr (1953).

Summary

For duodenal ulcer, excluding cases of acute bleeding but including a few perforated cases which required more than simple closure, the operation of abdominal vagotomy combined with a low gastro-jejunostomy is a very safe procedure and appears to produce good results lasting four to six years in 88%.

The failures (7%) were submitted to a further operation without mortality: all except one case have been relieved.

A Billroth I conversion was the most satisfactory secondary procedure; also, vagotomy combined with a Billroth I partial gastrectomy may prove to be the best primary procedure.

Vagotomy should be included in the treatment of duodenal ulcer because only 50% of permanent good results can be expected from gastro-enterostomy alone.

We now regard vagotomy combined with gastro-jejunostomy to be at least the best second-choice operation.

Most of the follow-up work was done by S. O'D., but we are indebted to Mr. Harrah Thompson for following up the cases at the Royal Southern Hospital during his tenure of the post of surgical registrar.

EFFECTS OF DORSO-LUMBAR SYMPATHECTOMY ON PEPTIC ULCERATION

BY

IAN MACPHERSON, M.B., F.R.C.S.Ed., F.R.F.P.S.
Consultant Surgeon, Victoria Infirmary, Glasgow

AND

A. A. FITZGERALD PEEL, D.M., F.R.F.P.S.
Consultant Physician and Physician for Diseases of the
Heart, Victoria Infirmary, Glasgow

Extensive dorso-lumbar ganglionectomy and splanchnicectomy as carried out from the treatment of hypertension interrupts the sympathetic nerve supply to the stomach (Bingham *et al.*, 1950); by masking symptoms it may have a harmful effect on the course of peptic ulcer. Frequently it is only by complications such as pyloric obstruction, perforation, or haemorrhage that the ulcer announces its presence. The following case illustrates these features.

Case Report

A male shipping clerk aged 38 was admitted in April, 1949, suffering from angina of effort. This had started six months previously, when he had breathlessness and pain

down the inner side of the left arm on exertion; a week later the pain became substernal and compelled him to stop when walking. During the six weeks before admission pain had come on at rest and had lasted about five minutes. He gave a previous history of an appendicectomy for vague dyspeptic symptoms in 1930; the operation had given him relief, but at intervals he had continued to have mild epigastric discomfort. There was no history of nephritis or other renal lesion. The family history was indefinite; his mother had died in childbirth and his father died suddenly at age 40, cause unknown.

He was a moderately well nourished man whose blood pressure remained between 230/130 and 220/130 during his stay in the medical ward. The fundi showed early vascular changes but no haemorrhages, exudates, or papilloedema. Clinical examination of the heart, lungs, abdomen, and central nervous system was negative and there was no albuminuria. A cardiogram taken in March, when he was an out-patient, had shown evidence of ischaemia in the shape of terminal inversion of the T waves in lead V₄; but on admission the cardiogram at rest was normal. Radiologically the heart shadow was normal and the lung fields were clear. Intravenous pyelography showed normal concentration and excretion of the dye, and no abnormality was demonstrated in either kidney. Urea clearance was 74%, maximum urea concentration 2.3 g. per 100 ml., and blood urea 36 mg. per 100 ml.

In May, 1949, a left dorso-lumbar ganglionectomy and splanchnicectomy was performed by the transpleural route, the ganglia from D6 to L1 being removed. After this he had complete relief from angina of effort. His blood pressure remained in the region of 155/110 until the beginning of October, when it began to rise again. During this period, however, he complained of vague epigastric discomfort and distension with occasional slight nausea.

He was readmitted in November, 1949, with a blood pressure of 198/118, and a right dorso-lumbar ganglionectomy and splanchnicectomy was performed, the ganglia from D6 to L1 being removed. After this operation he remained completely free from angina, and his own doctor never found his systolic blood pressure higher than 180. However, he began to have attacks of epigastric distension and vomiting. At first these attacks occurred at intervals of several months, but later the intervals shortened to two or three weeks. During the attacks vomiting was profuse and continued at 24 hours or more until the stomach was completely emptied; food taken the previous day was sometimes recognized. His appetite failed, he lost weight, and he experienced increasing constipation. Pain was absent throughout. He was seen in consultation on July 25, 1951, when a diagnosis of pyloric stenosis was made; at that time his blood pressure was ranging between 160/100 and 140/90. A barium-meal examination showed a large resting content in the stomach and a marked degree of pyloric stenosis, which was not lessened after treatment with atropine. He was admitted once more in August, and laparotomy was performed in September. There was a large active chronic ulcer of the anterior duodenal wall, covered by omental adhesions; the stomach was dilated and its muscular wall was much hypertrophied. A posterior (no-loop antiperistaltic) gastro-jejunostomy was performed.

He remained well for eight months, then began to have a sense of fullness after meals with anorexia but no pain. On August 24, 1952, he was awakened with sudden severe pain radiating over the whole abdomen and accompanied by tenderness and rigidity. A laparotomy was carried out (Mr. J. Hinton Robertson); after evacuation of a considerable quantity of gas and fluid, a perforated jejunal ulcer was located diametrically opposite the stoma of the gastro-jejunostomy. This was closed by suture. During convalescence a fractional test meal showed total acidity of 48 units and free HCl 22 units. Two months later the gastro-jejunostomy was undone and a partial gastrectomy was

carried out, four-fifths of the stomach being removed; continuity was restored by an anterior Polya with Hofmeister valve anastomosis.

When last seen (November 15, 1954) he was working again and doing more than he had been able to do for many years, but had given up sport. He has remained completely free from angina of effort, despite the fact that his blood pressure has returned to the pre-operative level; recent readings have been 220/130 (October 30, 1953); 200/110 (September 3, 1954); 240/134 lying, 220/130 standing (November 15, 1954). Changes in the retinal arterioles have advanced, but the heart shadow remains normal radiologically, and the cardiogram was still physiological. During the past year he has from time to time had pain in the left upper abdomen, sometimes three hours after food, sometimes waking him at night. A barium-meal examination showed normal progress from the remaining portion of the stomach to the jejunum, and no evidence of ulcer was seen: progress through the small bowel was accelerated.

Discussion

Painful sensations arising in the abdominal viscera are transmitted by afferent fibres which accompany the sympathetic nerves and pass uninterruptedly through the sympathetic ganglia to enter the spinal cord by the posterior nerve roots. Dorso-lumbar ganglionectomy will abolish those forms of abdominal visceral pain which are normally transmitted through the sympathetic. When perforation occurs structures supplied by other afferents are involved, including the parietal peritoneum; pain from here reaches the spinal cord by way of the peripheral nerves and is not abolished by dorso-lumbar ganglionectomy.

Froehlich *et al.* (1942) reported four cases in which sympathectomy was performed as treatment for gastric ulcer. In all of them the distress was relieved and the ulcer craters showed radiographic evidence of healing. Sicard *et al.* (1945) carried out splanchnicectomy in eight cases of gastroduodenal ulcer. Although there was some relief of ulcer pain, cure was not complete. Five required gastric resection within 18 months.

Harkins and Willard (1950) speak of the relief of pain as "a Pyrrhic victory" in reporting a case of peptic ulcer in which sympathectomy had adverse effects. Weeks *et al.* (1946) describe the case of a man with duodenal ulcer and malignant hypertension. A transthoracic vagotomy was performed and at the same time the left thoracic-lumbar sympathetic chain was removed from D5 and L2. Two weeks later the second-stage sympathectomy was carried out on the right side from D5 and L2, after which the patient became extremely ill and died on the 15th post-operative day. Necropsy revealed a perforated duodenal ulcer with general peritonitis. An interesting feature was the absence of abdominal pain in the presence of a perforated ulcer and peritonitis. The authors state: "His absence of pain may have been due to the removal of the viscerosensory fibres associated with the sympathetic side of the autonomic nervous system." Blegen and Kintner (1947) describe a case with gastric ulcer which had three massive haemorrhages following extensive unilateral sympathectomy, and point out that the sympathectomy relieved the pain but the ulcer progressed.

Mason and Pollard (1949) found 13 instances of peptic ulcer in a group of 1,498 patients who underwent splanchnicectomy for hypertension during an 11-year period. They point out that frequent and severe complications developed in 12 because the normal epigastric pain sensation was either abolished or greatly reduced so that ulcers were permitted to advance without giving the usual warning.

The present case illustrates progression of a duodenal ulcer and development of pyloric stenosis after bilateral dorso-lumbar ganglionectomy and splanchnicectomy carried out for hypertension; a jejunal ulcer subsequently developed and later perforated. Pain was conspicuous by its absence while the original ulcer was progressing and while the jejunal

ulcer was developing, but severe pain occurred when the latter perforated. After dorso-lumbar ganglionectomy and splanchnicectomy the pain which characterizes exacerbations of a peptic ulcer is abolished; it is therefore suggested that in such cases more attention should be paid to vague abdominal symptoms which may take the form merely of slight epigastric discomfort or fullness.

It is well known that the lowering of blood pressure which results from sympathectomy has often been transient. Hypertension has recurred within 5 to 10 years in a high percentage of cases (Smithwick, 1948). In the present instance hypertension was abolished for three years but had returned by the end of the fifth year. The mechanism underlying recurrence of hypertension after sympathectomy is not fully understood. During the fifth year abdominal visceral pain returned; but it may well have arisen in the colon. The sympathetic nerve supply from the colon was not interrupted by the original operations.

Summary

A case is presented showing the progression of a duodenal ulcer following bilateral dorso-lumbar sympathectomy and splanchnicectomy, the subsequent development of a jejunal ulcer, and its ultimate perforation. The effect of sympathectomy on the pain of peptic ulcer is described and its mechanism is discussed.

MALARIA AND THE SICKLING TRAIT

BY

ALAN B. RAPER, M.D., M.R.C.P., D.T.M.&H.

(From the Medical Laboratory, Kampala, Uganda)

This paper reports confirmation of Allison's (1954) conclusion that the possession of the sickling trait confers some protection against *P. falciparum* malaria, but it presents somewhat different views on the nature and extent of this protection.

Of the two experiments performed by Allison, one determined the parasite rates in children under 5 years of age in the Kampala region, mostly (Allison, personal communication) in the out-patient department of Mulago Hospital. Forty-three sickling children showed a parasite rate of 27.9%, and 247 non-sicklers a rate of 45.7%. This difference seemed so striking that it was reasonable to wonder why it had not already been noticed, or whether some feature of the experiment had accentuated a difference that was real, but actually of lesser magnitude. Indeed, since *P. falciparum* clearly can establish itself in the peripheral blood of sicklers, and can even multiply in the erythrocytes of cases of sickle-cell anaemia (in which there is no normal adult haemoglobin), it seemed reasonable to suppose that the effect of the presence of sickle-cell haemoglobin could not be to prevent an infection, though it might well limit the extent to which an infection could develop. If this were confirmed, quite sufficient explanation would have been given of the way in which *P. falciparum* infection could act as a selective agent in preserving high sickle-cell gene frequencies in endemic malarial regions, because it is

well known (Field, 1949) that the mortality from falciparum malaria is related to the height of the parasite count. But in that case some explanation would have to be found for the apparent difference in parasite rates observed by Allison in sicklers and non-sicklers respectively. And, since the results of Allison's inoculation experiments do not fully accord with the view advanced above, this view would have to be reconsidered if confirmation of his results should be obtained. This last question is not considered further here.

It was decided to repeat Allison's first experiment on the same type of patient, with the addition that parasite counts should be performed on all falciparum infections encountered, and to continue certain other observations that were already in progress.

Malaria Infection in Relation to Sickling

Three groups formed the basis for this study—two of children and one of adult women.

Group I

The subjects examined were 1,200 children under the age of 10 years presenting for any reason (very often "fever") at the medical out-patient department of Mulago Hospital, Kampala. They were taken without selection during a two-to three-hour visit by a native laboratory assistant, who recorded their personal details, and collected from each a thick and a thin blood film and a few drops of blood in saline. All the specimens were examined by me. Sickling was tested for in a 24-hour culture of *Bact. coli* and read at two to four hours, and paper electrophoresis was performed if necessary. Malarial species diagnosis was made on thick blood films, but the thin films were used if any doubt existed.

Malaria was detected in 638 of the children—90 times in 191 sicklers (47.1%), and 548 times in 1,009 non-sicklers (54.3%). For this difference in favour of sicklers, $\chi^2 = 2.65$, $n = 1$, $0.2 > P > 0.1$, and thus the possibility that the difference had arisen by chance was rather high. But this does not take account of the species of parasite present. If we exclude the *P. ovale* infections (7 in number), and 11 cases in which the species could not be determined with accuracy (there were no *P. vivax* infections), and consider only infections with *P. falciparum* and *P. malariae*, a different picture emerges. In compiling Table I, cases in

TABLE I.—Incidence of *P. malariae* and *P. falciparum* Infections in Sicklers and Non-sicklers, Among 1,200 Children under 10 years of Age at a Medical Out-patient Department

Age in Years	Sickling State	No. of Cases	<i>P. malariae</i>		<i>P. falciparum</i>		χ^2 (n.d.)
			No.	%	No.	%	
Under 1	Positive	68	7	10.3	32	47	1.15 (P > 0.2)
	Negative	325	15	4.6	130	40	
1-2	Positive	59	6	10.2	20	34.4	10.13 (P < 0.01)
	Negative	288	21	7.3	163	56.5	
2-10	Positive	64	3	4.7	21	32.8	7.11 (P < 0.01)
	Negative	396	37	9.3	201	50.8	
Total	Positive	191	16	8.4	73	38.2	7.4 (P < 0.01)
	Negative	1,009	73	7.3	494	49.3	

which these two species were present together have been counted as separate infections (in 36 children). In the whole 1,200 children there was no indication that the incidence of *P. malariae* was affected by the sickling state of its hosts, but the numbers showing this parasite were not great. *P. falciparum*, however, was very noticeably commoner in non-sicklers, except in the first year of life. It will be noticed that the apparent protection against all forms of malaria, and even against *P. falciparum*, is much less in this series than in Allison's (1954). It may be added that the two main tribal groups covered by this survey had closely similar sickle-cell frequencies: the largely rural Baganda

showed a higher malaria rate than the urban and suburban Nilotics, but the apparent protection against *P. falciparum* was present in each to a significant degree.

Group II

Long before the above investigation was started, however, data were being collected from another group. These were children under the age of 5 years, attending child welfare clinics in and around Kampala, under the care of Dr. H. F. Welbourn, to whom I am indebted for permission to quote the following facts. At these clinics the children attend as families for general supervision, and not primarily because they are ill, though illness may often determine the first attendance of a family. A laboratory assistant attended all the clinics, and specimens were brought to the laboratory and examined in the same way as for the hospital series. Sickling and malaria were tested for on the first attendance of each child, and the results given below refer only to the first attendances, or to the first occasion when the tests were performed—in any case, before any antimalarial treatment had been given. Malarial species diagnosis was not quite so certain as in Group I, and the figures quoted here are for all species, though of course *P. falciparum* predominated.

From April, 1952, to October, 1954, 1,194 children were tested on first attendance; of 192 sicklers, 58 (30%) showed malarial parasitaemia, while of 1,002 non-sicklers 334 (33.4%) did so—a difference that is quite insignificant, but of the same nature as that for gross malarial parasitaemia in Group I. Among these children the malaria rate was lower, and the proportion of Nilotics higher, than in the hospital series, but again the two main tribal groups gave closely similar results. The apparent protection against malaria in the sicklers was less in this group than in Group I, and a possible reason for this is suggested below.

Group III

One other group of persons was examined in the same way as the preceding: this was a consecutive series of 663 mothers of some of the children in Group I. They were not ill, and they were selected only in the sense that they had brought their sick children to hospital. Practically all would possess a considerable acquired immunity to the effects of malaria. All the 91 infections detected in them were of mild degree (only 5 showed more than about 1,000 parasites per c.mm.), and all were considered to be of *P. falciparum*, though proof was not always absolute when the parasites were very scanty. In the 135 mothers who were carriers of the sickle-cell trait there were 24 (18%) who showed parasites in the blood; in the 528 non-sicklers there were 67 (12.7%). These findings are the reverse of those for the children in Group I, but the difference is of about the same order of magnitude, and might with equal likelihood have arisen by chance ($\chi^2 = 2.35$, $n = 1$, $0.2 > P > 0.1$).

Parasite Count in Relation to Sickling

The following findings refer only to the *P. falciparum* infections encountered in Group I and to the counts determined, for each child, only on the day on which it first attended hospital. Parasite counts were performed on 558 consecutive falciparum infections (they were omitted in the first nine cases). Counts were made against leucocytes in parts of the field where the distribution was even, and the result was recorded on the assumption that the leucocyte count was 5,000 per c.mm. Noticeable leucocytosis was very rare in malarial children.

Table II shows that more than half the falciparum infections in the sickling children were of low intensity, while non-sickling children showed predominantly heavy infections. It may be added that the highest count found in a sickler was 160,000 per c.mm., whereas counts up to 800,000 per c.mm. were not unusual in non-sicklers. For this analysis, grouping by parasite density has been made on a logarithmic basis (in powers of 10) for convenience, and because this accords with the process of multiplication of an

TABLE II—Distribution of Parasite Densities in 558 Consecutive Infections with *P. falciparum* in Children under 10 years, in Sicklers and Non-sicklers

Parasite Count per c.mm.	Sicklers (72 Cases)		Non-sicklers (486 Cases)	
	No.	% of Total	No.	% of Total
Under 100	20	27.8	55	11.3
100–	17	23.5	57	11.7

10,000–	18	25.0	182	37.4
100,000+	3	4.2	45	9.4

TABLE III—Comparison of the Incidence of Parasite Counts under 1,000 per c.mm. in Sicklers and Non-sicklers at Various Ages, in 558 Children Infected with *P. falciparum*

Age in Years	Sickling State	No. of Cases	Cases with Counts under 1,000/cmm.		
			No.	%	χ^2 (n=1)
Under 1	Positive	30	16	53.3	11.99 (P<0.01)
	Negative	132	29	29.5	
1–	Positive	20	12	60.0	14.5 (P<0.01)
	Negative	162	34	20.9	
2–10	Positive	22	9	40.9	2.36 (0.2>P>0.1)
	Negative	192	49	25.5	
Total	Positive	72	37	51.4	21.94 (P<0.01)
	Negative	486	112	23.04	

organism. In this arbitrary scale a figure of 1,000 per c.mm. represents a point in the Table about which the difference between sicklers and non-sicklers is most pronounced, and Table III shows how a grouping of cases into those with counts of less than 1,000 per c.mm. and those with over 1,000 reveals a striking difference between sicklers and non-sicklers at all ages—least amongst the older children, but remarkable even in those under 1 year, in whom (Table I) *falciparum* infections were commoner in sicklers. Again, it may be added that these differences were as marked for the Baganda as for the Nilotic children.

Nature of the "Protection" Enjoyed by Sicklers

The view put forward here is that the presence of sickle-cell haemoglobin in a person's erythrocytes does not prevent his infection with plasmodia, but does limit the extent to which at least a *falciparum* infection may develop. This probably means also that attacks of *falciparum* malaria will be on the whole briefer and less disabling among sicklers, and that, in them, dangerous attacks will be rare. This view is derived from the observations of parasite counts in a certain group of children, and therefore the validity of this experiment must be discussed.

The present experiment was not designed to detect the highest extent to which parasitaemia could develop in sicklers and non-sicklers respectively, nor was it possible to record the duration of each attack at the time the examination was made—and very marked changes are to be expected in the count as an attack develops and recedes. In this locality a visit to hospital is likely to be considered for some time before it is decided upon, and thus low counts are extremely unlikely to represent attendance early in an attack of malaria; they represent either the possession of immunity or attendance towards the end of an attack. Significant immunity can be excluded in practically all these children. If, therefore, we are to draw conclusions from the greater frequency of low parasite counts in sickling children, we must be assured that they attended, on the average, at about the same stage of the attack as did the non-sicklers; or if they attended at a somewhat later stage of their attacks than the non-sicklers did we must find an explanation for this. In spite of the lack of clinical data, there is some evidence on this point.

Three features were encountered rather more often in the blood films of sicklers than in the rest—signs of erythropoietic activity (Raper, 1954a), well-grown trophozoites, and gametocytes. The latter were found in 31% of *falciparum* infections in sicklers, and in 21% of these infections in non-

sicklers. None of these features can be ascribed directly to sicklaemia, but they are all indications of the early recovery phase of malaria. The experiment, therefore, had admitted a slight excess of sicklers in the early stages of recovery from malaria, and the reason for this must be sought. In this area, sicklers are not more common in the more remote population than in that close to the hospital, nor in the lower social classes than in the higher; indeed, they are less common in the more primitive tribes included in this experiment. Thus social and educational factors, producing different attitudes to the use of a hospital, are unlikely to have determined the later attendance of sicklers. The only explanation likely to account for all the observed facts is that *falciparum* attacks in sicklers are unusually mild and brief. This is the hypothesis advanced here; the low counts observed in sicklers are a feature of the kind of malarial attacks they experience, and, though the present results may slightly exaggerate this feature, they could not have been produced unless it existed.

The establishment of this point makes it possible to offer an explanation for the inconclusive reports regarding gross parasite rates in sicklers and non-sicklers, both among those recorded here and among those of Beet (1946, 1947), Brain (1952), Edington (1954), and Moore *et al.* (1954). All but the last of these referred to hospital patients, most included adults as well as children, and none except the last distinguished between the species of parasite. Among such non-immunes as were included, the sicklers would attend hospital less often because of their milder attacks, and so would form a smaller proportion of all malaria cases diagnosed, thus accounting for the general tendency to record fewer malarial attacks among sicklers. There must have been less selection of this sort in the child welfare clinic children recorded here (Group II), and in them the apparent protection against all forms of malaria was somewhat less than in the hospital series (Group I). Where no selection whatever is employed, as in the field survey of Moore *et al.* (1954), a very small difference between the two groups could be expected to arise from the probability that sampling at any moment would detect slightly fewer infections in sicklers, simply because their attacks are rather briefer than in non-sicklers. But the number to be sampled before this difference appeared significant would be very great, certainly several times 2,394, which is the number of partially selected cases recorded here.

In this connexion it may be remarked that since attacks of quartan malaria are normally of long duration, and on the whole mild, the results recorded here for *P. malariae* are quite inadequate in number to decide whether sicklers do or do not enjoy any protection against this species.

If the subjects of a survey possess any other means of resisting the growth of plasmodia, this must affect the degree of protection they exhibit from possessing or lacking the sickle-cell trait. In a region of heavy malarial endemicity adults possess this protection by reason of their acquired immunity (or "premunition"). How far this operates in sicklers and non-sicklers respectively is not revealed by the results quoted above for the 663 mothers (Group II), because they were neither selected by illness nor distinguished by the degree of their parasitaemia. But all experience suggests that acquired immunity is at least as potent a protection as the possession of the sickling trait. Hence the inclusion of adults in a survey in an endemic malarial region will obscure any protection that the sicklaemic children may enjoy.

It has been mentioned above that the relative protection of sicklaemic children against heavy *falciparum* infections is enough to account for that increased chance of survival that is required to explain the persistence, or the building up, of high frequencies of the sickling gene in parts of Africa. I have emphasized elsewhere (Raper, 1954b) that the process is a dynamic one, and that the present situation in that continent need not be treated as static. Field (1949) saw very few deaths from *falciparum* malaria in Malaya in persons whose parasite counts were under 10,000 per c.mm., and no death with a parasite count of fewer than 2,300 per c.mm.

It has been remarked above that the difference between sickling and non-sickling children is particularly marked at about this level of parasitaemia. It is important to notice that for natural selection to operate in favour of heterozygous sicklers it must exert its effect before reproductive age; the view advanced here is that it can operate only in the absence of acquired immunity, and in an endemic area it is precisely those below reproductive age who lack effective immunity.

All this evidence is of course indirect; the decisive information—accurate mortality statistics for sicklers and non-sicklers before puberty—is nowhere available, and will be difficult to collect. Nevertheless, there is enough evidence to give support to Allison's (1954) hypothesis, and to justify attempts to show exactly how the metabolism of the various species of plasmodia is affected by the molecular structure of the haemoglobin in the erythrocytes that they invade.

Summary

In two large series of children living in the vicinity of Kampala, Uganda, the gross malarial parasite rate was found to be lower in those carrying the sickle-cell trait than in others, but not significantly so.

In a series of 1,200 children attending hospital the *P. falciparum* rate was significantly lower in sicklers than in non-sicklers.

Parasite counts in *P. falciparum* infections were very much lower in sickling than in non-sickling children.

It is maintained that the presence of sickle-cell haemoglobin in erythrocytes does not prevent, but limits, the severity of *P. falciparum* infections in non-immune subjects. Insufficient data are available to assess the effect of sickle-cell haemoglobin on other species of plasmodia.

I am indebted to the medical superintendent and physicians of Mulago Hospital and to Dr. H. F. We'bourn for access to cases under their care, and to the D.M.S. Uganda for permission to publish.

Television has been used by the American Medical Association since 1946 for health education, either in broadcasts to the public or on closed circuit to the medical profession, and the A.M.A. has recently published a handbook, *Television in Medical Education*, to give doctors guidance on the techniques of successful televising. The first part is devoted to the workings of television, which are clearly explained with the aid of photographs and diagrams. The second part gives practical help in producing a medical programme, suggesting ways in which information can be given, such as by monologue, interview, or documentary. Two scripts are reproduced, one for a public and one for a specialist audience. The reader is reminded that television is a visual medium, and he is shown how to include graphic and visual devices such as charts and sectional cut-outs in his programmes. Advice on dress, voice production, and approach is also given. The last section of the handbook describes what has already been achieved by this medium in medical education, and ends with a glossary of television terms. While, as the foreword points out, "learning by active participation has no peer," this publication is intended to enable doctors to make television a useful adjunct to their teaching programmes.

EFFECT OF SICKLE-CELL TRAIT ON RESISTANCE TO MALARIA*

BY

ERNEST BEUTLER, M.D.

Lieutenant, United States Army Medical Corps

RAYMOND J. DERN, M.D., Ph.D.

Captain, United States Army Medical Corps

AND

C. LARKIN FLANAGAN, M.D.

From the Army Malaria Research Unit, Department of Medicine, University of Chicago, Chicago, Illinois, U.S.A.

Type S (sickle) haemoglobin is present in the red cells of a sizable percentage of members of the negro race. The presence or absence of this abnormal haemoglobin type is genetically determined. Heterozygous individuals, whose red cells also contain type A (normal) haemoglobin, suffer no ill effects from the presence of the abnormal haemoglobin, although sickling of the cells may be demonstrated when the oxygen tension is greatly reduced. Such individuals are said to have the sickle-cell trait. When, on the other hand, type S haemoglobin is inherited in the homozygous form, sickle-cell disease, a severe chronic haemolytic anaemia, results (Pauling *et al.*, 1949; Neel, 1951). Thus, unless individuals with the sickle-cell trait possessed some selective advantage, the gene for sickle haemoglobin would gradually be eliminated from the population by the early death of those with sickle-cell disease.

Allison (1954) has suggested that an increased resistance to infection with malaria may be such an advantage. He reviewed evidence that the incidence of malaria in endemic areas was lower in those individuals with the sickle-cell trait than in those without the trait. He also noted that the incidence of the sickle-cell trait was highest in those areas in which malaria was prevalent. Upon inoculation of a series of highly immune subjects with an African or a Malayan strain of *P. falciparum* intravenously and, in some cases, also with infected mosquitoes, Allison found that only 2 out of 15 "sicklers" (sickle-cell trait) developed malaria, while 14 out of 15 "non-sicklers" developed malaria. In the present study we have attempted to evaluate the effect of sickle haemoglobin on resistance to malaria under carefully controlled conditions.

Materials and Methods

All subjects were inmate volunteers from the Stateville Branch of the Illinois State Penitentiary at Joliet, Illinois. Sixteen American negroes who had never previously had malaria were inoculated. Erythrocytes were examined for sickling by the 2% sodium metabisulphite method (Daland and Castle, 1948). In addition, haemoglobin from each volunteer was examined by filter-paper electrophoresis. Each of the eight "sicklers" had both type A and type S haemoglobin; each of the eight "non-sicklers" had only type A haemoglobin. In each of the three studies all subjects were inoculated with aliquots of a single freshly drawn

sample of heparinized, Group O, Rh-negative blood infected with trophozoites of the El Limon, Panama strain PF 6 (Jeffery and Eyles, 1954) of falciparum malaria. In studies 2 and 3 the donor's blood was diluted in his own plasma, so that the injected volume could be measured more accurately. The parasites in 0.1 c.mm. of blood were counted directly on stained thick smears (Earle and Perez, 1932). The infection was terminated with chloroquine whenever it was considered necessary to do so for the patient's safety; the decision whether or not to interrupt the infection in any given case was based on the course of the parasite count and on the clinical condition of the patient. All patients remaining in the study for 23 days after inoculation were cured at that time.

Results

Study 1.—Ten volunteers, five "sicklers" and five "non-sicklers," were inoculated with 500,000 parasites each. The parasite counts of these 10 men are presented in Table I. As this table indicates, it was necessary to interrupt the infections of three of the "non-sicklers" before it was necessary to interrupt the infections of any of the "sicklers." The parasite counts of the "non-sicklers" tended to be somewhat higher. On day 8 the difference between the means of the logarithms of the counts of the two groups slightly exceeded two standard errors, and may therefore be regarded as statistically significant at the 0.05 level. Earlier

differences did not reach this level of significance; later comparisons were not valid because of the interposition of treatment of some of the volunteers.

Study 2.—Because it was thought that 500,000 parasites might have been an overwhelming inoculum, six other volunteers, three "sicklers" and three "non-sicklers," were given an injection of only 50,000 parasites. The parasite counts of these subjects are presented in Table II. It was necessary to interrupt the infection in two of the three "non-sicklers" before it was necessary to interrupt the infections of any of the "sicklers."

Study 3.—In an attempt to determine the effect of acquired immunity on the resistance of "sicklers" and "non-sicklers" to malaria, the same 10 volunteers who had been inoculated with 500,000 parasites in study 1 were reinoculated with 50,000 parasites after a lapse of four months. The parasite counts during this study are presented in Table III. Up to and including day 10, when treatment was started on subject N3, the means of the logarithms of the parasite counts of the "sicklers" and "non-sicklers" never differed to a statistically significant degree. Although it was necessary to treat two of the five "non-sicklers" relatively early in the course of their infection, the other three were able to continue for the remainder of the study, while only one of the "sicklers" was able to do so.

Discussion

In comparing the resistance of individuals with and without sickle-cell trait to malaria, we have been able to demonstrate only unimpressive differences of questionable significance. These findings differ from those of Allison (1954). There are several possible explanations for this difference in results. While Allison used an African and a Malayan strain of falciparum malaria, we used a Panamanian strain. It is conceivable, although it does not appear very likely, that strain differences between the parasites used were sufficient to account for the different results. His subjects were highly immune; ours were non-immune in studies 1 and 2, and only slightly immune in study 3. It is also possible that any advantage which sickle-cell haemoglobin gives an individual infected with malaria is so slight in itself as to become manifest only when a high degree of acquired immunity already exists.

It would appear that further work is necessary to evaluate conclusively the role of sickle-cell haemoglobin in resistance to malaria.

Summary

Eight non-immune men with sickle-cell trait and eight non-immune men whose red cells contained only normal haemoglobin were inoculated with *P. falciparum* intravenously. Ten of these men were reinoculated four months after their initial course of malaria. The resulting parasitaemias tended to be somewhat less marked in the men with the sickle trait than in those without the trait, but the difference observed was unimpressive and of questionable significance.

We acknowledge the helpful advice of Dr. Alf S. Alving, of the Department of Medicine, University of Chicago, Illinois. The investigations reported in this paper would not have been possible except for the co-operation of the inmates and the administrative staff of Stateville Penitentiary, Joliet, Illinois, U.S.A.

EMERGENCY MITRAL VALVOTOMY AT FULL TERM

REPORT OF A CASE

BY

T. C. J. O'CONNELL, M.D., M.Ch., B.Sc.

Visiting Surgeon, St. Vincent's Hospital, Dublin;
 Consulting Surgeon, Coombe Lying-in Hospital, Dublin

AND

RISTEARD MULCAHY, M.D., M.R.C.P.

Assistant Physician, St. Vincent's Hospital, Dublin;
 Consulting Cardiologist, Coombe Lying-in Hospital, Dublin

Several reports have appeared in recent literature on the value of mitral valvotomy during pregnancy (Baker *et al.*, 1952; Logan and Turner, 1952; Sellors *et al.*, 1953; Mulcahy, 1954). These emphasize that, in a limited and properly selected group of cases, this procedure may play an effective part in lessening disability, and thus help to reduce the maternal mortality rate due to heart disease. These reports advise that, when indicated, operation should take place during the first trimester or as early in pregnancy as possible, and most of the recorded valvotomies in pregnant women have been done during these early months.

We here record the case history of a patient with pure mitral stenosis who had a valvotomy performed at full term, ten hours before the birth of her ninth child. No such case has so far been recorded, though the feasibility of this procedure at all stages of pregnancy has been suggested previously (Mulcahy, 1954).

Case Report

A married woman aged 35 was admitted to the Coombe Maternity Hospital on November 29, 1954, in the early stages of labour. She had been a "defaulter" from the antenatal clinic. Apart from the normal labour pains, she was observed to be considerably distressed with dyspnoea, orthopnoea, cough, and cyanosis. On examination she was found to have pure mitral stenosis. She was in regular rhythm, and, though there was no evidence of heart failure, she was regarded at the time as a likely subject for a later pulmonary oedema. This impression was supported by the tachycardia, the loud slapping first sound following the unusually harsh mid-diastolic and presystolic murmur, the easily palpable right ventricle and pulmonary artery, and the evidence of early pulmonary venous congestion on the skiagram taken twenty-four hours after admission. The film also revealed a large left auricle and pulmonary artery, but only minimal cardiac enlargement. Further factors, obviously important in her case, were the six-weeks history of persistent non-productive cough and the presence of anaemia, her haemoglobin being 55%.

This patient had attended the antenatal clinic beforehand, but, despite a history of increasing distress on exertion and of a long-standing cough, she had failed to report anything abnormal. At no time had she complained of haemoptysis. During her earlier pregnancies, the last having been 22 months previously, she recalled no notable symptoms, nor was she informed of any abnormality in the heart. There was no previous history of rheumatic fever.

Treatment was started at once. It included penicillin, 500,000 units twice daily, digoxin, 0.25 mg. eight-hourly, sedation, and efforts to suppress the cough. Notwithstanding these measures and despite the cessation of labour pains a few hours after admission, her condition showed little or no improvement. Morphine, $\frac{1}{2}$ gr. (10 mg.) six-hourly, intravenous aminophylline, and streptomycin were added

48 hours later, but next day (December 2) the probability of pulmonary oedema was more apparent. The heart sounds were now loudly slapping and the presystolic murmur was unusually harsh. A most noticeable feature was the obvious pulsation of the right ventricle and pulmonary artery, causing a parasternal lift of exceptional degree. This was a warning of the likelihood of pulmonary oedema—particularly, we believed, in the event of the resumption of labour. Some impairment of air entry in the base of the left lung was obvious for about two days, but by now increasing consolidation was apparent. This was an added complication and appeared to be uninfluenced by the antibiotics administered. In view of the patient's steady deterioration valvotomy as an urgent measure was advised.

The operation was performed uneventfully three days after admission. The lower lobe of the left lung showed considerable congestion when the thorax was opened, but this did not interfere with the surgical manipulations. The left auricular appendage was large and free of clot, and was dealt with in the routine manner. As expected, the valve was tight, but both commissures separated without difficulty. The pulmonary artery was large and tense at first, but less so towards the end of the operation. The patient was returned to the ward in a satisfactory condition, and after a short labour a live infant, weighing 8 lb. 4 oz. (3.7 kg.), was born 10 hours later without difficulty or distress to the mother.

She had more than the usual post-operative cough and sputum from the residual congestion and atelectasis of the left lower lobe. These symptoms, however, responded within a few weeks to antibiotics and symptomatic treatment. Her convalescence was otherwise quite uneventful, and she was discharged on December 31.

She has since been seen by us. Her general condition seems to be quite good, and there is considerable modification of the physical signs in her heart, the mid-diastolic bruit being shorter and audible only when she is lying on her left side. She is leading a normal active life, as she was before the start of her last pregnancy.

Comment

This case history illustrates the value of mitral valvotomy as an emergency procedure during the later months of pregnancy. The presence of moderate anaemia and of long-standing persistent coughing undoubtedly played an important part in this patient's final and irreversible deterioration. It is unlikely that valvotomy at this stage would have been necessary in the absence of these influences, and we are of the opinion that the avoidance of such important aggravating factors during pregnancy should almost preclude the necessity for operation at such a late stage. There is, however, still a definite indication for valvotomy in the early months of pregnancy in properly selected patients.

We are indebted to Dr. J. K. Feeney, Master of the Coombe Lying-in Hospital, under whose care this patient was admitted, for his advice on the obstetrical problem, and for the facilities afforded in his hospital; to Dr. M. I. Drury, consulting cardiologist, National Maternity Hospital, Dr. R. Davys, anaesthetist, and Mr. J. G. Maher, assistant surgeon, St. Vincent's Hospital, Dublin, for their invaluable assistance.

RESERPINE IN TREATMENT OF CHRONIC PSYCHOTICS PRELIMINARY OBSERVATIONS

BY

E. S. FOOTE, M.B., B.S., D.P.M.

Deputy Medical Superintendent, Herrison Hospital,
Dorchester

Recent work in America (Kline, 1954) on the treatment of psychotics with rauwolfia and its alkaloids suggests that the ancient Indian belief in the value of this root in the treatment of mental illness was well based. In view of that work it was decided to try the effect of this drug on a group of chronically mentally ill patients. The group, a small one of 32 male patients, consisted of 26 schizophrenics, 4 cases of schizophrenia superimposed on basic mental defectiveness, 1 chronic melancholic, and 1 with arrested G.P.I. The patients varied in the date of their admission to hospital from 1912 to 1952, all but six having been in this hospital for over five years.

They were segregated into a section of one of the wards for mentally disturbed males under a senior nurse, and it was arranged that their nursing care should be, so far as possible, maintained by the same nurses.

In choosing the patients for this test, only those in a satisfactory physical state were included, and all showed behaviour problems. Thus 11 were noted to be destructive, 13 were faulty in their habits, 11 were liable to impulsive violence, 4 required regular spoon-feeding, and others needed considerable prompting and occasional spoon-feeding with their meals. All 32 were unoccupiable. The degree of destructiveness among these patients was great. One of them, the most destructive in the hospital, destroyed on an average one blanket a night and one mattress a week, and had started to gnaw the wood on his bed.

Procedure

Initially, six patients were treated with reserpine ("serpasil"), being given 1 mg. four times a day, which seemed to be the dose most commonly used by the American authorities. In view of its known hypotensive effect, daily blood-pressure readings were taken on all patients for the five-months period of the trial. In addition four-hourly temperature and pulse rates were charted at first, but, as no significant findings were noted, these were later reduced to morning and evening readings. The hypotensive effect was variable: whereas most patients showed an initial small drop, in one or two the blood pressure fell considerably. Readings of 60/50 and 64/46 were obtained in two cases. These low blood-pressure readings were not found until the patients had been on reserpine for more than two weeks, and in both cases they were symptomless. Their occurrence, however, suggests the importance of regular blood-pressure readings when patients are first treated with this drug. The blood pressure in both these cases later returned to normal on a slightly smaller dose. Following this, it was decided to start with smaller amounts, and 0.5 mg. three times a day became the initial dose. The dose was constantly under review in all cases, and from the experience gained it seems that there is no fixed dose, though it was found that the effective dose varied from 0.5 to 1 mg. four times a day. In all cases the drug was administered by mouth.

Results

In one case the maximum improvement was noted when one dose was given during the night. Without this dose the patient's condition relapsed during the night, but he rapidly

improved after his morning dose. In the cases that responded to reserpine some sign of improvement was usually noted between the first and second weeks of treatment, but several showed definite improvement within three days, while others were unchanged for three months and then improved.

The results of the treatment in the first small group of six patients were most encouraging. The highly destructive and degraded patient mentioned above became clean and tidy, and lost his destructive habits within four days of being put on reserpine; and others of this group showed comparable improvement.

Other patients suffering from chronic psychosis were added to the series, and the effect of the drug on them compared with the rest of the ward was most marked. The reserpine patients became quiet and co-operative; impulsive actions and destructiveness disappeared; they fed themselves at meals, and helped each other at the table, in marked contrast to their former habits and those of the untreated patients in the ward. Occupational therapy classes were started, and 20 of the 32 patients were regularly employed in these sessions; 12 of these also did some form of useful work in tidying the ward, etc.

The main difference in the patients under reserpine, apart from the disappearance of the antisocial behaviour, was their receptivity to ideas and suggestions, whereas previously such suggestions had had no effect. Considerable prompting was needed to start occupational therapy and to improve table manners, but, once accepted by the patient, they were maintained.

Appetite was greatly increased and difficulties with feeding disappeared. The dietary had to be increased, as the normal amount did not satisfy their appetites. One patient, who used to stick his fingers down his throat and vomit after food, completely lost this habit and took his meals normally. Weight increase was variable, but the 32 patients, who were all weighed weekly, gained an average of 6 lb. (2.7 kg.).

Many patients now enjoy cinema shows, patients' dances, and other recreations, whereas previously they were not thought suitable for such activities.

Of the 32 patients, 4 were regarded as greatly improved, 14 much improved, 9 slightly improved, 3 not improved, and 2 worse. (The 5 patients who did not improve were 3 schizophrenics, 1 chronic-melancholic, and 1 G.P.I.)

Combination with other Forms of Therapy

One schizophrenic of five years' standing, who had been mute, hallucinated, incontinent, and utterly detached, became more alert, tidy in appearance, but still would not speak. He was given a short course of electric convulsion therapy, and promptly spoke normally and rationally, and for a time appeared to be making an amazing remission. This remission was, however, only temporary, and he again became mute and withdrawn. He was then started on insulin therapy, the reserpine being maintained while he was receiving subcoma doses of insulin. Some response has been noted, but not to a degree comparable to that previously found.

Side-Effects

Some drowsiness was noted with the higher doses, but this could be successfully combated by small doses of amphetamine sulphate. Little difficulty was experienced with looseness of the bowels, which was only transient when it did occur. Stiffness of the nose was noted in a few cases, but caused no great inconvenience.

Three cases developed oedema—in two, of the legs only, but in one of the face as well as the legs. These cases were carefully investigated. A cardiovascular or renal origin for the oedema was excluded. Estimation of blood urea, protein, albumin, globulin, thymol turbidity, alkaline phosphatase, van den Bergh, bile, serum sodium, serum potassium, and serum chlorides, together with complete blood counts, gave normal results. The occurrence of

oedema has been noted in Switzerland (C. Dale Falconer, personal communication). Gaunt *et al.* (1954), writing on the endocrine aspects of the pharmacology of reserpine, suggest that the drug stimulates the release of an anti-diuretic hormone in the posterior pituitary in rats, and this may possibly be the mechanism of the oedema production in these cases.

Opinion

While this group is too small to allow of a dogmatic opinion, the results obtained strongly suggest that reserpine has brought about a marked change in a ward consisting mainly of long-standing schizophrenic patients with gross behaviour disorders. The change in the nursing staff's work is most pronounced. Instead of custodial care, there is now considerable scope for active rehabilitation, with, as a result, increasing interest and enthusiasm in the work. Another striking point is the reduction in the amount of bed-linen and clothing destroyed by patients. Finally, the disappearance of incontinence among this group has been most dramatic; and this, combined with improvements in behaviour, encourages one to hope that such patients may in future be nursed in better wards, with greater amenities.

Summary

Thirty-two chronic mentally disturbed patients were treated with reserpine for periods of up to five months.

In the great majority, considerable improvement was noted in their habits and personal appearance and in their ability to occupy themselves. Impulsiveness and incontinence disappeared. A marked quietening effect was noted. Even those patients showing definite signs of dementia were superficially improved. Side-effects were slight, and occurred in only a few cases. Most patients who are going to respond show signs of this within a week or two, but some were on the drug for three months before definite improvement was noted. It is therefore suggested that, unless the patient's condition deteriorates, the method should be given at least a three-months trial.

The promising results obtained in this small sample of mentally disturbed patients suggest that an extensive trial of reserpine in psychotics of more recent onset should be made.

It seems to be important to make full use of occupational and recreational therapy so as to provide the stimulus for activities which the drug appears to permit.

I would like to thank Dr. A. C. Sinclair, medical superintendent of Herrison Hospital, for permission to publish this report; Ciba Laboratories Limited for a generous supply of serpasil; Dr. T. V. Cooper, of the Dorset County Laboratory, for carrying out the special investigations on the oedematous cases; and, finally, the nursing staff for their help and co-operation.

The Annual Report for 1954 of the department of rheumatology at the Royal Free Hospital comments on the reduction in the length of stay in hospital of patients who are admitted for the treatment of rheumatic diseases. This applies to all the disorders in the rheumatic group of diseases except osteoarthritis. In the case of rheumatoid arthritis, for instance, the average stay in 1954 was 48 days, compared with 61 days in 1953, and for ankylosing spondylitis the average stay in hospital was reduced from 63 in 1953 to 35 days in 1954. This reduction in hospitalization, the report remarks, is largely due to the more plentiful supply of hydrocortisone, which has enabled the department to treat isolated peripheral joints more effectively, and to the policy of using long-term hormone therapy in those cases which have failed to respond to other available forms of treatment.

POSTERIOR PITUITARY SNUFF TREATMENT OF NOCTURNAL ENURESIS

BY

F. G. W. MARSON, M.D., M.R.C.P.
Lecturer in Medicine, University of Leeds

It is not proposed to review the vast literature dealing with the causation and treatment of nocturnal enuresis. For the purpose of this article it will suffice to state that adolescent and adult sufferers exist in whom no obvious psychiatric or physical disorder can be found, and in whom accepted measures of treatment are of little value. Many such patients also suffer nocturnal frequency, and it is apparent that they have either relative nocturnal polyuria or that their bladders have a subnormal capacity. Such patients might be expected to benefit by a reduction in urine formation during sleep. The use of pituitrin snuff in cases of diabetes insipidus was first reported in 1924 by Choay and Choay; and Vidgoff (1932) and Smith (1934) reported full control of this condition by the use of snuff at eight to ten-hour intervals. It is well known that pituitrin has a similar depressant effect on the urine flow in normal persons (Gutmann, 1928).

Bonacorsi (1925), Blau (1926), and Jacobs (1930) reported the use of pituitrin in the treatment of nocturnal enuresis in children. It is difficult to understand the mode of action of the drug in these cases, as good results were stated to have followed short courses of injections of the drug. More recently, Hansen (1954) has reported satisfactory treatment of nocturnal enuresis by nightly administration of posterior pituitary snuff ("di-sipidin"). He found the results less satisfactory in small children. In none of these reports has the effect of pituitrin been contrasted with placebo therapy, and thus the possibility of a psychotherapeutic effect has not been excluded.

In the present study, four adolescent patients have been treated with pituitrin snuff or placebo snuff over periods of seven to eleven months. They are a special group in that each patient had persistent and frequent nocturnal enuresis, was normal on physical examination, appeared on general assessment to be of normal intelligence, and showed no marked psychiatric disorder. Throughout the period of study the patients kept a strict chart showing each night when enuresis or frequency occurred. The patients were seen every two to four weeks, and at each visit they received a sealed prescription for either pituitrin or placebo snuff, and this was dispensed at the hospital pharmacy. The patients were informed that different types of snuff would be prescribed, but did not know when a change was made or that placebo snuff was being given. The placebo snuff was identical in appearance to the pituitrin snuff. Each patient was instructed to avoid fluids within three hours of sleep, and immediately before retiring to bed a large pinch of snuff was inserted well into each nostril. (The dose was approximately 100 mg.)

Case 1

A sensitive and intelligent girl aged 19, a printer, was first seen on April 26, 1954. She complained of lifelong bed-wetting, usually occurring one to three times a week. The longest remission prior to present treatment had been for six weeks, and occurred three years previously. A large

quantity of urine was voided when enuresis occurred. She had always been a very deep sleeper and was never awakened by the discomfort of a full bladder or by incontinence. She had received various forms of medical treatment in the past without effect. She had tried avoiding fluids for four hours before sleep, but this measure was ineffective. There was no history of serious illnesses or any family history of enuresis. The prospect of enuresis persisting into adult life naturally caused considerable anxiety to the patient, but she was otherwise free from worries and enjoyed a happy social background. She normally slept from 10.30 p.m. until 6.30 a.m. On examination there were no abnormal physical findings. The urine was free from sugar and contained a trace of albumin. Microscopy of the urine was normal, as was an intravenous pyelogram.

No fluids were taken after 6 p.m. Within the period April 26 to December 5, 1954, pituitrin snuff was administered intermittently for a total of 26 weeks (182 days); during this time nocturnal enuresis did not occur on a single occasion. She received placebo snuff during six weeks (June 14 to July 5 and October 18 to November 8), and during these periods nocturnal enuresis occurred on 21 occasions (50% nights).

Case 2

A girl aged 15, a factory worker, was first seen on November 23, 1953. She complained of lifelong bed-wetting, usually occurring five or six times a week, a large quantity of urine being voided. She had always been a very deep sleeper and could not be awakened by a loud alarm clock. During a period in which she received amphetamine sulphate in a dosage sufficient to cause insomnia, the enuresis had been largely replaced by nocturnal frequency. Apart from this she had never experienced a remission for longer than two days. She had also suffered from lifelong diurnal frequency, which had been an embarrassment to her at school. There was a previous history of pink disease in the first year, attacks of migraine since the age of 4, and a mastoidectomy at 11. There was no family history of enuresis. She confessed to a certain amount of friction between her mother and herself, no doubt accentuated by the frequent bed-wetting, but was otherwise a happy person with enuresis as her only serious worry. She normally slept from 10.30 p.m. to 7 a.m. Examination revealed a small girl of average intelligence. There were no abnormal physical findings. The urine was free from albumin and sugar, and on microscopy was normal.

No fluids were taken after 7.30 p.m. Within the period November 23, 1953, to November 1, 1954, pituitrin snuff was administered for a total of 37 weeks (259 days); during this time nocturnal enuresis occurred on 10 occasions (3.9% total nights). On four of these occasions the patient had a coryza with profuse nasal discharge and she was unable to retain the snuff properly. She received placebo snuff for a total of nine weeks (January 18 to 25, 1954; May 17 to June 14; and November 1 to 29); during this time, when no coryza occurred, she had nocturnal enuresis on 19 occasions (30.2% nights).

Case 3

A youth aged 18, a fitter, was first seen on April 5, 1954. He complained of lifelong bed-wetting, which usually occurred from two to seven times a week, a large quantity of urine being voided. His longest remission had been for ten days. He had always been a very deep sleeper. The avoidance of fluids for four hours before sleep had proved ineffective. There was no history of serious illnesses or any family history of enuresis. Apart from the enuresis the patient said that he was free from worries and had a happy home background. He normally slept from 11.15 p.m. to 6 a.m. On examination there were no abnormal physical findings. The urine was free from albumin and sugar.

No fluids were taken after 7 p.m. Within the period April 5 to November 29, 1954, pituitrin snuff was administered

for a total of 30 weeks (210 days): during this time nocturnal enuresis occurred on 10 occasions (4.8% total nights). The patient volunteered that the quantity of urine voided into the bed was much diminished. He received placebo snuff during six weeks (May 10 to 24 and October 4 to November 1), and during this period nocturnal enuresis occurred on 10 occasions (23.8% nights). After both periods when placebo snuff had been given the patient remarked, "This last snuff was not as good as the previous stuff." He based this upon the increased frequency of enuresis and the quantity of urine passed.

Case 4

A youth aged 16, a clothing warehouse assistant, was first seen on April 12, 1954. He complained of lifelong enuresis, usually occurring once or twice a week, the longest remission having been for two weeks. He had also suffered from lifelong nocturnal frequency, which occurred once or twice nightly, except when replaced by enuresis. If, however, he did not awaken during the night there would be an even chance of enuresis occurring. There was no past history of serious illness and no family history of nocturnal enuresis. While naturally perturbed by the persistent bed-wetting, he was otherwise free from worries and had a happy social background. He normally slept from 10.30 p.m. to 6.30 a.m. Examination revealed a boy of average intelligence and asthenic build. There were no abnormal physical findings. The urine was free from albumin and sugar. An intravenous pyelogram was normal.

No fluids were taken after 7 p.m. Within the period April 12 to November 29, 1954, pituitrin snuff was taken

TABLE 1.—Incidence of Nocturnal Enuresis and Nocturnal Frequency during Administration of Pituitrin Snuff and Placebo Snuff in Case 4

Snuff	Duration in Days	Nocturnal Enuresis		Nocturnal Frequency		No Incident	
		Nights	%	Nights	%	Nights	%
Pituitrin	182	10	5.5	81	44.5	91	50.0
Placebo	49	9	18.4	31	63.2	9	18.4

for a total of 26 weeks (182 days); during this time nocturnal enuresis occurred on 10 occasions (5.5% total nights), nocturnal frequency on 81 nights (44.5% total), and on the remaining nights (50%) he slept without incident (see Table 1). He received placebo snuff for seven weeks (July 19 to September 6), and during this period nocturnal enuresis occurred on nine occasions (18.4% total nights), nocturnal frequency on 31 nights (63.2% total), and he slept without incident on nine nights (18.4% total).

Analysis of Results

The difference in frequencies of nocturnal enuresis during administration of pituitrin and placebo snuff were worked out by "2 x 2" tables, making use of χ^2 method (Fisher, 1946). Table II shows the results. In Cases 1, 2, and 3, $P < 0.001$, which indicates that the possibility of the results being a chance finding is less than one in a thousand. In Case 4 $P < 0.01$, indicating that the possibility of a chance finding is less than one in a hundred. It is clear that in

TABLE II.—Analysis of Incidence of Nocturnal Enuresis in Four Adolescent Patients during Total Period in which they Received either Pituitrin or Placebo Snuff

Case No.	Snuff	Wet Nights	Dry Nights	χ^2	P
1	Pituitrin	0	182	100.4	<0.001
	Placebo	21	21		
2	Pituitrin	10	249	42.8	<0.001
	Placebo	19	44		
3	Pituitrin	10	200	17.38	<0.001
	Placebo	10	32		
4	Pituitrin	10	172	8.48	<0.01
	Placebo	9	40		

all four cases there is a marked reduction in the incidence of enuresis during pituitrin treatment, the reduction being very highly significant in the first three patients.

Discussion

The list of therapeutic measures—medical, surgical, and psychiatric—bears witness to the relative inefficacy of any one of them in the treatment of nocturnal enuresis. Although first suggested by Bonacorsi (1925), the use of pituitrin in the relief of this condition has received scant attention in the literature. This is surprising, as the well-known effect of pituitrin in reducing the urine output might reasonably be expected to benefit certain patients. Hansen (1954), has reported satisfactory results with pituitrin snuff in older children and adults, and cites one case in which the incidence of nocturnal enuresis was reduced from nightly to once or twice a month.

This present study has been limited to four adolescent patients, comprising a selected group in that they were all of average intelligence, had a satisfactory social background, and were free from obvious physical or psychiatric defect. The possibility of a psychotherapeutic effect has been excluded by comparing the results obtained with pituitrin snuff with those during placebo administration. A reduced incidence of enuresis occurred in each patient during the periods in which pituitrin snuff was taken each night. The most favourable response (Case 1) consisted in complete relief from nocturnal enuresis during 23 weeks in which pituitrin snuff was taken, enuresis occurring frequently during the two periods in which placebo snuff was substituted. One patient suffered nocturnal frequency as well as enuresis, and a reduced incidence of both symptoms was observed during pituitrin therapy (see Table 1). No untoward effects were experienced during this study, and the only difficulty in administration was observed in the one patient who was unable to retain snuff completely in the presence of a coryza.

Pituitrin snuff is variously reported as acting for five to ten hours, and the shorter the period of sleep the more effective cover it should give. It may well prove of little value in children requiring upwards of 12 hours' sleep, but in adolescents and adults sleeping for eight to nine hours its effect is likely to persist for most of this time and should thereby effect an overall reduction in urine production during the period of sleep.

The results leave little doubt about the effectiveness of this form of treatment in the cases studied. They support Hansen's findings and suggest that pituitrin snuff therapy deserves a full trial in any adolescent or adult patient failing to respond to other forms of treatment.

Summary

Four adolescent patients with nocturnal enuresis have been treated with pituitrin snuff for six to nine months, and the results have been compared with those observed during the administration of a placebo snuff. Although obtained from a small series of selected cases, the results suggest that pituitrin snuff will prove of great value in the treatment of certain adolescent and adult cases of nocturnal enuresis.

I wish to thank Dr. W. MacAdam for referring Case 1; Dr. J. G. Dare for advice on the statistical analysis, and Professor R. E. Tunbridge for his helpful criticism in the preparation of this paper. I am indebted to Messrs. Paines and Byrnie Ltd. for the supplies of "di-sipidin" and the placebo snuff.

Medical Memorandum

Anaphylactic and Purpuric Manifestations due to Procaine Penicillin G in Aqueous Suspension

Although many millions of penicillin injections are given each year in almost every corner of the globe, the incidence of reported serious reactions is amazingly low. With its indiscriminate use, many of the drug's serious potentialities have often been overlooked, and it may be with surprise that one reads of 15 reported deaths in a period of 18 months from March, 1952 (Kern and Wimberly, 1953), and of a series of 20 unreported deaths collected by Welch and his co-workers (1953) by sending questionnaires to 95 large general hospitals in the country. Other serious reactions that have been reported include anaphylactic shock (Pick and Patterson, 1953), peripheral neuritis (Kolb and Gray, 1946), convulsions (Talbot, 1948), exfoliative dermatitis (Langdon, 1950), and severe serum-sickness type of reactions (Keefer *et al.*, 1943). Mention, too, has been made of the possible relationship of penicillin reactions to the later development of periarteritis (Harkavy, 1952) and lupus erythematosus (Gold, 1951).

A case of unusual penicillin sensitivity manifested by purpura and anaphylactoid type of reaction is here reported. Purpura (Crip and Cohen, 1951) is not a particularly common complication of penicillin administration, and its association with anaphylaxis is even less common. However, there have been reports of fatal reactions involving purpuric manifestations (Welch *et al.*, 1953). Cases have been reported of purpura as the sole manifestation, of purpura associated with other skin lesions or with serum-sickness type of reactions. Anderson (1947) reports a case of purpura associated with melaena and hematuria. In all cases so far the platelet count has been reported as normal.

CASE REPORT

A healthy white man of 28, with no past or family history of allergy, had always been in good health and to his knowledge had never received penicillin in any form. He had received procaine for dental work on several occasions without untoward reaction. His only complaint was that since serving in the second world war he had had a persistent mild recurrent epidermophytosis.

For a month before his hospital visit he had had a mild folliculitis of one buttock, which in the last two days had begun to spread so that he had developed an area of cellulitis with a fluctuant centre. There were no constitutional symptoms.

Prior to incision he was given 600,000 units of procaine penicillin G in aqueous suspension into the gluteal region. There was no immediate reaction, but four hours later he developed a generalized burning of the skin of the legs and trunk, and about an hour later, while urinating, noticed the development of a purpuric rash on his legs and in his groin. On examining himself further, he noticed that the rash was also present in his antecubital fossae and around the neck band. He was not alarmed, as he assumed that he was having a reaction to penicillin, having heard of and seen this type of thing before. He kept on working at his job as a truck helper. However, nine and a half hours after the injection he very suddenly felt quite ill and became apprehensive, pale, dizzy, and nauseated. His bowels moved and he had profuse watery stools.

On physical examination the patient was well nourished and well developed. He was pale, anxious, and sweating. His temperature was 97.6° F. (36.4° C.), pulse 120, and blood pressure 84/60 (usual blood pressure 120/75). Examination of his heart, lungs, and abdomen was unremarkable, but all over the body were scattered petechiae. These were widely scattered on the arms and upper trunk, but were marked, confluent, and ecchymotic on the legs and in the groin. There was no unusually severe reaction at the site

of the injection. The rash was also confluent in the antecubital fossae and around the neck. No petechiae were noted on the mucosal surfaces. At this time the hands and feet were slightly swollen. The tourniquet test (80 mm. for five minutes) was strongly positive.

He was immediately treated with adrenaline, ephedrine, and tripeleminamine, and his anaphylactic symptoms regressed rapidly, his pulse and blood pressure returning to normal. Although for the next eight hours he kept on with the ephedrine and tripeleminamine, his rash continued to spread. At the end of this time the rash no longer spread and he retired to bed, spending a restless night. There was minimal itching of the affected areas. At the height of the rash he showed 10 to 15 red blood cells per high-power field in his centrifuged urine specimen.

Next day he was taken off all medications. He was kept in bed for a week, making an uninterrupted clinical recovery, the skin lesions fading, with desquamation over the affected areas. Laboratory studies 24 hours after the onset of symptoms showed:—Blood: haematocrit, 48%; red cells, 5,610,000 per c.mm.; white cells, 14,200 per c.mm.; differential count normal except for 6% eosinophilia; red cells normal on smear; platelets, 202,000 per c.mm.; bleeding-time, clotting-time, and clot retraction were all within normal limits. The tourniquet test (five minutes at 80 mm. Hg) was positive. Urinalysis showed a trace of albumin and 10 to 15 red blood cells per h.p.f. Culture of pus taken from abscess at time of incision showed *Staphylococcus albus* resistant to penicillin.

Five days after onset the laboratory findings had returned to normal with the exception of the leucocytosis, which had risen to 23,000 with a shift to the left, and 4% eosinophils. The leucocytosis gradually subsided, so that within three weeks after the onset of the illness it was 10,000, with a normal differential.

Scratch tests to penicillin G solution and to procaine were negative, but there was a slight weal when using the procaine and penicillin G in aqueous suspension. Permission to inject intradermally dilutions of this was refused. Subsequent patients were given injections from the same bottle that was used on this patient without adverse effects.

COMMENT

It would seem that this was a case of severe reaction to procaine penicillin G in aqueous suspension in a patient in whom there was no knowledge that he had ever received penicillin before. However, it may be that he actually had had it prescribed for a minor laceration or skin lesion in the past without his knowledge when this type of medication was used locally rather extensively, or he may have had a cross-sensitivity with one of the fungi which had caused his athlete's foot, for this cross-sensitivity has been reported (Peck *et al.*, 1948). Although prior skin testing and questioning probably would not have helped in the decision to administer the penicillin, this case emphasizes the caution necessary in giving this drug, especially in combination with another foreign substance such as procaine. As it turned out, the organism was insensitive to the drug, and the only potentialities procaine penicillin had were for harm in this case, and time alone will tell whether any more serious manifestations are likely to follow these immediate severe anaphylactoid reactions.

Reviews

CLINICAL BACTERIOLOGY

Clinical Bacteriology. By E. Joan Stokes, M.B., B.S., M.R.C.P., M.R.C.S. Foreword by A. A. Miles, C.B.E., M.D., F.R.C.P. (Pp. 288+vi; illustrated, 20s.) London: Edward Arnold Ltd. 1955.

The methods used in different laboratories for bacteriological diagnosis are more diverse than in any other branch of applied pathology. The value of the results obtained depends not only on the methods used but on a high degree of technical skill in their application, and on a capacity for distinguishing between grain and chaff which only comes with experience. An account of how to do such work well is therefore a welcome addition to medical literature. Dr. Stokes's book centres round two chapters on how to isolate bacteria from various types of specimen, but others follow on the identification of species, on serological tests, on work involving antibiotics, and on the study of cross-infection. There is also a separate chapter on the investigation of tuberculosis and mycoses, and a final purely technical one dealing chiefly with the composition of culture media.

If the admirable methods advocated were generally followed, the standard of work in clinical laboratories would be greatly improved. They are perhaps a little idealistic and lavish: thus it is often said that three separate cultures should be made for incubation under different atmospheric conditions, whereas it can often be confidently anticipated that one will serve. It is rightly insisted that direct stained films should be made from specimens before cultivation as a guide to their bacterial content, and, indeed, to the cultural methods required. Oddly enough, this is said to be unnecessary for urine; if the author had made a practice of doing this she might be less sceptical about the frequency of mixed infections of the urinary tract. A healthy common sense is displayed in advocating that cultures consisting of saprophytes should be discarded: clinicians are being misled wholesale by detailed reports enumerating species of no consequence. Interesting methods advocated are the anaerobic incubation of all cultures for the identification of haemolytic streptococci, and an "optochin" sensitivity test for identifying pneumococci; the similar use of bacitracin for Group A *Streptococcus pyogenes* might have been mentioned. A little more might with advantage be included about simple technique: there are no instructions about how to spread a plate, and two useful tricks which have been devised for the direct demonstration of tubercle bacilli in cerebrospinal fluid are not mentioned.

This book sets a very high standard, particularly in insisting on full species identification, and in the principles laid down in an introductory chapter on the interpretation of results. It is much to be hoped that it will become a recognized guide to the practice of clinical bacteriology.

L. P. GARROD.

DISSEMINATED SCLEROSIS

Multiple Sclerosis. By Douglas McAlpine, M.D., F.R.C.P., Nigel D. Compston, M.A., M.D., M.R.C.P., and Charles E. Lumsden, M.D. (Pp. 304+viii; illustrated, 35s.) Edinburgh and London: E. and S. Livingstone Ltd. 1955.

The title of this book is perhaps unfortunate. "Disseminated sclerosis" is a term familiar to all medical practitioners and many laymen in Great Britain, but it is conceivable that some will not realize that "multiple sclerosis" is synonymous. The first eleven chapters discuss aetiological factors, clinical and laboratory investigations, and problems of prognosis, diagnosis, and treatment. Aetiology makes an unexpected reappearance in Chapter 13. Most neurologists have taken the view in the past that when disseminated sclerosis is diagnosed in two or more members of one family the probability is that the diagnosis

is incorrect and that the patients will, in fact, be found to be suffering from a different condition genetically determined. These authors take the opposite view and think the incidence of "familial" (though this does not necessarily mean "hereditary") examples is so considerable as to be of diagnostic significance. Their observations show that trauma is an aetiological factor in no less than 14%; the history of trauma was allowed to extend back for three months and even included such minor injury as dental extraction. It is strange that aggravation by pregnancy and parturition are largely discounted; it would seem not unreasonable to assume that, if extraction of a tooth can aggravate this disease, the trauma of parturition might well do so, quite apart from its psychological effects. Many neurologists believe that the disease does not occur in those of inferior intelligence, and some think there is a clear-cut pre-sclerotic personality; here these views are not mentioned, even to be discarded. Although emotional factors are accepted as being of some importance, no word with the prefix "psych-" appears in the index.

It is unfortunate that the important suggestions of Professor Platt (*British Medical Journal*, 1955, 1, 179) were not available before the book went to print. He suggests that artificial feeding in infancy may sow the seeds of this disease, and advances impeccable, if theoretical, biochemical arguments; such a view might well provide the answer to the curious geographical distribution of the disease.

Chapters 12 and 13 bring the problems of neuropathology completely up to date, and include a detailed review of the world's literature on this subject, together with many other possibly related, though rare, conditions, and for the specialist these two chapters must be considered to constitute the most authoritative article at present available.

HUGH GARLAND.

PSYCHOSOMATIC MEDICINE

Modern Trends in Psychosomatic Medicine. Edited by Desmond O'Neill. (Pp. 375; illustrated, 55s.) London: Butterworth and Co., Ltd. 1955.

This book of twenty-one chapters by numerous contributors constitutes a comprehensive survey of the field of psychosomatic medicine. The subject is of immense importance to both general practitioners and specialists; it is to the former that this book may make a particular appeal. Most of the chapters are written in a straightforward manner, are practical, and are concerned especially with the problem of aetiology and treatment. I am glad that this is so, because every day it is becoming more important that the doctor of the future should be a man who has been adequately and fully trained. That, of course, means that the more subjective side of medical work should have as much attention as the objective, and that the integration of mind and body should be in the forefront of medical practice. It is really a question of undergraduate training. Every successful general practitioner knows that that must be so, and the articles in this book written by Hopkins, Todd, and O'Neill respectively make that position abundantly clear. Todd emphasizes the position especially when he points out that the most ordinary case with the most ordinary signs and symptoms can still be an interesting person. The accurate recognition of the person back of the disease is the important issue. The doctor who knows that is the one who will obtain real satisfaction out of his work and will be of immeasurable help to those who consult him.

While this book serves an important purpose, yet it could easily have reached a much higher level. It is very uneven in its presentation. Some chapters can be highly recommended; others have little or no justification for their inclusion. It seems almost as if a certain amount of needless padding had been indulged in. The editor might, in case of another edition, give serious consideration to a reconstitution of this volume.

D. K. HENDERSON.

RORSCHACH TESTING

Psycho-analytic Interpretation in Rorschach Testing: Theory and Application. By Roy Schafer, Ph.D. (Pp. 446+xiv. \$8.75.) New York: Grune and Stratton. 1954.

To psychologist and psycho-analyst alike it is a truism that the value of any psychological test depends on the degree to which it is capable of correlation with a coherent theory of mental function. To which generalization the psycho-analyst naturally adds, *ex parte*, that the quiddity of psychological data, whether these be gathered from spontaneous introspections or, as in the Rorschach test, evoked by the application of set stimuli, can be appreciated only after they have been interpreted, preferably by a Freudian. It was in fact inevitable that the Rorschach test, which at first had only slender association with psycho-analytic thinking, should sooner or later be correlated with Freudian theory.

Dr. Schafer has made a conscientious attempt to effect this correlation. Starting with a careful survey of the "test situation" from both subjective and objective standpoints, he examines the "response process," "thematic analysis," and the criteria for judging the adequacy of interpretations. Having produced a mainly psycho-analytical classification of themes and variations, he then proceeds to examine the Rorschach test in terms of the psycho-analytical concept of mental "defence" and considers in series the processes of repression, denial, projection, and "obsessive-compulsive" mechanisms.

The book is one that calls for a specialized knowledge of both the Rorschach and the Freudian approach—a fact which might seem to limit its appeal to general clinicians. Despite this disadvantage it can be read with profit by those—and there are many—who have recourse to the test without knowing very much about it. Its main flaws are a verbosity which, in the case of terminology, borders on verbigeration, and, despite the assurances of the author, a rather naive belief that modern psycho-analytical constructs (narcissism, for example) are adequately defined. Incidentally some important, if rather diffuse, psycho-analytical concepts—for example, "introjection" and "sublimation"—have been left severely alone; and there are no parallel (control) correlations with other theories of mind. Perhaps some Jungian will remedy this omission.

EDWARD GLOVER.

TUMOURS OF LYMPHOID TISSUE

Tumours of Lymphoid Tissue. By George Lumb, M.D. Foreword by Sir Stanford Cade, K.B.E., C.B., D.Sc., F.R.C.S., M.R.C.P., F.F.R. (Pp. 203+viii; illustrated. 37s. 6d.) Edinburgh and London: E. and S. Livingstone Ltd. 1954.

This monograph is based on a clinical and pathological study of 410 patients with primary tumours of lymphoid tissue seen at the Westminster Hospital between 1940 and 1952. The tumours are classified under the headings follicular lymphoma, lymphosarcoma, reticular lymphoma, Hodgkin's disease, reticulum-cell sarcoma, and anaplastic tumours of lymphoid tissue, and the pathology of each is described along conventional lines, with special emphasis on the natural history of the disease. Chapters are included on problems of diagnosis and the effects of therapy, and 19 illustrative case histories are given in detail.

This is a simple and straightforward account of a difficult subject, but it says nothing that has not been said before. The many tables are unnecessarily bulky, and some of them could with advantage be omitted and their contents included in the text. The book is lavishly illustrated; 84 whole pages are devoted to illustrations, as well as many half-pages. While most of the photographs are excellent, some—notably Figs 9 and 11, 1, 2, 3, and 4—are poorly defined. There is much unnecessary repetition in the illustrations; in the chapter on Hodgkin's disease, for example, there are six very similar photomicrographs of abnormal reticulum cells and three of fibrosis in a gland. In the chapter on

effects of therapy there are four illustrations of collagen formation in a gland; and in the section on problems of diagnosis nine illustrations from the case of torulosis previously described by Galton and Whittick seems excessive. The index consists largely of a list of chapter headings and subheadings, and omits many of the subjects mentioned in the text.

If Dr. Lumb has added nothing new or original to our knowledge, we should at least be grateful that he does not still further confuse it.

W. GOLDIE.

CRIME COMICS AND JUVENILE DELINQUENCY

Seduction of the Innocent. By Fredric Wertham, M.D. (Pp. 397+x; illustrated. 21s.) London: Museum Press Ltd. 1955.

The traffic in crime comics in the United States has grown rapidly in recent years. In 1947 they represented about one-tenth of the total of all comic books, in 1949 one-third, in 1954 "the vast majority." About 90 million copies are now sold every month, and a million dollars a week are taken from the pockets of children. Copies pass from hand to hand in a brisk second-hand trade and are read by many children. Dr. Wertham estimates that the average American child reads over 14 comic books a week. The publishers, usually subsidiaries of big firms, constantly change their names and are, in effect, anonymous.

The trade is horrifyingly evil. Turning over the 16 pages of photographic reproduction in Dr. Wertham's book, one sees baseball played with a man's head; a close-up of the face of a hanged man (cover picture); two men tied to the back of a speeding car, their faces being "erased" in the grit; a girl screaming while her right eye is held open and a hand approaches it with a stiletto. Advertisements offer the child, for money sent through the post, switchknives, throwing knives, pistols shooting steel darts. To quote the author, "The cover of the comic book draws the child's attention to a crime, the text describes one, the pictures show how it's done, and the advertisements provide the means to carry it out."

It would seem self-evident that such a pabulum must have a debasing and demoralizing effect. This is, however, not the established psychiatric view in the U.S.A. Psychiatrists of repute can be hired by publishers to endorse the harmlessness of their products; and the child-guidance experts think the causation of juvenile delinquency is so complex that it would be altogether too "simple" to suppose that crime comics had anything to do with it. Psycho-analysis teaches us that the foundations of personality are laid down in the first six months, so that by the time he comes to read these books the child is already predestined to delinquency or to sanity.

Dr. Wertham's book is all too readable, and should be widely read; but it is not a satisfactory presentation of his powerful case. Facts and arguments are not marshalled in an orderly way, and the book badly needs a good index.

ELIOT SLATER.

Though he has seen much of the world, Dr. Harry R. Lillie reserves his most cordial enthusiasm for the glittering wastes of the polar regions in *The Path Through Penguin City* (Ernest Benn, 25s.), and he succeeds in communicating to the reader his love of the animals that are too often slaughtered there with needless or careless cruelty. "Whaling and sealing, written and talked about in the past as sagas of heroism and adventure, I had found to be largely sagas of brutality." His story makes a curiously personal travel book. Against a background of unusual voyages and places, the description of which he supplements with clear photographs, he sets his forceful plea for more kindness in man's treatment of wild animals. Certainly many medical men could only regard as abhorrent the manner in which the commercial exploitation of whales and seals is sometimes carried on. The author has himself had some success in encouraging the whalers to adopt more humane techniques, though the problem of excessive fishing has not been solved.

PROGNOSIS IN CANCER OF LARGE INTESTINE

In England and Wales in 1953 cancer of the large intestine caused 15,395 deaths.¹ Cancer of the rectum was responsible for 5,676 of this total, or 1 out of every 90 deaths from all causes, and cancer of the colon for 9,719, or 1 out of every 52. Figures obtained by the General Register Office show that, of the cases of cancer of the rectum registered in 1945 and 1946 at their initial hospital attendance, only 11% of the males and 17% of the females are alive at the end of five years. For cancer of the colon the comparable figures are 10% and 14%. Referring to the prognosis of cancer of the large bowel in the population of Detroit, D. A. Cameron, H. A. Chapnick, and D. W. McLean² conclude their analysis by stating: "Our study indicated that out of every 100 admissions for cancer of the large bowel 40 patients will leave hospital presumably cured, but only 15 will be alive and well five years later." These two series of statistics, the one concerning a population of 44 millions on this side of the Atlantic and the other one of over 1½ millions on the other side, are strikingly similar and represent the true overall prognosis of the disease.

Many workers have recorded the prognosis in operated cases which, since secondary deposits were absent from the liver, the surgeon had hoped to cure. Typical of the larger series is that of R. S. Grinnell,³ in the U.S.A., who analysed 521 such cases of cancer of the colon and 366 of cancer of the rectum. Of the colon cases 45.5% were alive at the end of five years (operative deaths being taken into account) and of the rectum cases 46.4%. On separating the survivors into those whose lymph glands were involved at the time of operation and those who had no metastases, the survival figures were approximately 37% and 68% for both cancer of the colon and cancer of the rectum. In Britain Gabriel's figures⁴ for the rectum of approxi-

mately 34% and 68% are closely similar. These figures suffice to show that the prognosis of cancer of the large intestine is lamentably poor and that the results of surgery depend largely for their success on the absence of affected lymph nodes at operation, or, if they are involved, on the possibility of their excision.

How may the prognosis be improved? First, by earlier diagnosis. In the anaplastic type of growth the lymph nodes may be infiltrated while the primary is still small and has only recently caused symptoms. At the other end of the scale, in the case of well-differentiated cancer, the lymph nodes may not be involved in spite of the fact that the growth is bulky and has caused symptoms for many months. Nevertheless these types of case are in the minority and in most the presence of metastases seems directly related to the duration of the symptoms of the disease. Diagnosis may be delayed by the patient not consulting his doctor when symptoms first appear or by the doctor not appreciating the significance of the symptoms and such signs as may be present. Since one out of every six deaths are attributable to cancer of all types, it is surely time the public were better informed about the early symptoms of the disease, for only thus can the main source of delay be reduced. The second source should serve as a challenge to the teachers at undergraduate hospitals. The earliest symptoms, not only of cancer of the large intestine but of all cancers, are perhaps apt to be forgotten by students because of the emphasis often placed on surgical technique and the biochemistry of post-operative care. Too little time is still spent at the bedside and too much in the operating-theatre. It is an unfortunate fact that in a series reported by S. O. Aylett⁵ 30% of cases of cancer of the rectum experienced an average delay of three months between first attendance on the doctor and reference to hospital. This delay would be minimized if, in particular, alterations of bowel habit, however small, and minor bleedings, even in young patients, were always thought of as being due to cancer of the large intestine until this cause was disproved by further investigation—and if a rectal examination was carried out in all such cases.

Developments in surgical techniques have their part to play in improving the prognosis of cancer of the large intestine. In 1938-9 the resectability rate of cancer of the colon was, according to the British Empire Cancer Campaign's figures, only 34.8%. In a series operated on between 1945 and 1953 by various surgeons and reported by Lawrence Abel at the combined meeting of the Association of Surgeons and the American College of Surgeons in the summer of 1954 the resectability rate was 67.3%. While the

resectability rate had nearly doubled, the operative mortality had been halved from 18.3% to 9.2%. These latter figures will probably be improved on again with recent advances in pre- and post-operative care and anaesthetic and operative techniques, permitting a more favourable prognosis. Many authors have drawn attention to the need for the widest possible excision of the areas of lymphatic drainage in treating cancer of the large intestine.⁶⁻¹⁰ These extensive operations, when carried out on reasonably fit patients by surgeons trained in colonic surgery, have a low mortality rate and should help to improve the prognosis. Another recently developed surgical concept is the "second look" procedure described by O. H. Wangenstein.¹¹ He advocates, in those cases in which at the first operation lymphatic metastases are found, reopening the abdomen six months after the initial excision. If the disease has recurred, resection is again carried out, and the abdomen is explored at six-month intervals until one operation is completed at which no cancer is discovered. It may certainly be a procedure worth undertaking for those cases in which the pathological examination of the specimen excised at the first operation shows lymphatic involvement as far as the ligature round the main vascular pedicle. The prognosis in this group of patients is particularly poor, and in Gabriel's series only 11% were alive at the end of five years.⁶ Earlier diagnosis and the most radical excisions undertaken by surgeons trained in colonic surgery offer at present the only hopes of diminishing the high mortality of this disease. Both hopes are, with high endeavour, attainable.

TREATMENT OF TUBERCULOUS MENINGITIS

A recent leading article in a contemporary on tuberculous meningitis contained the statement, "attempts to eliminate intrathecal therapy—are justified only if undertaken cautiously in specialized units."¹ Dr. Douglas Hubble² later contested this, referring to treatment without intrathecal injections as "nearly universal practice." No one will deny the introduction of isoniazid has greatly improved the prognosis in this disease, but it is only about three years since it was first generally used, and a survey of the experience gained is appropriate at this stage. There has been some diversity in the methods used, and it is interesting to see how the results and conclusions bear on the difference of opinion to which we refer.

Clark and his colleagues³ contributed the first enthusiastic report on the effect of isoniazid in both

meningeal and miliary tuberculosis. Many of their patients were Navajo Indians: fifteen had meningitis, and with the exception of two of them, who at one stage had intrathecal streptomycin, they were given either isoniazid alone or isoniazid and intramuscular streptomycin. It is now generally believed that treatment with any single drug is a mistake, but Appelbaum and Anderson⁴ report 7 recoveries in 10 cases treated only with isoniazid or iproniazid (1-isonicotinyl-2-isopropyl hydrazide). Torres-Gost,⁵ of Madrid, reported on an unusual method of treatment in 100 patients, among whom there had been only six deaths: this was intramuscular streptomycin together with both oral and intrathecal isoniazid. An accompanying paper by Fletcher⁶ reports that oral administration of isoniazid produces adequate concentrations of the drug in the cerebrospinal fluid, and it thus seems clear that intrathecal administration of this drug is superfluous.

Intrathecal administration of streptomycin, despite the advent of isoniazid, has been continued in several centres in Great Britain. Anderson and his colleagues⁷ treated seven patients, all of whom survived, one being given isoniazid only and the remainder also both intramuscular and intrathecal streptomycin, in four for only one week and in two for four weeks. Lorber⁸ gave streptomycin by both routes to 22 patients, of whom 12, with 11 survivals, also received oral isoniazid, and 10, with 8 survivals, did not. The former group needed fewer intrathecal injections, the average being 65, whereas in the group not receiving isoniazid it was 90. Lorber discussed the necessity for intrathecal streptomycin, and, having failed to find any record of a comparative trial of treatments with and without it, decided that there was insufficient evidence to justify its abandonment. The series of 60 patients at the Hospital for Head Injuries at Oxford described by Taylor⁹ is larger, and the verdict from such a source that "intrathecal streptomycin is considered to be the *sine qua non* of satisfactory therapy" must command respect. On the other hand, this paper does not discuss any improvement which may have resulted from the introduction of isoniazid, or indeed even state the number of

patients to whom this drug was given: it is concerned rather with the improvement in results attributed to intrathecal tuberculin.

A number of other authors have either reached or incline to the opposite conclusion. Bulkeley,¹⁰ of Durban, having treated in a variety of ways a long series of patients, nearly all children, finally adopted as a standard treatment intramuscular streptomycin with oral isoniazid and P.A.S., together with A.C.T.H. to prevent arteritis and the formation of organizing exudates. The last 17 patients in the series received this treatment, and among them there have been three deaths. It is stated that "intrathecal streptomycin is now a thing of the past in this hospital." Waddell and his colleagues¹¹ contrast the poor results previously obtained in children with those now given by intramuscular streptomycin and oral isoniazid and P.A.S., but the number of cases they treated was small. Spies and his colleagues¹² present a similar contrast on a larger scale: of their 61 pre-isoniazid patients only 11 survived, but of 26 treated with isoniazid 14 have survived. Half of this group were also given streptomycin by both routes, but the survivors were equally divided between these and the remainder. Spies *et al.* think it "likely that the penetration of isoniazid into the cerebrospinal fluid . . . will obviate the necessity for intrathecal streptomycin therapy in the future." Fitzpatrick,¹³ on the other hand, reached and acted on this conclusion some time ago: of four systems successively used in treating his series of 46 patients at Denver, the last and most successful consisted of oral isoniazid and P.A.S. and streptomycin by the intramuscular route only. He notes that the cerebrospinal fluid became normal during this treatment after an average of 6.1 months, compared with 11 months or more after all previous forms of treatment. An author who also commends this system of treatment, but without citing clinical evidence in support of it, is B. E. Douglass,¹⁴ of the Mayo Clinic. Perhaps the most striking, because graphically presented, evidence of the altered outlook in this disease is that furnished by the large-scale Veterans Administration study in the U.S.A.¹⁵ In the graphs of survival of 287 cases given four different systems of treatment, that for "isoniazid in combination" soars above all the rest. Most of the 8 deaths in the 39 patients so treated occurred early. It was elicited in the discussion on these findings that only 6 of these 39 patients were given streptomycin intrathecally. This is perhaps the most solid piece of evidence that the intrathecal injection of streptomycin may no longer be necessary, but the weight of other published American opinion also seems to favour this view.

SALICYLATE INTOXICATION IN CHILDREN

Salicylates have long been used in the treatment of acute rheumatism, and their toxic qualities are well understood. Lees,¹ who was one of the first to recommend large doses of sodium salicylate in the treatment of rheumatic fever—he prescribed 180 gr. (12 g.) daily—recognized in 1903 that hyperpnoea was the important symptom indicating intoxication. This hyperventilation was assumed to be due to acidosis, but Graham and Parker² in 1948 showed that it was the result of reflex stimulation of the respiratory centre by the high concentration of salicylate in the plasma, and therefore that its first biochemical sequel was a respiratory alkalosis. The kidney then allows bicarbonate to escape, while retaining chloride; so the plasma bicarbonate falls and plasma chloride rises.³ In those suffering from intoxication by salicylates alkalosis is therefore the first state, and acidosis the second but not final state if treatment is prompt and correct.

Accidental aspirin-poisoning apart, salicylate intoxication would probably be a rarity if Coburn⁴ had not suggested that it was necessary to achieve a salicylate level of 35–50 mg. per 100 ml. of plasma in acute rheumatism in order to obtain optimal therapeutic results. Subsequent investigations have established that, if blood concentrations of this degree are to be maintained, many patients will be poisoned. For example, Holt,⁵ in treating 52 children with acute rheumatism, tried to keep the concentration of salicylate at 30–40 mg. per 100 ml. of plasma, and 17 of his patients developed hyperpnoea. He concluded from this experience that if children are to be treated with salicylates in high dosage admission to hospital will usually be required. The question then immediately arises: are smaller doses of the drug and lower amounts of salicylate in the plasma equally effective in the treatment of acute rheumatism? The same group of Sheffield paediatricians⁶ has done something to answer this question. Acute rheumatism in 10 children treated by high doses of salicylate remitted in an average of 39 days, and a similar group treated with much smaller doses of salicylate remitted in an average of 50 days. The dose of salicylate was 1½ gr. (100 mg.) per lb. (0.45 kg.) of body weight—say, 60–120 gr. (4–8 g.) daily—in the

first group, and only 20–30 gr. (1.3–2 g.) daily in the second group. Would a more moderate commencing dose of 1 gr. (65 mg.) per lb. of body weight per day—say, 40–80 gr. (2.5–5 g.) daily—with a gradual reduction in dosage after two days, as usually recommended,^{7,8} achieve an optimal result with a negligible risk of intoxication? This is as yet uncertain, but it would be as well not to exceed this dosage as a general rule nor to neglect the first appearance of hyperpnoea.

Since acute rheumatism is uncommon under the age of 4, and aspirin is not a drug which is much used in this country either in the treatment of disease or for the relief of pain in the very young, therapeutic salicylate poisoning in infancy is rare. This is fortunate, for South African experience⁹ suggests that infants are especially liable to salicylate poisoning. In one year 15 infants were admitted to a Johannesburg children's hospital suffering from therapeutic salicylism, and 7 of them died. Two circumstances appeared to have enhanced the toxic properties of the salicylate. The children were usually suffering from pyrexial diseases likely to be accompanied by oliguria; and most of them had received a sulphonamide-aspirin mixture which was at that time (1951) a popular prescription in South Africa, and the sulphonamide may itself have interfered with renal tubular function. No similar mixture has been widely used in this country (it was popular in Sweden in 1947), and the cases of salicylate poisoning in infants admitted to hospitals in Britain are usually the result of accidental ingestion of the drug. The South African report is a reminder that aspirin has little place in the treatment of sick infants.

Gastric lavage should be used promptly in treatment if a large single dose has been taken; if the child's condition is not serious, this, and a high fluid intake, may be sufficient. Intravenous fluids will be required if the child is ill, both to ensure the rapid elimination of the drug through the kidney and to correct electrolyte disturbances. Heyman and his colleagues⁹ recommend that Ringer lactate solution should be used for intravenous infusion, followed by 5% dextrose-water solution. In one patient an exchange transfusion was probably life-saving, and the level of salicylate in the blood was reduced by this means from 53 mg. to 28 mg. per 100 ml.

INSECTICIDE VAPORIZERS

One advantage of the English climate, especially in a summer such as we experienced in 1954, is that flies are rarely such a nuisance as they are in warmer lands. Less fortunately, perhaps, standards of hygiene are not so high as they should be, and access to food by flies is

often lamentably easy. In many parts of the U.S.A. warm summers encourage fly breeding, and this fact, coupled with a higher general awareness of the risks of poor hygiene, has inspired a more concerted attack on flies at as many points as possible. Active sales-promotion methods there have led to the widespread use of insecticide vaporizers, and they are also on sale in Britain. The principle of these devices is the volatilization of substances like D.D.T. or, more commonly, gamma B.H.C. (lindane). The solid insecticides are vaporized from some heat source which may or may not be thermostatically controlled to regulate the rate of evaporation. Such devices are intended to maintain a constant concentration of insecticide in the air, though this is difficult in a normally ventilated room, where the air may change completely from five to several hundred times a day. Much of the insecticidal effect of the vaporizers is probably due to residues which they deposit on adjacent parts of walls and ceiling. Indeed, there seems to be little evidence that these machines, even if operating under optimum conditions, are more effective in killing flies than residual films of insecticide deposited by spraying. Nevertheless the idea of a continuous, virtually effortless control of flying insects in closed spaces by means of these vaporizing devices has obviously made an appeal in the U.S.A. that has led the public health authorities to feel considerable concern about the possible health hazards incurred. The A.M.A. Committee on Pesticides has issued three warnings within three years about the dangers from these machines.¹⁻³ An interdepartmental committee on pest control laid down performance standards for acceptable machines. The maximum output should not exceed 1 g. per 15,000 cubic ft. (425 cubic m.) per 24 hours, which gives a concentration of about 0.2 mg. per cubic metre. The committee noted that few machines conformed to what was considered to be a reasonably safe design. It has been observed that a vaporizer adjusted to emit 1 g. per 24 hours varied from $\frac{1}{2}$ to 2 $\frac{1}{2}$ g. according to prevalence of local air currents.⁴ They advised against their use in private houses or in premises where food was prepared or eaten. Exposed food can pick up 0.1–1 p.p.m. gamma B.H.C. each day of exposure in rooms where the vaporizers are used.

The Pesticides Committee has had its attention drawn to a number of cases of illness attributed to exposure to these vapours. Most are cases of irritation of the eyes and respiratory tract and dermatitis. Their occurrence clearly illustrates the selection of the few hypersensitive individuals from a large exposed population. More questionable is the association between a case of peripheral neuritis, one of anuria, and several of anaemia with exposure to these insecticides as vapours. Although gamma B.H.C. is generally regarded as relatively non-toxic, the committee records the case of a baby having convulsions within an hour of swallowing a tablet of gamma B.H.C., giving a dose

¹ *J. Amer. med. Ass.*, 1952, 149, 367.

³ *Ibid.*, 1954, 156, 607.

⁴ Spear, P. J., *Soap*, 1952, No. 8, 147.

⁵ McNamara, P. B., and Krop, S., *J. Pharmacol.*, 1948, 82, 140.

equivalent to 45 mg. per kg. But, if relatively non-toxic by mouth, gamma B.H.C. is very toxic when injected intravenously, and a dose of 5 mg. per kg. will cause convulsions in dogs.⁵ Inhalation of the vapour of gamma B.H.C. obviously more nearly approximates to an intravenous than to an oral route of administration. Reference is made in the A.M.A. Committee's report to observations that rats are affected by the continuous inhalation of 0.7 mg. of gamma B.H.C. per cubic m. of air seven hours a day for months and that the compound can accumulate in the brain.

Whether or not the use of these devices presents a real hazard to the majority of healthy people exposed to them, the hypersensitive minority are clearly going to suffer. In the absence of any good evidence of their value in insect control—an absence that may account for some of the sales-promotion methods used in America—it is to be hoped that their use will not become widespread in Britain. The prevention of breeding is the most satisfactory method of insect control when it can be effectively carried out. All flying insects alight sometimes, and the insecticide should be selectively deposited in such places by spray or a more permanent type of application. Widespread diffusion in the air of probably ineffective concentrations of insecticide is followed by a haphazard distribution of the condensed solid in the vicinity of the vaporizer.

ISONIAZID AND PYRIDOXINE METABOLISM

After the introduction of isoniazid for the treatment of tuberculosis, many workers reported that prolonged administration of the drug gave rise to unpleasant side effects, some of which resembled those due to vitamin deficiencies. Thus J. S. Pegum¹ described a patient who suffered from the "burning feet" syndrome after treatment with isoniazid, suggestive of a pantothenic acid or nicotinic acid deficiency. R. B. McConnell and H. D. Cheetham² refer to a patient receiving the drug who developed acute pellagra, and who recovered on treatment with the vitamin-B complex. During studies on the effect of high doses of isoniazid J. P. Biehl and R. W. Vilter^{3,4} noted that peripheral neuritis was a fairly common side effect, occurring in about 40% of their patients. The similarity of the neuritis to that caused by the pyridoxine (vitamin B₆) antagonist, desoxypyridoxine,⁵ led them to investigate pyridoxine metabolism in tuberculosis patients receiving isoniazid. Seventy-four patients were given isoniazid in doses ranging from 6 to 24 mg. per kilogram of body weight a day for periods of two to twelve months. The incidence of peripheral neuritis was greatest in those patients receiving the higher doses of the drug. Those given the standard dose showed no symptoms until six months had elapsed, but patients on high doses frequently developed neuritis in five weeks.

¹ Pegum, J. S., *Lancet*, 1952, 2, 536.

² McConnell, R. B., and Cheetham, H. D., *ibid.*, 1952, 2, 959.

³ Biehl, J. P., and Vilter, R. W., *Proc. Soc. exp. Biol. (N.Y.)*, 1954, 85, 389.

⁴ *J. Amer. med. Ass.*, 1954, 156, 1549.

⁵ Vilter, R. W., et al., *J. Lab. clin. Med.*, 1953, 42, 335.

⁶ Ungar, J., et al., *Lancet*, 1954, 2, 220.

When the isoniazid was withdrawn, symptoms disappeared in a few weeks, although residual effects persisted for a year or more in those patients receiving treatment for more than a few weeks after the onset of symptoms. When pyridoxine was given with large doses of isoniazid, neuritis did not appear, although it did in 40% of the patients receiving isoniazid without pyridoxine. It is of considerable interest that this drug-induced neuritis has not been reported in children or monkeys receiving high doses of isoniazid.

Biehl and Vilter followed the effect of the drug on pyridoxine and nicotinic acid metabolism by examining the urinary excretion of pyridoxine, pyridoxic acid (an inactive metabolite), and N'-methylnicotinamide, which is the normal excretion product of nicotinic acid. They also tested for pyridoxine deficiency. Since pyridoxine is essential for the normal metabolic breakdown of the amino-acid tryptophan, a deficiency of pyridoxine results in an abnormal breakdown of tryptophan to xanthurenic acid. Biehl and Vilter therefore gave test doses of tryptophan and interpreted the appearance of xanthurenic acid in the urine in high quantities as a sign of pyridoxine deficiency. After high doses of isoniazid the excretion of pyridoxine and xanthurenic acid was increased, but that of pyridoxic acid and the nicotinic acid metabolite was normal in all patients. The pyridoxine did not interfere with the antituberculous activity of the isoniazid. J. Ungar and his co-workers⁶ have shown that the toxic effects of isoniazid in mice, manifested by retardation of weight and involution of the testes and thymus, can be prevented by pyridoxine, which does not interfere with the antituberculous activity of isoniazid *in vitro* or *in vivo* in mice.

It has been assumed that isoniazid exerts an anti-vitamin effect by blocking the action of nicotinic acid and pyridoxine by competitive inhibition, just as the sulphonamides block the action of *para*-aminobenzoic acid.¹ Biehl and Vilter do not accept this view. They consider that isoniazid depletes the tissues of pyridoxine, and so causes a deficiency of this vitamin by the formation and excretion of the isonicotinyl hydrazone of pyridoxal, the formation of which can be demonstrated in the test-tube. If this explanation is correct, is it possible that other drugs with a hydrazide grouping, such as hydralazine (apresoline), might behave in a similar way?

HEART BEATS OFF THE MAINS

Treatment of the syncopal attacks of Stokes-Adams disease presents difficulties, especially when episodes of cardiac arrest become frequent and severe. Zoll and his colleagues¹ have used an external cardiac pacemaker to maintain adequate cardiac contractions until spontaneous ventricular rhythm reappeared. This instrument produces monophasic, rounded electric impulses, with an average duration of 2 to 3 milliseconds. The frequency of the shocks may be adjusted from 30 to 180 stimuli per minute and the amplitude from 0 to 150 volts.

¹ *Circulation*, 1954, 9, 482.

² *J. Amer. med. Ass.*, 1955, 157, 444.

The cardiac pacemaker is attached to the patient by two leads, which are connected to circular chest electrodes so placed upon the chest that the current flows across the heart. The instrument may be operated either from the mains or from a battery. Zoll and his colleagues report its use in fourteen patients with Stokes-Adams disease. Their patients were mostly in the seventh and eighth decades of life and were brought into hospital because of increasingly severe and frequent attacks of cardiac arrest. Treatment by the cardiac pacemaker was given either for short periods in individual Stokes-Adams attacks or for more prolonged periods during frequently recurring attacks, stimulation being maintained sometimes for as long as one hundred hours. In all patients except one sustained beats finally reappeared and stimulation was then stopped. Adrenergic drugs were given simultaneously as required. Of the fourteen patients treated thirteen responded satisfactorily to the cardiac pacemaker and five had survived for about a year; but the remaining eight, although temporarily improved, died within a few weeks of treatment. In another recent report Douglas and Wagner² describe how a 72-year-old man who was having frequent Stokes-Adams attacks, finally becoming deeply comatose, recovered after seven days' continuous treatment with the cardiac pacemaker and was asymptomatic on leaving hospital. The cardiac pacemaker appears therefore to be useful, and indeed life-saving, during an exacerbation of Stokes-Adams disease, but it affects only slightly the final prognosis in the majority of these elderly patients. Troublesome complications of this treatment are painful contractions of the intercostal and pectoral muscles and irritation of the skin by the electrodes: pethidine or paraldehyde have been given to relieve discomfort.

It is possible that the external cardiac pacemaker may be of practical use in the immediate treatment of unexpected circulatory arrest during anaesthesia. The method has the advantage that it is safe and easily applied, and if circulatory arrest were due to ventricular standstill the cardiac pacemaker would probably resuscitate the patient. Should it fail, however, much valuable time would have been lost unless simultaneous preparations for an immediate thoracotomy had been made, so that cardiac massage could be carried out at once and, if necessary, electric defibrillation across the heart attempted.

ASSAY OF POLIOMYELITIS VACCINES

It is of paramount importance that methods of assaying a vaccine be standardized before it passes from experimental to general use, and the recent news from the U.S.A. that cases of paralytic poliomyelitis have been diagnosed following vaccination¹ has drawn attention to the need for strict control of biological products. An American public health officer is reported² to have predicted the "revival of the double and triple checking done in the Salk field trials last year."

The formalized poliomyelitis vaccine is an aqueous suspension of killed poliomyelitis viruses of Types I, II,

and III in approximately equal proportions. In Britain manufacture is governed by the Therapeutic Substances Act, and tests for safety and potency are carried out, first by the manufacturer, and then by the Biological Standards Division at the National Institute for Medical Research.

The methods of assay and safety testing in general use (and they may be altered in the light of experience) can be considered under four main headings. First, tests are carried out for bacterial sterility, including *Mycobacterium tuberculosis*, before inactivation with formaldehyde. Secondly, tests for viruses other than poliomyelitis, particularly B virus and lymphocytic choriomeningitis virus, are performed by subculture into animals (rabbits and mice) and into tissue culture. Thirdly, and after inactivation, tests for live poliomyelitis virus are made by subculture into tissue culture. If these tests are satisfactory, the batches of vaccine made from each of the three types of virus are pooled, and more safety tests of the same kind are carried out on the pooled vaccine. At this stage special tests are made to detect minimal quantities of live poliomyelitis virus. Samples of vaccine are inoculated into monkeys and into tissue culture, which are then carefully observed for signs of infection, and histological examination of the central nervous system is carried out for minimal lesions of poliomyelitis infection. Fourthly comes the quantitative assay, the level of the immune response that a given vaccine batch will produce. Again, animal inoculations are necessary and the results are compared with those obtained with a reference or standard vaccine. Finally, a suitable preservative is added, and if all conditions are satisfied the product is released for use.

GOLDEN JUBILEE OF THE "NURSING TIMES"

When the *Nursing Times* first appeared fifty years ago nursing was still a comparatively young profession, as distinct from a vocation or occupation, and there were still some years to run before the Nurses' Registration Act of 1919 established a General Nursing Council to make rules for the training, examination, and registration of nurses. The golden jubilee number of the *Nursing Times*, published last week, contains articles reviewing some of the changes which nurses have seen in the last fifty years, changes reflecting the technical advances in medicine as well as the political trend towards the welfare state. As the official journal of the Royal College of Nursing since 1926, the *Nursing Times* has played an influential part in improving the professional status of nurses and in advancing their education. It is a journal edited by nurses for nurses, though medical men and women have always been among its prominent contributors. Nurses are fortunate in having such a live and successful journal to keep them informed about the progress of their own profession and of the closely related profession of medicine, and we are glad to add our congratulations to the many received by the *Nursing Times* on its fiftieth birthday, a birthday most happily celebrated by a luncheon given last week by the publishers, Macmillan and Co., Ltd.

EMERGENCIES IN GENERAL PRACTICE

ACUTE FOOD-POISONING

BY

CHRISTOPHER HARDWICK, M.D., F.R.C.P.

Physician, Guy's Hospital

Single cases and outbreaks of food-poisoning still occur with some frequency, especially in the holiday season. If the general level of personal and public hygiene was high enough no doubt these infections would cease, but it will be a very long time before this desirable state is reached. We must therefore continue to recognize and treat each case as it occurs.

Aetiology

The symptoms in all patients are very similar, but aetiological two types can be recognized. In *toxic food-poisoning* the food is either poisonous in itself and is eaten by mistake, or the food is heavily contaminated by a poison, usually a bacterial toxin. Thus the toadstool fly agaric (*Amanita phalloides*) may be eaten instead of field mushrooms (*Agaricus campestris*), or the food may be infected with bacteria, especially staphylococci, which multiply and produce an exotoxin. Subsequent cooking may kill the bacteria but their poisons remain.

In *infective food-poisoning* the food is heavily infected by pathogenic organisms of the salmonella group, and it is the multiplication of these within the patient which gives rise to the illness. Typhoid and paratyphoid fevers come into this category, but as there is a long incubation period between the ingestion of the bacilli and the development of the disease they do not concern us here.

Protein is essential for bacterial growth, and so meat, fish, and milk are particularly likely to cause trouble. Sausages and any processed meats rightly have bad reputations as vectors of food-poisoning. Their preparation gives room for infection by cooks who may be carriers, and the mixing required makes it very easy for an unscrupulous maker to introduce cheap tainted meat into them. After they are made the sausages may only be smoked or very inadequately cooked before they are eaten. An outbreak of trichiniasis at the start of the second world war was attributed to the practice which was common amongst work-people of a midland town of taking sandwiches to work which were filled with raw sausage-meat. Tinned foods did have a bad reputation, but with modern methods of canning the danger has largely gone; infection of the meat after a tin has been opened may, however, still occur. Recently duck eggs have come under a cloud; organisms of the salmonella group may infect the birds or may penetrate the eggs after they have been laid.

Symptomatology

Abdominal pain, vomiting, and diarrhoea occur in both types of food-poisoning. In the toxic form these symptoms may occur within a few hours of the food having been eaten. In the infective type some time must elapse before the bacteria, growing within the host, cause trouble, and so symptoms may be delayed for two or three days.

Although several people may have eaten the tainted food only one may develop symptoms of food-poisoning. The occurrence of the illness in a single member of a family does not therefore exclude the diagnosis. Children are particularly likely to be affected. Amongst adults those who have eaten the contaminated food on an empty stomach will suffer the worst. It is possible to see all gradations of the disease in the members of a family. The younger children may have a severe gastro-enteritis whilst the elder children may only vomit a few times. The parents may have a few hours of abdominal colic with one or two loose stools.

Vomiting is usually the first symptom. It occurs frequently and after a time streaks of bright blood may be brought up. Anything taken by mouth is immediately returned, and in a severe case the patient may become shocked and collapsed. The abdominal pain is colicky in nature and is usually situated in the centre of the abdomen. If vomiting is severe there will in time be soreness in the epigastrium. Similarly, when diarrhoea is frequent there may be pain and tenderness over the colon. Diarrhoea usually starts a little after these two symptoms. Frequent watery stools may be passed and in a severe case blood and mucus.

The general disturbance will vary in degree. It is usually most pronounced in children, but in a severe infection even adults may become acutely ill. The temperature rises to about 100° F. (37.8° C.), and there may be headache and pains in the limbs. Frequent vomiting and the passage of many watery stools can easily lead to dehydration. The patient's pulse rate rises, he becomes increasingly restless, and finally collapses with a rapid thready pulse, cold extremities, and ashen-grey colour.

Differential Diagnosis

When there is an outbreak of food-poisoning the diagnosis in each sufferer should not be difficult. In isolated cases, however, there may be considerable difficulty in diagnosis, particularly before diarrhoea has started. Acute intestinal obstruction and acute appendicitis must both be excluded. The rare possibility that the patient is not suffering from food-poisoning but from the effects of some irritant poison, such as arsenic, deliberately introduced in the food must also be remembered.

Outbreaks of bacillary dysentery, the infecting organism being *Shigella sonnei*, occur occasionally. Mental hospitals and, less often, children's homes still provide the bulk of these cases, but workers in such institutions may carry the infection to their homes. Adults are seldom very ill with *Sonne* dysentery, but babies and toddlers suffer severely.

Treatment

Acute food-poisoning may be of varying severity even though the patients are infected at the same time. For purposes of treatment it is useful to regard the cases as falling into two groups—mild or severe. Mild cases recover rapidly and need only symptomatic measures. Severe cases require urgent treatment, and the patient may die despite everything that is done for him. Such a division is not rigid, for a patient who is seen early may be thought to have only a mild infection, whereas a few hours later it may be obvious that the infection is severe.

Previously healthy adults will usually withstand even a severe attack of food-poisoning successfully. In elderly people, however, particularly if they have disabilities such as coronary atherosclerosis or nephritis, the outlook may not be so good and their admission to hospital may be advisable. This is also true for children, particularly below the age of 2 years. At this age the reserves of body fluids are small and the margin between hydration and dehydration is narrow. A few hours of vomiting may be enough to cause severe symptoms. If, therefore, the practitioner is in any doubt about the severity of an attack of food-poisoning in a child, it is best to recommend its immediate removal to hospital.

Mild Cases

Mild cases of acute food-poisoning recover most quickly if the patient is in bed. If there are children in the house-

hold, rest in bed should be insisted upon, especially if there is any suspicion that the infection might be dysenteric. A hot-water bottle, wrapped in a piece of flannel or put inside an old sweater, will relieve the abdominal pain. Despite his vomiting, the patient should take warm drinks as often as possible. These may consist of water, milk and water, or fruit juice with added sugar. An alkali which will not cause alkalosis, such as aluminium hydroxide or magnesium trisilicate in doses of 2 dr. (8 g.), will help if the gastritis is extensive. The former has the advantage that it is constipating and so will help to relieve the diarrhoea. Other mixtures which may be used include: mist. kaolin, B.P.C., $\frac{1}{2}$ oz. (14 ml.) four-hourly; or mist. kaolin. et morph., B.P.C., $\frac{1}{2}$ oz. 14 ml.) eight-hourly; this contains approximately 1/65 gr. (1 mg.) of anhydrous morphine. Mist. cret. aromat. c. opio, B.P.C., $\frac{1}{2}$ oz. (14 ml.) eight-hourly, is another useful mixture; this contains 10 min. (0.6 m.) of tincture of opium in each dose, which is equivalent to about 1/9 gr. (7 mg.) of anhydrous morphine.

Even though the headache and the generalized pains may be severe, aspirin is best avoided, for it is known to be a gastric irritant, especially when taken on an empty stomach. In its place Dover's powder (pulv. ipecac. et opii), 10 gr. (0.65 g.), may be given.

Severe Cases

In severe food-poisoning symptomatic measures will still be required, but, in addition, dehydration and shock as well as bacterial infection may have to be dealt with. Rest and warmth should be given, with full nursing care. The chalk and opium mixture will be required, to try to quieten the intestinal unrest. Owing to the excessive vomiting, feeding by mouth may be very difficult, but if possible the patient should be given small quantities of boiled water, to each pint (say half a litre) of which has been added $\frac{1}{2}$ oz. (15 g.) of castor sugar and $\frac{1}{2}$ dr. (4 g.) of salt.

Dehydration and the consequent shock are shown by a diminishing output of urine, a rising pulse rate, and a falling blood pressure. All these can be measured, so that the appropriate steps can be taken before the patient becomes grey and sunken, with cold extremities and delirium. Intravenous infusion will be required to replace the water and chlorides which have been lost in the faeces and the vomit. In the absence of laboratory facilities, a mixture of equal quantities of normal saline and isotonic glucose solution should be used, in quantities sufficient to enable the patient to pass a pint of urine in every eight hours.

Intravenous infusion is a rapid and effective way of restoring body fluids. It is, however, a very artificial method and both the quantity and the rate of infusion must be carefully controlled. When fluid is given by mouth the patient can regulate its absorption and excretion so that the circulation is not overloaded. When the intravenous route is used the volume of circulating fluid is immediately increased. If this goes too far, then the patient will become waterlogged, the heart will suffer, and his condition may be as bad or even worse than when he was dehydrated. This will be especially so in children, in whom the volumes of fluid required are less, and in old people, whose myocardium may be unhealthy.

It is impossible to give a definite figure for the quantity of fluid that may be needed. In a severe case 3 to 4 pints (1.5 to 2 litres) may have to be given as quickly as possible to combat the acute symptoms. Once these have been overcome the infusion can be given more slowly, say a pint (0.5 litre) every four hours. The aim should be to correct the acute symptoms and then to give the patient enough fluid to replace that lost during the previous 24 hours in the vomit, urine, and faeces, with the addition of 2 pints (1 litre) to make up for the fluid lost through the skin and lungs. As soon as the patient has ceased to vomit the infusion should be stopped and feeding by mouth begun again. Overloading of the circulation is shown by restlessness, increasing pulse rate, and finally by the appearance of moist sounds at the lung bases.

If the food-poisoning is of the toxic variety then chemotherapy can be of no help. If the disease is infective one of the sulphonamides which are poorly absorbed and which will remain in the intestine to deal with the salmonella organisms should be used. At least 18 g. of sulphaguanidine a day should be given: an initial dose of 6 g. and then 3 g. four-hourly for three or four days. If succinylsulphathiazole is used the dose can be less, but at least 10 g. should be given each day: an initial dose of 4 g., then 2 g. every four hours for four days.

Next article on Emergencies in General Practice.—"Severe Asthma," by Dr. A. Margaret C. Macpherson.

Refresher Course Book.—Copies of the second volume of collected articles from the Refresher Course for General Practitioners published in the *Journal* are still available at 25s. (postage 1s.) each. The volume contains 60 articles, all of which were revised by their authors for publication in the book. The first volume is now sold out and out of print. Copies of the second volume may be obtained from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller.

Nova et Vetera

A POST-MORTEM POPULATION SURVEY FOR ARTHRITIS

Surveys to discover the incidence of certain disease groups in selected samples of the population are becoming increasingly popular, and an investigation of this kind was recently conducted in a Midland town to estimate the frequency of osteoarthritis. The unique opportunity has recently been taken of carrying out a survey for a similar purpose on the skeletons of the entire male population of the town and region of Visby, which is situated on the island of Gotland, off the coast of Sweden. The population in question was slaughtered by invading Danes in the year A.D. 1361, the bodies being thrown into a common grave, which was recently opened and examined by Dr. Bo. E. Ingemark, of the Department of Anatomy of the University of Upsala.

A detailed examination was made of the 1,085 skeletons which were found in this common grave at the site of the slaughter (later dignified with the name of a battle).^{*} It was reported that "a good many morbid processes could be established in this material. Thus many of the vertebrae showed more or less pronounced spondylosis deformans," occurring mostly in the spines of middle-aged and elderly victims. Pott's disease was found in four cases, and some other joints were also found to have been the site of a tuberculous infection, and Dr. Ingemark gives a photograph of a knee-joint ankylosed as the result of this process. There also occurred "a fairly large number" of degenerative osteoarthritic joints. Hip-joints were affected in this way in 20 cases—"malum coxae senilis"—and one advanced case is illustrated. This disease had also occurred in about 25 cases in the elbows and wrist-joints. He points out that these people were obviously quite unfit for war service, and suggests that the cause of this rather high incidence of arthritic change may perhaps have been due to the hard work which they had to perform on the land, as they were mostly feudal peasants.

W. S. C. COPEMAN.

^{*}Dr. Ingemark's findings are published as chapter 4 (pp. 149-209) of *Armour from the Battle of Wisby* (1939), vol. 1, by Bengt Thordeman.

Old Fort York. This fort housed the Queen's Rangers in 1793, when the building of Toronto was begun.

TORONTO, THE MEETING-PLACE

BY

S. S. B. GILDER, M.B., B.S., B.Sc.
Toronto

Tradition has it that the name Toronto comes from an old Indian word meaning a meeting-place. Here, at the mouth of the Humber River—now the site of the biggest traffic jams in the city—the red men coming south from Lake Simcoe met their brothers on the lakeshore trail. Here, close to a site now occupied in summer by an amusement park reminiscent of Blackpool or Southend, the French built a small fort in 1749, and called it Fort Rouille, in honour of the then Colonial Minister of France. When the Seven Years' War brought English troops up from Fort Niagara, the tiny garrison burnt their fort and left the future site of Toronto to the wilderness and the Indians for the next twenty-five years.

Early History

With the close of the American War of Independence, thousands of United Empire Loyalists were expelled from the United States for their allegiance to King George III. From 1783 their migration northward into Nova Scotia and Quebec began, and it was an overflow from these who began the colonization of a new province known as Upper Canada and later as Ontario.

The site of Toronto, which lies on gently rising ground above a natural harbour, was evidently considered favourable for development, for in 1787 government agents negotiated with the Mississauga Indians for its purchase for a sum of £1,700 in cash and kind, thus obtaining a quarter of a million acres at a bargain rate. Oddly enough, the sale was not completed until 1805.

In 1788 Captain Gother Mann of the Royal Engineers was instructed to survey the area, and drew up a plan of the proposed town and harbour. Toronto has in fact been a planned city right from the start—there were 16 different plans in 66 years.

In 1793 Governor John Graves Simcoe, first Governor of the new province, came with his lady by lake to Toronto and said, "Here will be built a great

city in the spring." The great city took much longer than that to materialize, but otherwise the command was obeyed to the full. At this point the new city was named York in honour of Frederick, Duke of York, who was then enjoying a sporadic success against the French. York it remained until 1834, when the little town incorporated all the small adjacent communities to form the city of Toronto.

Progress was slow at first. For two years there were only log cabins, and the first white baby was born only in 1800, but there was no major setback until April, 1813, when an American fleet of 14 sail came in and took and burnt the town after heavy fighting. In this engagement Dr. William Beaumont, the father of gastric physiology, served as surgeon to the Americans. At the end of July the Americans paid

another brief visit, contenting themselves this time with burning a few buildings and looting stores.

From then on Toronto enjoyed a peaceful development until 1837, a year in which political feeling was running high between the Family Compact or Tory oligarchy and the reform party, whose Toronto leader was a former mayor, William Lyon Mackenzie. Mackenzie, an indifferent and indecisive commander, made an attempt to take the city in a rebellion doomed to failure from the start. He was outlawed for some years, but eventually returned from the States and ended his days in Toronto. The only significance of this rebellion is that it is still said to divide certain Toronto citizens whose ancestors took part on one side or the other.

From 1837 on, there was no major excitement in Toronto life. One author speaks of its enviable history and pictures the city "wearing with embarrassed rectitude the title of Toronto the Good." The focal points of city life seem to have been the churches, of which Toronto still possesses a phenomenal number. A Toronto historian, writing some 50 years ago, says: "The stern discountenance of any and every form of recreation [on Sundays] is said to be the cause of so many people going to church." The Sabbath is still kept to an extent now unfamiliar in England, in marked contrast to the rival city of Montreal.

The University of Toronto. Most of the buildings in this picture belong to the University, including the stadium in the background, behind which runs Bloor Street.

University Avenue, Toronto, leading up to the Parliament Buildings. Half-way up on the left is the Mount Sinai Hospital. Facing this is the Sick Children's Hospital, and further up the Avenue is the Toronto General Hospital.

We are left, then, with the picture of a solid, prosperous, conservative city of about the size of Birmingham and with an atmosphere of stability such as we associate with Edwardian England. But this atmosphere is rapidly changing. Recent years have brought in a flow of immigrants from all over Europe, so that the older predominantly Anglo-Saxon population, mentioned at the last B.M.A. meeting in Toronto in 1906, is now well diluted with other races. All the tongues of Europe are to be heard on the street-car, and there are a number of "colonies." On College Street there is a German sector; immediately west of this is a small Italian sector with two Italian cinemas. Around Spadina Avenue is a Hungarian colony; on Queen Street are the Poles, and up Bathurst Street the Ukrainians; on Elizabeth Street are the Chinese citizens.

What does all this imply? What sort of city is this to live and work in? Toronto lies in a climatically favoured part of Canada; winters are neither so severe nor so prolonged as elsewhere. From the business point of view, it is the capital of a province tremendously rich in agriculture and industry. The coming of the St. Lawrence Seaway will make it richer still. If its cultural and educational amenities were compared point by point with those of a city of similar size in the United Kingdom, Toronto would almost certainly emerge as victor. On the point of cleanliness it would win hands down.

Medicine in Toronto

In its early years the town depended on military surgeons for its medical care. The identity of the first civilian doctor is doubtful. A Dr. Glennon, "formerly at one of the finest colleges in Europe," started business in a baker's shop in 1807, but the first comer is usually acknowledged to have been an Edinburgh graduate, Dr. W. W. Baldwin, who found so little work to do that he doubled the parts of lawyer and physician, on one occasion interrupting his pleading to deliver a woman in labour. They were healthy folk

in those days. A contemporary Toronto poet, A. J. Williamson, says:

The doctor only pines an' dees
For want o' wark in Canadie.

The first to practise full-time in York seems to have been the Hon. Christopher Widmer, the father of surgery in Upper Canada, who came in 1816 and had a finger in every pie. He and other ex-military surgeons from the medical schools of Edinburgh, Dublin, and London laid the foundations of medical practice in Toronto. Their first hospital, now the fine Toronto General Hospital, was started in 1820 with money originally intended to provide medals for loyalists. Their first students appeared in the early 'thirties, and the first of these qualified in medicine in 1836.

The history of organized medical education, and indeed of higher education in general, in Toronto is a complicated one. The University of Toronto, which always has been a provincial rather than a municipal university, began as King's College in 1843, as a result of the exertions of a formidable Aberdonian, Bishop John Strachan, who came to Canada as a

Presbyterian schoolmaster and ended up as an Anglican Bishop, having founded a university, an English-pattern public school (Upper Canada College), and a cathedral *en route*. His Anglican University became secularized in 1849; but, nothing daunted, Bishop Strachan founded a rival establishment, Trinity College, in 1851, and this has remained true to the Anglican faith ever since. Visitors this year will have occasion to admire its lovely new chapel, at present under construction. By the 'fifties there were three medical schools, one for each of the universities and a third founded by a brilliant teacher, Dr. John Rolph, who had spent six years in exile for his assistance to Mackenzie in 1837. The resulting chaos was not sorted out completely until the final fusion of all existing establishments in 1903 to form the huge University of Toronto. This university's outstanding contribution to medicine was, of course, the discovery of insulin by Drs. Banting and Best. Their names are now commemorated in the Banting and Best Institutes

Sunnybrook Hospital, on the north-east fringe of Toronto, cares for sick veterans of the world wars.

The Royal York Hotel, the largest in the Commonwealth, where the conjoint B.M.A.-C.M.A. meeting will be held.

for medical research. The university medical faculty has all of the advantages to offer that could be found in any major school in the world. One unusual feature is a department of art as applied to medicine, for the training of medical illustrators.

The university occupies a central and spacious site in the city; it has many fine buildings, notably a gem of a Georgian hall of residence and Hart House, the finest academic club-house in North America, which has to be seen to be believed.

In Toronto, the counterpart of the Royal Society of Medicine is the Toronto Academy of Medicine, formed in 1907 by the fusion of four existing societies—the Medical Society, the Pathological Society, the Clinical Society, and the Ontario Medical Library Association. The Academy has the second best medical library in Canada (McGill, in Montreal, comes first) and a good auditorium, Osler Hall. It lies next door to the Medical Arts Building and close to the offices of the Canadian Medical Association.

The Sights

As Toronto grows, the number of shopping centres grows with it. The original main down-town shopping area lies close to the City Hall, an odd tall Victorian structure about which various opinions have been expressed. Here are the two rival department stores, Eaton's and Simpson's, across the street from each other, with a policeman controlling the surge of shoppers who rush across Queen Street from one store to the other. Why they do so is a mystery, since both stores seem to sell everything one could possibly want to buy. The main stem from this area north is Yonge Street, originally laid out by Governor Simcoe, and now roofing over Toronto's new and efficient underground railway. A mile or so north lies Bloor Street, at right angles to Yonge and just north of the university. If Yonge Street is the Oxford Street of Toronto, Bloor is the Bond Street, full of tempting little shops to delight the womenfolk.

The Royal Ontario Museum lies on Bloor Street, and is well worth a visit by even the most blasé. It is particularly strong in Chinese exhibits. The Art Gallery, opened in

1910 in The Grange, one of Toronto's older houses, is also recommended to visitors. It houses an interesting permanent collection, with good representation of Canadian artists, including the Group of Seven, who established a national school of painting. In addition, the Gallery is most progressive in arranging loan exhibitions. The highlight in 1955 has been the exhibition of paintings by Dutch masters, brought together from Europe and the U.S.A. The Public Library is excellent by any standards. It has a collection of Canadiana and the biggest circulation of foreign-language books to be found anywhere.

The historically minded will not fail to visit Old Fort York, down near the Exhibition Grounds, where it was established in 1793 by Governor Simcoe to protect a town that existed only in Captain Gother Mann's plans. A little to the west, along the lake-shore, lie the grounds of the Canadian National Exhibition, the largest annual exhibition in the world, held each year at the end of the summer. This is also the site of Fort Rouille, now marked only by a plaque. Across the harbour from the waterfront lies the Island, which is really a series of islands cut off from the mainland by east and west channels. This is a favourite spot for picnics, and a pleasant place to spend a peaceful time in. It can be reached by ferry from the waterfront.

No sight-seeing tour of Toronto would be complete without a visit to its fantastic twentieth-century castle, Casa Loma, perched on a hillside and about as incongruous a building as anyone could imagine. It is as if someone had dumped down a Moorish palace in Kensington.

Eating and Drinking

Gastronomes will have no difficulty in obtaining in Toronto the cuisine to which they are accustomed. A word about the drinking customs of the town may be helpful, however. It must be remembered that the battle for temperance rages more fiercely in Ontario than it has for many a year in Britain. To obtain spirits it is necessary to buy a liquor licence at a Government liquor store, and any liquor bought must be taken straight home (that is, for visitors, to the hotel bedroom) and not consumed outside. This applies to wines and beer as well (obtained from wine stores or brewers' retail stores). It is a serious offence to have opened bottles in a car. Cocktail bars exist in certain hotels and restaurants where alcoholic drinks may legally be consumed.

The Arts and Sport

Toronto is noted for its music. The Conservatory, started in 1886, has a proud history of achievement, and now has associated with it the well-known conductor Dr. Boyd Neel, once a medical practitioner in London. The Toronto Symphony Orchestra and the Mendelssohn Choir, with their conductor Sir Ernest MacMillan, are also well known outside Canada.

In Canada the theatre suffers from the enormous distances which touring companies must travel between cities, but there is a professional theatre, the Royal Alexandra, in Toronto, and a repertory unit, the Crest Theatre. To make up for the lack of professional shows there are thriving amateur groups in and around Toronto, including those who perform in the delightful little theatre in Hart House.

There is no need to comment on the cinema, save to mention that the democratic Canadian has one, and only one, price of admission.

Every summer sport practised in the United Kingdom has also its devotees in Toronto—even cricket, which has been edged out in the popular esteem by baseball, played at the Maple Leaf Stadium. Golf courses abound.

Warm Welcome

A warm welcome awaits the visitors from the United Kingdom in Toronto. Let them come with the resolve to enjoy Canada and to learn something of the country and its dynamic, friendly people. From my own experience, I can assure them that they will not be disappointed.

Queen's University, Kingston. Photo by the Photographic Survey Corporation Ltd., Toronto, Canada.

TOURS FROM TORONTO

[FROM A SPECIAL CORRESPONDENT]

It would be a pity to travel all the way to Canada without seeing more than Toronto. Restrictions unfortunately preclude free indulgence in the type of tour advertised in connexion with former B.M.A. meetings in Canada, such as the trip to Vancouver through the Rockies or the digression into the northern United States. It is not too much to hope, however, that a number of participants will find it possible to spend a few more days in Canada after the meeting and make some modest excursions into the beauty spots of Ontario. It is also hoped that the following brief outline of possibilities for such excursions may prove helpful to prospective tourists.

There are, of course, many other delightful holiday areas in Eastern Canada, both in Quebec and in the Maritime Provinces, and visitors may, for example, prefer to go direct to Montreal or Quebec and use either of these cities as a touring centre, in which case a fascinating introduction to French Canadian culture awaits them. It is nevertheless assumed that visitors with only a few days to spare will not wish to spend much time on travel, but will concentrate on areas within, at the most, 300 miles of Toronto. It should be emphasized that the Province of Ontario has an enthusiastic and efficient touring service, of a scope almost unknown in Britain, and is prepared to give very detailed advice on all tourist requirements. Prospective tourists should write to the Department of Travel and Publicity, Province of Ontario, Queen's Park, Toronto, Ontario, for information on such matters as accommodation.

Visitors from Britain may find themselves somewhat handicapped in touring Canada, since much holiday travel on the American continent is based on the assumption that the tourist has a car. Most tourists

nowadays used roadside motels rather than the older type of hotel, and, whereas accommodation in the centre of a town is likely to be difficult and perhaps even primitive, clean and highly satisfactory motel cabins are seldom lacking along the more-travelled highways. If, therefore, the visitor can beg, borrow, or hire a car (there are several car-hire organizations in Toronto, and the rates are not too ruinous if several people share a car), his way will be made much easier. If not, he must rely on the train and the long-distance bus. All the areas mentioned below can be reached by public transport, and it should be remembered that the express motor coach in Canada really is an express (the Toronto-Barrie bus covers 55 miles in 1 hour 20 minutes).

Two more points should be noted in connexion with this article. Firstly, the reader should have a map of Ontario beside him. Incidentally, no one buys road maps in Canada: the filling stations give them away on request. Secondly, it is not proposed to devote much space to cities. The scenic glory of Canada is the work of nature, not of man. For those who must have a sight of bricks and mortar, however, there are suggestions below, such as visits to Ottawa, Kingston, and London (as a handy headquarters for one or more evenings at the Stratford Festival).

Ottawa and Kingston

Ottawa, the federal capital, is 280 miles by road from Toronto, and accessible by plane, rail, or bus. It stands on the Ontario bank of the Ottawa River, facing the province of Quebec, and owes its existence, like Canberra in Australia, to inter-city rivalry. Queen Victoria chose the then small town for the federal capital in 1857 to put

The mouth of the St. Lawrence, showing Old Fort Henry in the foreground and the city of Kingston in the background. Photo by Dick Herrington.

an end to the rival claims of Montreal, Kingston, and Toronto; hence all that is worth seeing in Ottawa is comparatively modern. The chief showplace is the group of Gothic buildings on Parliament Hill which house the Federal Parliament. Visitors are conducted through the building and up to the top of the Peace Tower, which commands a very fine view of the city and its beautiful setting, rich in parkland. There is a tourist bureau in the city, at which information on other sights can be obtained. The latter include the public archives, the Royal Mint, the National War Memorial, and the National Art Gallery, which has a good collection of Canadian paintings. The leading hotel is the Château Laurier, which sets a very high standard. Visitors are warned, however, that Ottawa is notorious for the scarcity of hotel accommodation, and booking well in advance is essential. A four- or five-day tour might be arranged from Toronto, with a first stop at Peterborough, as a centre for the Kawartha lakes (q.v.), and a second at Ottawa. The Peterborough-Ottawa road passes through some lovely and slightly wild country, and runs close to at least one little town worth an hour's visit. Perth, 58 miles from Ottawa, looks exactly like a small and neat Scottish town in pleasing grey stone set down in the midst of gentle countryside, which might also be Scottish. As might be expected, the town was settled by Scots, who have kept up the traditions of their native land. Although the Scot is ubiquitous in Ontario, there are certain enclaves where he is openly dominant, as in the little town of Fergus, in Western Ontario, where Highland Games are an annual event.

The return journey from Ottawa to Toronto might be made via Brockville, on the St. Lawrence. There are direct rail and motor-coach services between these towns, and Brockville, a pleasant and prosperous-looking town, is a centre for the Thousand Islands area (q.v.). The Peterborough-Ottawa highway and the Ottawa-Smith's Falls-Brockville highway both skirt the Rideau Lake district, a fine centre for fishing, swimming, or canoeing. The Rideau Lake district is traversed by the 126-mile Rideau Canal, completed in 1832 and linking Ottawa with Kingston. A six-day canoe trip along this canal is a possibility. The whole area is quiet and unspoiled.

Ambassador Bridge, linking Windsor, Ontario, and Detroit and Canada's greatest border point of entry.

Aerial view of Stratford, Ontario.

There is a charming road from Brockville to Kingston (about 50 miles); about 17 miles from Kingston the road forks, and the left-hand route runs through lovely scenery close to the point where the St. Lawrence leaves Lake Ontario. Kingston itself is an old university and military town dating from 1784, on to which a modern and unpleasing industrial area has been grafted. To appreciate the city it is necessary to turn aside from the completely characterless main street and look at the campus of Queen's University (1841), St. George's Cathedral (1825 on), and City Hall (1843). To the east, across the winding Cataraqui River, lies Old Fort Henry, built in 1832 and much visited by tourists.

The 165-mile road between Kingston and Toronto is pleasant enough, and is punctuated by a number of mellow small towns, of which Port Hope has perhaps the most character; but anyone finishing this trip by rail will have missed little.

London and Stratford

The opening of the current Shakespearean Festival at Stratford, now well known and well established, follows closely on the end of the B.M.A.-C.M.A. Annual Meeting. Tyrone Guthrie is sharing the direction this year with Michael Langham. The opening dates are: *Julius Caesar*, June 27 and 30; *Oedipus Rex*, June 28; *Merchant of Venice*, June 29 and July 1. A musical festival with Boyd Neel as conductor and internationally famous soloists begins on July 9. Festival information is obtainable from Stratford Shakespearean Festival, 109, Erie Street, Stratford, Ont.

Stratford is a small town 100 miles west of Toronto, of no particular cultural significance until, a few years ago, a local citizen had the inspiration to start an annual Shakespearean Festival, and the wit to see that nothing less than the best would prosper. Alec Guinness and James Mason are among those who have crossed the Atlantic to lend a hand in this commendable venture. While it is possible to visit the festival from Toronto, it would be much less fatiguing to make the city of London, 40 miles away, a headquarters. London, which lies on the little River Thames (as Stratford does on the Avon), was originally intended to be the capital of Upper Canada, but Toronto somehow displaced it. The city has on its north side the University of Western Ontario, including one of Ontario's

Some of the thousand islands of the St. Lawrence. Photo by Clint Melville.

four medical schools (the others are at Toronto, Ottawa, and Kingston), and offers the best accommodation and shopping facilities in the area. Pleasant bathing beaches on Lake Erie are to be found at Port Stanley, only 25 miles south of London.

The Muskoka Area

It is not until you fly over Canada that you realize how much of the country is under water, and why the birch-bark canoe is particularly associated in the mind with Canadian travel. It has been estimated, for example, that there are two million lakes in Ontario alone, so that it is hard to find a holiday resort that is not associated with a lake. To the north and north-west of Toronto there is a sort of horseshoe of lakes. Starting about 60 miles north of Toronto, the western end of the horseshoe begins at Lake Simcoe and its northern continuation, Lake Couchiching. Their close proximity to the city means that most of the shore has now been bought up for summer cottages, and the visitor will probably be better advised to continue north to Gravenhurst, just over 100 miles north of Toronto, easily reached by rail or bus, and the gateway to the next part of the horseshoe, the Muskoka Lakes. The top of the horseshoe lies north-east of Gravenhurst and is known as the Lake of Bays area; the horseshoe then sweeps down to the south-east through the Haliburton Highlands area (the best choice for those wanting to get off the beateh track) to the Kawartha Lakes area, more or less ending at the Toronto-Ottawa highway.

The Muskoka area is perhaps the most popular of these playgrounds for Torontonians, and the most developed. Lying at an altitude of about 1,000 ft. above sea level, there is a chain of three lakes with small resorts all round, and lovely scenery everywhere. It is possible to take a 100-mile steamer trip through the lakes, beginning and ending at Gravenhurst, and lasting all day. It is also possible to find most other forms of enjoyment somewhere in the area, such as swimming, boating, fishing, golf, tennis, and riding.

Lake of Bays

This area takes its name from the largest of the lakes it contains. To reach it the visitor must continue north by road or rail from Gravenhurst for 35 miles to Huntsville, the only town in the area, from which hotels of varying degrees of seclusion can be reached by taxi. The recreations are, as in the Muskoka area, fishing for bass and trout (perhaps with better success than in the more heavily fished south), boating and canoeing, and swimming.

Just south of the Lake of Bays there is one phenomenon much frequented by medical associations—indeed, some of the more rurally minded societies will be meeting there this June. This is the smart and luxurious Bigwin Inn, with 300 rooms and all indoor and outdoor amenities. Bigwin is on an island, and has to be reached by car and ferryboat from Bracebridge, a small town between Gravenhurst and Huntsville. For those who do not want to wear formal clothes in the evening, there are many simple hotels in the area, offering peace without dance bands.

Algonquin Park

The visitor who has got as far as Huntsville now has two alternatives (indeed, three, if he wants to extend his trip still further north, into the wilder country near Lake Nipissing). He may swing round to the east and then south to the Highlands of Haliburton as a preliminary to returning to Toronto via the Kawartha Lakes, or he may go somewhat north and east to Algonquin Provincial Park. This is a Government game reserve, containing 2,700 sq. miles of wilderness in its natural state, and a wonderful area for the photographer. Fishing is permitted but not hunting, so that deer, bear, moose, and beaver go about their business without fear. A railway line and one highway run through the southern tip of the Park. There are hotels and cabin accommodation in this southern strip. If you want to explore the Park there are only two ways of doing so—by canoe or on foot. It is possible to hire a canoe and all the necessities for camping at the Park Headquarters. It is also possible to hire a guide, and have a canoeing trip with portages from lake to lake planned for you. The most venturesome are not likely to come to harm without a guide, for maps are available and portages clearly marked, and in July the wilderness is by no means solitary.

Scene typical of the Muskoka area. Photo by Ontario Department of Lands and Forests.

Haliburton Highlands

The Highlands of Haliburton, which contain another 500 lakes or so, lie south of Algonquin Park and are worth a visit for three good reasons: there are even fewer people about than in the areas mentioned above; the scenery is, if anything, lovelier than anywhere else in Ontario; and the climate is invigorating. All this, it should be added, within 100 miles or so of Toronto. There are only two villages in the area—Haliburton and Minden—and everything is still very unsophisticated. The Highlands are recommended for the walker, the photographer, and the fisherman; swimming, sailing, and canoeing are also available. Lack of sophistication does not mean lack of accommodation, and there is a Highlands of Haliburton Tourist Association to help.

The Kawartha Lakes

South of the Highlands of Haliburton lies yet another lake area, the Kawartha Lakes, on an old Iroquois trail. This area is more developed than the Highlands and has two fair-sized towns—Peterborough (on the Toronto-Ottawa highway) and Lindsay—on its doorstep. In its centre lies the village of Bobcaygeon, with good accommodation and a very fishing-minded community. The lakes are connected by the Trent Canal, making canoe trips easier for the lazy. The scenery is well up to standard, and not as wild as further north. The main road south from Haliburton Highlands runs through this district to Lindsay, which is about 80 miles from Toronto by good roads. All these places mentioned are also accessible by rail.

The Thousand Islands

This area was mentioned in connexion with the return journey from Ottawa to Toronto via Brockville and Kingston. The thousand islands of the St. Lawrence are scattered through the river from Kingston to Brockville. Some are privately owned and have houses on them; some are mere tufts of grass sticking out of the river; some have fortunately been acquired by the Provincial Government as a national park and may be camped and picnicked upon. Their presence confers an exceptional beauty upon the river, and the occasional appearance of rapids adds to the attraction. The islands may be visited by one of the innumerable boats plying for hire either from Brockville or from Gananoque, a little holiday resort about halfway between Brockville and Kingston which lives for and on the river.

Conclusion

If any of the areas mentioned above seem particularly attractive to a prospective visitor, fuller information about it and a list of accommodation can be obtained from the Public Relations Officer, Ontario House, Charles II Street, London, S.W.1, or Department of Travel and Publicity, Province of Ontario, Queen's Park, Toronto, who are ready to advise on anything to do with holidays, from canoeing routes to non-allergenic areas. Fishermen in particular will be glad of the guidance this department can give.

INTERNATIONAL SOCIETY OF UROLOGY TENTH CONGRESS

[FROM A SPECIAL CORRESPONDENT]

The tenth Congress of the International Society of Urology was held at Athens from April 10 to 18, under the presidency of Professor OECONOMOS. The subjects for discussion were the treatment of carcinoma of the prostate, renal angiography, and the post-operative management of urinary lithiasis.

Prostatic Cancer

The discussion on carcinoma of the prostate revealed a cleavage of opinion between those who advocated radical

surgery and those who supported oestrogen therapy. It was agreed by all that the correct diagnosis in the early stages of the disease was difficult and that surgical intervention was likely to be successful only when the growth was mobile. There were some speakers who stated that they treated their cases in the first instance with hormones, and it was only when these failed they resorted to prostatectomy. Others pointed out that prostatic carcinoma was a chronic disease, and even without any treatment patients would live many years. There was no known cure for cancer of this organ, and both surgery and hormone therapy, though prolonging life, were palliative methods. FISH, of New York, claimed good results with massive doses of oestrogen, 500 mg. per day. MIGLIARDI, of Turin, considered that castration was a humiliating operation even in the elderly, and that synthetic hormone therapy had taken its place. Two British members, H. P. WINSBURY WHITE and J. D. FERGUSON, made important communications. The latter described the results of adrenalectomy followed by cortisone therapy. This was one of the best scientific papers presented to the congress. There was no support for radiotherapy in cancer of the prostate, and treatment by isotopes was considered to be still in the experimental stage.

Renal Angiography

The reporters on renal angiography were J. C. DOS SANTOS (Lisbon); E. W. RICHES and I. H. GRIFFITHS (London); OLSSON, LINDBLOM, and SELDINGER (Sweden); and FABRE (Toulouse). All of them produced excellent papers. DOS SANTOS, the son of the first surgeon to introduce arteriography, claimed that complications could be avoided and were entirely due to errors of technique. RICHES and GRIFFITHS considered renal angiography a safe and simple procedure, but only an accessory method of diagnosis. It did not involve the use of costly apparatus. They preferred the lumbar route to the femoral, and advocated for the contrast medium 70% diodone, an organic iodine solution, whereas Dos Santos favoured 100% "shiodan." OLSSON preferred diodone. His paper should be read by all interested in this subject. LINDBLOM and SELDINGER pointed out that renal angiography had its limitations even in differentiating between renal cysts and tumours. FABRE stressed the importance of team-work. In the subsequent discussion the consensus of opinion was that the procedure is comparatively safe, and there was general agreement with the views expressed by Lindblom and Seldinger. N. OECONOMOS, in a thoughtful paper, stated there were only two indications for renal angiography: as an aid to the diagnosis of tumour, and to determine renal function.

Urinary Calculus and Other Subjects

The discussion on the post-operative treatment of urinary lithiasis was disappointing. There was a repetition of all the well-known methods which have been tried to prevent the recurrence of stones. Nothing new emerged from the various papers presented by urologists from all parts of the world. LEWICKI, of Poland, stated that he could control proteus infection of the urinary tract by sulphafurazole ("gantrisin"). TAYLOR, of New York, claimed that with "solution G" most phosphatic stones could be dissolved. On the other hand L. N. PYRAH, of Leeds, got good results with aluminium hydroxide. His paper was an interesting one. The other British urologist to take part in the discussion was H. P. WINSBURY WHITE. FEY, of Paris, in his communication pointed out that the calculus was not the primary condition, and that, apart from sepsis, mechanical obstruction, and parathyroid disease, we did not know the origin of the illness.

On the fourth day various short papers were read and a number of films shown. This in some respects was the most instructive session of all, the films in particular being excellent. T. I. CHAPMAN (Glasgow) showed his film, already known to British audiences, of the punch operation for prostatic obstruction. His running commentary was excellent, and that and the film were well received. SERRALLACK'S

(Barcelona) film of perineal prostatectomy caused much amusement, as the speed of its presentation was such that the whole operation appeared to be completed in five minutes, but every detail of it could be easily followed.

Fey (Paris) and H. G. HANLEY and J. J. STEVENSON (London) demonstrated the use of the image intensifier in urology. Hanley and Stevenson's film was outstanding and was one of the highlights of the congress. It gave a remarkable picture of the movements of both the normal and the diseased ureter.

For the first time since the war representatives of Russia, Czechoslovakia, Poland, and West Germany were present at the congress. Your correspondent was informed by the President of the Polish Society of Urology that in his country specialists are allowed to accept fees for private consultations, but all operations are free and have to be performed in the State hospitals. No drugs other than streptomycin are available from Russia.

Following the resignation of Dr. GEORGE GILBERT SMITH (Boston, U.S.A.), Mr. A. CLIFFORD MORSON (London) was elected President of the International Society of Urology.

During the congress there were the usual social engagements for the members and their ladies. About 300 were present at the banquet. Professor OECONOMOS presided, and in his speech paid tribute to British urology. Mr. CLIFFORD MORSON proposed his health. After the congress there were visits to islands in the Aegean, and a few hours were spent at Crete, Rhodes, Cos, Delos, and Mykonos. The meeting was well organized by our Greek colleagues, to whom the thanks of all members are due for their hospitality and unflinching courtesy.

Future Arrangements

At the meeting of the general assembly it was agreed that the congress in 1958 should be held in Stockholm under the presidency of Professor Hellström and that the following subjects should be discussed: the bladder in neurology; the use of intestinal grafts in urology; and essential haematuria.

HYPNOTISM IN DERMATOLOGY

DERMATOLOGISTS GROUP DISCUSSION

A meeting of the Dermatologists Group of the Association was held at B.M.A. House on April 21, when a brief discussion took place on the impact of psychiatry on dermatology, with special reference to hypnotism. Dr. D. I. WILLIAMS was voted to the chair.

The discussion was opened by Dr. E. A. BENNET, speaking as a psychiatrist and a member of the subcommittee which produced the recent B.M.A. report on hypnotism (see *Supplement*, April 23, p. 190). The subcommittee, he said, was appointed following considerable publicity, in the press and elsewhere, concerning hypnotism. Medical men were being asked questions by their patients about the efficacy of hypnotism, and they sought guidance from the Association as to the correct attitude towards hypnotic treatment and its applications. The subject was regarded as mysterious by some; others looked askance at it—not without reason, as hypnotism had hovered for years on the borderline of medical respectability.

The B.M.A. Report

The subcommittee had examined the past and, in particular, the recent history of hypnotism, and discussed its use with physicians who had observed hypnotic treatment and with psychiatrists who had personal experience of its clinical applications. They reached the conclusion that no one—not even enthusiastic hypnotists—knew exactly what hypnotism was. Nevertheless, it was clear that a great deal was known of its value and limitations in medical practice and in dentistry. It seemed clear, moreover, that the doctor-patient relation in hypnotic therapy was of special importance—as it was in other forms of psychological treatment.

Further, suggestion was known to play a part, and often a decisive one, in certain types of medical treatment, perhaps despite the doctor's intention. Certainly a common element in different and even in apparently opposite methods of psychological treatment was the relation formed between doctor and patient.

Dermatology was no exception to this common experience, said Dr. Bennet, and suggestion, wittingly or unwittingly, was an element in treatment. Hypnosis was an extension of suggestion, and in no essential way did it differ from it. It had been used with success in the treatment of skin complaints. The direct (as opposed to the indirect) use of suggestion was often ineffective because the therapist gave the suggestion in an expectant but haphazard fashion. Suggestions, he continued, should always be spontaneous, and set phrases were best avoided. The therapist must be sincere: it was worse than useless to give suggestion whose value was doubted. And concrete suggestion was far more valuable than abstract suggestion, as it enabled the patient to form a mental picture, for example, of the disturbed or diseased part of his body.

An opinion widely held but without foundation was that the hypnotist possessed a special "gift"—the hypnotic eye or some esoteric endowment withheld from lesser mortals. There was no mystery about the induction of hypnosis and no special skill was required. Indeed, one of the dangers of hypnotism lay in the fact that it was so simple. Consequently it was seized on by charlatans who had no sense of responsibility for the patient and no regard for the medical code of ethics. The report on hypnotism advised that hypnosis should be in the hands of medical men trained to recognize the characteristics of over-dependence. Research on this topic was required. The subcommittee had no clear evidence upon the extent of the danger or the quality of the danger to a patient which some psychiatrists claimed inevitably followed the induction of hypnosis.

Psychiatry in the Skin Department

Dr. HUGH GORDON, physician in charge of the skin department at St. George's Hospital, described a psychiatric attack on skin patients, mostly chronic, conducted from June, 1951, for roughly 2½ years. The work resulted from Dr. Kathryn Cohen's experience in her appointment as junior registrar. By taking more time and showing more interest in the chronic patients she came to the conclusion that many of the cases were primarily skin reactions to emotional stress. It was determined to collect 100 or so cases, keep careful records, and follow them up. Altogether records had been obtained of 144 patients. Hypnosis was started in the form of simple suggestion. Varying degrees of hypnotic trance were obtained, and during the hypnotic state the suggestion was given that the skin condition would resolve and return to normal and that irritation, if present, would go. In most of the conditions treated pruritus was a marked feature, and it was certainly found that the anti-pruritic effect of simple hypnosis was often very striking.

It soon became apparent that under hypnosis the doctor-patient rapport was considerably enhanced. Patients became much more willing, so to speak, to "let their hair down." Consequently psychotherapy was added to hypnosis. The largest group of cases was atopic eczema, and at the outset they had one of those possibly therapeutic freaks in which the direct effect of hypnosis was surprisingly good. A boy of 12, a constant sufferer from eczema and asthma from the age of 2, was completely cured of both in about six sessions, and had remained clear for 2½ years. Later a number of cases were encountered which had proved extremely resistant.

During the last 18 months, continued Dr. Gordon, Dr. Cohen had felt that in many cases the underlying psychosis required lengthy treatment, and such patients had been referred to the Cassel Hospital.

It was too early as yet to assess the results. Two cases, however, had taught them an important lesson. An exacerbation of the skin condition was expected during therapy,

but it occurred so drastically that these two patients had to be readmitted to the general wards. The raised temperature and grave superficial sepsis did, in fact, clear up very quickly. But this incident illustrated the necessity of one department being able to tackle the patient throughout.

There were four cases of dermatitis herpetiformis among those treated. Two were described as failures, but in fact broke off treatment for other reasons. In the other two very striking successes were obtained, said Dr. Gordon. One of them with a 10-years history was controlled by arsenic, but developed severe and obscure retinal lesions. On stopping the arsenic the latter improved, but the dermatitis herpetiformis relapsed. Both skin and eye lesions cleared up rapidly under hypnosis and psychotherapy, and had remained so for two years.

What part did hypnosis *per se* play in achieving these results in dermatological cases, such as they were? Had the results obtained been due to a combined dermatological-psychiatric approach with perhaps a slightly new slant? He himself saw the patients before, during, and after treatment. He did practically none of the treatment himself, and he had tried so far as possible to play the part of an unprejudiced observer. He believed it was possible—indeed probable—that the psychiatric factor was of aetiological importance in varying degrees from 100% down to 50% in a wide range of common skin disorders. In the so-called frictional type he thought it might well be 100%. But even if it was felt that the psychological factor was likely to be a high percentage, most dermatologists would agree that they were justified in trying purely symptomatic treatment, such as local applications, sedation, x rays, or hydrocortisone, which last had certainly proved to be sometimes extremely effective in cases of localized neurodermatitis.

If it was felt that cases must be treated from the psychiatric angle, then there were two alternatives for the dermatologist: either to refer the patient to the psychiatrist or to attempt the treatment himself. They would all choose to refer the patient, but this might mean an undue influx in the psychiatric department. Dr. Gordon concluded that hypnosis appeared to be of value in treating these skin patients, and he felt that dermatologists should undertake a greater part of the psychiatric treatment themselves.

In the course of a very brief general discussion—brief because of the imminence of another meeting—Dr. KATHRYN COHEN gave some details of her experience at St. George's, bearing out Dr. Hugh Gordon's statements.

In reply to Dr. C. H. WHITTLE, Dr. BENNET said that transference inevitably occurred, but that something similar to it occurred in every relationship of a confidential nature, medical or lay.

Dr. WHITTLE said that a great deal of the difficulty of getting patients into the mood to be approached by a psychiatrist might be overcome by having the psychiatrist in the room at the same time as the patient was being seen by the dermatologist. This double approach had worked well, but was time-consuming.

Reports of Societies

DISEASES FROM PETS

On April 20 the Section of Comparative Medicine of the Royal Society of Medicine met to discuss "Some Diseases of Pets Transmissible to Man."

Psittacosis

Professor S. P. BEDSON, F.R.S., opened the meeting with an account of psittacosis. Although, he said, it had been recognized for eighty years that parrots suffered from a disease to which man was susceptible, it was not until the investigations of the pandemic of 1930 that the connexion was firmly established by the isolation of the same virus from human and psittacine cases. It was now known that

there was a group of psittacosis viruses with similar morphological and staining characteristics and sharing an antigen. A wide variety of avian species were naturally susceptible, and both domestic and wild birds had been found to harbour the virus. Atypical pneumonia in the Faroe Islands had been shown to be due to psittacosis virus, the infection coming from fulmar petrels, and many human infections originating in pigeons, turkeys, ducks, domestic fowls, pheasants, and other birds were on record. Mammals, such as the cat, sheep, cattle, and laboratory mice, had also been shown to be the natural hosts of related viruses, but these mammalian viruses appeared to be less closely related to the avian strains than the latter were to one another. There was no good evidence that these mammalian viruses produced infections in man, though outbreaks of a febrile exanthema among natives in the Belgian Congo seemed to be connected with an infectious disease in cattle, sheep, and goats often resulting in abortion, and a psittacosis-like virus seemed to be responsible for both.

All the avian strains seemed capable of producing disease in man, went on Professor Bedson. As a source of human infection psittacine birds were of more importance than the non-psittacine. There were several reasons for this. For one thing parrots and their like lived in closer association with man than do the other avian hosts of the virus. Psittacine birds responsible for human cases were usually recently imported birds suffering from acute disease as a result of the conditions under which they were transported, and acutely ill birds excreted vastly more virus than healthy carriers. Lastly the strains of virus from psittacine birds seemed more virulent for man than the so-called ornithosis strains. Laboratory infections had been numerous and passage from man to man occurred occasionally; a number of cases gave no history of even remote contact with an infected bird. Under natural conditions infection in the bird was nearly always silent, though occasional outbreaks of disease did occur. The young birds were infected by their parents whilst in the nest, and the virus was excreted in the droppings. Spread of infection to man was through the air in the form of dried droppings, though direct contact with infected birds was occasionally responsible.

Attempts had been made in this and other countries to protect man against psittacosis by imposing controls on the importation of parrots, but realization that non-psittacine birds harboured the virus resulted in the ban being lifted in some countries. As a consequence there was a sharp increase within a few months in the number of human cases of psittacosis in England, and the disease appeared for the first time in New Zealand, a country which had previously been free. The ban was soon reimposed.

Salmonellosis

Dr. A. BUXTON discussed the incidence of salmonellosis among pets. The organisms were widely distributed among animals, and surveys had shown an infection rate of about 1.5% among domestic dogs and cats. As many as 18% of the animals in kennels might be found to be infected, probably owing to the presence of salmonella organisms in their food. For example, 26 out of 98 samples of a proprietary preparation of dog food containing meat had proved to be infected. Children were particularly liable to infection because they tended to handle and fondle pets more than adults.

In America many salmonella types had been recovered from animals, but in England only a few had been identified, of which *S. typhi-murium* was the most important. Dogs might carry several different types without showing symptoms, while in contrast over 40% of clinical infections were due to *S. typhi-murium*. Pigeons were salmonella carriers, and occasional human cases had been traced to this source. Tortoises were also known to be infected, but the danger of human infection was probably slight. There was little evidence available about other pets, but all were probably susceptible.

The danger of human infection must not be over-emphasized, said Dr. Buxton in conclusion, but it was necessary

to stress the importance of hygiene when dealing with pets, especially during epidemics, and the need for eradicating salmonella from their food.

Parasitic and Fungal Diseases

The last contribution was by Mr. G. C. BRANDER, who spoke on parasitic and fungal infections. The development of insecticides and fungicides had done much to reduce the incidence of infection, he said, but there was still need for liaison between the doctor and the veterinary surgeon. It was often easy to overlook the animal while treating the infected child. Immunity to parasites undoubtedly increased with age, but host resistance could be lowered by other infections and there were considerable individual variations in response. Parasitic infections were liable to become eczematized if not treated early, and, in the case of mange, irritation might remain for a considerable time after the mite had been eradicated. Individual lesions due to fungi were often difficult to spot in animals, and tended to be situated deep in the hair follicle. Thorough treatment of the whole animal was important, but it should be borne in mind that cats were particularly sensitive to many types of drug.

In the discussion which followed it was stressed that, with the possible exception of fungal and leptospiral infections, human infection from pets was relatively infrequent, even when attendants were in contact with outbreaks of disease among such animals as monkeys and poultry.

RESISTANCE TO INFECTION

Metabolic and Other Factors

Dr. RENÉ DUBOS, of the Rockefeller Institute, New York, was the guest speaker at a meeting of the Section of Pathology at the Royal Society of Medicine on April 25. After welcoming him, Professor L. P. GARROD, president of the Section, invited Dr. Dubos to open the meeting with a paper entitled "The Effects of Metabolic Factors on the Infectious Process."

Starvation and Susceptibility

Dr. DUBOS began by describing variations in the rate of growth of *Mycobacterium tuberculosis* in mice whose metabolism had been artificially disturbed. Dr. Dubos said that he had produced metabolic changes in the following ways: by giving thyroxine and dinitrophenol in doses sufficient to prevent weight gain; by adding sodium citrate and hexabutyrate to the standard diet; and, lastly, by depriving the mice of food for 36 hours at a time. All these measures had increased the susceptibility of the mice to tuberculosis as well as to other bacterial infections.

The effect produced by fasting was not merely due to diminution of caloric intake. It was rapidly reversible: within 48 hours of giving the full diet, resistance returned to the normal level. Neither was it due to loss of weight, since diets partly deficient in protein which prevented weight gain did not affect resistance. All the experiments using *M. tuberculosis* were measured by means of survival times.

Mice starved for 36 hours before injection were more susceptible to a heat-killed suspension of Gram-negative bacilli or a toxin derived from *M. tuberculosis* than were normal mice. By starving for 48 hours and subsequently feeding on a protein-free diet the susceptibility was increased tenfold. From this Dr. Dubos concluded that altered tissue metabolism enhanced susceptibility.

In one experiment, using *Klebsiella pneumoniae* Group C, there were two groups of mice. One, the control group, was fed on the standard Sherman diet. The other group was fed for seven days on a protein-free diet and was completely starved for 24 hours before the intravenous injection of the organism. Recovery rates of the organism ten hours after injection were several thousand times greater in the test than in the control group. This type of experiment was repeated in many circumstances in an attempt to find a direct cause in the diet.

In most of these experiments, staphylococci were the organisms used. If, 48 hours after injection, food was withdrawn for a period of 36 hours rapid multiplication of the organisms took place. Substitution of carbohydrates for the normal diet also hastened death of the animal. Where normal mice showed a steady decline in the number of recoverable organisms, mice whose weight gain was retarded by thyroxine showed a rapid rise in the number of organisms and subsequent death. Dr. Dubos interpreted this as an interference with the metabolism of the cells of the reticulo-endothelial system.

The standard Sherman diet restored resistance in 48 hours. However, diets containing vitamins, minerals, amino-acids, carbohydrates, and fats, but deficient in a "complete" protein were found to be inadequate. Not every protein was found to restore resistance, but casein did so in every case.

Possible Mechanisms

Dr. Dubos had confirmed previous work showing that mice were rendered more susceptible to infection by the use of "Krebs cycle poisons." Susceptibility to infection was increased by procedures resulting in at least three metabolic disorders—depletion of intracellular glycogen, reduction in the glycolytic activity of inflammatory cells, or an increase in the tissue levels of certain polycarboxylic acids and ketones. Interference with ordinary antibody responses could not account for the increased susceptibility of the mice, as the huge differences in tissue bacterial population were evident long before any immune response could have occurred. Furthermore, starvation did not lessen the immunity of vaccinated mice.

In conclusion, Dr. Dubos expressed his belief that some of his findings might have a wider epidemiological bearing. His experiments illustrated, for example, that susceptibility to infection could change rapidly and reversibly, independently of the immunological state, merely in response to physiological stresses of the kind encountered in everyday life. The findings in mice also suggested that the sugar-vitamin-amino-acid mixtures so commonly given to patients in emergency situations might not be the best for restoring resistance. Nor were the food factors essential for growth, reproduction, and other normal physiological processes necessarily the most important in promoting resistance to infection.

The Immediate Vascular Reaction

Professor A. A. MILES, director of the Lister Institute, London, said he proposed to discuss an earlier stage of infection, more physiological than biochemical. In an attempt to assess the value of the defence reaction, using guinea-pig skin, he injected a known dose of organism and assessed the effect of local modifiers by the subsequent size of the lesion. The most useful modifier was found to be adrenaline in a dose whose sole effect was two to three hours' local ischaemia.

Arguing from the degree of enhancement of infection produced by the adrenaline, the early vascular reactions inhibited by the adrenaline were responsible for a 99% to 99.9999% kill of the injected bacteria, according to the species of pathogen used. Moreover, this defence reaction, which determined the maximum size of the lesions in the skin, could be shown with many organisms to be complete within a decisive period of four hours. In infections with slower-growing mycobacteria, as might be expected, this decisive period was much longer.

Professor Miles also produced evidence suggesting that in allergic animals, though delayed allergy promoted infection with tubercle bacilli, the early exudation resulting from the anaphylactic element of tuberculin allergy might have survival value for the animal.

Importance of Insulin

Dr. D. A. LONG, of the National Institute for Medical Research, Mill Hill, said that bacterial infection was a cause

of "stress" which induced a profound change in hormone balance in the rat and adrenocortical stimulation in man. The guinea-pig, went on Dr. Long, responded to "stress" like man, was readily sensitized to tuberculin, and produced antitoxin that quantitatively and qualitatively resembled that produced by man. Also, loss of body weight, and suppression of gamma globulin and antitoxin synthesis, were not induced by large doses of cortisone in man or guinea-pig, although observed in the rat, rabbit, mouse, and ferret.

Dr. Long said that he had shown thyroxine-treated guinea-pigs to be more sensitive to intradermally injected tuberculin and to produce more diphtheria antitoxin than control animals. Cortisone depressed sensitivity to tuberculin in both thyroxine-treated and control guinea-pigs, but was without significant effect on antitoxin synthesis. Insulin increased sensitivity to tuberculin, but, owing to the compensatory phenomenon induced, a direct study of the effect of insulin on antitoxin production could not easily be made. However, partial pancreatectomy abolished both hypersensitivity and hyperimmunity resulting from treatment with thyroxine.

From a study of the interrelationships of these effects, Dr. Long concluded that insulin output was the most important single hormonal factor that influenced immune and allergic responses of the guinea-pig to bacterial infection.

Role of the Gut Flora

Dr. G. G. MEYNELL (Postgraduate Medical School) discussed two factors influencing the dose of a highly streptomycin-resistant strain of *Salm. typhi-murium* required to infect mice by the oral route. The acidity of the gastric contents did not always play an important part under experimental conditions. By giving 50–1.6 mg. streptomycin to mice 24 hours before challenge by this strain of *Salm. typhi-murium* he found a great increase in the subsequent numbers of the organism in all parts of the gut. He also found that 50 mg. streptomycin greatly increased the susceptibility of mice to infection, the LD50 being reduced from $>10^8$ to two organisms, so confirming the work of Bohndorff and her colleagues. Both findings were presumably due to the action of streptomycin on the normal gut flora. Dr. Meynell also described a spontaneous epidemic due to an oxytetracycline-resistant strain of *Proteus* which occurred in a mouse stock under treatment with oxytetracycline and which was ended by withdrawing the antibiotic.

In the discussion Dr. DUBOS criticized Dr. Meynell's use of hydrochloric and citric acid as a suspending medium, suggesting that citric acid had a protective action on the organism. He quoted experiments showing that pH, *per se*, was of only relative importance and it was the anion which exerted a specific effect. He suggested that the resistance was due to the metabolic state at the site of infection. Accumulation of carboxylic, keto- or lactic acids could completely change the environment. Immunity processes could not be independent of the metabolic state. They acted by accelerating and focusing the inflammatory state at the site of infection.

Professor GARROD pointed out that gastric acidity was of importance in the destruction of organisms given by the oral route. Professor CRICKSHANK agreed, and suggested that in view of this the assessment of infection was more easily controlled by using the conjunctiva as the site of infection.

Dr. DUBOS regarded the actual dose as of less importance than the nutritional state of the mouse, which he claimed varied greatly in a short time. Some discussion followed about the suitability of the mouse as an experimental animal. When asked if he considered that one common factor was operating at the site of infection, Dr. Dubos said that indeed many apparently unrelated stresses might operate through only one or a very few essential mechanisms. For example, many various types of metabolic or toxic disturbances could cause a depletion of glycogen followed by failure of phagocytosis and loss of lactic acid production leading to a decrease in resistance.

Correspondence

Tuberculosis After B.C.G. Vaccination

SIR,—In your leading article on tuberculosis after B.C.G. vaccination (*Journal*, April 30, p. 1076) you quote Ustvedt as saying that a primary focus can result from the superinfection of a person successfully vaccinated with B.C.G. This statement is so self-contradictory that I consulted the report to see if you had misquoted it, but I found that your quotation was accurate. I then consulted the full report of the Conference on European B.C.G. Programmes¹ (on which the *Bulletin of the World Health Organization* concerned appears to have been based), and on page 271 the following statement by Ustvedt appears: "There is no reason to doubt that a lung focus develops on superinfection (cf. the investigations in guinea-pigs by K. A. Jensen), but this focus does not usually seem to reach such an extent that it becomes visible on the chest film. The disappearance of the manifestations of primary tuberculosis seem [sic] to a high degree to characterize most of the groups of B.C.G. vaccinated individuals studied." I have no doubt that this statement is the correct expression of Ustvedt's views. The other statement may have suffered by mistranslation.

As regards the occurrence of tuberculous meningitis and miliary disease in vaccinated persons, Ustvedt² states that, from the work of the Joint Enterprise in various European countries (6 million vaccinations), the Danish campaign in Germany, and the Norwegian campaign in Italy, 21 cases of tuberculous meningitis and miliary disease had been reported. Many of these occurred within two months of vaccination, and by your own terms these are excluded ("disease that follows a natural infection occurring just before vaccination or a few weeks afterwards during the pre-allergic phase"). This may not be convincing statistical evidence, but it is impressive.

The occurrence of fatal tuberculosis due to the vaccine itself is, as you say, of great interest, and the findings presented in some of the original reports are difficult to interpret. In the case reported by Meyer and Jensen³ the post-mortem findings showed "a peculiar picture of atypical tuberculosis." The pathologist who made the post-mortem examination reported that he could not categorize the findings and had no explanation to offer for the atypical pathological condition. In Thrap-Meyer's⁴ case the patient was known to have had a raised erythrocyte sedimentation rate (40 mm.) for many years before vaccination, and although there was an interval of 4½ years between vaccination and death from generalized tuberculosis histological examination of lungs, spleen, urinary bladder, rectum, and bone failed to reveal any tubercles. The failure of the patient's tissues to react to the infection with B.C.G. was not explained. Your conclusion that the danger of B.C.G.-produced tuberculosis is too remote to be alarming is justified by the facts. —I am, etc.,

Whitehead, Belfast.

H. G. CALWELL.

Non-virilizing Androgens

SIR,—Substances like methylandrostenediol and methyl-androstan 17ol-3-one are being presented by the makers to medical men as "non-virilizing androgens" and "free from the side-effect of virilization in the recommended dosage." These statements are true relative to testosterone and methyl testosterone, with which these substances are compared. The statements may even be absolutely true for the majority of patients. However, in my clinical experience, although these substances may not produce true virilism, they may produce some growth of facial hair and even some deepening of the voice when given over prolonged periods in the

"recommended dosage." Since they are easily taken by mouth, and since they are advocated in a large number of conditions for "adults (both sexes) and children (boys and girls)," I think it prudent for practitioners to be aware that these substances are mildly androgenic, especially if they are prescribed for patients who are not seen for long intervals. The androgenic effects may be disconcerting, but tend to disappear on ceasing the "therapy."

In animals, immature rats,¹ taking the weight of the seminal vesicles as a criterion, "the compound (methylandrostenediol) was found to have about one-third the androgenic action of testosterone, subcutaneously, and about the same activity as methyl testosterone, orally." Although other tests—e.g., capons—indicate only one-fiftieth the activity of testosterone, and although the anti-oestrogenic and nitrogen anabolic activity are undoubtedly greater than the androgenic action, comparing methyl androstenediol with methyl testosterone, the experimental evidence does not permit one to ignore that methylandrostenediol and methylandrostenolone are potentially androgenic, even if feebly so. This letter is not, of course, an attempt to assess usefulness in appropriate cases.—I am, etc.,

Measurement of Cholinesterase Activity of Whole Blood

SIR,—The periodic measurement of blood cholinesterase activity provides a valuable guide in the protection of spraying operators and other users against the risk of cumulative over-exposure to anticholinesterase organic phosphorus insecticides.¹ Unfortunately, the methods until recently available, as reviewed by Aldridge,² prove somewhat demanding as regards laboratory time, trouble, equipment, or experience, and in this country few laboratories are able to provide the prompt routine testing service really needed. However, in 1953 Limperos and Ranta³ described a simple and speedy colorimetric method which has already been successfully used in North America.⁴

The principle of Limperos' method is that the cholinesterase activity of the whole blood sample determines the rate of colour change in a system comprising the enzyme (blood sample), substrate (acetylcholine), and indicator solution (soluble bromthymol blue, green-blue at pH 7.2, continuously changing to orange-brown at pH 6.2). Blood samples of unknown cholinesterase activity can thus be compared with normal control samples from healthy unexposed persons, either by measuring the time needed for the full colour change to be completed under standard conditions, or by measuring the amount of colour change occurring in the unknown samples when a normal sample has just completed the colour change, or after some arbitrary incubation time. The latter approach seemed to offer certain advantages in practice, and has led to the development of a series of permanent coloured glass standards calibrated at intervals of 12.5% normal cholinesterase activity, permitting the use of a visual comparator to ensure consistent readings in successive tests.

The method described, therefore, consists of pipetting 0.01 ml. whole blood from a normal unexposed person, and then from each worker to be tested, into clean reaction tubes each containing 0.5 ml. of an 0.044% aqueous solution of the bromthymol blue. The substrate, 0.5 ml. of an 0.5% solution of acetylcholine perchlorate, is then added to each reaction tube at a convenient time interval—for example, 1 minute. All tubes are allowed to stand at room temperature, the progressive colour changes occurring in the "control" tube being followed by periodically decanting the solution into the comparator cell, and matching with the series of calibrated disks. When the control tube contents just attain "100% activity," usually within 25 to 30 minutes at temperatures in the 15 to 20° C. range, the unknown samples are successively matched against the disks, again at 1 minute intervals, and the per cent whole blood cholinesterase activity read off. Precautions must be taken against acid or alkaline contamination (even by respiratory CO₂), against residual insecticide on the worker's skin, and against deterioration of the substrate solution. With those precautions, we have found the method very satisfactory in its speed and simplicity, the results obtained agreeing very well (within one disk, or 12.5%) with the

correct activity of normal and low-activity samples, as measured by the Michel electrometric method.⁵

The main advantages of the colorimetric method using comparator and calibrated disks are that it can be carried out on very small samples of blood, with simple equipment, reasonable accuracy, and good reproducibility, away from the laboratory if and when necessary. The degree of error of the method is considered acceptable for both routine and emergency estimations. The 95% range of normal whole blood activity extends from 80% to 120% of the mean value, while major anticholinesterase intoxication is most unlikely at blood activities above 25% normal. Between 25% and 75% normality, symptomless over-exposure to an anticholinesterase may recur.

The visual comparator, calibrated "cholinesterase disk," and full technical details of the method are now available from Messrs. Tintometer Limited, Waterloc Road, Salisbury, for whose collaboration we are most indebted. The early work on this modification was carried out by Mr. K. P. Fellowes.—We are, etc.,

Intramuscular Chloroquine

SIR,—There has been much criticism on the intramuscular use of quinine for the reason that such method had on occasions developed localized necrosis of the muscular fibres with subsequent abscess formation, thus creating a favourable cultural medium for tetanus and other organisms. In addition to the abscess formation, gas gangrene and streptococcal septicaemia may ensue. Intramuscular quinine injections have also been known to produce very painful fibrous nodules which after many years may break down and give rise to suppurating sinuses.

To obviate such potential complications, I have started to use intramuscular chloroquine injections for my malarial cases. The site chosen was the anterolateral aspect of the middle part of the thighs. Since May, 1953, intramuscular injections of chloroquine have been given to 617 cases of malaria, mostly of cerebral type, with temperatures ranging from 101° F. to 105° F. (38.3° C. to 40.6° C.). The cases included mostly infants and children under conditions where the oral route was found impracticable. The figure 617 included 415 cases under 1 year, 130 cases under 6 months, 80 cases under 3 months, and 27 cases under 1 month. The youngest infant to receive the injection was 3 days old.

Not a single case showed any local abscess formation or other complications. It is hoped that the observations made will be of much guidance to those who have abandoned the intramuscular use of quinine among their patients, especially the infants and children, for fear of abscess formation.—I am, etc.,

Pertis, Malaya.

ABDUL WAHAB ARIFF.

Chlorpromazine in E.C.T.

SIR,—In a small series of in-patients receiving modified electroplexy we have been impressed by the value of chlorpromazine as a pre-operative sedative. The average dosage of the drug which we employ is 50 mg., given by mouth two hours before treatment; this is followed by a hypodermic injection of scopolamine 1/150 gr. (0.43 mg.), or atropine 1/75 gr. (0.86 mg.) one hour before treatment. Anaesthesia is induced with a sleep-dose of thiopentone followed by succinylcholine 50–75 mg.

We have found that this use of chlorpromazine gives the following results: (1) A markedly tranquillizing effect (most welcome in the agitated depressive types, so often resistant to repeated treatment); (2) venous dilatation accompanying an increase in the warmth of the extremities. This latter

feature has greatly facilitated venepuncture in patients in whom the extremities were habitually cold, the veins contracted and impalpable, even in warm surroundings.

Since the exhibition of chlorpromazine considerably reduces the amount of thiopentone required to abolish consciousness, recovery time is not significantly retarded; this would suggest that, in suitably selected cases, the drug could be used safely in this way for ambulant patients.—We are, etc.,

J. D. W. PEARCE.

H. L. THORNTON.

Measles

SIR,—In your leading article (*Journal*, April 23, p. 1018) I was interested that the occasional difficulty in distinguishing between measles and the early stages of scarlet fever should have been mentioned at a time when I was about to report the following rather unusual case.

A boy, aged 2½ years, had scarlet fever in January, 1955. On April 1 he had a running nose, a hard, dry cough, and Koplik's spots so typical that they were demonstrated to his mother. By April 7 he had the typical rash of measles, and his sister, aged 5½, who slept in the same bed, was found by the mother to have Koplik's spots, and when seen by me the same evening looked miserable, with a temperature of 102° F. (38.9° C.), a hard cough, running eyes and nose, and photophobia. The following day a colleague saw the sister and confirmed the diagnosis of measles from the typical rash, which was becoming confluent when seen by me the next day. By April 10 the boy was much better, but the girl had striking circumoral pallor with the beginning of desquamation on the cheeks: her temperature was still raised to 102° F. (38.9° C.); she had a strawberry tongue, injected fauces, and enlarged cervical glands. On April 11 her measles rash was still present, but the fingers, palms, soles, and cheeks were now peeling, and superimposed on the measles rash was a typical scarlatiniform eruption. Granny, who had raised 16 children through every infectious fever without the help of a doctor, confidently diagnosed a combination of measles and scarlet fever—a diagnosis with which I concurred. On April 13 the boy was completely better, but the girl still had a temperature of 102° F. (38.9° C.) despite having started sulphonamides two days before. On April 15 she was much better and both rashes were fading.—I am, etc.,

London, W.6.

DAVID JACKSON.

Roseola Infantum

SIR,—Dr. E. L. McQuitty's article on roseola infantum (*Journal*, April 23, p. 1005) wisely draws attention to the most commonly occurring member of the exanthemata in infants under the age of 2. I have been noticing sporadic cases in my practice ever since the annotation in the *Journal* in 1950.¹ Dr. McQuitty mentions the paucity of references to the condition in the literature, but his most recent reference is 1950. Almost a page is given to it in my book² in the chapter on "Common Disorders Recently Recognized." In my opinion the importance of the recognition of this, and of other mild disorders encountered mainly in general practice, lies in the fact that exact diagnosis increases a general practitioner's confidence in himself and thus his patients' confidence in him.—I am, etc.,

Plymouth, Devon.

Cross-infection in Hospital

SIR,—I have read with interest the articles by Dr. E. J. L. Lowbury (*Journal*, April 23, p. 985) and Dr. P. N. Edmunds and his colleagues (p. 990).

The reservoirs of antibiotic-resistant pathogenic staphylococci are: (1) Blankets on ward beds and waiting-room or casualty couches, or on theatre trolleys: these blankets should be washed every month in a solution of "lissapol" and then soaked in "fixanol" solution, and dried without further rinsing. (2) Pillows and mattresses: these should be treated with hot, moist, gaseous formalin in the hospital sterilizer every 10 days or every time the bed has a new occupant, whichever time is the shorter. (3) Floors, ledges, shelves, locker tops, table tops, etc., should be treated every day with the M.R.C. urea ninol mixture. (4) Hands: nurses' hands should be protected by thin rubber gloves when the napkins of infants are being changed, bedpans carried about or cleaned, dressings changed, etc. The "washing" of a nurse's hands is a farce. Gloved hands, however, can be "washed" effectively in water containing a substance like "milton." A nurse should wash up, dry her hands on a sterile towel, and then apply sterile powder to her hands and don dry thin sterile rubber gloves. Whilst wearing her gloves she can wash her hands dozens of times, with effect each time. (5) Nurses should wear an efficient mask and a sterile overall when at work. (6) All plates, cups, saucers, and other crockery, including drinking-glasses, knives, forks, and spoons, and any other cutlery should be boiled after every meal, in addition to ordinary cleansing procedures. (7) In addition to the above measures, the M.R.C. technique for dressing wounds should be adopted and strictly enforced. Septic plasters, septic burn wounds, and septic surgical cases should be segregated from clean cases; and these septic cases should not have their dressings changed or removed in an open ward or theatre used also for clean cases. A special theatre and ward should be kept for septic cases, and attendants working there should have their noses and throats swabbed at frequent intervals. If the attendants are found to be infected, the organism should be examined bacteriologically to find an antibiotic to which it is sensitive; the attendants should then be treated with this particular antibiotic until nose and throat swabs are clear. Emergency admissions and infectious cases should not be admitted to an open ward but placed in cubicles for 48 hours: the disposal of the case should then be reviewed.

Many of the measures recommended are described in an article in the *Lancet*, 1954,¹ and can be seen in action in a hospital in greater London.—I am, etc.,

Epping, Essex.

The Changing Face of Medicine

SIR,—Mr. Clifford Kennedy's stimulating address (*Journal*, April 30, p. 1045) contains ideas of great importance, as well as a few crusty notions belonging to an age now departed and never likely to return. When, however, he says that the surgeon finds he is loath to undertake the risky case, I feel a challenge to be essential. If this is true the state of the profession is indeed inglorious. I don't believe it. Nor do I believe Mr. Clifford Kennedy when he says, "I have done it myself."

The responsibility of the doctor, physician or surgeon, is to make up his mind on the ascertainable facts and to take the action best suited to the patient under his care. No fear of possible legal consequences can alter that. The alternative is to resign and take up a job in a less responsible occupation. It is the hallmark of the doctor that he must decide. On his decision his own actions and those of many other persons—medical auxiliaries of all varieties—depend. The idea that the younger generation lacks courage and a spirit of adventure is common to all ages of history, and it is almost always untrue. The fact is that adventure

to-day is found on different pathways than in the first decade of the century because the history of our country and our calling has moved on in time.

As to the recent litigation, we are all concerned about it, and it behoves us to so order our affairs that negligent actions are as far as humanly possible eliminated. But the doctor who fails to act in the way he believes to be right when confronted with a patient needing his help, because of the fear of some unfortunate consequence to himself, should never have taken his medical diplomas in the first place. That is the central question. The case of the young resident who does not readily apply for a casualty post is in some respects not typical. Some courageous young doctors do undertake this type of post, but if others are more cautious there is reason in their position. For many years now we have been told that casualty cases should be seen by a competent accident surgeon having the F.R.C.S., and there are still hospitals where this arrangement has not yet been made. Perhaps one useful by-product of the recent High Court decisions is to compel hospital authorities to develop a more modern policy for their accident departments.

As for the attitude of the legal profession, doubtless relations could be improved. I feel, however, that there is a great deal to be said for their side of the story. High Court judges are usually men with great objectivity of mind and a sense of fairness. Perhaps they have their blind spots, but it would be presumptuous to suggest that their recent decisions were influenced by some lack of sympathy with the profession of medicine rather than a full consideration of the ascertainable facts laid before them. We must at all costs avoid an attitude which might suggest that we hold the view that the profession of medicine should stand above the law.—I am, etc.,

Bushey, Herts.

PETER ROE.

Natural Childbirth

SIR,—I have read with interest the recent correspondence on natural childbirth. Being a mother who was considerably helped by this method, I feel that it cannot be encouraged enough in order that the next generation will not grow up with the tales of agony and suffering which used to surround childbirth. From the attitude of the previous generation, the result for me was a great fear of childbirth and the associated agony which I believed it to be (and I know I am not alone in this). I attended antenatal classes and practised relaxation throughout pregnancy, and together with the other mothers-to-be was told of the events of labour and the signs to look for through each stage. It was explained that labour was, as the word implies, very hard work. I must say I am surprised indeed that Mrs. Constance Lynn (*Journal*, April 2, p. 851) was not told to expect this. Through this education in the events of labour I entered into this great job of work free from the dreadful fear that had been with me since adolescence.

As we were told, less fear—less tension—less pain. Therefore my labour was by no means as painful as it would have been if I had not been instructed beforehand. Toward the end of a seemingly endless first stage, with fairly severe contractions, I found myself unable to relax. However, my husband (himself a doctor), who had practised natural childbirth with me, was able to remind me of the type of breathing I should be using. This was the greatest help to me at this difficult time of labour, and I feel that a woman in labour should be attended by some person experienced in natural childbirth. The father-to-be is generally considered to be a nuisance to all concerned; but if husband and wife have read and followed together the breathing and relaxation—as is often the case in natural childbirth—then he can be of considerable help to both mother and staff. A woman in labour should not be left alone to “get on with it”; and the midwife rarely has time to spare. Would not the husband be better employed in helping his wife than pacing the corridor outside?

I would be interested to know what Dr. Constance Beynon (*Journal*, April 9, p. 908) calls a normal birth. Is it one

free from “abnormalities,” in which the mother is unconscious at the moment of birth, and is introduced to her baby a half-hour or more later; or is it one in which the mother is conscious (remembering that the gas and air machine is at hand if required), feels her baby born, hears its first cry, and holds her baby a few moments after birth? For me, personally, the latter was possible; although the birth of my daughter—9 lb. (4 kg.)—was not completely normal owing to the necessity for an episiotomy. I was completely conscious throughout, and the knowledge that I was actually assisting when the moment of birth arrived is a joy I shall never forget. None of this would have been possible for me had it not been for the instruction I received beforehand in natural childbirth. I believe that, for this generation to have its babies naturally in the true meaning of the word, education during pregnancy is essential. Then, perhaps, the coming generation will grow up to know only tales of joy, instead of pain and agony. Surely natural childbirth must be encouraged.—I am, etc.,

Woking, Surrey.

MARGARET McLAREN.

SIR,—I have been following the correspondence on natural childbirth. My first child was born nine weeks ago, and as a member of a hospital staff I had attended all antenatal clinics, including classes for exercises. I had read widely around the subject of childbirth, and knew exactly what to expect in theory. I certainly had no fears, especially as I knew well the staff who would assist me in labour. I had also watched a normal delivery.

The onset of labour came suddenly, and the pain was so intense that within half an hour I was completely incapacitated. I was given trichlorethylene, which gave no relief, and subsequently gas and air, which was more helpful. Labour was short, under four hours, and uncomplicated, but it was from beginning to end so intensely painful that all my preconceived ideas on how I should assist were abandoned. Afterwards I felt, apart from physical exhaustion, an extreme disappointment that I had not been able to participate in the experience as I expected I should be able to. I hope I am the exception.—I am, etc.,

London, S.W.3.

MARY B. DEW-JONES.

Aftermath of Hysterectomy

SIR,—With reference to the letters by “Doctor’s Wife” and Dr. Katharina Dalton (*Journal*, April 30, p. 1093). I have had the opportunity to treat some 900 women suffering from uterine fibroids with haemorrhage since 1939. I used intrauterine radium for approximately three days. Apart from the rare submucous fibroids, treatment stopped bleeding at the following period or the period after.

Dyspareunia was the only ill-effect following the radium treatment. And the dyspareunia disappeared within six months on its own, and sooner when treated with vitamin E, which was better tolerated in these cases than artificial female hormones. The treatment needs only three days of immobilization in bed after a short anaesthetic, followed by no recovery period, so that the patient can return to her duties almost immediately. There were no other ill-effects, apart from temporary dyspareunia, and I wonder why this is not the treatment of choice in cases of subserous and intramural fibroids.—I am, etc.,

London, S.W.3.

E. F. BLUMBERG.

Ban on Heroin

SIR,—I must join in the protest at the ban on the manufacture of heroin. We are only too familiar with the phrase “just as good” applied to substitute products—but who chooses the *ersatz* when he can obtain the genuine product? Clinical experience teaches, beyond the power of contradiction by laboratory experiments, that there is no satisfactory substitute for heroin in certain cases where pain relief is required. Surely, if abuse of a valuable drug by a small section of the community (and not even the British

community) is to be considered an adequate reason for imposing a ban on its manufacture, then both alcohol and tobacco should have gone long ago, whereas—quite properly—they have not been banned.—I am, etc.,

Aberdeen.

C. D. NEEDHAM.

SIR,—I fully concur with the opinions of your correspondents in the great disaster that would result by the imposition of a ban on heroin. This drug is the only effective weapon that the general practitioner possesses in combating the agonizing pain of patients suffering from advanced malignant disease. There are, of course, many other preparations on the market, but despite the claims of the manufacturers they are in no way so effective. Presumably the Government may have a very good reason for restricting the circulation of this drug, but surely a compromise could be reached whereby the procurement of heroin could be tightened up—for example, such as a consultant’s signature on the prescription in addition to that of a registered general practitioner. The advisers of the Government on this matter are shouldering a heavy responsibility should this advice be implemented.—I am, etc.,

London, W.1.

D. K. MULVANY.

Alcoholic Addiction

SIR,—I have recently been consulted by general practitioners concerning the treatment of three cases of alcoholic addiction. The patients were ruining the family finances and causing great suffering to all those around them, but they refused to be admitted to hospital for treatment. I am writing this letter in the hope that those in power will be stimulated to recommend some form of legally compulsive treatment in such cases.

I am aware that it is against our tradition to interfere with the “private lives” of citizens, and I can well imagine people arguing that if a person wishes to drink himself to death he should have the right to do so. Others may argue that playing at roulette, betting on horses, and gambling on the Stock Exchange can equally ruin family finances and happiness. And yet I think most of us will agree that alcoholic addiction, both because of the size of its problem and of the peculiarly unpleasant suffering it causes in the family circle, stands in a class by itself.—I am, etc.,

Basingstoke.

I. ATKIN.

Telangiectatic (“Nape”) Naevi

SIR,—The “nape” naevus (*Journal*, April 9, p. 913) is so extremely frequent that the question of heredity seems to be of no significance. This kind of naevus is known on the Continent as naevus telangiectaticus nuchae Unna, who in his *Histopathology of the Diseases of the Skin*¹ dealt extensively with this subject. He regarded these lesions as due to intrauterine pressure, and rejected Virchow’s branchial fissure theory and the possibility that they may be connected with irregularities in the embryonic development.

These telangiectatic naevi are of what one could term an ontogenetic character, whilst other naevus forms—e.g., the blue, the “mongolian” naevi, and the face moles representing rudimentary sensory organs^{2,3}—are of a distinctly phylogenetic nature.—I am, etc.,

London, W.1.

Hypodermic Injection Technique

SIR,—I have found the letters on the above subject both stimulating and helpful, especially when applied to injections of A.P.T. in small children where a painful episode with the doctor may give rise to a long-lasting aversion. I am not ashamed to confess that my own routine starts with a small bribe. I keep a stock of small, soft, brightly coloured sweets, and the health visitor who assists me distributes one to each mother. The mother holds the child on her lap and as I approach she pops the sweet into the open-

ing provided for it. I grasp the upper arm gently at first with my left hand, then I increase the strength of my grip nearly to the point of producing pain and at this moment the needle is swiftly inserted. In future I shall combine this with Dr. John Richards’s stretching technique (*Journal*, April 30, p. 1092). Between the pleasurable sensation of the sweet taste and the near-painful sensation of the firm grip the penetration of the sharp point is almost lost sight of. In most cases the episode passes without a cry and the small patient receives his meed of congratulation.—I am, etc.,

Birmingham, 33.

H. J. HOYLE.

Noradrenaline

SIR,—Your leading article on noradrenaline (*Journal*, April 9, p. 896) has the following sentence: “The greater pressor action of noradrenaline is explained by the fact that it constricts the vessels in the muscles as well as those in the skin and viscera, whereas adrenaline dilates those in the muscles.”

This makes strange reading for any anaesthetist, even though he may be aware that similar observations, at least with regard to the action of adrenaline, have been made regularly by physiologists since Hoskins, Gunning, and Berry first made them in 1916.¹ An anaesthetist well knows that if, prior to such an operation as a thoracotomy, he infiltrates the heavy muscles which are to be cut with, say, 200 ml. of sterile water to which has been added 1 ml. of 1/1,000 adrenaline, bleeding will be greatly reduced. Again, those anaesthetists who, like myself, have attempted to reduce bleeding by infiltrating these muscles with 200 ml. of sterile water to which has been added 1 ml. of noradrenaline will know, from what they see and what they hear from the unhappy surgeon, that bleeding is greatly increased.

Perhaps the answer to this riddle lies in the dosage of these drugs; that a fairly high concentration of adrenaline such as that mentioned above will cause not dilatation but constriction of the vessels of skeletal muscles; and that the rise in blood pressure which resulted from infiltration of the noradrenaline solution was sufficient to increase muscular bleeding in spite of any constriction of the vessels which may have occurred.—I am, etc.,

Worcester.

Recovery from Chronic Lymphocytic Leukaemia

SIR,—In reply to Dr. F. A. Bearn’s letter (*Journal*, April 23, p. 1031). I have looked up Gutmann’s paper.¹ This seems to be one of the many doubtful cases in which the literature abounds. At no time was there any anaemia, and the highest number of white cells was 11,000. No myeloblasts were present, and the diagnosis of aleukaemic leukaemia would seem to require marrow biopsy for confirmation. No enlargement of liver or spleen was found clinically. The patient was followed up for two years only, and all the blood pictures except the last one were abnormal. Eleven years later Dr. Bearn found the patient to be suffering from “a typical lymphatic leukaemia.” It would be interesting to have details of the blood picture.—I am, etc.,

Bradford.

Spontaneous Haemopneumothorax

SIR,—The most interesting account of spontaneous haemopneumothorax by Colonel A. J. Clyne and Wing-Commander F. H. D. Hutter (*Journal*, April 30, p. 1058) recalled to my mind the only case I ever saw in almost 20 years of general practice. This occurred early in 1946 when I was a medical officer attached to a field dressing station in Germany.

The patient was a private soldier whom I admitted to our casualty reception station in a state of near collapse, and who complained of sudden onset of severe pain in the right side of the chest. There was no history of injury, nor

indeed of any previous illness. The pain rapidly increased in intensity and was accompanied by dyspnoea, pyrexia, and rapid pulse. It was most severe even on slight movement and on inspiration. I made a tentative diagnosis of spontaneous pneumothorax, but soon after decided that it must be a haemopneumothorax on account of increasing restlessness, pallor, air hunger, and other phenomena of shock. He was too ill to be moved, so, employing the limited facilities at my disposal for treatment of such a case, I fitted up an underwater intercostal drainage apparatus. With the help of this and with the administration of a continuous intravenous saline drip, together with adequate sedation and penicillin cover, the patient improved dramatically and out of all recognition from day to day. As a result I was able to transfer him (in accordance with Army regulations) on the fourth day to a Canadian general hospital in Holland.

I visited him on two occasions there, and found that the diagnosis had been confirmed radiologically, that several pints of blood had been aspirated, and that he was greatly improved. It was thought that the tubercle bacillus was the causative agent in this case. He was later drafted back to England and unfortunately I lost trace of his subsequent progress on account of my own demobilization.—I am, etc.,

Glasgow, S.1.

M. FREEDMAN.

Cyst Formation

SIR,—I was interested to read Mr. A. G. Rutter's report (*Journal*, April 16, p. 951) of another case of gross cyst formation following cutis graft repair of an inguinal hernia. During and shortly after the war a series of inguinal herniorrhaphies was performed by this method in this hospital, and in 1952 we reported two cases of gross cyst formation with survival of hair follicles and sweat glands.¹ Since that time the total number of our cases in which this complication has occurred has risen to over half a dozen, including one in which the cyst formation was bilateral. It is worthy of note that in none of these patients was there any recurrence of the hernia. We have therefore been encouraged to carry out preliminary experiments in freeze-drying redundant skin taken from patients undergoing umbilical herniorrhaphy with the object of killing the epithelial elements and enabling the cutis to be stored and used safely for hernial repair in other patients.

Specimens have been taken with aseptic precautions and cultures have been negative after the freeze-drying process. We have found, however, that the cornified layers of the skin assume a rather unpleasant white appearance, and it may be that the superficial layers should be removed with a dermatome before processing. The process of rehydration is also rather tedious. If these problems could be overcome it might be possible to obtain all the advantages of cutis grafting without the disadvantages which are becoming increasingly obvious.—I am, etc.,

Liverpool, 9.

Coal-workers' Pneumoconiosis

SIR,—The article by Drs. J. C. Gilson and G. S. Kilpatrick (*Journal*, April 23, p. 994) is extremely informative and will be helpful to those attempting to deal with respiratory cripples from the coalfields. There are thousands of ex-miners in London who left the pits during the great mining depressions, and many of these are slowly dying, often without compensation, from the effects of dust inhalation. It would be helpful to those doctors who have to urge men to continue working to know the exact definition of "dust-approved conditions." Can we know the scientific evidence on which it is asserted that men can work, for many years, without harm in such an atmosphere?

As far as I can discover from clinical observation there is little difference in symptoms from pneumoconiosis and bronchitis and emphysema. Certainly few miners would

know the difference, and they believe the cause is the same. A practitioner relative of mine found that in his colliery practice, since the war, over 40 miners and ex-miners had died from chronic chest disease; of these, two only had been certified as having dust disease. National statistics are now available for the morbidity from chronic bronchitis. The National Coal Board must know the incidence in the mining community. Can these figures be published so that we can have realistic discussions on the effect of work on the miners' respiratory capacity?

Finally, Sir, may I urge that, since complicated pneumoconiosis is almost certainly due to dust and tuberculosis, we eliminate tuberculosis from our coalfields forthwith. Mass radiography, annually, of miners and relatives, as in the Rhondda, would discover infectious cases. Treatment can now be made available universally and one at least of the miners' hazards would be abolished. Knowledge comes, but application lingers.—I am, etc.,

London, N.W.10.

HORACE JOULES.

An Aid for Parkinsonism

SIR,—This is a photograph of an appliance I had made for a case of post-encephalitic parkinsonism, and it may be of interest to others. The lady had reached the stage in which she could sit down, but was unable to get off her chair without assistance. She lives at home with a sister who is out all day. Consequently she had to sit by herself from morning to night, and her muscles were becoming stiffer and weaker. She was unable to go out by herself, and had to be pushed in a bath-chair.

The appliance consists of a box, closed except at one end, which has a sliding panel. The box is filled with bricks to make it immovable. Above the box is a banister rail. By hooking her fingers around the rail the patient can pull herself on to her feet with ease, and, after steadying herself, can walk without any trouble. She has been using the appliance for the past three months, and is now more active than she has been for the last seven years. She goes out walking by herself, and says she can manage a quarter of a mile without distress. She is much more confident and self-reliant, goes shopping and to church, and is very much less dependent on her sister.

She uses the tray on top for her meals and the top of the box as a container for books, newspapers, etc. The box measures 3 ft. by 2 ft. at the sides and 2 ft. by 2 ft. at the ends. The superstructure is 1 ft. in height.—I am, etc.,

London, N.14.

W. SIMPSON.

Coma Following Dental "Gas"

SIR,—In a questionnaire that I recently sent to a random sample of the dental surgeons of the United Kingdom I asked: "Have you ever known a patient who did not immediately regain consciousness after gas but remained unconscious or stuporous for half an hour or more?" From the replies so far received I feel able to report that at least one in three of all dental surgeons who make extractions under nitrous oxide would answer "yes" to this question; many could relate several such cases, and the coma often lasts longer than half an hour. The nitrous oxide is almost always given with oxygen, though, of course, the oxygen is very much restricted.

One report tells of a child of 6 who was anaesthetized for the extraction of a single deciduous tooth. The anaesthetist was a doctor of outstanding ability, experienced in this kind of work. This child took the gas well and the extraction was quickly made. Apart from the restriction of oxygen that is always a feature of this method, it is impossible to suppose that there was any fault or lack of skill in the way in which the anaesthetic was given. Yet the child went into coma and remained unconscious for several days. After this, cerebral function returned very gradually so that it was many weeks before the child could be discharged from hospital.

It is possible that such desperate examples of this syndrome are very rare, but in view of the apparent frequency of its occurrence in lesser degree, and in the hope of discovering its cause, nature, and incidence, I think it worth while to direct the attention of your readers to it.—I am, etc.,

London, S.E.1.

J. G. BOURNE.

POINTS FROM LETTERS

Damages for Hot-water Bottle Burns

Dr. F. E. GRAHAM-BONNALIE (Exeter) writes: With reference to your medico-legal report (*Journal*, April 2, p. 856), now that it is taught that coolness and not heat is the better treatment for shock, could not hot-water bottles be dispensed with altogether?

Hospital Improvements

Miss OLIVE MATTHEWS (The Old Forge, Coaley, near Dursley, Glos.) writes: A few years ago I brought out a booklet called *Hospital Improvements*—how to improve the daily life of the patient in the ward. This is illustrated, and deals with topics like the early morning wash, noise, visiting hours, and bedside lockers. It received many kindly reviews, including your own (*Journal*, October 14, 1950, p. 879), and since then has reached hospitals in at least 32 different countries and colonies of the world—more than 2,000 copies have gone, but over 300 remain. I am now willing to give them away to the reader who will send me fourpence to cover the cost of postage and envelope.

Night Cramps

Mr. RICHARD WARREN (Weston-super-Mare) writes: I have lately seen a good many letters in your *Journal* on the subject of cramps. I have had attacks of cramp far too often for my liking during the past 60 years or more, sometimes very painful indeed, until I learned how to cope with them. It occurred to me that contraction was reported to produce sarcolactic acid in muscle. I wondered in my simple brain if excess of sarcolactic acid might be the cause of cramp. If so, the obvious course was to neutralize the acid *quam celerrime*. The most rapidly diffusing alkali I knew was ammonia, which I took in the form of sal-volatile, or later, because they were more easy to carry, soda-mint tablets, which contain a small amount of ammonium carbonate. The effect on me was magical, complete relief in a very few minutes or even seconds. You may say psychical, or wishful thinking, but it has never failed in my case, and has saved me hundreds of attacks of severe pain. I have put many friends and patients up to this little tip, usually, so far as I remember, with success. Several indeed carry some tablets with them habitually.

Hair-grips

Dr. IVOR HOOPER (Dublin) writes: In my opinion hair-grips should have metallic blunt ends for better usefulness and greater safety, and I hope that this suggestion will catch the eye of the appropriate manufacturers.

Obituary

W. G. MUMFORD, O.B.E., M.B., F.R.C.S.

Mr. W. G. Mumford, consulting surgeon to the Royal United Hospital and the Royal Mineral Water Hospital, Bath, died at Eastbourne on April 27. He was 84 years of age.

Wilfred George Mumford, who was born on June 14, 1870, was a medical student at Guy's Hospital, where he qualified M.R.C.S., L.R.C.P. in 1895. For the next few years he remained in London, studying for the M.B., which he obtained in 1902, passing the final examination with honours in medicine. By this time he had decided on a surgical career and in 1903 he took the diploma of F.R.C.S. Mumford elected to settle in practice at Bath, which he did soon after obtaining his Fellowship. His connexion with the Royal United Hospital began in 1905, when he was appointed anaesthetist, and five years later he became assistant surgeon. The status of full surgeon followed in due course, and when he retired he was appointed consulting surgeon. During the first world war he served in the R.A.M.C. and for some time was employed as a surgical specialist at the military orthopaedic hospital at Southmeads, Bristol. He attained the rank of major, and was appointed O.B.E. in 1919 for his war services. After the war his surgical practice in Bath became a large one and he was appointed surgeon to the Royal Mineral Water Hospital, to the Ministry of Pensions orthopaedic hospital at Bath, and to the Bath and Wessex Children's Orthopaedic Hospital at Combe Park.

When the Annual Meeting of the B.M.A. was held in Bath, Mumford, who was honorary secretary of the Bath Division at the time, was appointed local general secretary of the meeting. It so happened that the incoming President, Dr. F. G. Thomson, was prevented by illness from attending the various functions, and the local executive committee appointed Mumford to take his place. Mumford rose to the occasion with conspicuous success and enhanced his already high reputation. In the following year he served as one of the vice-presidents of the Section of Surgery at the Annual Meeting at Nottingham, and he was also elected president of the Bath Division. In 1931-2 he was president of the Bath and Bristol Branch. His great characteristics were conscientiousness and scrupulous attention to detail, and these, added to his striking and handsome presence, made him an impressive figure.

Mumford moved to Willingdon, in Sussex, in 1934, when he retired from active surgical work. He is survived by his widow and one son and two daughters.

P. K. DIXON, M.D., F.R.C.S.I.

Dr. P. K. Dixon, surgical specialist at the Government African Hospital, Lusaka, Northern Rhodesia, and lecturer in surgery in the African Medical School, died at Lusaka on April 21 at the age of 56. Before taking up these appointments early in 1953 he had done outstanding work as a medical missionary in the Luapula valley of the Belgian Congo for over a quarter of a century, work which he gave up only on account of ill-health.

Patrick Kerr Dixon was born on September 21, 1898, the son of the late Professor A. Francis Dixon, who was dean of the Faculty of Physic at Trinity College, Dublin, from 1924 until his death in 1936. From St. Andrew's

College, Dublin, Patrick Dixon entered Trinity College in 1916, but he interrupted his studies there to serve with the Royal Garrison Artillery in France, being mentioned in dispatches. He returned to Trinity College in 1919 and graduated in science in 1922, being awarded first-class honours in mathematics and experimental science and a gold medal in natural science (his father as a student also won the gold medal). In 1924 he obtained his medical degrees, with honours, and in the same year took the D.T.M.&H. of the English Royal Colleges. He proceeded to the M.D. in 1925, and became a Fellow of the Royal College of Surgeons in Ireland in 1934. After graduating in medicine he held house appointments at the Royal Alexandra Hospital for Sick Children, Brighton, and Hove General Hospital, and then, in 1926, he joined the Garenganze Evangelical Mission in the Belgian Congo. He was twice married: first, in 1926, to Miss Olive Archer, who died in 1927, and second, in 1934, to Miss I. H. Russell, who, with one daughter, survives him.

G. P. N. writes: Dr. P. K. Dixon was a man of outstanding ability, and this was coupled with a humility and charm of character which made him many lifelong friends. He had many severe trials. He lost his first wife soon after her arrival in the Congo; he was severely mauled by a lion; and subsequently he suffered prolonged illness. In spite of these misfortunes he did magnificent work in the Congo over a period of nearly 30 years, work which included the founding of a hospital at Chibambo, on Luapula river, a hospital which now stands as a monument to his labours. Trachoma and eye diseases in general are among the main problems of the Luapula valley: in order to fit himself to deal with these Dixon spent six months studying ophthalmic diseases under Sir Henry Holland in India in 1929, and later his own hospital became a renowned centre for the treatment of eye diseases. In recognition of his long and meritorious services he was decorated by the King of the Belgians.

WILLIAM BURRIDGE, D.M.

Dr. William BurrIDGE, who was professor of physiology in Lucknow University for many years, and later dean of the faculty of medicine and principal of King George's Medical College, died at Dartford, Kent, on April 21. He was 69 years of age.

William BurrIDGE was born on July 1, 1885, the son of Mr. John BurrIDGE. He entered Christ Church, Oxford, as an exhibitioner in 1904, and continued to study and teach physiology after taking his B.A. degree. He added to the brilliance of his scholastic record by winning the Dixon Research Scholarship and the Mark Quedstedt exhibition in 1909. The award of the Rolleston Memorial Prize for original research in physiology and pathology followed in 1912 and the Radcliffe Prize in 1917. Receiving his clinical training at Guy's Hospital, he graduated B.M., B.Ch. in 1916, and some twelve months later entered the R.A.M.C. for service in the first world war, in the course of which he was employed at Malta—an island to which he was attracted more than once after his return to civilian life—and at the Swanage military hospital.

In 1922 BurrIDGE proceeded to the D.M., and went to King George's Medical College, Lucknow, as professor of physiology. Later he became principal of the college and dean of the faculty of medicine, and he served also as a member of the United Provinces Medical Council. In 1933-4 he was president of the United Provinces Branch of the British Medical Association. He left India in 1938, and since the end of the second world

war had spent his life almost equally between Malta and Oxford. He had a brief term of office as dean of the faculty of medicine in Rangoon University in 1946-7, and in 1954 he obtained an appointment at Liaquat Medical College, Hyderabad. Besides contributing many short papers to scientific journals, Professor BurrIDGE was the author of *Excitability: a Cardiac Study* (1932); *The New Physiology of Sensation* (1932); and *A New Physiological Psychology* (1933).

GEORGE DOUGAN, M.D., D.P.H., M.P.

The death took place on April 7 at his home at Portadown of Dr. George Dougan, Member of the Parliament of Northern Ireland since 1941. He was 73 years of age.

The son of the late Dr. G. Dougan, of Portadown, George Dougan studied medicine at Trinity College, Dublin, where he graduated M.B., B.Ch. in 1906. He proceeded to the M.D. in the following year and took the D.P.H. of the Irish Royal Colleges in 1908. After graduation he joined his father in practice and soon established himself in the confidence of his patients, who came to love him and to have absolute faith in his efficiency as a doctor. After service with the R.A.M.C. in the first world war he returned to Portadown, where he became an enthusiastic member of the British Medical Association, seldom missing a meeting of the Portadown and West Down Division, of which he was chairman in 1922. He also represented his constituency at five Annual Representative Meetings from 1931 to 1941. His colleagues, by whom he was held in very high esteem, often sought his opinion on every kind of medico-political problem and highly valued his advice. In 1941 Dr. Dougan was returned unopposed as the Member of the Northern Ireland Parliament for Central Armagh, and he continued to hold the seat until his death, having defeated his Commonwealth Labour opponent at the 1945 General Election. He was also a deputy lieutenant for Co. Armagh, coroner for northern Armagh, and a member of the General Synod of the Church of Ireland. In the world of sport, too, he was a prominent figure. At the time of his death he was the oldest member of the Portadown Boat Club, and he was a past captain of the golf club. He was a Serving Brother in the Venerable Order of St. John of Jerusalem, and a foundation member and president of the local Rotary Club. By his passing Portadown has lost a fine doctor and a noble character who will be long remembered by his patients and fellow doctors alike. He is survived by his widow, formerly Miss Mary McDonald, and two sons, Dr. George Dougan, junior, who has been associated with him for some years in the practice, and Dr. Donald Dougan, who lives in Canada. A third son, Lieutenant-Colonel Hampton A. Dougan, died on active service in the second world war.—D. L. H.

Dr. G. A. RORIE, who was in practice in Dundee for more than 40 years until his retirement in 1952, died at Broughty Ferry on March 23 at the age of 78. George Arthur Rorie was born on August 2, 1876, the son of Dr. James Rorie, physician-superintendent of Dundee Royal Asylum. He was educated at Dundee High School and at Edinburgh University, where he graduated M.B., Ch.B., with distinction, in 1898. Developing his father's interest in mental health work, he held the post of assistant medical officer at Edinburgh Royal Asylum under Dr. T. S. Clouston, and later gained further experience as clinical assistant to

Dr. Hughlings Jackson at the National Hospital for Nervous Diseases, London. In 1898 he obtained the certificate of the Royal Medico-Psychological Association, and thereafter held posts at the Cumberland and Westmorland Mental Hospital, Carlisle, and at Herrison Hospital, near Dorchester, where he worked for ten years. He proceeded to the M.D. in 1906. In 1912 he decided that general practice held more interest for him and he returned to Dundee, obtaining the D.P.H. of St. Andrews in the following year. He soon attracted a large practice, which he conducted for the next forty years, broken only by service in Egypt in the first world war, when he held a temporary commission in the R.A.M.C. In Dundee he took a keen and active part in the local affairs of the British Medical Association, and was president of the Dundee Branch in 1931-2, chairman of the Dundee Division in 1947-8, and a member of the Scottish Committee from 1945 to 1949. His chief recreations were walking and climbing, and when over 70 he was still able to climb a Cuillin. His retirement was forced upon him, much against his will, by the onset of glaucoma, but he continued to walk several miles daily until the day before his death. He is survived by his widow, a daughter, and three sons, one of whom is a psychiatrist in Dundee.

The death occurred at his home in Northampton on March 28 of Dr. STEPHEN ROWLAND, who was medical officer of health for Northampton County Borough from 1926 to 1946. Aged 82, he had been seriously ill for some months. He was perhaps unique among medical officers of health in holding the square-rigged master's certificate. Stephen Rowland was born in Blackburn, Lancashire, on September 1, 1879. He went to sea as an apprentice in a barque, the *Muncaster Castle*, and served five and a half years. In 1897 he passed his second mate's examination and joined the *Wray Castle*, a full-rigged ship. Two years later he passed as first mate and in 1901 the square-rigged master's examination. Soon after obtaining his master's certificate he entered Edinburgh University as a medical student, and graduated M.B., C.M. in 1907. Taking the Cambridge D.P.H. in 1909 with a career in the public health service in view, he was appointed senior assistant medical officer at Monsall Isolation Hospital, Manchester, in the following year, and then, in 1912, he became medical officer to a waterworks at Birchinlee, a small place in North Derbyshire not far from Sheffield. He left this appointment to serve throughout the first world war in the R.A.M.C., attaining the rank of captain. After the war he secured a post at the Northampton Tuberculosis Dispensary. In 1924 he proceeded to the M.D., and two years later succeeded the late Dr. J. D. McCrindle as medical officer of health, school medical officer, and chief tuberculosis officer of the county borough of Northampton, an appointment he held until he retired in 1946. He was president of the Northamptonshire Branch of the British Medical Association in 1934. He never lost his love for sailing ships, and his skill in modelling them was exceptional. Four of his models are in the permanent collection at Edinburgh Museum, while his last—one of the largest he made—is at the Royal Maritime Museum, Greenwich. He leaves a widow and two sons, Flight Lieutenant Stephen Rowland and Lieutenant-Commander Bernard Rowland, R.N., and a grandchild.—C. G. P.

The profession in West Lothian generally, and in Bo'ness particularly, has suffered a severe loss through the tragic death on April 12, after a disastrous motor accident, of its senior active practitioner, Dr. W. A. SHAFTO. His wife and son were seriously injured at the same time. A native of Forfarshire, William Alexander Shafto was born on September 27, 1886, and studied medicine at Edinburgh University, where he graduated M.B., Ch.B. in 1910, proceeding to the M.D. in 1913, in which year he also took the D.P.H. He settled at Bo'ness in 1914 as assistant to and, later on, partner with Dr. John Graham, whose death left him in full control of the practice. During the first world war,

Dr. Shafto served with the R.A.M.C. in the Middle East, becoming medical officer at Bagdad and receiving a mention in dispatches. On demobilization he returned to Bo'ness and settled down to consolidate the practice. In this he was eminently successful. He became medical officer to the Post Office, and later on he was appointed medical referee to the sheriff court at Linlithgow for West Lothian cases under the Workmen's Compensation Act. He was a very sound and wise practitioner and a real friend to all his patients. Although he did not play any active part in public work, he did take his full share in the deliberations of the West Lothian Local Medical and Panel Committees. He was a very keen and competent golfer, with, at his best, a low single-figure handicap. The deepest sympathy of all who knew him, fellow-practitioners, patients, and friends, will be extended in full measure to his widow, his daughter, and his son.—H.

A. McW. G. writes: There are few houses in Bo'ness and the surrounding districts of West Lothian which have not been penetrated by the shadow of sorrow attending the tragic death of Dr. W. A. Shafto. Few men were so privileged as was he in the possession of so much of that inner flame which radiates a deep, confident, satisfying peace, eclipsing all personal care and the shadows of adversity. This presence, this aura of peace, was in him a composite of a life of learning, meditation, and service to people with whom he felt deeply in all his senses. His essential goodness was a fountain from which the whole community gained elevation. Apart from the professional sphere, in which he was so notable, Dr. Shafto's interests lay in his family, his garden, his books, of which Shakespeare was most favoured, his dog, which was almost as well known as his master, and lastly, but by no means least, his golf. He is survived by his wife, who is slowly recovering from serious injury, and by a son and a daughter, who is also a medical graduate of Edinburgh University.

The news of the sudden death of Dr. W. J. DAWSON at Cheltenham on April 17, at the early age of 33, has deeply shocked his many friends. Descended from farming stock, William John Dawson was born on May 2, 1921, and educated at Fraserburgh Academy and at Aberdeen University, where he graduated M.B., Ch.B. in 1943. After holding hospital appointments in Wolverhampton, in Grantham, and at the North Middlesex Hospital, he was in general practice at Slaithwaite, Yorkshire, before settling at Cheltenham in 1948.

I. D. I. writes: Although of a retiring disposition, Johnny Dawson brought many gifts to those he honoured with his friendship—a delightful sense of humour, love of serious disputation, a joy in quiet conviviality, and a ready wit. He had a full and enjoyable student career, and his influence, though unobtrusive, was real and valuable and felt in many fields of activity. He was an accomplished though occasional artist, producing caricature or set design with efficiency, while music was an abiding interest. Nor, despite his mitral lesion, of which he was aware, was he averse from games, playing hockey especially with enjoyment. At Cheltenham he readily established himself in the respect and esteem of colleagues and friends, who appreciated the integrity and idealism behind his modest exterior. In recent months it seems that his illness worsened and he was to have undergone cardiac surgery, but this was not to be. So we, who mourn the loss of one whose good companionship we have been privileged to share, extend our deepest sympathy to his widow and her children in their grievous sorrow.

Dr. FREDERIC LONGHURST, formerly anaesthetist to St. George's Hospital and the Grosvenor Hospital for Women, died at his home in Fowey, Cornwall, on April 19, aged 79. Frederic William Longhurst, whose father was Dr. A. E. Temple Longhurst, of Eaton Square, London, was educated at Westminster School and St. George's Hospital, where he qualified M.R.C.S.

L.R.C.P. in 1900. After holding resident appointments at the Worcester General Infirmary and at the Hospital for Sick Children, Great Ormond Street, he went into general practice in London, living in Hobart Place, London, S.W.1. His first appointment as an anaesthetist was to the Gordon Hospital, and later he became anaesthetist to St. George's Hospital, the Grosvenor Hospital for Women, and the General Lying-in Hospital in Lambeth. Frederick Longhurst had a most lovable disposition, and he obtained fame in London as the very handsome doctor whose patients were never sick after receiving an anaesthetic at his hands, which certainly was an unusual feat in those days of ether and chloroform anaesthesia. He took a very active interest in the medical school at St. George's, and was a keen lawn-tennis player until his arthritis drove him off the courts. Very young in heart and refusing to be incapacitated by this disability, he courageously submitted himself late in life to a severe surgical operation, and he was able to enjoy a happy and reasonably active life to within a day or two of his death.

Medical Notes in Parliament

DOCTORS' RIGHT TO PRESCRIBE

A debate on the social services which occupied the House of Commons on May 4, like all the debates in the last week of a Parliament now dissolved, had a marked election flavour, and was for the most part a compound of comment on party manifestos and a refurbishing of views on Health Service expenditure and changes recently made in pension and benefit rates.

Dr. EDITH SUMMERSKILL (Fulham, West, Lab.) castigated the Government for what she called their callous disregard of the Phillips Report on the economic and financial problems of the provision for old age and their niggardly treatment of recipients of national assistance. She then came to the Is. prescription charge, and asked whether it should be continued in view of the hardship it imposed and the administrative burden entailed. She quoted in support the resolution of the B.M.A. conference at Cardiff, and some of the speeches calling it a major retrograde step and asserting that because of it children in large families were not receiving proper treatment.

Unnecessary Expense in Prescribing

Then she came to drugs, and engaged the Minister in a duel on the doctor's right to prescribe. About £50m. a year was spent on drugs, she said, and about 30% of this went on proprietaries. How could the Minister allow this huge sum to go to swell the profits of the big drug houses when he had to be so cheese-paring in other directions? He had done everything except take strong action. He should refuse to sanction unnecessary expense in prescribing where there was a satisfactory alternative. Only the hypochondriacs and those in big business making colossal profits would object, and the taxpayers would be delighted.

Mr. MACLEOD said that what she was asking was that the Minister of Health should take powers to tell a doctor that he must not prescribe something that he thought best for the patient. That was the fundamental difficulty in the proposal. It would no doubt be desirable in many cases if doctors would prescribe what was in the *National Formulary*. But if a doctor, for whatever professional reasons, thought it right to prescribe a certain drug, did Dr. Summerskill think it proper to forbid him to prescribe it?

Dr. SUMMERSKILL said that the Minister already exercised certain powers. His officials examined a cross-section of prescriptions, and if they concluded that a doctor was guilty of excessive and expensive prescribing the doctor was informed. The Minister had established the principle. What he was asking her was a question of degree.

Mr. MACLEOD said that he understood Dr. Summerskill's proposal would take that discretion away from the doctor.

Mr. JAMES GRIFFITHS (Llanelly, Lab.) interposed to give the case of a constituent who believed that a certain proprietary medicine was the best for him, and had been receiving it on a Health Service prescription from his doctor. Then it was stopped. He wrote to the Minister, and it was clear from the reply that it was stopped because it was thought that other prescriptions would be of equal value.

Mr. MACLEOD said it was suggested to doctors that certain asthma preparations were not of proved therapeutic value. But if in his discretion a doctor still decided that they should be prescribed it was quite legitimate.

Dr. SUMMERSKILL said the Minister was on a very bad wicket. In asthma there was a nervous element, and a patient might feel convinced that a certain preparation was the best for his complaint. On this question she would say that the doctor had probably a right to prescribe it, because he was prescribing for a nervous patient who had faith in that particular drug. She was shocked to learn that he could tell a doctor that he could not prescribe something for a nervous patient. The Minister did not know what his policy was or should be. Obviously, where there was a satisfactory alternative—in the case quoted it was not satisfactory—the doctor should be told that he must prescribe it.

Mental Hospitals

Continuing, Dr. Summerskill spoke of long waiting-lists for operations of a simple kind, and asked if the Minister thought he was justified in allowing beds to be earmarked for fee-paying patients. About mental hospitals there had been alarming questions. They had heard about overcrowding and shortage of nurses, and these, combined with the activities associated with mental patients, had presented a horrifying picture reminiscent of Hogarth's "Bedlam." Yet there was no pressure group on behalf of mental patients. Why? Often because mental patients filled people with fear; there were few visitors to see the conditions; and there were even some doctors who were inclined to regard money spent on mental disease as wasted because of the doubtful return in dividends in terms of healthy, useful people to the community.

Mr. OSBERT PEAKE, Minister of Pensions and National Insurance, answered the point about the Phillips Report. He said there were a number of important questions still before the National Insurance Advisory Committee. It was fairly clear that, arising from these, and from the Phillips Report itself, there would have to be legislation amending the National Insurance Scheme. But he thought they built fairly well in 1946, and he would be reluctant to introduce changes just for the sake of change.

Mr. MACLEOD in the interval had sent for the letter he wrote to Mr. Griffiths, referring to the prescribing of a proprietary medicine for asthma, and quoted from it:

"I am advised that [this medicine] is not therapeutically superior to the standard preparation. . . . On the other hand, it is much more expensive, and, believing as I do that doctors would not wish the funds available for the Health Service to be spent unnecessarily, I have asked them not to prescribe it. I cannot prohibit them from doing so, and, while I hope the doctors generally will comply with my request, I am sure they quite understand that they are still free to prescribe whatever they think necessary in the individual case."

On the advice of the Cohen Committee, he said, it was from time to time suggested to doctors that they should not prescribe a certain drug, but he did not interfere in any way—he would regard it as improper to do so—with the clinical freedom of doctors, if they so wished, to prescribe a particular drug in relation to a particular patient.

Mr. GRIFFITHS apologized for his memory having been at fault, but asked if there was any question of doctors being charged or questioned about prescriptions afterwards.

Mr. MACLEOD said that if a doctor chose to go against the advice given him he would not be surcharged for that. It was possible—a different point—that his prescribing as a whole might be looked at, and one element might be the over-prescribing of one particular drug. The difficulty he was in was that he could not see how what Dr. Summerskill

had in mind, relating to the prescribing of ordinary substances on the list, could be achieved without interfering with the clinical freedom of doctors.

Private Beds

On the question of private beds, he said that about 1% of beds in the Health Service were private, and about one-third of those at any given time were occupied by non-paying patients, on the grounds of medical urgency or to see that the beds were filled. It was incredible that the Labour Party must concentrate its only practical proposal on two-thirds of 1% of the beds. The proposal was a breach of pledges by Socialist Ministers, and a breach of faith with millions of people who paid into contributory schemes so that they might have some privacy in hospital. He would believe in the proposal when the Opposition practised what they preached, and he saw members of the party who were ill going into the public wards of hospitals.

On the cost of drugs, he said the total bill was about £43m. (not including hospitals), and within that sum £24m. was due to proprietary medicines. Many of the greatest discoveries had been made by private firms—the antibiotics were an obvious example—and the industry had an important export trade. He was in close touch with the Association of British Pharmaceutical Industry, and they had been working out formulas which would enable a satisfactory guide about suitable profits to be reached.

As to mental beds, the mental hospitals had no waiting-list, but on the mental-deficiency side there was a waiting-list of about 7,000. There were plans for the construction of 6,000 more beds in progress, and in addition the substantial hospital building programme recently announced would include a share for the mental-deficiency side.

Nuclear Radiation Committee

The membership of the committee appointed by the Medical Research Council to prepare a report on the medical aspects of nuclear radiation was announced on May 4 and is as follows:

Sir Harold Himsworth, F.R.S. (chairman), Secretary of the Medical Research Council.

Sir Ernest Rock Carling, Consultant Adviser, Ministries of Health and Home Office (Civil Defence), and member of the Health Policy Committee of the Atomic Energy Authority.

Sir John Cockcroft, F.R.S., Director, Atomic Energy Research Establishment.

Professor A. Haddow, Director, Chester Beatty Research Institute.

Dr. J. F. Loutit, Director, Medical Research Council Radiobiological Research Unit.

Professor K. Mather, F.R.S., Professor of Genetics, Birmingham University.

Professor W. V. Mayneord, Professor of Physics applied to Medicine, London University.

Professor P. B. Medawar, F.R.S., Professor of Zoology and Comparative Anatomy, University College, London.

Professor J. S. Mitchell, F.R.S., Professor of Radiotherapeutics, Cambridge University.

Professor L. S. Penrose, F.R.S., Galton Professor of Eugenics, University College, London.

Sir Edward Salisbury, F.R.S., Director, Royal Botanic Gardens.

Dr. F. G. Spear, Deputy Director, Strangeways Research Laboratory, Cambridge.

Professor J. R. Squire, Professor of Experimental Pathology, Birmingham University.

Professor C. H. Waddington, F.R.S., Professor of Animal Genetics, Edinburgh University.

Sir Lionel Whitby, Regius Professor of Physic, Cambridge University.

Professor B. W. Windeyer, Professor of Radiology (Therapeutic), London University.

Lists of Patients for Voting

The MINISTER OF HEALTH made his promised statement on the use of doctors' lists for the purpose of the postal vote on May 3. He said that he had studied carefully the documents sent him by Mrs. B. Castle (Blackburn, West,

Lab.), who had said that pressure was being used by local Conservative associations on doctors to send the names and addresses of sick, blind, and aged persons for the purposes of the postal vote.

Mr. MACLEOD stated that it was desirable that everyone should be aware of their right to a postal vote, and equally important that any information given should be made available to all political parties who asked for it. There was nothing wrong in responsible citizens, doctors or others, bringing to the notice of those concerned, whatever their politics, their rights as postal voters. On the specific question about extracting patients' names from doctors' lists, he would not expect information concerning doctors' N.H.S. patients, which was normally regarded as confidential, to be disclosed for some entirely different purpose. He was sure that doctors understood the position, and that no special communication was necessary.

Chest Disease on Tyneside

Mr. BLENKINSOP (Newcastle-upon-Tyne, East, Lab.) asked the Minister of Health on May 2 whether he was aware of the high level of chest diseases, particularly tuberculosis and bronchitis, on Tyneside compared with the rest of the country; and whether he would give all possible support both to research into causes and to provision of adequate facilities for treatment. Mr. IAIN MACLEOD replied "Yes." There was a particular research project in hand dealing with bronchitis in Newcastle. He understood the regional board had a number of plans for additional chest clinics, and he thought it was intended to give priority to Gateshead, where the problem was perhaps more serious than elsewhere.

Poliomyelitis Vaccine

Dr. BARNET STROSS asked the Parliamentary Secretary to the Ministry of Works, as representing the Lord President of the Council, whether, in view of the difficulty in obtaining a sufficient number of monkeys to provide the new vaccine for use against poliomyelitis, he would encourage by all possible means research on the use of an alternative medium. Mr. J. R. BEVINS stated on May 3 that the current programme of poliomyelitis research co-ordinated by the Medical Research Council might show whether there was any practicable alternative to the use of monkeys in preparing a poliomyelitis vaccine, but he was advised that an adequate substitute for monkeys was unlikely to be found in the near future for a vaccine of the Salk type. It was hoped, however, that adequate supplies of monkeys would be available again shortly.

Dr. STROSS said it was rather nauseating to think in terms of breeding and destroying so many of these tiny creatures whose kidneys had to be used. He asked for an assurance that every possible means would be used to find a substitute, which in the end might be better as well as simpler. Mr. BEVINS assured him that research to find a promising substitute was in progress.

Mr. PETER FREEMAN (Newport, Lab.) asked the Minister of Health on May 4, in view of the deaths, injuries, and paralyses that had already occurred to children injected with the vaccine obtained from the kidneys of the corpses of monkeys for the alleged cure of poliomyelitis, if he would prohibit all further experiments on children in the country by this method; and if he would give an assurance that children would only undergo this injection after the authorities had obtained the parents' prior consent in writing. Mr. IAIN MACLEOD replied that naturally the recently reported events in America were being fully considered by the Medical Research Council, and a member of their staff was going over there immediately to get first-hand information. This should be ready for study here before the routine safety tests, now being conducted on batches of vaccine, were finished, and therefore before any of the proposed trials on children over here were due to begin. Meanwhile arrangements for these trials continued. There was no intention of inoculating any child unless the full consent of the parents had been first obtained.

A Doctor's Telephone

Mr. M. EDELMAN (Coventry, North, Lab.) asked the Postmaster-General whether he had studied the case of a doctor who refused to permit his patients to call him by telephone; and whether he would make it a condition for the priority given to doctors in issuing them with telephones that they should not apply such restrictive measures to their patients who sought to summon them on legitimate occasions.

Dr. CHARLES HILL replied on May 4 that this case was the only one of its kind which had come to notice, and the doctor was not the actual subscriber. On the general issue it would be impossible to enforce the observance of such a condition as Mr. Edelman suggested, even if it were desirable to impose it.

Welfare Foods

Mr. H. MARQUAND (Middlesbrough, East, Lab.) asked the Minister of Health for a statement indicating the trend in the consumption of welfare foods since responsibility for their distribution was transferred to local authorities. Miss PAT HORNSBY-SMITH, Parliamentary Secretary, stated on May 2 that there had been a downward trend. These foods were, of course, intended for those whose diet might otherwise be deficient, and the arrangements of the local authorities were well adapted to concentrate attention on this group. In the community as a whole the downward trend might well continue with the continuing improvement in the general diet and standard of living. In the second half of 1953 the distribution of national dried milk was 12.34 million tons; January to June, 1954, 11.92 million tons; and July to December, 1954, 11.33 million tons. The corresponding figures for cod-liver oil are: 3.28 million bottles, 3.30, and 2.79; vitamins A and D, 1.03 million packets, 1.03, and 0.83; and orange juice: 15.58 million bottles, 14.81, and 13.41. The figures were estimates.

Building Industry Accidents

Dr. BARNET STROSS asked the Minister of Labour on May 3 to what causes he attributed the increase in the accident rate in the building industry by 50% between the years 1948 and 1953, in spite of the introduction of regulations in 1948; and how he proposed to lower the rate at which men were injured in this industry. Mr. HAROLD WATKINSON replied that the apparent increase in the accident rate at building operations could be attributed, in part at least, to the efforts constantly being made by the Factory Inspectorate to secure a better understanding by employers of their obligation to report accidents in accordance with the provisions of the Factories Act. Fatal accidents, which were reported almost without exception, had not increased.

Nutritional Value of Flour

The MINISTER OF AGRICULTURE, FISHERIES, AND FOOD has arranged for an authoritative review of the scientific and medical evidence on the differences in composition and nutritional value of flour of varying extraction rates.

Lord Adrian, P.R.S., has nominated for the conduct of this review the following panel of persons:

Sir Henry Cohen (chairman), Professor of Medicine, University of Liverpool.

Professor L. J. Wits, Professor of Clinical Medicine, University of Oxford.

Professor J. H. Gaddum, F.R.S., Professor of Materia Medica, University of Edinburgh.

Dr. A. C. Chibnall, F.R.S., formerly Professor of Biochemistry, University of Cambridge.

Professor R. A. Morton, F.R.S., Professor of Biochemistry, University of Liverpool.

The formal terms of reference of the panel are:

"In the light of the scientific and medical evidence now available—

"(1) to determine the differences in composition and nutritive value between (a) National flour as defined in the Flour Order, 1953; (b) flour of extraction rates less than National flour as defined in the Flour Order, 1953, to which the three token nutrients have been restored; (c) flour of extraction rates

less than National flour as defined in the Flour Order, 1953, to which the three token nutrients have not been restored; and
"(2) to advise whether any such differences are significant from the point of view of the health of the population.

Beds and Centres.—In each year from 1951 to 1954 inclusive the number of hospital beds unoccupied through shortage of staff were 27,812, 23,013, 18,874, and 17,049 (provisional). The number of new health centres provided each year were one, three, none, and one.

Wages and Salaries.—About £5½m. more than was estimated to have been required in 1954-5, as a result of wage and salary increases has been provided for in the 1955-6 Health Service estimates.

Vital Statistics**Graphs of Infectious Diseases**

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1946-54 are shown thus -----, the figures for 1955 thus ———. Except for the curves showing notifications in 1955, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

**INFECTIOUS DISEASES AND VITAL STATISTICS**

Summary for British Isles for week ending April 23 (No. 16) and corresponding week 1954.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrar-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Infectious Diseases

A decreased incidence was recorded for most infectious diseases in England and Wales during the week ending April 23. The largest falls in the numbers of notifications were 4,544 for measles, from 32,969 to 28,425, 138 for dysentery, from 1,191 to 1,053, 130 for scarlet fever, from 597 to 467, and 116 for acute pneumonia, from 804 to 688. The only large rise was 184 for whooping-cough, from 1,474 to 1,658.

The largest declines in the incidence of measles were 857 in Warwickshire, from 3,565 to 2,708, 677 in London, from 3,291 to 2,614, 644 in Middlesex, from 2,597 to 1,953, 439 in Kent, from 1,252 to 813, 423 in Yorkshire West Riding, from 3,726 to 3,303, and 273 in Buckinghamshire, from 652 to 379, and the largest exceptions to the general decline were increases of 166 in Southampton county, from 976 to 1,142, and 150 in Staffordshire, from 1,309 to 1,459. The rise in whooping-cough was mainly due to an increase of 99 in Middlesex, from 47 to 146, and this rise was due to an outbreak of 107 cases in Southall M.B. The largest fall in the number of notifications of scarlet fever was 39 in Lancashire, from 104 to 65. 14 cases of diphtheria were notified, being 7 more than in the preceding week; these cases involved 12 areas. 6 of the 15 cases of paratyphoid fever were notified in Durham, Sunderland R.D. 6 cases of acute poliomyelitis were notified, and these were 13 fewer for paralytic and 1 fewer for non-paralytic cases than in the preceding week. 2 cases were notified in Somersetshire, Yeovil R.D., and Lincolnshire, Grimsby C.B.

The largest centres of dysentery were Lancashire 422 (Oldham C.B. 80, Chadderton U.D. 62, Blackpool C.B. 33, Liverpool C.B. 32, Manchester C.B. 28, Worsley U.D. 28, Blackburn C.B. 27, Whiston R.D. 14, Crompton U.D. 12, Royton U.D. 12), Durham 149 (Felling U.D. 29, Gateshead C.B. 26, Easington R.D. 25, Seaham U.D. 24, South Shields C.B. 16, Stanley U.D. 12), Yorkshire West Riding 72 (Leeds C.B. 17, Goole M.B. 15), Leicestershire 54 (Leicester C.B. 47), Surrey 50 (Banstead U.D. 24, Beddington and Wallington M.B. 11), London 47 (Shoreditch 11, Hackney 10), Northumberland 44 (Newcastle-upon Tyne C.B. 14), Yorkshire North Riding 31 (Middlesbrough C.B. 30), and Norfolk 30 (Norwich C.B. 20).

Week Ending April 30

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 461, whooping-cough 1,768, diphtheria 9, measles 22,537, acute pneumonia 540, acute poliomyelitis 19, dysentery 879, and paratyphoid fever 15.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Medical News

Eighth World Health Assembly.—The assembly opened on May 10 in Mexico City under the chairmanship of last year's president, Dr. JOSEPH N. TOGBA, director-general of the Liberian National Health Service. One of the more difficult problems before the assembly is to decide how best to allocate W.H.O.'s limited resources in the field of atomic medicine: should priority be given to developing the use of radio-isotopes or to the protection of populations against radiation health hazards?

Human Trial of Live Polio Vaccine.—On May 3, at the meeting of the Association of American Physicians in Atlantic City, U.S.A., Dr. ALBERT B. SABIN, director of the Children's Hospital Research Foundation, University of Cincinnati College of Medicine, announced a successful human trial of live poliomyelitis vaccine. According to the account in the *New York Times*, Dr. Sabin reported "the finding of viruses of the three known polio types that were capable of stimulating the formation of antibodies although they did not cause polio symptoms in monkeys or chimpanzees." After 18 months' testing the characteristics of the attenuated viruses had been established, and a vaccine prepared from them was given to 26 volunteers at a Federal reformatory. "The volunteers," continues the *New York Times* report, "were between 21 and 30 years old. They swallowed doses of the attenuated polio viruses, but developed no symptoms of the infections, Dr. Sabin said. Antibodies were formed, but no signs of paralysis or other illness observed." After reading his report, Dr. Sabin is quoted as emphasizing that the work with live viruses was still "in an experimental stage," and that it might be a long time before a workable live virus vaccine could be achieved.

Salk Vaccine.—Meanwhile the Salk (dead virus) vaccine continues to claim the anxious attention of the American public. The Federal Government has recommended a further postponement of the vaccination programme, and vaccination is reported to have ceased in every state except Michigan. Dr. LEONARD SCHEELE, the U.S. Surgeon General, in a statement on May 8 said that among the five million children already inoculated with Salk vaccine there had been 50 cases of paralytic and 2 of non-paralytic poliomyelitis, 44 of which followed vaccination with the banned Cutter product. Testifying earlier before the Congressional banking committee, Dr. Scheele referred to the expert working party which is investigating these cases. Its report, he said, would determine whether the public health service would continue to examine batches of vaccine "by protocol"—that is, by close scrutiny of the maker's written evidence of safety and efficiency, a day's procedure—or whether it would have to test each batch by animal inoculation, a process, Dr. Scheele testified, that would take 28 to 33 days. A dispatch from Washington records the arrival there on May 9 of Dr. W. L. M. PERRY, the Medical Research Council's emissary (see *Journal*, May 7, p. 1166). Current British methods of screening poliomyelitis vaccine are described on p. 1204 of this issue.

Places in Special Schools.—According to a survey of physically handicapped children in England and Wales, undertaken by the Ministry of Education, there were on October 1, 1954, 1,052 children of compulsory school age awaiting places in special schools. These children were those known to local authorities whose condition came within the terms of the School Health Service and Handicapped Pupils Regulations, 1953; blind, deaf, and "delicate" children are not included. Of the total, 202 needed places in day schools, and 850 in boarding schools. Parental consent had been given in 525 of the latter cases. No less than 485 of these unplaced pupils were suffering from cerebral palsy. The next commonest conditions were poliomyelitis (100), heart defects (78), muscular dystrophy (73), and spina bifida (68). According to the Ministry enough

additional boarding-school places are likely to come into use in the next two or three years to accommodate all the children whose parents are likely to consent to their attending boarding schools.

Rectorship of Edinburgh University.—On May 5, with traditional pomp, Sir SYDNEY SMITH was installed as Rector of Edinburgh University. In his address he spoke of the State's increasing monetary interest in the universities: Up to the present, said Sir Sydney, there had been no interference with the methods by which the universities carried out their functions, but "the dependence on Government grants for 75% of their expenditure may represent the writing on the wall."

Medical Candidates.—Since our list of medical candidates for the General Election was printed (*Journal*, May 7, p. 1149) two more have come forward. They are: DAVID GORDON EVANS, Buckingham, Labour (1938). Assistant General Secretary, Medical Practitioners' Union; Lecturer at London School of Tropical Medicine and Hygiene; formerly regional medical officer, J. Arthur Rank Organization; member, Association of Industrial Medical Officers; Squadron-Leader, R.A.F.V.R., 1940-6. And GERARD FOLLIOTT VAUGHAN, Poplar, Conservative (1947). Chief Assistant in the Department of Psychological Medicine at Guy's Hospital. (The date in parentheses is the year of the candidate's qualification.)

Dr. Stott Commemoration Fund.—A fund is being raised to commemorate Dr. L. B. STOTT's 33 years' service as medical officer to the Papworth Village Settlement for the treatment and rehabilitation of sufferers from tuberculosis. Dr. Stott retired last December because of ill-health. The fund will be used for one or more of the following: Prizes for children at Papworth School; grants to children at the school or resident in Papworth who win scholarships; the erection of a shelter in the children's playing fields. Contributions should be sent to the Secretary, Dr. Stott Commemoration Fund, St. Peter's Hostel, Papworth Everard, Cambridge.

Cadmium Poisoning.—Whether cadmium poisoning should be a "prescribed disease" under the National Insurance (Industrial Injuries) Acts, and, if so, for what occupations, is being considered by the industrial diseases subcommittee of the Industrial Injuries Advisory Council. Persons and organizations interested in the question of prescribing cadmium poisoning are invited to submit written evidence. Communications should be addressed to the Secretary, Industrial Injuries Advisory Council, 10, John Adam Street, London, W.C.2, to arrive not later than June 6.

Sir Arthur Keith's Estate.—The late Sir Arthur Keith, whose death occurred on January 8 (see *Journal*, January 15, p. 168) left estate of £11,778 gross value. Among his bequests were £500 to the Royal College of Surgeons, for the upkeep of Down House, and such of his books, manuscripts, and papers as the librarian may select. He also bequeathed £500 to the Royal Anthropological Institute of Great Britain and Ireland, £200 to the Royal Medical Benevolent Fund, £100 to the Anatomical Society of Great Britain and Ireland, and 100 guineas to Aberdeen University for the anthropological museum in Marischal College.

W.H.O. Appointments.—Dr. R. M. DOWDESWELL, formerly deputy director of laboratory services in Kenya and more recently visiting professor of bacteriology at the American University, Beirut, has been appointed director of the El Calioab Public Health Demonstration Project in Egypt. Dr. T. EVANS, assistant director of medical services, Northern Rhodesia, has been appointed deputy director of the W.H.O. Regional Office for Africa at Brazzaville.

Hunterian Society.—At the annual general meeting on May 2 Mr. A. DICKSON WRIGHT was elected president for 1955-6 in succession to Dr. W. S. C. COPEMAN. Professor E. N. DA C. ANDRADE, F.R.S., gave an address on "Isotopes."

News in Brief.—Mr. C. E. ENGEL, of the photographic department of Guy's Hospital, London, won the prize for foreign medical films in this year's competition organized by the French journal *La Presse Médicale* (see *Journal*, December 11, 1954, p. 1431). His film was "Mitral Valvulotomy for Mitral Stenosis." Dr. PETER HANSELL, director of the Westminster Hospital's photographic department, was accorded an "honourable mention" for his film "Grafting on the Cornea."

Dr. L. GORDON HOPKINS was presented with the second Sydney Body gold medal at a ceremony at Southend General Hospital in March. It was awarded for his "distinguished services to medicine in Southend for the past 50 years." Dr. Hopkins is 80.

COMING EVENTS

Association of Medical Records Officers.—One-day Medical Records Exhibition at the Bonnington Hotel, Southampton Row, London, W.C.1, from 10 a.m. to 6 p.m. on May 21. Exhibition open to all interested in problems of records storage, out-patient waiting, medical correspondence and indexing. At 11 a.m. Dr. N. M. GOODMAN (Ministry of Health) will lecture on "Statistics and Records of Cancer."

Medical Association for the Prevention of War.—Annual conference on June 4, 2 to 6 p.m., at 45, Russell Square, London, W.C.1, on "The Medical Effects of Radioactive Explosions." Speakers include Dr. W. R. S. DOLL, Dr. R. H. DOBBS, and Dr. G. DISCOMBE. Open, free, to all members of the medical profession and others interested.

National Association for Maternal and Child Welfare.—Annual conference at Church House, Westminster, June 22-24. Details from secretary, N.A.M.C.W., Tavistock House North, Tavistock Square, London, W.C.1.

NEW ISSUES

British Journal of Industrial Medicine.—The next issue (Vol. 12, No. 2) is now available. The contents include:

MORTALITY FROM LUNG CANCER IN ASBESTOS WORKERS. Richard Doll.
PRIMARY LUNG CANCER IN SOUTH WALES COAL-WORKERS WITH PNEUMOCONIOSIS. W. R. L. JAMES.
PULMONARY FIBROSIS IN NON-FERROUS FOUNDRY WORKERS. H. E. Harding and A. I. G. McLaughlin.
LEPTOSPIRAL SEROLOGY IN SCOTTISH COAL-MINERS. R. S. F. Adam and P. N. Edmunds.
DIURNAL VARIATION IN MENTAL PERFORMANCE. Bo Bjerner, Åke Holm, and Åke Swenson.
PHYSIOLOGICAL OBSERVATIONS ON MEN WORKING IN SUPPOSEDLY LIMITING ENVIRONMENTS IN A WEST AFRICAN GOLD-MINE. W. S. S. Ladell.
THE INFLUENCE OF INSPIRED AIR TEMPERATURE ON TOLERANCE TO WORK IN THE HEAT. A. R. Lind.
INVESTIGATIONS INTO THE EFFECTS OF EXPOSURE TO TRICHLORETHYLENE IN MECHANICAL ENGINEERING. E. Grandjean, R. Münchinger, V. Turrian, P. A. Haas, H.-K. Knöpfel, and H. Rosenmund.
CONFERENCE OF THE BRITISH OCCUPATIONAL HYGIENE SOCIETY ON RADIATION HAZARDS IN INDUSTRY.
THE HEALTH OF WORKERS EXPOSED TO IONIZING RADIATIONS. A. S. McLean.
RADIATION SAFETY AT AN ATOMIC ENERGY FACTORY. D. R. R. Fair.
PROTECTION AGAINST X RAYS AND GAMMA RAYS IN THE INDUSTRIAL FIELD. W. Binks.
SAFETY CRITERIA IN ATOMIC ENERGY. F. R. Farmer.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, May 16

EDINBURGH UNIVERSITY.—At West Lecture Theatre, University New Buildings, 5 p.m., Dr. D. J. Guinier: Anaesthesia, Antiseptics, Antibiotics.
INSTITUTE OF PSYCHIATRY.—5.30 p.m., lecture demonstration by Dr. E. Stengel.
ST. ANDREWS UNIVERSITY.—At Physiology Lecture Theatre, Queen's College, Dundee, 5 p.m., open postgraduate lecture by Dr. R. Heim de Balsac (Paris): Observations on the Vascular Factor in the Radiology of the Lung Fields.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.—At Physiology Theatre, Gower Street, W.C., 4.45 p.m., Professor Emil L. Smith (University of Utah): Mode of Action of Proteolytic Enzymes.

Tuesday, May 17

ILFORD MEDICAL SOCIETY.—At King George Hospital, Ilford, 8.45 p.m., annual general meeting. Dr. C. V. Bloom: The Deprived Child Today.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. S. C. Gold: Drug Eruptions.
OXFORD UNIVERSITY MEDICAL SOCIETY.—At Maternity Lecture Theatre, Radcliffe Infirmary, 8.15 p.m., Mrs. E. J. Radley Smith: Leucotomy.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C., 5.15 p.m., Cushny Memorial Lecture by Dr. J. D. N. Nabarro: The Adrenal Cortex and Renal Function.

WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY.—5 p.m., Altmouth Wright Lecture by Dr. A. T. R. Mattick: The Lactobacilli and Some Streptococci.

Wednesday, May 18

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. O. Oliver: Prevention of Hospital Infection.
NORTH-WESTERN TUBERCULOSIS SOCIETY.—At Aintree Hospital, Liverpool, 5.30 p.m., Dr. J. Baxter: Rehabilitation of Tuberculous Patients; Dr. J. O. O'Rourke: Escape from Sanatorium: Some Aspects of Self-determined Discharge.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Professor G. Payling Wright: General Pathology of Tuberculosis (III).
SOUTH-WEST LONDON MEDICAL SOCIETY.—At Bolingbroke Hospital, 8.10 p.m., Bolingbroke Lecture by Mr. A. Dickson Wright: Varicose Veins.
WILLESDEN GENERAL HOSPITAL MEDICAL SOCIETY.—At Department of Physical Medicine, Willesden General Hospital, 8.45 p.m., Dr. E. A. Blake Pritchard: Migraine.

Thursday, May 19

BRITISH INSTITUTE OF RADIOLOGY.—8 p.m., annual general meeting; 8.30 p.m., Dr. J. A. C. Fleming: Some Reflections on the Position and Scientific Role of the Institute.
EDINBURGH UNIVERSITY.—At West Lecture Theatre, University New Buildings, 5 p.m., Dr. D. J. Guthrie: History of Medical History.
HONYMAN GILLESPIE LECTURE.—At University New Buildings, Edinburgh, 5 p.m., Dr. J. H. Wright: Unilateral Renal Hypertension.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. C. M. Fletcher: Atmospheric Pollution and Disease.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor H. R. S. Huxley: Subphrenic Abscess, with particular reference to the Spread of Infection.
ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—7.30 p.m., Professor A. Corradetti: Studies on Comparative Pathology and Immunology in Mammal and Bird *Plasmodium* Infections.
ST. ANDREWS UNIVERSITY.—At Physiology Department, Medical School, Small's Wynd, Dundee, 5 p.m., Professor A. Kekwick: Obesity.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., postgraduate demonstration in neurology.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.—At Physiology Theatre, Gower Street, W.C., 4.45 p.m., Professor Emil L. Smith (University of Utah): Mode of Action of Proteolytic Enzymes.
WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—At Royal College of Physicians of London, 8.30 p.m., Cavendish Lecture by Sir Charles Dadds, F.R.S.: The Renaissance of Treatment.

Friday, May 20

BRITISH INSTITUTE OF RADIOLOGY.—5 p.m., meeting of medical members.
FACULTY OF RADIOLOGISTS.—At Royal College of Surgeons of England, 4.30 p.m., Skinner Lecture by Dr. S. Whately Davidson: Some Anomalies of the Respiratory System.
● INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. R. M. B. MacKenna.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., clinical demonstration by Dr. J. G. Scadding.
LONDON UNIVERSITY.—At St. Thomas's Hospital Medical School, 5 p.m., special university lecture in pharmacology by Professor V. Erspamer (Bari): Biological Significance of 5-Hydroxytryptamine and Related Substances.
OSLER CLUB OF LONDON.—At Royal Army Medical College, 8 p.m., meeting in honour of Sir Anthony Bowly, Bt. (May 10, 1855-1929). Sir Gordon Gordon-Taylor: Reminiscences of Some Famous Surgeons of the 1914-18 War.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—(1) 2 p.m., Mr. A. L. d'Abreu: Surgery of Congenital Heart Disease; (2) 4 p.m., Dr. I. Douglas-Wilson: Words without End.
ST. ANDREWS UNIVERSITY.—At Department of Medicine, Queen's College, Dundee, 2.30 p.m., discussion to be opened by Dr. J. Wright, Dr. R. W. D. Turner, Professor R. Walmsley, and Dr. K. G. Lowe: Pulmonary Stenosis as an Isolated Lesion and with Associated Atrial Septal Defect (Fallot's Triology).
ST. MARK'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Dr. F. S. W. Brimblecombe: Lactation and Breast Feeding.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C., 5.15 p.m., Cushny Memorial Lecture by Dr. H. Harris: Genetic Aspects of Tubular Function.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Clare.—On April 27, 1955, at St. David's Hospital, Cardiff, to Mary Hancock, wife of Deryck Edwin Clare, M.B., B.S., C.P.H., a son.
Drummond.—On April 11, 1955, at St. George's Hospital, London, S.W., to Ann, wife of Dr. P. Drummond, a son—Christopher Gordon.
Edwards.—On May 5, 1955, at Southmead Hospital, Bristol, to Hetty, wife of Errol M. Edwards, M.R.C.O.G., a daughter—Deirdre.
Fleischl.—On April 25, 1955, to Charmian (formerly Quinton), M.B., B.S., wife of Peter Fleischl, M.B., M.R.C.P., a son—John Murray.
Hume.—On May 5, 1955, at St. David's Hospital, Cardiff, to Rosamond (formerly Hyslop), wife of Dr. Michael Hume, a daughter—Caroline Morwena.
Perrem.—On May 4, 1955, at Battledown Manor, Cheltenham, Glos., to Mary, wife of Dr. John F. Perrem, R.A.F., a son—Timothy John.
Watson.—On May 5, 1955, to Audrey, wife of Dr. David Lister Watson, Wiveliscombe, Somerset, a son—Neil Clarke.

DEATHS

Chilcott.—On April 9, 1955, at 26, Stormont Road, Highgate, London, N., Arthur Edward Chilcott, M.D., aged 91.
Grosvenor.—On April 12, 1955, at Salisbury, Southern Rhodesia, Harold Octavius Washington Grosvenor, M.R.C.S., L.R.C.P.
Haynes.—On April 1, 1955, at 57, Crown Street, Brentwood, Essex, Horace Guy Lankaster Haynes, T.D., M.R.C.S., L.R.C.P., Lieutenant-Colonel, R.A.M.C.T., retired.
Heesom.—On April 19, 1955, at his home, Berkswell House, High Trees, Reigate, Surrey, Alan Hedley Beecroft Heesom, M.R.C.S., L.R.C.P., L.D.S.
Macewen.—On April 17, 1955, at Gartferry, Innellan, Argyll, Hugh Allan Macewen, O.B.E., M.B., Ch.B., D.P.H.

Any Questions ?

Exertion after Hernia Repair

Q.—Does strenuous exertion after a repair of an inguinal hernia predispose to a recurrence or does it strengthen the abdominal muscles and thus reduce the tendency to recurrence? Does the use of unabsorbable suture materials lessen the chances of recurrence after repair of a hernia?

A.—Strenuous exertion should certainly be avoided for the first month or six weeks after a repair operation for inguinal hernia—particularly in fat or flabby patients; graduated abdominal exercises, however, are all to the good. By far the majority of recurrences after hernia operations occur within the first year, and probably two out of three of these within the first six weeks. "Hasten slowly" is therefore a good motto for this initial period.

The absorbable suture probably produces a better fibrous reaction than the non-absorbable. However, because of the likely possibility of stretching this new fibrous tissue in the fat, the flabby, the chronic bronchitic, or the patient whose occupation involves constant severe strain, in these cases more reliance should be placed on the non-absorbable materials.

Tuberculosis in Pet Monkeys

Q.—My small children keep as a pet a Mona monkey. I have heard that there is a good deal of pulmonary tuberculosis in monkeys in captivity, and I am therefore a little doubtful about whether I should allow them to retain the animal. I have no reason to suspect that he is not in good health. I should be grateful for your advice about this.

A.—Most species of monkey are susceptible to tuberculosis, but in the wild state do not have any opportunity of acquiring the infection. They may, however, become infected after capture, and in this case the infection will be of the primary type, often progressive and terminating fatally. Such monkeys will be dangerously infective to man.

Monkeys kept as pets should always be tested with old tuberculin, a convenient site for inoculation being the upper eyelid. A positive reaction indicates present or past infection. A negative reaction suggests freedom from infection, but does not absolutely exclude it. They should therefore in addition be examined clinically, and also radiographed for signs of pulmonary tuberculosis. The absence of any sign of infection after proper investigation should reassure the owner.

Tuberculous persons or tuberculous milk are potential sources of infection to captive monkeys.

Pineapple Finger

Q.—I would be glad of any information or reference you can give me on the form of industrial dermatitis known as "pineapple finger" and on any other illness peculiar to people canning pineapples.

A.—According to Schwartz, Tulipan, and Peck¹ the peeling of pineapples may cause dermatitis because of the sharp spears on the pineapple and the high content of sugar in the juice. A full account of pineapple dermatosis has been given by I. Polunin.² He describes erosions of the fingertips caused by a proteolytic enzyme in pineapple juice which causes separation of the superficial layers of the skin. Pineapples have long been used in cooking to soften tough meat, and photographers in the past used the juice to remove the gelatin from old photographic plates.

Testosterone for Birth Control

Q.—Testosterone inhibits spermatogenesis. Is it of value in birth control? What possibility is there of its producing malignancy? What dose is required to inhibit spermatogenesis?

A.—It is true that testosterone in sufficient dosage will inhibit spermatogenesis, but it could certainly not be recommended as a form of birth control. It is uncertain, for example, whether, after sufficiently prolonged administration of testosterone, testicular recovery could take place. So far as the writer knows, there is no likelihood of testosterone producing malignancy. The amount of testosterone required to inhibit spermatogenesis completely varies in different individuals, but it is probable that for most men a weekly injection of 100 mg. of testosterone phenyl propionate would, within a period of two months or so, reduce the rate of sperm production to infertile levels.

Treatment of Tinnitus

Q.—What can be done to help a woman of 60 with severe tinnitus—periodic attacks of buzzing noises in both ears so severe that she is reduced to tears? She has been treated over the last two years with drugs, but the tinnitus has now reached a stage (attacks twice weekly lasting 1–24 hours) when none brings her any relief.

A.—There is no specific drug or treatment that can abolish the tinnitus. If the cause be wax in the ear, fluid in the tympanum, or any of the ototoxic drugs such as quinine, salicylates, or occasionally aspirin, removal should result in the tinnitus disappearing. Troublesome tinnitus such as mentioned in the question is, however, usually due to some disturbance of cochlear function. Destruction of the cochlea or even section of the auditory nerve has been repeatedly carried out for tinnitus without success in but rare exceptions. In fact, this lack of success after the hopes of the patient may have been built up by the operation may often result in the tinnitus becoming more intolerable than ever. In itself tinnitus can do no harm, but it can be distracting, particularly to a nervous or introspective person.

Various forms of treatment designed to increase the blood supply to the internal ear have been tried, but usually give no definite relief. Very occasionally an injection of the stellate ganglion with a local analgesic may produce some temporary change, and might be tried in this case.

Indications for Vitamin B₁₂

Q.—In what conditions is vitamin B₁₂ definitely indicated? Advertisers suggest its use in a wide variety of conditions.

A.—It has been suggested that cyanocobalamin (vitamin B₁₂) increases the weight of premature babies and underweight children, that it has some general tonic effect in adults, and that it is of value in the treatment of diabetic neuropathy. The main weight of scientific and clinical evidence does not support these claims and suggests that its use should largely be confined to the treatment of Addisonian pernicious anaemia, in which its therapeutic efficacy appears to be identical with that of liver extract, including its ability to prevent and to ameliorate the nervous complications of the disorder. Its cost is less than that of liver extract, the amount needed for injection is smaller, and it does not cause allergic reactions. In consequence it is probable that cyanocobalamin will replace liver extract in the future. It is occasionally effective in other high colour-index anaemias (the megaloblastic anaemias of pregnancy, infancy, malabsorption, and the Tropics), but in these folic acid is usually the drug of choice. Subacute combined degeneration of the cord hardly ever occurs in these latter anaemias, but it is wise for maintenance purposes to supplement folic acid with parenteral therapy with cyanocobalamin or liver extract, since severe peripheral neuritis may occur in patients taking folic acid alone for a long time.

Sympathomimetic Drugs and Asthma

Q.—What drugs should be included under the heading of sympathomimetic drugs? Is it true that if such drugs are given to a child with asthma they lead to addiction, tend to make the asthma chronic, and may harm the heart?

A.—The following drugs are included under the heading of sympathomimetic drugs—ephedrine, adrenaline, nor-adrenaline, isopropyl-noradrenaline, "propadrine," methyl ephedrine, amphetamine, "paredrine," "kephrine," and "paredrinol."

Those of the above that are used in asthma do not lead to addiction, do not harm the heart, and do not make the asthma chronic. Ephedrine and adrenaline have been used for very many years and in all countries, and are generally acknowledged to be of very considerable benefit to asthmatics; in some cases adrenaline is life-saving. Side-effects such as palpitation or general excitability may occur, but these are not dangerous or harmful and can be reduced by the addition of a mild sedative such as phenobarbitone and by keeping the dose to the minimum necessary to relieve the attack.

Intolerance to Humidity

Q.—Is it known why some individuals are intolerant of humidity? A woman of 51, formerly unaffected by tropical climates, has for the past seven years become most sensitive to increases in humidity even in the United Kingdom. Such increases precipitate headache, stifling respiration, nasal congestion, and profuse sweating of the head and neck, leading to a complaint of intolerable "heat" although the actual temperature may be moderately cool and the majority of the community feel comfortably warm or even cool. Is there any means of helping such patients to tolerate raised humidity?

A.—This type of complaint is not unknown in some women in the Tropics at or about the menopausal age. The hyperhidrotic areas are those supplied by the cervical sympathetic, and these regions are often unaffected in anhidrotic heat exhaustion. The chief points of interest here are the long duration of the disorder and its association with humidity. On the other hand, the head, and particularly the forehead, is one of the first places, after the palms, to be affected in emotional sweating. As the patient also gets headaches, this may indicate that the trouble is psychogenic rather than endocrine in origin.

Presumably the questioner means relative humidity. When the relative humidity is high sweating anywhere is more apparent, as the "saturation deficit" is low and hence evaporation slow. There is, however, no physiological reason for humidity to affect heat loss and hence stimulate sweating in a resting clothed subject until the air temperature reaches 75° F. (23.9° C.), or in a nude man until it reaches 85° F. (29.4° C.); these limits are lower for working subjects. Provided there are no obvious signs of humidity, such as damp walls, men are as comfortable in 80 or 90% relative humidity in air at 60–70° F. (15.6–21.1° C.) as in lower humidities. On damp overcast days, however, the diffuse sky radiation, which cannot be avoided like sunlight, is very much greater than on clear dry days; recent work suggests that thermal radiation to the skin causes an increase in the heart rate, independent of any effect due to a raised body temperature; and it is well known that thermal radiation from any source if it warms the skin results in nasal congestion ("nose closing" effect); this may be of importance in specially sensitive persons. These effects, combined with the impossibility of getting any shade from a diffuse radiation which comes from all over the sky, might well be a precipitating factor in psychogenic sweating. The bad temper and vague malaise often complained of by people in sub-tropical regions during winds carrying high fine dust,

such as the Khamseen or Harmattan, may also be caused in this way, as dust has the same effect as water vapour in diffusing solar radiation.

Pityriasis Rubra Pilaris

Q.—I have a patient suffering from pityriasis rubra pilaris of long standing. He has visited skin specialists in this country (Ireland), England, and on the Continent, but unfortunately nobody has helped him. Is there any modern advance in the treatment of this condition? Would the topical application of cortisone benefit him?

A.—It is generally accepted that pityriasis rubra pilaris is extremely resistant to treatment. A temporary improvement can sometimes be produced by the use of salicylic acid ointment, and irritation may be relieved by the usual measures.

In recent years this disorder has been treated by the administration of vitamin A concentrate, 24,000 units two or three times daily continued for some months. In some cases apparently there is a definite improvement, but more often the results are indecisive and some cases are not helped at all. However, the treatment is probably worth a trial.

I have no information regarding the local application of cortisone in this disease. Pityriasis rubra pilaris is usually thought to be a naevoid condition, and, on general principles, one would not expect improvement to follow the application of cortisone.

Significance of Nocturnal Polyuria

Q.—I should be very grateful for any information about the possible causes of nocturnal polyuria with frequency. The case in which I am interested is that of a man aged 76 in normal general health. For the past 10 years he has been troubled with nocturnal frequency of micturition—about five or six times between the time of going to bed (about midnight) and rising (7 a.m.). Between 35 and 40 ounces (about a litre) of urine is passed, of S.G. 1010, neutral in reaction, and with no abnormal constituents. Practically no fluid is taken after dinner at 7.30 p.m., and then only half a pint of cider (284 ml.) as a rule. During the day there is no polyuria or frequency. There is no palpable enlargement of the prostate, and there has never been any difficulty in passing urine. I remember reading in the "Journal" some years ago that prisoners of war were troubled by nocturnal polyuria, but do not remember if any explanation of the condition was offered.

A.—In health, the rate of urinary excretion of water, sodium, potassium, and chloride is less during the night than in the day. This patient shows a reversal of this diurnal rhythm, with nocturnal polyuria rather than oliguria. This abnormality tends to occur in any condition in which there is expansion of the extracellular fluid volume due to sodium retention. It has been found, as stated, in starvation, in congestive heart failure with or without oedema, in cirrhosis of the liver,² and during treatment with cortisone.³

The most likely cause in a patient of 76 is incipient heart failure. This symptom of nocturnal polyuria may occur at a stage when there are few signs of failure, and where the only other symptom is exertional dyspnoea. It is suggested that treatment by restriction of dietary salt might result in considerable relief. If there is other evidence of heart failure—e.g., increase of jugular venous pressure or cardiac enlargement—digitalization would be of great benefit.

Syphilis and Sterility

Q.—How does syphilis cause sterility? Is its action to be explained simply on the basis of gummatous changes in the gonads? How often are the ovaries affected?

A.—Syphilis may cause male sterility, either by gummatous changes in the testis; by obstruction of the epididymal canal with cellular debris; or by secondary testicular failure due apparently to impairment of the gonadotrophic stimulation of the testis. In this last case it would seem that the testicular failure is part of a more generalized pattern of endocrine dysfunction.

In the female, syphilis by no means regularly results in sterility, though the sequence, abortion—stillbirth—syphilitic live-birth—normal live-birth, is a well-known one. It is doubtful if the ovaries are at all commonly directly affected by syphilis.

Nowadays, syphilis is a relatively rare, and an increasingly less common, cause of infertility. This of course is the result of the much more effective means of treating the early stages of the disease now at our disposal.

Hymenolepis Nana Infections

Q.—What is the best treatment for infection with *Hymenolepis nana*? I have had no success with male fern, mepacrine, and chloroquine.

A.—This is a difficult worm to eradicate, though fortunately, except in very heavy infections, it seldom gives rise to symptoms. It is advisable to starve the patient for 48 hours before administering the anthelmintic and to follow the treatment with a saline purgative. As the adults live in the upper ileum it is important that, whatever the anthelmintic used, it should be liberated in this region. For this reason capsules of male fern are less suitable than a draught such as extract of male fern (extractum filicis) 90 minims (6 ml.), syrup of ginger 90 minims (6 ml.), peppermint water to 1½ oz. (42 ml.). Male fern administered in this way is probably the best of the anthelmintics available, but another which might usefully be tried is hexylresorcinol.

Peripheral Neuritis after Isoniazid

Q.—Can you give me any information on the development of acute peripheral neuritis due to the administration of isoniazid?

A.—Peripheral neuritis may occur in patients receiving large doses of isoniazid (6–10 mg., or more, per kilo per day). It is very rare indeed in patients receiving 200 mg. daily (or 3 mg./kilo), the standard dose used in the Medical Research Council trials. The neuritis is probably a direct toxic effect and not an allergic reaction. It usually clears up when the drug is stopped, or even, in the milder cases, if the dose is lowered.

NOTES AND COMMENTS

Hairy Tongue.—Dr. W. TOMASZEWSKI (Edinburgh) writes: In your answer ("Any Questions?" April 9, p. 924) the parasitic theory is given as one of the causes of hairy tongue. It is an old textbook story which is totally lacking in proof. Although the presence of some types of fungi (mainly monilia) has been described, in a number of cases inoculation of the tongue with these fungi has failed to reproduce the clinical condition. The presence of fungi is incidental, the matted long filiform papillae being a favourable nidus for their growth and persistence. The same types of fungi can be found also on a normal tongue. Conversely in nearly 50% of cases of idiopathic, black, hairy tongue the presence of fungi has not been demonstrated.¹ There is also a statement that "recently studies of the tongue with Wood's light have shown that the flora of the dorsum of the tongue may change very rapidly in the apparently normal, healthy mouth. . . ." This is not a wholly true statement, as examination in Wood's light merely enables one to follow changes in the fluorescence of the tongue.² The changes of the bacterial flora on the tongue can be reliably ascertained only by microscopical

examinations of tongue scrapings. I wrote about these spontaneous changes of bacterial flora in a recent letter.³ I have made a large number of examinations of the bacterial flora in black tongue, but so far there is no evidence that any particular microflora is associated with the occurrence of this condition.

2. *Ibid.*, 1951, 1, 117.
3. *Ibid.*, 1954, 2, 1420.

OUR EXPERT writes: I would not agree that the parasitic theory of black hairy tongue can be ruled out, if for no other reason than the excellent therapeutic results obtained with gentian violet, but it may well be that *Candida albicans*, when present, serves to keep the condition going.^{1,2} I am a little surprised that anyone could think it possible to study the flora of the tongue without a microscope, and to avoid further ambiguity let me also add that such studies of fluorescence of the tongue not only need Wood's light and a microscope but appropriate cultural aids as well. Finally, Laskaris and Curtis³ report a fairly consistent microflora with hairy tongue, so it would seem that much more work will have to be done on the bacteriology and mycology of these lesions before it will be safe to dogmatize about them.

3. Bruce, D. F., *Glasg. med. J.*, 1953, 34, 354.

"Once a Caesarean."—Dr. D. F. BRUCE (Glasgow) writes: I should like to comment on two points raised by your expert under the heading "Once a Caesarean" ("Any Questions?" April 16, p. 983). Firstly it is unnecessary to anaesthetize the patient in order to examine the scar of a previous lower-segment caesarean section. Provided that this examination is carried out immediately after completion of the third stage of labour, satisfactory exploration of the lower uterine segment is possible without causing discomfort. This is the routine practice in the Obstetric Unit of the Southern General Hospital, Glasgow. The second point concerns the risk of rupture of a transverse lower-segment scar in subsequent labour. In a short series of 54 cases of labour following caesarean section¹ there was no instance of rupture of the uterus. In 41 of these cases the previous caesarean section was of the lower-segment type, the incision having been transverse in each instance. In four cases the labour was the second following caesarean section. In no case was sterilization indicated. These cases were, of course, selected as being suitable for trial of labour.

REFERENCE

1. Bruce, D. F., *Glasg. med. J.*, 1953, 34, 354.

OUR EXPERT writes: In practice, most women with a caesarean section scar in the uterus are delivered with forceps applied prophylactically, so some sort of anaesthesia is already in use when labour is complete. In other cases it is a matter of opinion whether an anaesthetic should be administered for the sole purpose of exploring the uterus, and there are arguments for and against. Often, as Dr. Bruce says, the scar can be palpated satisfactorily without anaesthesia, provided the patient is in the lithotomy position. Dr. Bruce's statistics on the risk of rupture of the scar are valuable and go to swell those which have been appearing in various medical journals and maternity hospital reports during recent years.

Books of "Any Questions?"—The second and third volumes of "Any Questions?" are available, price each 7s. 6d. (postage 6d.), from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller. Each contains some 200 selected expert answers, and the third volume a cumulative index to the three published books.

CLASSIFICATION OF THE EPILEPSIES*

BY

Sir CHARLES SYMONDS, K.B.E., C.B., D.M., F.R.C.P.

Physician for Nervous Diseases, Guy's Hospital; Physician, National Hospital, Queen Square

No lecture on epilepsy can begin without reference to Hughlings Jackson, who almost a century ago defined epileptic seizures as the expression of occasional, sudden, excessive, rapid, local discharge in the grey matter. This definition needs hardly any qualification to-day. Yet within the last fifteen years our knowledge of epilepsy has greatly expanded owing to the introduction of the electroencephalogram, a method by which the discharge, which was for Jackson hypothetical, can now be seen and recorded in many seizures. The knowledge thus gained is still in process of assimilation, and what we believe to-day may no longer be true in a year's time. I am not perturbed by this reflection. It is necessary for clear thinking to have beliefs. It is equally important that we should be prepared to change them, which is not so easy. I would commend to you in this connexion Sir Thomas Browne's saying that "to purchase a clear and warrantable body of truth, we must forget, and part with, much of what we know."

If we are to think clearly about epilepsy we must begin by arranging our observations in some kind of order. The classification of seizures in terms of medical science is in itself a problem which has exercised many minds in recent years. I shall put before you the method of classification which I have proposed myself and believe at present to be the most satisfactory. It requires tabulation of the data under separate headings, and the most convenient arrangement is in parallel vertical columns.

The first heading is Clinical. A seizure is a clinical event, and the symptoms observed, or elicited by questioning the patient, must be classified in terms of clinical usage. What these terms should be I will discuss later. It will suffice for the moment if I say that under the Clinical heading we shall record clinical phenomena only—for example, loss of consciousness, convulsive movements, odd behaviour, and abnormal sensations. The heading for the second column is Anatomical. If we accept Hughlings Jackson's definition—and there is no reason to doubt it—the discharge must begin somewhere in the brain. It will be our aim under this heading to indicate the site of origin of the discharge. The third heading is Physiological. Seizures may be accompanied by observed disorder of function in the neurones. Of this the only example at present known is the physical disturbance recorded by the E.E.G.

The fourth column is Pathological. The terms of classification in this column will be those to which we

*A clinical lecture delivered at Guy's Hospital.

are all accustomed, inflammation, trauma, new growth, and so on. Finally, I think it useful for practical purposes to have a column in which to record any specific response of seizures to particular drugs or other forms of treatment. A convenient heading will be Therapeutic. In this column we shall make such entries as dione-responsive, primidone ("mysoline")-responsive, and so on. Our object, of course, will be to establish correlations between groups of data in the different columns.

Clinical Patterns of Seizure

I will now go back to consider the classification of seizures in clinical terms. The simplest method is to make use of the plan followed in recording a neurological examination. We begin with the mental state and record loss or clouding of consciousness, disordered behaviour, disturbance of thought, hallucinations, and illusions. Next comes speech, which may be arrested or disorganized in a seizure. After this we take the special senses, any of which may be involved in an attack. Then we have the motor system to consider, which will include a large part of our clinical data—convulsive movement, tonic or clonic, generalized or localized. Sensation will also include many data provided by the patient's account of numbness, tingling, and other somatic sensory experience in attacks. Finally, there is the important heading for visceral symptoms, which may be motor—for example, vasoconstriction, salivation, or involuntary micturition—or sensory—for example, the well-known epigastric aura. The visceral symptoms are commonly both motor and sensory.

I shall not attempt to describe the great variety of symptoms or combinations of symptoms that may be observed in epileptic seizures. The point I wish to make now is that it has been possible to relate certain clinical patterns of seizure to certain anatomical sites of discharge, so that we can speak of pre-central or post-central seizures, temporal-lobe seizures, occipital-lobe seizures, and so on.

In this process of clinico-anatomical correlation the E.E.G. has proved very useful, for when the epileptic discharge arises near the surface of the brain it is associated with a localized electrical disturbance which can often be recorded, either in association with seizures or in the intervals between them. This is a more delicate, and often a more certain, method of establishing the site of the discharging lesion than any other, and has made us more confident of the relationship between clinical pattern and anatomical site than when we had to depend upon the evidence provided by pathological lesions. Sometimes the E.E.G. will indicate the site of discharge when the clinical pattern is of doubtful value. On the other hand, the clinical pattern may sometimes be distinctive when the E.E.G. fails to reveal any localized discharge, probably because the discharge is arising deeply and is therefore not picked up by the scalp electrodes.

Contribution of the E.E.G.

Apart from its localizing value, the E.E.G. may sometimes provide data for use in the pathological column. For example, replacement of the normal alpha rhythm by localized very slow wave activity indicates an active or recent destructive lesion. Generalized slow-wave activity is met with in the presence of increased intracranial pressure.

But the main contribution of the E.E.G. to the study of epilepsy has arisen from the discovery that there is a large group of seizures associated with a particular pattern of electrical disturbance. In this instance the data belong to the physiological column. The distinctive feature of this pattern of discharge is that it is bilateral, synchronous, and symmetrical. Now, taking the physiological column as our point of departure, we may proceed to see what correlations can be established with data in the other columns. The clinical pattern of seizures associated with this type of E.E.G. is quite simply described, but at this point we must digress for a moment to define terms commonly, and sometimes loosely, used in the clinical description of seizures—major or grand mal, and minor or petit mal. It is generally accepted that a major seizure is one in which there is loss of consciousness and generalized convulsive movement. Any other kind of seizure is usually described as minor epilepsy. This division is, I think, unsatisfactory, for there is a great variation, not only in the pattern but in the duration of seizures which would thus be included in the minor category. I can see no completely satisfactory solution for this difficulty, but if we take as our measure the duration of the attack we shall find that there is a large group in which the seizure is over in less than a minute. As a term of clinical usage petit mal was often in the past employed to describe these very brief seizures, but, as I shall later explain, petit mal has now lost its purely clinical meaning. It is convenient to have a term for these little attacks, and minimal seizure is, I think, appropriate, provided that we remember that the word "minimal" refers only to the duration of the seizure.

Now, when we examine the clinical features of attacks associated with the bilateral, synchronous, and symmetrical discharge we find that they are either minimal seizures of a particular kind or major seizures which from the moment of onset are attended by loss of consciousness and generalized convulsion. I must reiterate that these major seizures are not preceded by any other symptoms. As we shall observe later, an epileptic discharge arising in any part of the brain can spread to involve the whole of it and will then be attended by loss of consciousness and generalized convulsion. In such attacks—focal or partial seizures—there is nearly always some initial symptom corresponding with the site of the initial discharge, and if the onset of an attack can be recorded by the E.E.G. localized discharge will be apparent, preceding the general spread. But in the seizures of the group which we are now discussing both the convulsive movements and the electrical discharge are symmetrical and generalized from the first.

Minimal Seizures

The minimal seizures of this group are of two kinds, each as a rule well defined. The most frequent form is the "lapse" or "absence." There is a sudden, brief suspension of mental function with loss of consciousness. The whole episode lasts from 5 to 15 seconds, and may easily pass unnoticed. During the attack the patient has a fixed stare and is motionless, but there is sometimes twitching of the eyelids and occasionally of the arms, and the eyeballs may turn upwards. The seizure ends as abruptly as it began, and the patient will continue with what he was previously doing or saying as if there had been no interruption. Sometimes the lapse may be longer and last up to a minute, but it is probable that in such cases there has been a very rapid succession of brief attacks. Occasionally the lapse may be incomplete—that is to say,

consciousness is not lost, but clouded, and the patient may be able to describe a momentary state in which he is dimly aware of what is going on around him but unable to initiate thought or action. But where consciousness is lost—and this is the general rule—he has no memory of the time during which the seizure occurred, being aware of the interruption only when it is over.

The other form of minimal seizure observed in patients of this group is the myoclonic attack. This consists of involuntary jerks of the muscles without loss of consciousness. These jerks are usually bilateral and symmetrical, but vary in their extent and distribution. They are often confined to the upper limbs. The duration of the jerks is very brief, not more than a fraction of a second, but there may be a succession or volley of jerks. If the jerk is of large extent whatever is held in the hand may be flung into the air, or if the trunk and lower limbs are involved the patient may be thrown to the ground. Occasionally there may be loss or clouding of consciousness in a myoclonic seizure, but as a rule the patient is aware of all that is happening.

A third variety of minimal seizure has been described as belonging to the group under consideration—the so-called "akinetic" attack in which the patient falls, without loss of consciousness and without myoclonus. Doubt has been cast upon this interpretation, the alternative explanation being that the fall is due to a brief single myoclonus involving the lower limbs. Of this it is difficult to be certain, but I believe from my own observation that true akinetic seizures do occur, and this belief is supported by accounts given by intelligent patients who describe their minimal seizures as of three separate kinds—"blanks," "jerks," and "falls."

Differences in E.E.G. Wave Form

This, then, briefly is the clinical range of attacks associated with the bilateral, synchronous, symmetrical abnormality in the E.E.G.: major seizures of the generalized type, and two, or possibly three, species of minimal seizure. Corresponding with these different types of seizure there are differences in the wave form of the E.E.G. In the major seizure the normal alpha rhythm is replaced by waves of a much higher voltage, though of about the same rate—10 cycles per second—giving rise to a series of spikes, which continues unaltered throughout the tonic phase of the convulsion. In the clonic phase the series of spikes is interrupted by rhythmic slow waves corresponding with the intervals between the clonic spasms. In the form of minimal seizure represented clinically by a lapse of consciousness, the E.E.G. shows a regular sequence of alternating spikes and slow waves at a fairly constant rate of three spike-and-wave complexes per second. The myoclonic jerks are associated with isolated spikes or short runs of spikes which may be mixed up with an occasional slow wave. The akinetic seizure, whose existence is now doubted by some authorities, is accompanied by an E.E.G. of the same type as that seen in myoclonic seizures.

Anatomy and Pathology

We have now established in some detail correlations between physiological and clinical data for this group of seizures and must proceed to examine the data in the other columns. The anatomical site of discharge as determined by the E.E.G. would appear to be generalized, but it seems probable from animal experiments that bilateral, synchronous, symmetrical discharge in the cerebral cortex may represent the effect of an initial discharge arising in the central grey matter and propagated to the cortex. The evidence for this is strong enough to have given rise to the term "centrencephalic," or more simply central epilepsy, for this group of seizures, so that we may provisionally enter the word central under the anatomical heading.

Under the pathological heading there are no positive data to record, for no one has ever been able to discover any histological basis for this group of seizures, which therefore remains idiopathic in the traditional sense of that word.

We may therefore enter the word idiopathic under the pathological heading. Incidentally it is in this group of seizures that heredity seems to be of more importance than in any other, so that we might perhaps add genetic in brackets under idiopathic.

Therapeutic Data

There now remains the therapeutic column, and in this we have important data to record, for the minimal seizures of this group often respond in dramatic fashion to the dione group of drugs, of which troxidone ("tridione") is that generally used. Dione-responsiveness appears to be specific for this particular type of seizure. It has no beneficial effect upon the major seizures of this group and may even increase their frequency. On the other hand, the drugs which are often effective in controlling the major seizures have usually no effect upon the minimal seizures.

To summarize the data we have now recorded for this group of seizures, they are as follows:

Clinical	Anatomical	Physiological	Pathological	Therapeutic
1. Major—generalized		Bilateral, synchronous, symmetrical E.E.G. discharge	Idiopathic (genetic)	—
2. Minimal (a) lapses (b) jerks	Central			Dione-responsive

"Central Epilepsy"

We now need a single descriptive term for this group of seizures. So far as the E.E.G. is a guide, the discharge being generalized, we might use the term "generalized epilepsy." Or we might speak of "central epilepsy" or of "idiopathic epilepsy," and in fact all these terms have been, and still are, used. This, I suppose, does not matter so long as we all understand what is meant. For myself, I prefer the term "central epilepsy," because it is a new one and therefore less liable to misinterpretation than terms which have been used in the past in other ways.

There are, however, some further problems of nomenclature which must be discussed if we are to understand what is being written about the epilepsies. You will find that petit mal is now generally used in a specific way to denote minimal seizures of the central type. Sometimes they are called true petit mal, with the implication that, although minimal seizures of similar clinical appearance may occur in association with other forms of E.E.G., it is only those minimal seizures having the bilateral synchronous patterns of E.E.G. that should truly be described as petit mal. The use of the name petit mal in this sense has been widely accepted, and I have no objection to it so long as it is remembered that it is a definition in terms of the E.E.G. and not a term of clinical description.

If we are going to call the minimal seizures of central epilepsy petit mal, it would seem quite logical to call the major seizures grand mal, again remembering that the E.E.G. is the criterion, and using grand mal only to describe major seizures of the central type. Having thus defined central epilepsy with its subdivision into petit mal and grand mal, I must deal very briefly with the natural history of the disease.

Petit mal seizures nearly always begin in childhood, and from the first occur with great frequency, up to 20 to 30 times a day. They are sometimes controlled by troxidone, but even if they are not they may cease about the age of puberty, never to recur. The lapses are so brief that they need not as a rule interfere with normal education, and the same is true of the jerks, unless they are so extensive as to cause falling. In a considerable proportion of the cases, however, the petit mal seizures are followed sooner or later by grand mal, and the liability to seizures of this type is likely to persist, with or without continuation of the petit mal. A series of myoclonic jerks during the first hour after waking in the morning is especially apt to conclude with a generalized convulsive seizure.

Grand mal seizures, with or without petit mal, may begin at any age, but rarely after 30. The drugs which have proved most effective in the treatment of grand mal are phenobarbitone and phenytoin sodium in combination, primidone, and methoin. The principles of treatment are simple. The drug or drugs chosen should be given first in moderate dosage. If the attacks continue, the dosage should be gradually increased up to the point at which either the attacks cease or intolerable toxic symptoms occur. In the latter case another drug or combination of drugs should be tried in the same way. Each therapeutic trial should be continued long enough for a just appraisal of the effect, having regard to the frequency of seizures before treatment was started. In this way the best medication can be determined, and in a considerable number of cases the seizures, even if they are not abolished, can be brought down to a frequency which is not incapacitating.

"Partial Epilepsy"

In all forms of epilepsy other than that which I have defined as central epilepsy, the clinical and E.E.G. data indicate a discharge arising in some part of the brain. It may be restricted to this part or spread to other parts, but the initial discharge is localized. This is what in the past has been called focal epilepsy, but Gastaut (1954), whose recent monograph, *The Epilepsies*, I would commend to you, prefers the term partial epilepsy for good reasons. It was for a long time supposed that focal epileptic seizures always arose from cells in the cortex and that there was a specific relationship between a particular cortical focus and a particular pattern of seizure. This no longer appears true, the fact being that the cortical neurones represent only one link in a circuit comprising at a deeper level neurones of the central grey matter. Cerebral function is represented not in a cortical mosaic but in sectors of brain which include cortex, optic thalamus (and other basal ganglia), and connecting neurones. The discharge responsible for a partial (as opposed to a generalized) seizure may arise either in the cortical or in the central grey matter. Partial epilepsy, proposed by Gastaut instead of focal epilepsy, is therefore a better term, and I think it should be adopted.

Of the symptoms of partial epilepsy there is an endless variety. I have been especially interested in the clinical patterns of seizures all my clinical life and continue to learn new ones. Hughlings Jackson penetrated to the core of the matter when he said 75 years ago that there were as many different epilepsies as there were sites of discharging lesions. Partial seizures may be of the major, minor, or minimal degree, depending upon the amount of spread of the discharge. In the major seizures there may be little or no clinical evidence of a localized onset, though careful questioning of the patient or a witness of the attack will often bring some important point to light, as, for example, twisting of the head and eyes to one side before the onset of generalized tonic spasm, or the memory of an unpleasant smell or visual hallucination before consciousness was lost. The minor or minimal seizures are much richer in clinical clues, for consciousness is often preserved, or is lost relatively late in the attack, and the patient is able to give an account of the initial symptom. Many partial seizures are thus easily identified—pre- and post-central from localized spasm or sensory disturbance, occipital from crude visual hallucinations, postero-inferior frontal from adverse movement of head and eyes, and some of the temporal lobe seizures from the occurrence of an olfactory aura, masticatory movements, or a dreamy state.

Murray Falconer (1954) has given an excellent account of the many seizure patterns that may result from discharge in different parts of the temporal lobe region. But discharge arising in this region or in the frontal lobe may begin and end with loss of consciousness. It may therefore be very difficult, sometimes I think impossible, to distinguish clinically between a minimal seizure arising from

the frontal or temporal regions and the lapse of petit mal, and here the E.E.G. may be of critical importance in arriving at a correct diagnosis.

You will have observed that I have attached a good deal of importance to the E.E.G. in distinguishing between central and partial seizures and in the localization of the site of discharge in the latter, but, as I have already indicated, the E.E.G. is by no means infallible. A positive E.E.G. depends first upon the chance of an epileptic discharge occurring while the record is being made. This chance may be a very small one, though various methods are now used to precipitate what are called subclinical seizures while the record is in progress. Nevertheless there are a great many cases in which we can be quite sure from the clinical evidence that the patient is suffering from epilepsy yet the E.E.G. is negative. This may be true for partial seizures even though the patient is having clinical attacks at the time the record is made. We recently had in the wards a man who was having partial seizures of pre-central origin with tonic and clonic convulsive spasm involving the left side of the face and adversion of head and eyes to the left. These occurred frequently during the period of the E.E.G. record, which showed no abnormality. It is probable in this case that the discharge was arising deeply.

One of the most interesting developments in recent years has been in our knowledge of the pathology of partial seizures, for which it seems possible that there is always an organic cause to be found—that is to say, a demonstrable histological lesion. The importance of scars, due to birth injury, neonatal anoxia, or encephalitis, has been increasingly revealed from the study of brain substance excised by neurosurgeons. Mr. Murray Falconer's lecture has told of what is now being done in the surgical treatment of partial epilepsy.

Conclusion

I will conclude with a brief account of the steps which should be taken in the investigation of a case of epilepsy. First and foremost there is the clinical history, including, of course, the family history, birth, neonatal symptoms, and past history, with special reference to any head injury, or encephalitis complicating one of the exanthemata, leading up to the description of the seizures, by patient and witness. Next comes the neurological and general examination. When this has been completed the distinction between central and partial epilepsy can very often be made on clinical grounds. It is, however, I think essential to have an E.E.G. in every case, for the combination of clinical and electrical data provides the surest basis for diagnosis and treatment. If the clinical and E.E.G. evidence agree in indicating the diagnosis of central epilepsy there is no need for radiographs of the skull, but in every case of partial epilepsy, or *when-ever there is any doubt*, radiographs should be taken. It is true that they will usually reveal nothing, but if this step is not taken the presence of a benign tumour may be missed, at a stage at which there are no symptoms of increased intracranial pressure or any abnormal physical signs—the stage, in fact, at which a benign tumour can be most safely removed. Many benign tumours of the kind which present with epileptic seizures contain areas of calcification; others may cause a shift of the calcified pineal, or erosion or thickening of bone. It has happened to me twice in the last three years to have encountered a patient in the early teens with seizures taking the form of attacks of unconsciousness, sometimes going on to generalized convulsive spasm, with no certain clue to the site of discharge, and without any other symptoms or signs, in which the radiograph revealed a calcified mass in the left temporal lobe. In each instance this proved to be a benign intraventricular tumour, which was successfully removed.

Senior Clinical Research Fellow, Kanematsu Memorial
Institute for Pathology, Sydney Hospital, Sydney

The increasing popularity of barbiturates as suicidal agents has created a world-wide problem, and over the past decade the amount of barbiturate used on both sides of the Atlantic has more than trebled, while the incidence of barbiturate coma has increased fivefold (Nilsson, 1951; Locket and Angus, 1952; Clemmesen, 1954; Goldstein, 1947; Koppányi and Fazekas, 1950, 1952, 1954; Möller, 1954; *Lancet*, 1951, 1953; Goodman and Gilman, 1947). Until recently the over-all death rate from barbiturate intoxication treated with central analeptics of different types has remained steady at about 10%, increasing to over 20% in serious cases (defined by Nilsson as "one which has been in coma for 24 hours or in which complications are present"). This figure has now been reduced as a result of improved medical care (Nilsson, 1951; Locket and Angus, 1952; Clemmesen, 1954) and possibly, although to a much less extent, the more judicious use of the newer central analeptics (Koppányi and Fazekas, 1950, 1954; Eckenhoff *et al.*, 1949). We wish to discuss a new method of treatment incorporating the use of two new substances, $\beta\beta$ -methylthylglutarimide (NP13) and 2:4-diamino-5-phenylthiazole hydrobromide or hydrochloride (D.A.P.T.), which we feel should, when used in conjunction with good medical treatment, further reduce the death rate from this condition.

In our small series of 41 cases of pure barbiturate intoxication, of which nine were serious, there was one death, which we suggest was not due to the treatment, and we feel that the method has been promising enough to warrant further large-scale clinical trials.

The merit of the method lies in the fact that the more active agent, NP13, unlike the central analeptics in current use, appears to exert, in therapeutic doses at least, a direct antagonism to the offending barbiturate, and will readily restore the patient from a deep coma to a desired state of light anaesthesia—"the safe state"—from which spontaneous recovery to full consciousness usually occurs within eight hours. This removes the need for strict and prolonged medical and nursing care (Nilsson, 1951; Locket and Angus, 1952; Clemmesen, 1954; Möller, 1954) and virtually eliminates the risk of complications. The chemical structure of NP13 indicates a definite resemblance to the barbiturate ring system.

*Supported by a grant from the National Health and Medical Research Council of Australia.

D.A.P.T., itself a weak barbiturate antagonist, is, however, a good synergist to NP13 as well as an excellent respiratory stimulant. It greatly reduces the risk of toxic manifestations, which sometimes occur when NP13 alone is given rapidly and in high dosage. Both substances in therapeutic doses appear to cause a slight rise in blood pressure, and a large dose (75 mg.) given intravenously to a barbiturized patient has produced a large rise in blood pressure and sweating, suggesting a direct effect on the autonomic ganglia. However, both substances, especially NP13, in high dosage, and particularly if given rapidly, will cause convulsions in both barbiturized and normal animals (Benica and Wilson, 1950; Shaw *et al.*, 1954), and we have often deliberately induced convulsions in dogs several times in the course of a single experiment without the loss of an animal. However, full animal investigation (Shaw and Bentley, 1952; Shaw *et al.*, 1954) has indicated that these substances possess a high therapeutic index, and no signs of toxicity have been observed with the suggested method of treatment. Investigation of the mode of excretion of NP13 and estimations of the barbiturate content of the cerebrospinal fluid, blood, and urine of our patients were carried out in collaboration with N. E. W. McCallum, Department of Pathology, University of Melbourne. Preliminary work has shown that much of the NP13 is excreted in the urine unchanged.

Method of Treatment

The treatment suggested for cases of barbiturate intoxication consists of: (1) general medical treatment; and (2) specific treatment with NP13 and D.A.P.T.

1. General Medical Treatment

As our patients were returned fairly quickly (two hours) to the "safe state" we have been able to dispense with many of the elaborate procedures employed by Nilsson *et al.* in their prolonged management of the comatose patient. We have found the following minimal procedures satisfactory. A laryngoscope is passed in the casualty department to assess the pharyngeal and laryngeal reflexes. If these are absent a cuffed tube is inserted, and the stomach contents are carefully aspirated if the patient is treated within 4-5 hours of ingesting the barbiturate. Gastric lavage should not be performed (Möller, 1954; *Lancet*, 1951). An antibiotic "cover" should be employed. The patient is then transferred to the ward if necessary and a clear airway and adequate oxygenation are ensured. Close watch should be kept for complications.

2. Specific Treatment with NP13 and D.A.P.T.

This should preferably be given in the ward, and an emergency tray containing, amongst other things, 2.5% thiopentone sodium should be at hand in case the patient should show any idiosyncrasy to these drugs. The two drugs are administered in physiological saline in the following dilutions: NP13 0.5% (5 mg. per ml.) and D.A.P.T. 1.5% (15 mg. per ml.).

Preparation of Solutions.—NP13 is relatively insoluble in water at neutral pH and room temperature, and 0.5% approaches the maximum degree of solubility obtaining under

these conditions. This low solubility is not a disadvantage, as it minimizes the risk of overdosage. Of the crystalline powder 2.5 g. should be dissolved in 500 ml. of physiological saline at 80-90° C. The resulting colourless solution is autoclaved and is then ready for use. This solution appears to retain its activity for over three months.

D.A.P.T. decomposes on autoclaving when in solution, but is perfectly stable in the solid state; consequently 300 mg. of the dry sterilized powder is dissolved in 20 ml. of physiological saline as required. The resulting colourless solution is stable at room temperature for up to 24 hours.

Mode of Administration.—Our experience to date has led us to adopt the following procedures:

Set up a 5% glucose intravenous infusion (dextran if indicated) as a means of affording rapid action of the drugs.

Inject, by two separate (20-ml.) syringes, into the rubber tubing of the drip every three to five minutes, 1 ml. D.A.P.T. solution, followed immediately by 10 ml. NP13 solution. This probably allows more control than would direct infusion of the two solutions. Decrease these quantities by half if the patient's response should cause concern. The response is assessed by the following, noted after each injection: Pulse, respirations, blood pressure, tone, reflexes (knee, ankle, plantar withdrawal; the return of laryngeal and pharyngeal reflexes is judged by their effects on the endotracheal tube or, in its absence, by signs of swallowing and coughing); eye signs (movement, lacrimation, reaction of pupil to light); presence of voluntary movement, reaction to supraorbital pain stimulus (often misleading); phonation, state of peripheral circulation, colour and temperature of skin. These afford a good progress report of a patient's recovery.

Continue the injections until the patient is brought to the "safe state," denoted by a return of tone and reflexes (including pharyngeal and laryngeal). This is usually associated with groaning, voluntary movement, and return towards normal of pulse rate, respiratory rate, and blood pressure. The treatment generally takes about two hours in a deeply comatose patient. A total dose of 200 ml. (1.0 g.) NP13 solution and 20 ml. (0.3 g.) D.A.P.T. solution is usually adequate in most cases (see Tables I and II). No attempt should be made to wake the patient.

Once the "safe state" has been reached, remove the endotracheal tube and treat the patient as if recovering from light anaesthesia. Spontaneous recovery to full consciousness usually occurs within eight hours.

Signs of Toxicity

Vomiting or retching is usually the earliest, and may be the only, clinical sign of incipient toxicity. This may rarely be followed by slight flickers of the fingers. In bringing a barbiturized patient to the "safe state" toxic effects are unlikely unless the drugs are given more rapidly or in larger doses than suggested. Should they occur, however, treatment should be temporarily suspended, and, should they be severe, they may be readily reversed by a small intravenous dose of 2.5% thiopentone sodium. A more accurate indication of incipient toxicity is obtainable if the treatment is carried out under electroencephalographic control.

Regression

If after the patient has been brought to the "safe state" his condition regresses, further small treatments may be given as required (Cases 10, 12, 14, 15, 21, 24, 25, 35, 36, 39). Regression is more likely to occur when the coma has lasted a long time before treatment is started, or if the barbiturate concerned is a long-acting one (such as phenobarbitone).

Advantages

The rapid restoration of the comatose patient to the easily manageable "safe state" has three advantages: (1) It obviates the need for prolonged endotracheal intubation; (2) it minimizes both the immediate risk to the patient's life and the remote risk associated with possible complications

of prolonged barbiturate coma; and (3) it is valuable from the viewpoint of hospital economy in that it affords relief from prolonged and strict nursing.

Results of Treatment

Details of illustrative cases are presented in Table I, showing (a) the response to treatment with NP13 and D.A.P.T. of a patient suffering from an overdose of a short-acting barbiturate (Case 17); (b) the response in a patient with an overdose of a long-acting barbiturate (Case 18); (c) the response of a "serious case" (Cases 11 and 24); (d) regression (Case 24); and (e) the effects of NP13 overdosage (Cases 1 and 26). Table II gives a synopsis of the other cases treated.

The proportion of serious cases in our series (10, 11, 12, 15, 24, 25, 32, 35, 36) was about 25%. Eight patients (Cases 6, 7, 9, 19, 27, 30, 33, 34) presented a picture of light barbiturate coma and would probably have awakened spontaneously without specific therapy, although not nearly so quickly. We found phenobarbitone to be the most frequently ingested barbiturate, with "seconal" (quinalbarbitone), "carbrital" (phenobarbitone+carbromal), and "nembutal" (pentobarbitone) slightly less common. Our oldest patient was 84, the youngest 14. The longest periods of coma preceding treatment were 80 hours (Case 10) and 6 days (Case 32).

Nine patients were treated with NP13 alone (Cases 1-6, 8, 26, 37), and one (Case 33) with D.A.P.T. alone. Signs of overdosage were observed in four of our earliest cases (1, 2, 3, 26), and were due to administration of excessive doses of NP13 in an endeavour to restore complete consciousness immediately. The risk of overdosage was subsequently minimized by using a mixture of NP13 and D.A.P.T. and stopping when the patient had reached the "safe state."

This condition of overdosage, manifested by excessive excitement and restlessness on awaking, was effectively

reversed by sedation with paraldehyde or a barbiturate such as quinalbarbitone, amylobarbitone, or diallylbarbitone. No residual effects were encountered.

Thirty patients given a mixture of NP13 and D.A.P.T. (Cases 7, 9-25, 27, 30-32, 34-41) were readily brought to the "safe state," from which they awoke spontaneously, usually within eight hours. No toxic manifestations, either acute or chronic, followed.

Ten patients (Cases 10, 12, 14, 15, 21, 24, 25, 35, 36, 39) regressed and received more than one treatment. This generally followed (a) the ingestion of a large dose of barbiturate, usually of the long-acting variety, or (b) a long delay before specific treatment was started. In Case 14 the second treatment was purely diagnostic to assess the degree of regression.

The largest effective single dose of NP13 used in one treatment was 2.0 g. (Case 8), and of D.A.P.T. 0.62 g. (Case 12). The largest effective over-all dose of NP13 used in one patient was 5.49 g., and of D.A.P.T. 1.70 g. (Case 24).

The most reliable single sign of a favourable response was the plantar withdrawal reflex, its increased activity usually paralleling the patient's progressive recovery. The fact that NP13 has some analgesic properties of its own made the response to supraorbital pressure an unreliable index of recovery.

Our experience to date indicates that treatment with NP13 and D.A.P.T. is quickly effective in reversing the most severe respiratory and circulatory depression accompanying barbiturate intoxication. Indeed, on restoring the patient to the "safe state" the blood pressure, pulse rate, and respiratory rate usually return towards normal. The respirations, previously shallow, irregular, and sometimes stridulous, assume a deep, regular, and more even character. We have had no occasion to give vasopressor agents once the specific treatment has been instituted, and we feel that these should be

TABLE I.—Reports of Selected Cases of Barbiturate Intoxication

Case No.	Age and Sex	Agent and Quantity Taken	Duration of Coma before Treatment (Hours)	State before Specific Treatment	Total Specific Treatment (Dose in Grammes)	Dose (in Grammes) Required to Produce "Safe State"	State after Treatment	Comments
17	F 40	Quinalbarbitone 2 g.	5	P. 120, R. 22, B.P. 140/90. Atonia, areflexia, no response to supraorbital pressure. Pupils sluggish to light. Moist crepitations in chest	NP13 0.45 0.2 in 1 hour D.A.P.T. 0.2 in 1 hour	NP13 0.45 0.2 in 1 hour D.A.P.T. 0.2 in 1 hour	P. 80, R. 18, B.P. 170/110. Brisk reflexes, good tone. Tried to walk out of hospital; restrained. 4th day: Signed herself out. Routine tests: Only abnormality low serum potassium (3.6 mEq/l.). E.E.G.: Return to normal pattern, no signs of drug toxicity	No regression. Following morning: Feels well; rational; wants to go home; no signs of toxicity. 3rd day: Tried to walk out of hospital; restrained. 4th day: Signed herself out. Routine tests: Only abnormality low serum potassium (3.6 mEq/l.). E.E.G.: Return to normal pattern, no signs of drug toxicity
18	M 34	Phenobarbitone 3.3 g. + alcohol	7	P. 120, R. 26, B.P. 120/80. Knee reflexes slightly active only. Ankle clonus. Atonia, pupils fixed and unreactive. No response to supraorbital pressure. Peripheral return poor, rectal temp. 35° F. (35° C.)	1.8 0.57 in 3 hours	1.8 0.57 in 3 hours	P. 132, R. 24, B.P. 125/80. Reflexes brisk, good tone, swallowing, coughing, groaning, trying to get up, obeying orders. Pupils react briskly to light. Colour and peripheral return good	No regression. Quite conscious and trying to get up. Following morning: Talking rationally though a little dull; eating. 3rd day: Well, wants to go home, asks about wife; uneventful recovery. Routine tests: No abnormality detected. E.E.G.: Within normal limits
11	F 36	Butobarbitone 8.3 g.	17	P. 120, R. 6, B.P. 85/60. Cold and cyanosed. Atonia, areflexia, incontinent. Pupils irregular and fixed. No response to supraorbital pressure. Peripheral circulatory failure	3 doses of 9 mg. picotoin given 1-hourly produced transient return of reflexes 1.2 0.44 in 1½ hours	1.2 0.44 in 1½ hours	P. 110, R. 18, B.P. 110/80. Reflexes brisk, groaning, voluntary movement of head and body, good tone, brisk pupillary light reflex	No regression. 6 hours later: Co operative, speaking, obeying orders. 2nd day: Tried to walk out of hospital; restrained. 3rd day: Discharged for psychiatric treatment. Routine tests: Only abnormality low serum potassium (3.3 mEq/l.). E.E.G.: Normal tracing on day of discharge
24	F 47	Phenobarbitone 7 g.	30	P. 80 (weak), R. 10, B.P. 50/20. Areflexia, atonia, fixed pupils. No response to supraorbital pressure. Cyanosed, peripheral circulatory failure, chemotic conjunctivae	(1) 0.9 0.15 in 2 hours	0.9 0.15 in 2 hours	P. 90, R. 32, B.P. 95/60. Some reflexes present. Patient spastic. Respirations good depth and regular, full pulse	Patient returned from critical toward safe state. Regressed. Given further treatment on 2nd day (2)

TABLE I.—continued

Case No.	Age and Sex	Agent and Quantity Taken	Duration of Coma before Treatment (Hours)	State before Specific Treatment	Total Specific Treatment (Dose in Grammes)	Dose (in Grammes) Required to Produce "Safe State"	State after Treatment	Comments
24	(continued)			P. 108, R. 16, B.P. 75/50. Areflexia, atonia, fixed pupils. Slight cyanosis and poor peripheral return. No response to supraorbital pressure	NP13 1.35 0.57 in 2½ hours D.A.P.T. 0.57 in 2½ hours	NP13 1.35 0.57 in 2½ hours D.A.P.T. 0.57 in 2½ hours	P. 108, R. 24, B.P. 90/55, T. 99° F. (37.2° C.). Reflexes present, fair tone, good plantar response. Good peripheral return. No cyanosis. Swallowing. No response to supraorbital pressure. Brisk pupillary light reflex	5 hours later: Some regression; "intra-dex" substituted for 5% glucose. 10 hours later: Developing R. basal pneumonia; T. 101.5° F. (38.6° C.). Has allergic penicillin rash. Given aureomycin. Regressed. Given further treatment (3)
				P. 128, R. 26, B.P. 80/60. Atonia, areflexia, slight pupillary reflex. No response to supraorbital pressure. Peripheral return adequate	(3) 0.5 0.15 in 45 minutes	0.5 0.15 in 45 minutes	P. 132, R. 28, B.P. 90/60. As in (2) above. Conjunctivae still chemotic. Response to supraorbital pressure	3rd day: Again some regression. Forced cough occasionally present. Oral therapy by Ryle's tube. Right chest consolidated. Regressed again on 4th day. Given further treatment (4)
				P. 92, R. 18, B.P. 60/35. Atonia, areflexia, mildly cyanosed. Poor peripheral return. Right lung consolidated, some dullness left base	(4) 0.95 0.29 in 1½ hours	0.95 0.29 in 1½ hours	P. 96, R. 16, B.P. 110/65. Active reflexes, good tone. Swallowing, moving jaw. Colour peripheral return good. No response to supraorbital pressure	6 hours later: Slight regression, but B.P. 125/70. Regression on 5th day. Given further treatment (5)
				P. 108, R. 18, B.P. 110/65. Sluggish reflexes slight tone; pupillary reflex good. Right chest still consolidated. No response to supraorbital pressure	(5) 0.3 0.1 in 40 minutes	0.3 0.1 in 40 minutes	P. 100, R. 15, B.P. 120/75. Brisk reflexes, good tone. Definite response to supraorbital pressure, swallowing and chewing. Raising eyelids. Colour and peripheral return good	6 hours later (6th day): Some regression, but condition satisfactory; good urinary output. Given further treatment (6)
				P. 100, R. 18, B.P. 115/75. Decreased reflex response, slight tone. No response to supraorbital pressure. Colour and peripheral return good	(6) 0.45 0.14 in 45 minutes	0.45 0.14 in 45 minutes	P. 84, R. 18, B.P. 125/65. Brisk reflexes and good tone; yawning, coughing, swallowing, moving jaw and eyelids. Groaning. Marked response to supraorbital pressure	14 hours later (7th day): Some regression, but condition satisfactory. Given further treatment (7)
				P. 108, R. 25, B.P. 115/65. Decreased tone and reflexes. No response to supraorbital pressure. Colour and peripheral return good. Right lung still fully consolidated	(7) 0.65 0.19 in 55 minutes	0.65 0.19 in 55 minutes	P. 108, R. 22, B.P. 135/75. Brisk reflexes, good tone; swallowing, coughing, moving jaw, and opening eyes. Groaning	Large quantities of barbiturate still present in urine. 15 hours later: Some regression. Given further treatment (8). Patient started menstruating. Serum electrolytes: Sodium 139 mEq/l.; potassium 3.4 mEq/l.; proteins, 6 g.%; pH of serum 7.4. Given 8 g. KCl per day
				P. 84, R. 22, B.P. 120/65. Decreased tone and reflexes. Some response to supraorbital pressure. Colour and peripheral return good	(8) 0.25 0.08 in 30 minutes	0.25 0.08 in 30 minutes	P. 104, R. 20, B.P. 135/75. Brisk reflexes, good tone, coughing more strongly. Opening eyes and rejecting oral airway. Groans on supraorbital pressure	Pneumonia resolving; slow progress over next 2 days. Still much barbiturate in urine. Further treatment next day (9)
				P. 108, R. 16, B.P. 105/60. Decreased tone and reflexes. Groaning on supraorbital pressure	(9) 0.15 0.04 in 15 minutes	0.15 0.04 in 15 minutes	P. 112, R. 16, B.P. 120/65. Brisk reflexes, good tone. Obeying orders and trying to talk in a slurred voice; moving head and biting airway	No regression; patient talking rationally on 12th day. Very weak. Eating. No apparent residual cortical damage. Good insight into domestic problems. Chest almost clear. Slow progress and uneventful recovery
1	F 26	Cyclobarbitone 3.6 g.	2	P. 88, R. 18, B.P. 105/90. Atonia, areflexia, pupils sluggish to light, no reaction to supraorbital pressure	1.75 in 95 minutes	0.25 0.35 in 20-30 minutes	P. 92, R. 18, B.P. 115/80. Restless, moaning, retching; brisk reflexes	Patient overdosed, required paraldehyde after 8 hours. 2nd day: Still restless and confused. 3rd day: Quieter. 4th day: Normal, no after-effects
26		Voluntary patient given 0.75 g. sodium pentobarbitone under E.E.G. control	1	P. 84, R. 12. Decreased tone, depressed reflexes, some intercostal paralysis. Slight response to supraorbital pressure	1.0 in 30 minutes	0.3 —	Reflexes exaggerated, groaning, moving whole body and opening eyes. Flushed, vomiting. Did not wake completely	3 hours later: Flushed, irritable, dizzy, confused; rambling speech. Reflexes exaggerated, tossing in bed, slight muscular twitches of fingers, arms, and isolated facial muscles. P. 92, R. 14, B.P. 100/70. Patient presented with picture of cerebral irritation due to NP13 overdosage. Sedated with paraldehyde, "sodium amytal," and "luminal." Took 2 days to return to normal. There were no residual after-effects, but there was amnesia for the event. E.E.G.: The "spikes" indicative of incipient NP13 toxicity were initially hidden by muscle spikes and appeared only later, whereupon NP13 was stopped

TABLE II.—Summary of Other Cases Treated

Case No.	Age (Years) and Sex	Agent and Quantity Taken	Duration of Coma before Treatment Started (Hours)	Complications Present	Regression Present	No. of Treatments Given	Total Dose (grammes)	Comments
2	F 38	Quinalbarbitone ? dose	6	Nil	—	1	NP13 D.A.P.T. 1.8 in 90 minutes	One of our earliest cases. Patient overdosed. At safe state with 0.5 g. Restless 3 days
3	M 54	"Sedormid" ? dose	14	"	—	1	0.75 in 45 minutes	Overdosed. Safe state with 0.4 g. Restless 3 days
4	F 21	Phenobarbitone ? dose	13	"	—	1	0.45 in 2½ hours	Some regression 6 hours later, but uneventful recovery
5	F 14	Phenobarbitone ? dose (7 also small amount of bromide or paraldehyde)	11	"	—	1	0.6 in 2 hours	No regression or signs of toxicity. Uneventful recovery
6	F 27	"Carbital" ? dose	9	"	—	1	1.7 in 1½ hours	Awake 1 hour later. Uneventful recovery
7	F 44	Quinalbarbitone 1.6 g.	7	"	—	1	0.43 0.1 in 2 hours	No signs of toxicity. E.E.G. 3 days later, normal rhythm
8	M 28	Phenobarbitone ? dose	?	"	—	1	2.0 in 50 minutes	Completely conscious after 2 days. Uneventful recovery. Some signs of toxicity due to rapid administration
9	F 32	"Carbital" (pentobarbitone sodium 1 g., carbromal 2.7 g.)	4	"	—	1	0.3 0.18 in 25 minutes	Well next day. No signs of toxicity
10	F 49	"Carbital" and phenobarbitone ? dose	80	Bronchopneumonia and peripheral circulatory failure	Yes	2	0.9 0.5	2nd day co-operative; 5 days later approaching normal
12	M 84	?	?	Bronchopneumonia	"	2	2.1 0.77	Conscious 2nd day, talking 3rd day, normal 5th day
13	F 28	Bromvaletone 20 g.	12	Nil	—	1	0.7 0.3 in 1½ hours	Uneventful recovery next day
14	M 42	"Carbital" (pentobarbitone sodium 3 g., carbromal 8 g.). Phenobarbitone ? dose	12	"	Yes	2	0.4 0.57	Uneventful recovery
15	F 49	Phenobarbitone 5 g.	12	Peripheral circulatory failure	"	4	1.55 0.63	Patient took 5 days to return to normal. No after-effects
16	F 23	Quinalbarbitone 2.5 g.	?	Nil	—	1	0.8 0.3 in 2 hours	Well next day. Uneventful recovery
19	M 25	"Carbital" (pentobarbitone sodium 3 g., carbromal 8 g.)	13	"	—	1	0.4 0.12 in 40 minutes	" " " " " "
20	F 46	Butobarbitone 2.4 g.	14	"	—	1	0.25 0.1 in 30 minutes	" " " " " "
21	F 50	Phenobarbitone 6.5 g.	3	"	Yes	3	0.85 0.45	Patient took 5 days to return to normal. No after-effects
22	F 22	"Carbital" (pentobarbitone sodium 1 g., carbromal 3 g.)	8	"	—	1	0.6 0.18 in 1½ hours	Well next day. Uneventful recovery
23	F 28	"Carbital" (pentobarbitone sodium 2 g., carbromal 5.6 g.)	3	"	—	1	0.5 0.17 in 1½ hours	" " " " " "
25	M 57	Phenobarbitone 3 g.	30	Peripheral circulatory failure. On nor-adrenaline drip	Yes	4	1.85 0.63	Conscious after 5 days. Slow subsequent uneventful recovery
27	M 50	Given phenobarbitone sodium 1.4 g. in an attempt to control hiccup over 5 days	—	—	—	1	0.13 0.1 in 20 minutes	Patient initially drowsy, quickly recovered. Subsequent regression, return of hiccups
30	M 53	Pentobarbitone sodium 2.5 g.	7	Nil	—	1	0.3 0.1 in 45 minutes	Uneventful quick recovery
31	F 54	"Carbital" (pentobarbitone sodium 2 g., carbromal 5.5 g.)	10	"	—	1	0.5 0.15 in 1½ hours	Quick response, uneventful recovery
32	F 64	Phenobarbitone ? dose	6 days	Early pneumonia	—	1	0.2 0.08 in 20 minutes	Patient not very deep; quick response. Took 3-4 days for full recovery
33	F 38	Quinalbarbitone sodium 3 g.	12	Nil	—	1	— 0.18 over 30 minutes	Patient in light coma at start of treatment. Quick response; no regression; uneventful recovery
34	M 36	Pentobarbitone sodium ? dose	14	"	—	1	0.15 0.05 over 15 minutes	Patient bright when treatment started. Quick response, uneventful recovery
35	M 65	Phenobarbitone 6 g.	Over 24	Early bronchopneumonia and peripheral circulatory failure	Yes	2	0.95 0.3	Very ill. Good response to safe state with 1st treatment. Regressed. Not fully recovered for 5 days

used only as supportive measures during the initial acute phase of the coma pending the start of treatment.

NP13 has been used to advantage as an aid in the differential diagnosis of cerebrovascular accident and barbiturate intoxication in a patient whose condition was rapidly deteriorating and in whom no localizing signs were present (Case 28).

Control electroencephalograms (E.E.G.s) were taken in three patients (Cases 11, 15, 22) and one volunteer (Case 26). In ten other cases (7, 10, 16-23) recordings were made at the end of treatment. The volunteer was given an overdose of NP13 in an endeavour to effect immediate and complete awakening, and the E.E.G. showed the characteristic spikes of cerebral irritation. The remaining patients all received a mixture of NP13 and D.A.P.T. In the cases under E.E.G. control treatment was stopped either before, or as soon as, there was any suggestion of sharp wave activity. All records taken after termination of therapy showed varying degrees of abnormality indicated by slow or increased low-voltage fast activity. Serial records revealed a gradual disappearance of these abnormalities. Complete clinical recovery was usually apparent for some time before the E.E.G. pattern became normal, especially in patients who had taken long-acting barbiturates.

Routine investigations were carried out in 14 cases (10, 11, 12, 14-23, 25) during the week following recovery. These included tests of renal and liver function, full blood count, naked-eye and microscopical examination of cerebrospinal fluid, electrocardiography, and estimation of serum electrolyte balance. The only abnormality detected in seven cases (11, 15-17, 20-22) was a low serum potassium value of the order of 3.5 mEq per litre. This was occasionally accompanied by a concomitant imbalance of the other ions.

Case 24 deserves special mention. This patient (probably the most seriously ill patient in our series) was comatose for ten days, and during this period was given nine consecutive treatments with NP13 and D.A.P.T., with eventual restoration to full consciousness. Her subsequent rehabilitation was slow and uneventful. We followed this procedure as we felt that the patient's severe and prolonged coma was in part due to a secondary cerebral hypoxia of hypotensive origin superimposed on the primary barbiturate hypoxia. We were therefore disinclined to give more than minimally adequate doses of NP13 and D.A.P.T. (to maintain the "safe state"), to avoid the risk of excessively stimulating an already overburdened nervous apparatus and mechanism. An adequate blood pressure and high renal output were maintained throughout. Large quantities of barbiturate were still being excreted in the urine seven or eight days after the coma began.

One patient (Case 29) died, but death was not thought to be due to the specific treatment. Details of this case follow.

Report of a Fatal Case

A woman aged 61 took 50 "carbital" capsules (containing 5 g. pentobarbitone sodium and 12 g. carbromal) about 12 hours before treatment was instituted. On admission: pulse rate 72 per minute; shallow, irregular respirations (rate 32 per minute); blood pressure 120/70 mm. Hg. No reflexes could be elicited. She was atonic, hypothermic (temperature 95° F.—35° C.), and unresponsive to painful stimuli, with unreactive pupils and a poor peripheral return. She was given 1 g. NP13 and 0.3 g. D.A.P.T. in two treatments over three hours. There was a rapid return of reflexes and some response to painful stimuli, but facial twitches suddenly developed and there were signs of respiratory depression. The twitching was quickly controlled with thiopentone sodium; the patient was intubated and artificial respiration started. Owing to a fault in the circuit the patient rebreathed air with a high CO₂ content for several hours before it was discovered. When, eight hours later, in an attempt to promote normal respiration, a small dose of D.A.P.T. (60 mg.) was given in divided doses over 12 minutes, the patient had a unilateral left-sided epileptiform convulsion which 0.4 g. thiopentone sodium failed to

control. Lumbar puncture gave a blood-stained cerebrospinal fluid with a protein content of 1,600 mg. per 100 ml. and showing xanthochromia on sedimentation of the red cells. There were no localizing signs of a cerebro-vascular episode.

In spite of prolonged artificial respiration following tracheotomy and the administration of a continuous nor-adrenaline drip, the blood pressure progressively fell and the patient died.

Significant Post-mortem Findings.—The skull was normal. The arteries to the brain were well preserved and showed minimal atheroma. In the middle cranial fossa there was a little brownish-yellow staining of the dura. Over the parietal surface of the left cerebral hemisphere there was a very small localized area of subarachnoid bleeding, not sufficiently marked to lift the membrane off the brain; there was also a very small amount of subdural bleeding in this area. The brain did not show evidence of compression; it was symmetrical and the convolutions appeared normal. On routine serial section of the substance of the brain no naked-eye abnormality was detected. There was no bruising or evidence of injury on the scalp. The coronary vessels showed marked thickening and calcification. The heart was a little enlarged. No infarction or scarring was visible in the heart wall. There was patchy atheroma of the aorta. Both lungs showed extensive consolidation and waterlogging. The liver and kidney contained $\frac{1}{2}$ gr. of carbromal and 1/10 gr. of pentobarbitone per lb. (124 and 14 mg. per kg.).

Discussion

There are at present two schools of thought as to the treatment of acute barbiturate intoxication. Both agree that the basis of good management is thorough and intelligent medical care. They are, however, at variance regarding the concomitant use of central analeptics, of which only picrotoxin, leptazol, "geastimol," and occasionally amphetamine and nikethamide are in present-day use.

The conservative school is led by Nilsson, who regards acute barbiturate intoxication as "an anaesthesia which is drawn out to last for days instead of lasting, like a common so-called surgical anaesthesia, for at most a few hours," and who therefore treats the condition "in accordance with anaesthesiological principles." Nilsson (mortality rate 2-3%), Locket and Angus (mortality rate 3-4%), and Clemmesen (mortality rate 1.6%) relied solely on a carefully planned medical regimen. None used central analeptics, and indeed all stressed the dangers involved in their use. Their excellent results afford strong support for their expectant routine of treatment.

This mode of management has been criticized by the protagonists of the analeptic school of treatment led by Koppányi and Fazekas (1952), who insist that there is still a definite place for central analeptics, especially in cases of severe barbiturate intoxication.

In the absence of adequate information concerning the mode of action of central analeptics (Eckenhoff *et al.*, 1949), and in the presence of many animal experiments (Maloney, 1935, 1936; Mousel and Essex, 1941; Schmidt, 1945; Davis *et al.*, 1944) and clinical data (Nilsson, 1951; Locket and Angus, 1952; Clemmesen, 1954) indicating the dangers involved in their use, we find ourselves drawn more closely to the conservative school of treatment led by Nilsson. There appear to be, however, two disadvantages to this conservative management. (1) One can never be sure, with a patient in deep barbiturate coma, if and when he will regain consciousness, and if and when complications which could alter the whole outlook of the case will develop. Naturally, the more prolonged the coma the greater would be the risk of this occurring, despite the most scrupulous medical care. (2) The management of a case of prolonged barbiturate coma presents a serious problem in a busy overcrowded hospital. Our new method of treatment helps by bringing such a patient in two hours to a desired state of light anaesthesia—the "safe state"—from which

spontaneous recovery to full consciousness usually occurs within eight hours. It thus removes the immediate risk to the patient's life, prevents the onset of complications often associated with prolonged barbiturate coma, and also promotes a speedier discharge from hospital. We do not attempt to restore full consciousness, for not only have we found this to be impossible in many cases, but there is also the risk, especially when using NP13 alone, of producing an excited, irritable patient who often needs prolonged sedation. Our inability to awaken the patient fully may be due to a concomitant cerebral hypoxia and disordered cerebral metabolism resulting from the prolonged action of the barbiturate (Bailey *et al.*, 1953; Bain, 1952; Brody and Bain, 1954), and naturally time must be allowed for restitution to normal.

We have previously suggested that NP13 in therapeutic doses may exert a direct antagonism to the barbiturate, as indicated by the fact that rabbits can be put to sleep or awakened almost at will by the alternate intravenous administration of thiopentone sodium and NP13. This change can be rapidly and repeatedly effected without any apparent harm to the animal. The antagonism is further supported by our observations, both in patients suffering from deep barbiturate coma and in dogs under deep pentobarbitone anaesthesia, of a rapid clinical and somewhat slower encephalographic recovery to the unnarcotized state after the administration of NP13 or a mixture of NP13 and D.A.P.T. This is in direct contrast to the findings of most workers, who agree, on both clinical and experimental grounds, that all of the central analeptics in current use, except possibly picrotoxin, are of little value in the treatment of deep barbiturate coma. It is also in direct contrast to the observations of Mousel and Essex (1941), who found that nikethamide, leptazol, picrotoxin, α -lobeline, and geastimol all failed to produce demonstrable change in the E.E.G. of dogs deeply anaesthetized with amytal.

Present evidence suggests that NP13 is the best substance yet used in the treatment of barbiturate coma, and in combination with D.A.P.T. should ensure a quick, safe recovery without risk of convulsions and secondary depression, which often follow treatment with central analeptics.

Finally we wish to emphasize the value of D.A.P.T. not only as a barbiturate antagonist, but also as a potent, non-specific respiratory stimulant. This latter property has been specially important in the management of barbiturate coma where pneumonic complications have supervened. We elsewhere (Shulman and Shaw, 1955) suggest other clinical uses for D.A.P.T., especially in relieving prolonged and severe pain and in the fields of anaesthesia and obstetrics.

Summary

A new method of treating acute barbiturate intoxication, incorporating the use of two new substances— $\beta\beta$ -methyleneethylglutarimide (NP13) and 2:4-diamino-5-phenylthiazole hydrobromide or hydrochloride (D.A.P.T.)—has been outlined. It compares more than favourably with other methods in that it minimizes the risk of complications and removes the need for strict and prolonged medical and nursing care without incurring the risk of convulsions and secondary depression sometimes accompanying treatment with analeptics.

Animal and clinical investigations have revealed that NP13 and D.A.P.T. possess a high therapeutic index and quickly relieve the acute phase of severe barbiturate coma, whereby the patient is deliberately restored to an easily manageable state of light anaesthesia—the "safe state," from which spontaneous recovery to full consciousness usually occurs within eight hours.

The pharmacology of NP13 and D.A.P.T. has been briefly described, and evidence presented to suggest that NP13, which has a structural resemblance to the barbiturate ring system, may exert its effect by a direct antagonism to the offending barbiturate.

Results of treatment with these drugs in 41 cases of barbiturate intoxication have been summarized.

It is suggested that these substances may provide an effective means of controlling anaesthesia induced by barbiturates, both in enabling a rapid recovery to the conscious state where desired and in counteracting any emergency such as laryngeal spasm.

The value of D.A.P.T. as a non-specific respiratory stimulant is pointed out and suggestions are made as to its further clinical use.

We wish to thank the superintendents and staff of the Alfred, Heidelberg Repatriation, Prince Henry, and Royal Melbourne Hospitals (Melbourne), and Sydney and St. Vincent's Hospitals (Sydney) for their kind co-operation in this investigation. Our thanks are also due to Miss Joan Peacock (Alfred Hospital) for the encephalographic studies, and to Miss M. Bick (Alfred Hospital) for help with the barbiturate estimations. We are indebted to Nicholas Pty. Ltd. (Australia) for their gift of NP13, and to Professor W. Davies, of the Chemistry Department of the University of Melbourne, and Mr. E. I. Rosenblum, of Felton, Grimwade, and Duerdins Pty. Ltd., for supplying the D.A.P.T. We are most grateful to Drs. A. Bignell, D. A. Coats, and E. R. Trethewie, and to Miss M. Bell, Miss S. Loewe, Miss M. Parker, Mr. R. Capponi, and Mr. W. Straffon for their technical assistance. Finally we wish to express our special thanks to Professor R. D. Wright for his kindly advice and guidance during this investigation.

The role of the family doctor in research was discussed by Professor J. M. MACKINTOSH in the first John Matheson Shaw lecture, delivered at the Royal College of Physicians of Edinburgh last November. Tracing the history of the general practitioner through the nineteenth century, Professor Mackintosh showed that it was not until the end of that period that research by general practitioners came to be taken seriously. To-day the College of General Practitioners can guide his investigations, making his contribution part of a large survey, and the Public Health Laboratory Services provide him with facilities he used to lack. In several fields the family doctor has an advantage over the specialist; with his knowledge of family background perhaps extending over two or three generations, he can report on hereditary defects; again, the knowledge of background and environment is vital to a study of mental illness and stress diseases. The effectiveness of new drugs and vaccines, the epidemiology of common ailments, the incubation periods of well-known infections can all be studied best in general practice, and "we all know that the family doctor is the only medical worker to-day to see disease in its early stages." Professor Mackintosh suggested that the chief obstacle to general-practitioner research lay in the defective undergraduate training, which did not, for instance, include even elementary statistics, and the chief incentive is the co-operation between doctors and the College of General Practitioners.

MEGALOBlastic ANAEMIA OF PREGNANCY AND THE PUERPERIUM

BY

J. BADENOCH, D.M., M.R.C.P.

SHEILA T. CALLENDER, M.D., M.R.C.P.

J. R. EVANS, M.D.

A. L. TURNBULL, M.D., M.R.C.P.

AND

L. J. WITTS, M.D., F.R.C.P.

From the Nuffield Department of Clinical Medicine,
Radcliffe Infirmary, Oxford

Investigation of patients with megaloblastic anaemia of pregnancy and the puerperium is handicapped by the urgency with which treatment must be carried out and by the tendency of the anaemia to remit spontaneously after delivery. Strauss and Castle (1933) suggested that this anaemia was due to a temporary reduction in the secretion of intrinsic factor, but the failure of parenteral liver extracts and vitamin B₁₂ to bring about remission in most cases has made it clear that this cannot be the only explanation. Three cases have been described in which defective absorption of fat was discovered on subsequent admission to hospital (Davidson, 1948; Tuck and Whittaker, 1950; Thompson and Ungley, 1951), and Tuck and Whittaker (1950) have proposed that, in some instances at least, the underlying mechanism may be an occult idiopathic steatorrhoea, which is unmasked by pregnancy. In the present observations on nine patients, particular attention has been directed to the detection of abnormalities of gastric secretion and defects of the absorption of fat and labelled vitamin B₁₂ from the intestine. We show that there was no evidence of reduction in the secretion of intrinsic factor or in the absorption of fat in these patients.

Clinical Features

The salient clinical features are presented in Table I. Four women were investigated before term and the remaining five were seen after delivery; in all cases the diagnosis was confirmed by finding megaloblastic changes in the sternal marrow. Of particular interest is the high incidence of complications such as vomiting, diarrhoea, and haemorrhage, which might tend to decrease the supply of or increase the demand for haemopoietic factors during pregnancy and the puerperium. The tongue was sore in three patients. There was atrophy of the papillae in four patients—complete in

two and confined to the edge of the tongue in two. Aphthous ulcers were present in four patients, three of whom had leucopenia. The spleen was palpable in two patients, in whom the level of haemoglobin was less than 5 g. No neurological abnormality was detected in any of the patients.

Treatment was with folic acid by mouth or vitamin B₁₂ by injection. Folic acid was given in a dose of 20 mg. daily. Vitamin B₁₂ was given on a single day only, in a dosage of 2,000 μ g.; this was the "flushing dose" which was employed in measuring the excretion of labelled vitamin B₁₂ in the urine. In Case 8 only 100 μ g. of vitamin B₁₂ was given.

Of the three patients seen three weeks or more before delivery, one responded well to folic acid alone, another failed to respond to vitamin B₁₂ but subsequently improved with folic acid, and the third showed no improvement up to the time of delivery with combined folic acid and vitamin B₁₂ therapy. A fourth patient was treated with vitamin B₁₂ and folic acid one week before delivery without apparent effect, but gradual improvement occurred during the puerperium.

In three patients the diagnosis was made early in the puerperium. An optimal response followed treatment with vitamin B₁₂ in one and folic acid in another. The third received both vitamin B₁₂ and folic acid, and showed a progressive increase in haemoglobin, although the reticulocytes did not rise above 3%. Since spontaneous remission is common following delivery, it is not certain that these responses were due to specific therapy.

Two patients were seen with severe anaemia six weeks after delivery. There was no response to vitamin B₁₂ over a period of eight days in Case 8, but prompt symptomatic and haematological remission followed the administration of folic acid. Case 9 was transfused initially and then treated with vitamin B₁₂ with an optimal reticulocytosis and rise in haemoglobin and the haematocrit reading.

Special Investigations

(A) Methods

1. *Gastric Secretion.*—Gastric acidity was measured directly in seven subjects and indirectly by the "diagnex" technique (Conway and Meikle, 1953) in one (Case 5). In two patients free acid was found in the resting juice and no stimulant was given. Fractional test-meal examinations were carried out on four patients with histamine and one patient with gruel. The urinary excretion of uropepsinogen over a 24-hour period was measured in seven subjects (Aitken *et al.*, 1951).

2. *Gastric Biopsy.*—Biopsy of the gastric mucous membrane was carried out in four patients, using Wood's flexible gastric biopsy tube (Wood *et al.*, 1949).

3. *Absorption of Vitamin B₁₂.*—The absorption of vitamin B₁₂ was tested by measuring the amount of radioactivity which was found in the faeces after an oral dose of 0.5 μ g. of vitamin B₁₂ labelled with cobalt⁶⁰ (Heinle *et al.*, 1952). This gave an indirect assessment of the secretion of

TABLE I

Case	Age	Previous Pregnancies	Diagnosis of Anaemia	Complicating Features	Hb Before Therapy (g./100 ml.)	Response to Therapy
1	22	4	Ante partum 4 weeks	Fifth pregnancy within 5 years	4.6	Transfused—Hb 6.8 g. Folic acid—good response
2	18	0	Ante partum 4 weeks	Twin pregnancy	9.8	B ₁₂ —no response 14 days. Folic acid—good response
3	20	0	Ante partum 3 weeks	Vomiting and anorexia throughout pregnancy	9.9	B ₁₂ and folic acid—no improvement up to time of delivery
4	23	1	Ante partum 1 week	Poor diet; hypertension	10.3	B ₁₂ and folic acid—no reticulocytosis, improved post partum
5	34	2	Post partum 1 week	Very poor diet; appendicectomy in first trimester	8.9	B ₁₂ —good response
6	28	2	Post partum 2 weeks	Anorexia, diarrhoea, mild toxæmia, and post-partum haemorrhage	3.9	Transfused—Hb 9.7 g. Folic acid—good response
7	20	2	Post partum 1 week	Post-partum haemorrhage; third pregnancy in 3 years	9.2	B ₁₂ and folic acid—moderate rise Hb, reticulocytosis 3%
8	22	0	Post partum 6 weeks	Post-partum vomiting; puerperal fever—endometritis	5.3	B ₁₂ —no response 8 days. Folic acid—good response
9	29	1	Post partum 6 weeks	Ante-partum diarrhoea; breast abscess first week post partum	4.7	Transfused—Hb 9.6 g. B ₁₂ —good response

intrinsic factor. In six patients a parenteral injection of 2,000 μ g. of non-radioactive vitamin B₁₂ was given with the oral dose in order to rid the body of as much of the absorbed radioactivity as possible (Schilling, 1953). Normally 15% or more of the oral dose of 0.5 μ g. of Co⁶⁰-vitamin B₁₂ is excreted in the urine with this technique (Callender and Evans, 1955). The collection of stools was incomplete in Case 3, and only the radioactivity in the urine was measured.

4. *Absorption of Fat*.—The absorption of fat was estimated in six of the subjects by a four-day fat balance with a measured dietary intake of 70 to 100 g. of fat daily.

5. *Serum Vitamin B₁₂*.—The level of vitamin B₁₂ in the serum was determined by microbiological assay, in two cases with *Euglena gracilis* and in four cases with *Lactobacillus leichmannii*.

TABLE II

Patient	Free Acid in Gastric Juice	Uropepsinogen Excretion (Units/24 hr.)	Percentage of Oral Dose of Co ⁶⁰ -vitamin B ₁₂ in Faeces	Fat Absorption (% of Dietary Intake)	Serum Vitamin B ₁₂ (μ g./ml.)

9	+	48	28	96	220

* Gastric biopsy. † Radioactivity in urine.

(B) Results (Table II)

1. *Gastric Secretion*.—The fractional test meal revealed achlorhydria in two patients, but in one of these (Case 1) the uropepsinogen excretion was within normal limits, and in the other (Case 6) the biopsy showed no atrophy of the gastric body glands. Uropepsinogen excretion was low in two patients, within the range encountered in pernicious anaemia, but in both of them free acid was present in the gastric juice.

2. *Gastric Biopsy*.—Histological examination of the gastric mucosa revealed no abnormality. There was evidence of superficial gastritis in Case 6, but no atrophy of the gastric body glands was noted.

3. *Absorption of Vitamin B₁₂*.—The absorption of vitamin B₁₂ was normal in all nine patients, implying that the secretion of intrinsic factor was adequate.

4. *Absorption of Fat*.—The absorption of fat was within normal limits in the six patients tested. The low normal result on the basis of a four-day fat balance does not absolutely exclude the possibility of steatorrhoea in Case 2.

5. *Serum Vitamin B₁₂*.—Normal quantities of vitamin B₁₂ were present in the serum of five patients. The values in Case 4 are just above the range observed in untreated pernicious anaemia, and might be explained by the grossly inadequate diet which she took throughout her two pregnancies and the intervening period.

Discussion

The preceding investigations do not provide conclusive evidence of the nature of the disturbance of haemopoiesis in megaloblastic anaemia of pregnancy and the puerperium or of its pathogenesis. The secretion of intrinsic factor, as determined by the absorption of radioactive vitamin B₁₂, was normal and there is therefore no support for the theories of Strauss and Castle (1933). The absorption of fat was also normal in our patients, as it was in six cases of megaloblastic anaemia of pregnancy recently studied by Moore *et al.* (1955). It must therefore be concluded that, though megaloblastic anaemia in pregnancy may occasionally be due to adult coeliac disease, this is by no means a common cause.

Although the absorption of vitamin B₁₂ is normal the possibility exists of a deficiency of the vitamin in the diet. This is probably not uncommon in India (Das Gupta, 1954), and it has been described in Europe. Nieweg *et al.* (1954) report two patients responding to vitamin B₁₂ therapy in whom the evidence favours a deficiency of the vitamin. In one the serum vitamin B₁₂ was very low (40 μ g. per ml.), and in the other the blood folic acid was normal. In 20% of a group of patients studied during pregnancy and lactation, Heinrich (1954) found low serum vitamin B₁₂ levels and reduced excretion of vitamin B₁₂ in the urine, although there was no evidence of macrocytic anaemia. Oral administration of vitamin B₁₂ was effective in restoring normal serum levels and urinary excretion in these patients, and Heinrich suggested the existence of a state of hypovitaminosis-B₁₂ due to increased demands for the vitamin during pregnancy and lactation.

However, Mollin and Ross (1954) report serum vitamin B₁₂ levels in 31 cases of megaloblastic anaemia of pregnancy and the puerperium, and in only two were the levels as low as is seen in untreated cases of pernicious anaemia. In our cases, likewise, the level of vitamin B₁₂ in the serum was within normal limits. Hence it would appear that, although vitamin-B₁₂ deficiency may occur in Europe, it is not commonly responsible for the development of megaloblastic anaemia in pregnancy. In the two women who improved with vitamin B₁₂ therapy in the present series the response may have been mediated by some indirect mechanism, related to the massive size of the dose, for in both of them the serum levels of vitamin B₁₂ were normal. This conclusion is supported by the work of Moore *et al.* (1955), who obtained a satisfactory response to vitamin B₁₂ in 13 out of 17 cases of megaloblastic anaemia of pregnancy by giving massive doses, of the order of 1,000 μ g. Five of their patients were treated before delivery and 12 after. The four women who did not respond to vitamin B₁₂, which in two instances was pushed to 5,000 μ g., responded to folic acid.

At present it is difficult to assess the folic acid status of the organism other than by the response to treatment. Folic acid in large doses is usually effective in the megaloblastic anaemia of pregnancy, both before and after delivery. This observation favours a folic acid deficiency, though this deficiency, like that of vitamin B₁₂, is more likely to be relative than absolute, for remission may occur after delivery in patients who receive no treatment at all.

It seems likely that patients with megaloblastic anaemia of pregnancy and the puerperium do not represent a homogeneous group, and this may explain the variable findings and response to therapy. Complications of pregnancy and the puerperium occur frequently in relation to megaloblastic anaemia. Toxaemia and infection may interfere with the utilization of haemopoietic factors; haemorrhage and multiple or rapidly repeated pregnancies may increase the demands; while poor diet and gastro-intestinal upsets reduce the natural supply. However, in some patients pregnancy alone may induce the anaemia, and in such cases the cause appears to be the development of resistance to vitamin B₁₂ and folic acid.

Summary

Nine patients with megaloblastic anaemia of pregnancy and the puerperium have been studied. The incidence of complications of pregnancy and the puerperium was high.

No abnormality in the secretion of intrinsic factor or the absorption of fat was discovered in any case.

The serum vitamin B₁₂ levels were normal.

In women treated before delivery folic acid was more effective than vitamin B₁₂.

Although an absolute deficiency of folic acid cannot be excluded, the anaemia seems more likely to be due to resistance to the action of the haemopoietic factors than to deficiency.

We are grateful to Dr. Lester Smith, of Glaxo Laboratories Ltd., for supplies of labelled vitamin B₁₂; to Dr. G. I. M. Ross and Dr. G. H. Spray for microbiological assays of serum vitamin B₁₂; and to Dr. W. D. Richards for histological interpretation of the gastric biopsy specimens. We are indebted to Dr. A. M. Cooke and to the obstetricians of the Maternity Department of the United Oxford Hospitals for permitting us to study patients under their care. Miss Julie Pink and Mrs. Alison Jones have given valuable technical assistance. The expenses of this investigation were in part borne with a grant from the Medical Research Council.

MEGALOBlastic ANAEMIA
FOLLOWING ANTICONVULSANTS

BY

N. BERLYNE, M.B., Ch.B.

Registrar, Prestwich Hospital

M. LEVENE, M.R.C.S., L.R.C.P.

Senior Registrar in Pathology, North Manchester Hospitals

AND

A. McGLASHAN, M.B., Ch.B., D.P.H.

Senior Hospital Medical Officer, Prestwich Hospital

Two cases of megaloblastic anaemia occurring in epileptics who had been taking phenobarbitone and phenytoin were reported by Badenoch (1954), who suggested that the anticonvulsants might have played a part in the production of the anaemia. Other cases have been reported by Hawkins and Meynell (1954), Chalmers and Boheimer (1954), and Rhind and Varadi (1954).

In April, 1954, we first encountered a megaloblastic anaemia in a patient who had been receiving phenytoin and phenobarbitone. In the absence of any obvious cause we speculated whether anticonvulsant drugs could have had any causative relationship. Our suspicions were strengthened when in July a further epileptic patient under our care developed a megaloblastic anaemia which had no obvious cause. The cases reported recently, together with the cases we now record, seem to indicate that megaloblastic anaemia may arise after the prolonged use of anticonvulsant drugs, and that this anaemia is probably due to phenytoin.

Case 1

A man aged 28 was admitted to Prestwich Hospital with an epileptic psychosis in August, 1952. He had suffered from major and minor fits for seven years and had been taking both phenytoin and phenobarbitone for at least

eighteen months. At the time his anaemia was detected he was taking phenytoin 1½ gr. (100 mg.), and phenobarbitone, ½ gr. (50 mg.), thrice daily. He was a good eater and was on a full mixed diet. There was no history of steatorrhoea.

On April 23, 1954, he was noted to be pale and he complained of weakness. Physical examination revealed nothing beyond pallor of skin and mucous membranes and a loud apical systolic murmur. A blood count showed: haemoglobin, 50%; red cells, 2,660,000 per c.mm.; white cells, 6,800 per c.mm. (polymorphs 48%, lymphocytes 50%, monocytes 2%). Anisocytosis and poikilocytosis were present. A fractional test meal revealed a small quantity of free acid. Sternal marrow puncture revealed megaloblastic erythropoiesis, the predominant cells being early and intermediate megaloblasts. The white-cell series showed early forms, some of which were larger than normal.

On May 4 vitamin B₁₂ was started (100 μ g. daily), but in spite of this his blood picture continued to deteriorate and there was no reticulocyte response. By May 10 the blood count was: haemoglobin, 25%; red cells, 1,800,000 per c.mm.; white cells, 3,200 per c.mm.; and reticulocytes, 3%. His physical condition was unaltered. He had a smooth tongue but no active glossitis, a loud apical systolic murmur, and high pulse pressure (B.P. 110/50). There was no evidence of subacute combined degeneration of the cord or any clinical evidence of steatorrhoea or liver disease.

On May 10 he was put on oral folic acid, 5 mg. four times a day. On the 11th his reticulocytes were 5%, and by the 13th they had reached 8%. In addition to folic acid, 20 mg. daily, he received a crude liver preparation ("hepatex T," 4 ml. daily) from May 11 to 13. Otherwise he was maintained solely on folic acid.

On the 13th he was transferred to the Manchester Royal Infirmary under the care of Dr. J. F. Wilkinson. His reticulocytes reached a peak of over 30%, and on his return to Prestwich Hospital on June 2 his haemoglobin had reached 70%. By July 9 the blood count showed: haemoglobin, 90%; red cells, 5,000,000 per c.mm.; white cells, 13,600 (normal differential).

He was discharged home in August, his mental state having improved. He remained on phenytoin and phenobarbitone throughout his illness, and at the time of discharge was taking folic acid, 20 mg. daily.

Case 2

A 26-year-old male epileptic had suffered from epilepsy following a head injury at the age of 5 which had left him with a left hemiparesis. He was also suffering from an epileptic psychosis. He had been on phenobarbitone and phenytoin since 1950. In May, 1954, he was put on to primidone, 0.25 g. thrice daily, in addition to phenytoin, 1½ gr. (100 mg.), and phenobarbitone, ½ gr. (32 mg.), thrice daily to obtain better control of his fits. He was a good eater and was on a full mixed diet. There was no history of steatorrhoea.

Physical examination on August 24, 1954, revealed intense pallor, a left hemiparesis, an apical systolic murmur, and a blood pressure of 140/70 mm. Hg. He had mild hypertrophy of the gums but no significant glossitis. There was no evidence of subacute combined degeneration of the cord or any clinical evidence of steatorrhoea or liver disease. A blood count showed: haemoglobin, 28%; red cells, 1,620,000 per c.mm.; white cells, 3,600 per c.mm. (polymorphs 31%, lymphocytes 64%, monocytes 3%, eosinophils 3%). Anisocytosis, poikilocytosis, punctate basophilia, Howell-Jolly bodies, and Cabot rings were obvious in the blood film. Sternal marrow puncture showed a megaloblastic marrow, early and intermediate megaloblasts predominating. No abnormality was noted in the white-cell series.

A fractional test meal with histamine showed free acid present. There were no fat globules in the faeces, and faecal-fat estimation showed total fat 28%, with a normal split/unsplitted ratio. The glucose-tolerance test showed normal

absorption of glucose (fasting blood sugar, 85 mg. per 100 ml.; 30 minutes, 150 mg.; 60 minutes, 170 mg.; 90 minutes, 140 mg.; 120 minutes, 80 mg.). Liver-function tests were normal (serum bilirubin, 0.4 mg. per 100 ml.; serum alkaline phosphatase, 7.5 King-Armstrong units; thymol turbidity, 2 units; thymol flocculation, 0; colloidal gold, 0).

On August 25 he was started on vitamin B₁₂ (100 µg. intramuscularly daily). By the 28th he had still shown no reticulocyte response (reticulocytes remaining stationary at 1%). As the blood picture was deteriorating (haemoglobin, 24%; red cells, 1,300,000 per c.mm. on the 28th) and he was having occasional major fits, he was started on folic acid, 10 mg. twice daily.

On August 30 the reticulocytes were 3%, but on the 31st they rose to 12%. By September 2 a reticulocyte response of 30% had been achieved. The blood picture improved rapidly until on October 12 it showed: haemoglobin, 90%; red cells, 4,980,000 per c.mm.; white cells, 7,800 per c.mm. (normal differential count). The patient is now in good general health and is being maintained on folic acid, 20 mg. daily. He has continued on phenytoin and phenobarbitone throughout, primidone having been discontinued when his anaemia was first noted.

Discussion

Megaloblastic erythropoiesis is found in pernicious anaemia, the sprue syndrome, abnormalities of the gastrointestinal tract, nutritional deficiency, diphyllobothrium infestation, and, rarely, in liver disease. Recently, megaloblastic anaemia has been reported in patients who had been receiving anticonvulsants (Badenoch, 1954; Hawkins and Meynell, 1954; Chalmers and Boheimer, 1954; Rhind and Varadi, 1954).

Our two cases were encountered among the epileptic patients in a large mental hospital. The type of patient restricted full investigation, but in both cases the well-known causes of megaloblastic anaemia did not seem to be present. Free acid was found in the gastric juice, there was no evidence of nutritional deficiency or of steatorrhoea or liver disease, and there was nothing to suggest organic disease or previous surgical intervention in the gastrointestinal tract. Both cases responded well to folic acid, but the clinical impression was that vitamin B₁₂ was ineffective.

In Case 1 no reticulocyte response was obtained after six days' treatment with vitamin B₁₂. In Case 2 there was no reticulocyte response five days after commencing vitamin B₁₂, although a response appeared on the sixth day (three days after the start of folic acid treatment). In both cases a good reticulocytosis followed the use of folic acid, and with this drug alone the blood picture was restored to normal and maintained at this level. Both cases had been on phenytoin and phenobarbitone for a period of years, and both continued to receive these drugs during their illness.

Vitamin B₁₂ resistance has been reported in all the other cases except one of those reported by Badenoch (1954). Folic acid produced a favourable response in the other recorded cases.

The mechanism of this type of anaemia is obscure. There are numerous instances of the effects of the hydantoins, particularly methoin, upon bone marrow, but only agranulocytosis and aplastic anaemia have been reported in the past (Jones, 1951; MacArthur, 1952). Phenobarbitone rarely causes marrow damage, although a few cases of agranulocytosis have been recorded (Watkins, 1933). Primidone was given to one of our cases, and Chalmers and Boheimer had one of their patients on the drug. Serious blood dyscrasias, however, do not seem to have been recorded in trials so far with this drug, though the fact that it is a dione and a relatively new addition to therapeutics suggests that we may see such results in the future.

Phenytoin would appear to be responsible for the megaloblastic anaemia in these cases. It was the only drug used in the case recorded by Hawkins and Meynell, and it had been used in all other cases reported, although, in these, other drugs had been given in conjunction with phenytoin. If phenytoin is responsible it is remarkable that no previous cases of this type of anaemia associated with the drug have been recorded, for it has been in use since 1938. There is the possibility that previous cases have been dismissed as idiopathic megaloblastic anaemias and the relationship to phenytoin has not been recognized. Another possibility has been suggested by Hawkins and Meynell, to the effect that anaemia may appear only if the patient has taken the drug for a long time. Their patient had been on phenytoin for 13 years. However, most of the recorded cases were on phenytoin for much shorter periods, although the length of time on the drug has been more in the nature of years than months. A further interesting point is that, whilst the number of epileptics on phenytoin is enormous, this complication appears to be a rarity. At this hospital 75 other epileptics receiving anticonvulsant drugs have been screened so far, but none has shown any evidence of anaemia, though in age, type of epilepsy, food, and living conditions, in addition to anticonvulsant medication, they closely resemble the two recorded cases.

Hawkins and Meynell suggest that phenytoin may either affect absorption of haematopoietic factors or act as a folic acid antagonist. In only one case, that of Rhind and Varadi, has there been evidence of malabsorption, and even this was inconclusive. The normal vitamin B₁₂ serum levels in those cases in which this has been determined (Badenoch, 1954; Chalmers and Boheimer, 1954; Rhind and Varadi, 1954), and the excellent response to folic acid, suggest that this anaemia is essentially a folic acid deficiency, whatever its precise mechanism. It is extremely difficult to produce a folic acid deficiency in the experimental animal, but, in man, megaloblasts have occasionally been found in the bone marrow in cases of acute leukaemia treated by aminopterin (Stickney, 1952). Wintrobe (1951) reports that in pigs a vitamin B₁₂ refractory megaloblastic anaemia can be produced, but only by reducing dietary vitamin B₁₂, excluding folic acid from the diet, and giving a folic acid antagonist in conjunction with succinylsulphathiazole. This porcine anaemia responds promptly to folic acid and resembles the anaemia in the cases on phenytoin reported here.

Whatever the mechanism, it seems essential that epileptics treated with anticonvulsants be watched for the possible advent of this anaemia. The severity of the condition and the excellent response to folic acid make this imperative. Further work will be necessary to elucidate the precise mechanism involved and to produce means of preventing this complication.

Summary

Two cases of megaloblastic anaemia which developed after the prolonged use of anticonvulsants are recorded. Both cases responded well to folic acid, and the evidence suggested that they were refractory to vitamin B₁₂. The literature is briefly reviewed and possible causative mechanisms of this anaemia are discussed.

Thanks are due to Dr. J. P. McGuinness, medical superintendent of Prestwich Hospital, for permission to record these two cases; to Dr. J. F. Wilkinson and Dr. M. C. G. Israels for help with the treatment of Case 1; and to Mr. T. Read for the laboratory procedures.

LIPODYSTROPHIA PROGRESSIVA AND TEMPORARY HYDRONEPHROSIS

BY

P. B. S. FOWLER, D.M., M.R.C.P.

Assistant Physician, Charing Cross Hospital

If the association of two diseases in a patient is not fortuitous their relationship to each other may throw light on the aetiology of one or both diseases. Lawrence's (1946) study of a woman with lipodystrophia progressiva and insulin-resistant diabetes supports the concept of two types of diabetes mellitus and suggests the simple explanation that the elderly obese person develops diabetes because she is unable to convert any more carbohydrate into fat.

In this paper the association of temporary hydronephrosis with lipodystrophia progressiva is reported and the renal disorders which have been described with this disease are reviewed. It is suggested that in some of the case reports the renal changes may have been similar to those present in the patient described here.

Gross hydronephrosis can develop in a week and disappear completely if the obstruction is removed early enough, and the term "temporary hydronephrosis" has been used to describe these transient changes (Fowler and Frankel, 1947).

Ellis (1951), writing about lipodystrophia progressiva, mentions the association of this condition with renal disease. He makes a brief reference to the occurrence of oliguria in Gerhartz's case (1916). The daily urinary output of this patient was 400-1,100 ml., and it is difficult to believe that this is a significant oliguria. Klien (1921) reports on a patient with lipodystrophia and mentions polyuria. Recently a patient with this disease was shown at the Royal Society of Medicine (Tizard, 1954), and the summary of the case included the information that "she is said to drink and void excessive quantities of fluid." The glucose-tolerance test in this patient was normal, but full urinary investigations including a pyelogram had not been done. Following the paper by Lawrence (1946) on the association of lipodystrophia and diabetes, any patient with lipodystrophia complaining of thirst and polyuria may be examined for further evidence of diabetes mellitus only, as happened to our patient, when studied for a short period at another hospital.

In 1932 two cases were reported in which lipodystrophia progressiva and uraemia occurred in the same patient. They were both thought to have had chronic nephritis, but in neither did the diagnosis appear likely, nor was it confirmed. They both had unusual clinical features in common with the patient described in the present paper.

Horton and Emmett (1932) report the case of a woman of 61 with a history of increasing nausea for one year with occasional attacks of vomiting. The patient was alert, and physical examination was essentially negative except for lipodystrophia affecting the legs. There were no symptoms or signs suggesting uraemia. On admission the blood urea was 400 mg. per 100 ml. After five weeks on a diet containing 25 g. of protein and 3-4 litres of fluid daily, the blood urea fell to 60 mg. per 100 ml. It was stated that pus cells, grade III, were present in the urine, but no mention of urine culture was made. The renal lesion was diagnosed as chronic

diffuse glomerulonephritis after the possibility of polycystic kidneys had been considered and dismissed, as no enlargement of the kidneys could be found on abdominal palpation.

Berger (1932) reported the case of a woman aged 26 who developed lipodystrophia at the age of 3½ years. Pyelitis occurred at 6 and another attack a year later. At the age of 19 the blood pressure was found to be raised and albumin was present in the urine. A diagnosis of acute exacerbation of chronic nephritis was made. Following a severe reaction to vaccination, the patient for a short time passed into uraemic coma. During the next seven years she remained well, and clinical examination at the end of this period was essentially negative except for the lipodystrophia. The blood urea was then 21 mg. per 100 ml.

Igersheimer (1948) described the case of a patient who had lipodystrophia progressiva, bilateral hydronephrosis with aberrant renal arteries, and other congenital abnormalities.

Case Report

The patient was the youngest of four children. Her parents and siblings were healthy. At the age of 2½ years she had scarlet fever and was in bed for three months with subsequent "kidney trouble." She had several attacks of sore throat until tonsillectomy at the age of 5. Between the ages of 5 and 9 she remained well except for mild attacks of measles, chicken-pox, and rubella. In 1950, at the age of 9, she was referred to the out-patient department with a ten-day history of abdominal pain and nausea. Her doctor wrote that she was "very lethargic and looked cadaverous."

She presented with the typical appearance of lipodystrophia progressiva with the so-called "death's head" and circumoral wrinkling on speaking or smiling. Loss of subcutaneous fat was symmetrical and complete down to the pelvic girdle, where there was an abrupt change. Below this level subcutaneous fat was present in normal but not excessive amounts. Her weight was 3 st. 10 lb. 4 oz. (24.2 kg.). Examination was otherwise negative. In view of the recent illness further investigations were done: a Mantoux test, which was negative; E.S.R., 4 mm. in the first hour; Hb, 98%; W.B.C., 5,000; and x-ray examination of the chest, normal. No investigation of the urinary system was done at this time except for a routine examination of the urine, which contained no abnormal constituents. The mother was told that improvement in the child's appearance was unlikely, but that she would remain healthy.

In September, 1951, fifteen months later, the mother, anxious for something to be done to improve the child's appearance, took her to a London teaching hospital, where she was an in-patient for fifteen days. In the case summary on her discharge it was noted that the child "was said to be rather thirsty." The glucose-tolerance test was normal. No special urinary-tract investigations were done. It was concluded that she was "a case of lipodystrophia progressiva unassociated with evident endocrine disorder."

In February, 1952, four months later, the child was admitted to Bromley Hospital with a history of repeated vomiting for five days, and abdominal pain and red urine for three days. The temperature at the onset had been 103° F. (39.4° C.) and there had been repeated rigors, dysuria, and frequency. On examination she showed the features of lipodystrophia unchanged from when she was first seen twenty months previously. The child now looked toxic and dehydrated, with a dry furred tongue. The pulse was of poor quality and the rate 100 before admission. In hospital the rate was at first about 90, later rising on occasion to over 120. The temperature settled to 99° F. (37.2° C.) and for the next three weeks there was a low-grade pyrexia up to 99.5° F. (37.5° C.). During the fourth

week the temperature fell and was normal for the remaining three weeks in hospital. For the first few days tenderness was present in the right loin. There was no tenderness in the left loin or over the bladder. The B.P. was 120/80, and, with the exception of the urine, the remainder of the physical examination was negative.

The urine on admission was scanty and contained a very heavy cloud of albumin. There were numerous red cells, pus cells, and isolated cellular casts. Catheter specimens of urine were sterile. Five days after admission the blood urea was 330 mg. per 100 ml.; W.B.C., 19,000, with 80% polymorphs; E.S.R., 25 mm. in the first hour.

Four days later the blood urea was still 320 mg. per 100 ml. and oliguria persisted. The Bull-Borsh regime was then started, and the blood urea fell to 183 mg. per 100 ml. after a further five days and in the next fortnight to 40 mg. per 100 ml. The child's condition improved with the fall in

FIG. 1.—Intravenous pyelogram done on March 26, 1952.

FIG. 2.—Intravenous pyelogram done on October 9, 1953.

the blood urea. An intravenous pyelogram, when the blood urea had fallen to normal, showed bilateral hydrocalicosis, hydronephrosis, and hydroureter more marked on the right (Fig. 1). Cystoscopy showed no abnormality. The child was discharged from hospital on April 9, weighing 4 st. 6 lb. (28.1 kg.), and returned to school one month later.

During her stay in hospital there was striking mental instability, the child being one moment aggressive and abusive and the next exceedingly timid. This was in marked contrast to her mental state when her condition improved. Her personality then becoming stable and pleasant. The mental changes appeared to be a manifestation of uraemia, improving as the blood urea fell.

When seen in the out-patient department three months later she was free of symptoms, was feeling well, and had won the high jump at school. No abnormal constituents were found in the urine, the intravenous pyelogram showed only slight bilateral hydronephrosis and hydroureter affecting mainly the right side.

Her progress was watched in the out-patient department and she continued to remain well until fourteen months later. While on holiday she was admitted on August 13, 1953, to the Royal County Hospital, Ryde, with a history of vomiting, abdominal pain, headache, and dark urine for four days. The urine contained large amounts of albumin, many pus cells, and red blood cells with a moderate amount of granular and cellular casts. The B.P. was 130/80, E.S.R. 47 mm. in the first hour, and Hb 90%. The blood urea was 73 mg. and later rose to 109 mg. per 100 ml. Before transfer back to Bromley Hospital the blood urea had fallen to 28 mg. An intravenous pyelogram (Fig. 2) showed little change from that done one year previously, but there was marked improvement as compared with the first x-ray films taken soon after the most severe uraemic episode. On discharge from hospital on October 12 she was free of symptoms and her general condition was satisfactory, although there was still a moderate albuminuria.

When seen in the out-patient department in March, 1954, she was feeling well. The B.P. was 140/80. The urine contained 0.5 g. of albumin and a moderate number of red cells and pus cells. The blood urea was 32 mg. per 100 ml. and the urea clearance (Van Slyke) 54%. An E.E.G. in November showed no abnormality.

Discussion

In retrospect, it appears likely that the first illness in June, 1950, was due to incipient or transitory uraemia and that she has therefore been in renal failure three times. The nature of the kidney trouble at 2½ years old is unknown.

Although the equanimity of most patients with lipodystrophy emphasizes their mental stability, psychological disturbances have occurred in a number of patients. Warin and Ingram (1950) reported two such cases and reviewed other instances of this association. The presence with lipodystrophy of mental disorder due to organic disease of the brain lends some support to the theory that this disease results from a lesion in the central nervous system. In our patient the mental changes were due to uraemia, and, although in none of the case reports was mental change attributed to this cause, renal and other organic disease may pass unrecognized when presenting with mental symptoms (Stokes *et al.*, 1954).

In this child the three attacks of uraemia were clearly due to the hydronephrosis. The cause of the uraemia in the patients with lipodystrophy described by Horton and Emmett (1932) and Berger (1932) was obscure. In Berger's patient it seems improbable that an acute exacerbation of chronic nephritis had caused uraemia when seven years later the patient was in good health and the blood urea 21 mg. per 100 ml. Intravenous pyelography, which might have shown a hydronephrosis, was not done in either of these two patients. This technique had not been introduced at the time Gerhartz (1916) and Klien (1921) described their cases.

Renal failure did not occur in Igersheimer's (1948) patient with lipodystrophy and hydronephrosis. Igersheimer maintained that lipodystrophy is due to a defect of the mesenchyme and described various mesenchymal abnormalities in his patient. He reviewed other published cases to support his view. The hydronephrosis in his patient was believed to be due to an aberrant renal artery. This was found at operation and cut. A subsequent intravenous pyelogram showed no change from the appearance before operation.

Igersheimer summarily dismisses the nervous, endocrine, and other causes suggested for lipodystrophia progressiva. The different hypotheses concerning aetiology have been fairly reviewed by Ellis (1951). There is much evidence to suggest that lipodystrophy may result from a lesion in the central nervous system (Warin and Ingram, 1950).

Besides that of associated mesenchymal defects or mere chance, there is another possible explanation for the occurrence together of uraemia and lipodystrophy. Lesions of two closely related areas of the brain, anterior to the hypothalamus, may be responsible for trophic changes and uraemia, both of these effects occurring if both areas are involved. Evidence that the cause of lipodystrophy may lie in a lesion related to the hypothalamus is found in the diencephalic syndrome (Russell, 1951), where profound wasting is a prominent feature. In Tizard's patient (1954) the profound wasting was a true lipodystrophy with disappearance of subcutaneous fat and no muscle-wasting. Dr. Russell, who saw this child, thought it likely that she had a diencephalic lesion. Evidence that trophic changes and uraemia can be due to lesions in closely related areas anterior to the hypothalamus is furnished by McLardy (1950). After prefrontal leucotomy, trophic changes with gross wasting and uraemia have often been described. These complications of the operation usually occur when the incisions go too far back (Freeman, 1953). McLardy has shown that prefrontal leucotomy can be followed by uraemia or trophic changes, depending upon which of two areas is damaged. Injury to posterior area 47 of the orbital cortex leads to uraemic death, and the severance of connexions between the caudate nucleus and Brodmann's (non-granular) cortical areas 8 and 6 is concerned with the trophic fatalities. The immediate cause of renal failure in McLardy's series of uraemic deaths is not known, but he mentions the work of Cort, who claimed to reproduce Trueta's renal shunt mechanism in cats by electrical stimulation of the cortex of area 13.

If renal failure in lipodystrophy is due to a lesion in the central nervous system, this could be caused by abnormal function of the autonomic innervation of the urinary tract, producing hydronephrosis, or of renal cortical arterioles, producing a Trueta shunt effect. Besides the evidence of the present case, hydronephrosis as a functional disorder of the urinary tract is common in man. The rare cortical necrosis of the kidney during pregnancy is the only disease which may be comparable to Trueta's shunt mechanism in the experimental animal.

Lesions affecting autonomic centres are responsible for diverse vegetative effects, including uraemia. The common idiopathic hydronephrosis with no organic obstruction may be due to disease of the central nervous system involving an autonomic centre regulating the function of the renal tract.

Summary

A case of lipodystrophia progressiva, temporary hydronephrosis, and recurrent uraemia is described.

The occurrence of renal disease with lipodystrophy is reviewed. The association of the two diseases may be fortuitous; the result of a mesenchymal defect; or the result of a lesion of adjacent centres in the central nervous system, responsible for the renal and trophic changes.

Evidence is submitted that a lesion anterior to the hypothalamus may be responsible for these changes.

My thanks are due to Dr. N. S. Plummer for permission to publish this case and for his helpful criticism.

MALIGNANT GRANULOMA OF THE NOSE

BY

MAXWELL ELLIS, M.D., M.S., F.R.C.S.

Surgeon to the Royal National Throat, Nose, and Ear Hospital, London; E.N.T. Surgeon to the Central Middlesex Hospital

The condition known as malignant granuloma of the nose is uncommon and almost invariably fatal. The chief purpose of this report is to present a unique result—a treated case which has remained healed for over five years. The secondary purpose is to present another case of a different and unusual type.

Only five cases of recovery appear in the literature, but closer examination of the case records and subsequent history reveals inconsistencies. Woods's case (1921) healed locally after interstitial irradiation, but the patient died within two years, of generalized sarcomatosis. The diagnosis of the original lesion must therefore be suspect. In the case of M'Arthur and Dew (1925) the local lesion healed after three doses of deep x rays, but the patient died four years after the last dose from what was called "miner's phthisis." No necropsy was permitted, and Stewart (1933) quotes a letter from M'Arthur in which the possibility of pulmonary sarcomatosis was envisaged. Schütz (1938) records eight cases, in one of which spontaneous resolution occurred, but the account is too brief to be entirely acceptable. Hoover (1941) describes an admittedly atypical case which apparently healed after excision of the granulomatous area followed by antisyphilitic treatment.

An exhaustive survey of the literature by Williams (1949) failed to reveal any cases of survival other than those cited above. His discussion of the pathology is most instructive, particularly in assessing a link with periarteritis nodosa and with certain types of hypersensitivity reactions. Following upon this paper, Williams and Hochfilzer (1950), Moore *et al.* (1951), and Woodburn and Harris (1951) have had some success with cortisone and A.C.T.H., but the follow-up period recorded is too short for appraisal.

Finally, Sneddon and Colquhoun (1952) claim a cure with chlortetracycline ("aureomycin") and chloramphenicol, but the patient died a year or so later, and, furthermore, the precise nature of the lesion was never identified by biopsy. They considered the lesion to be staphylococcal in origin, but no other case has been recorded in which the local lesion healed with antibiotics (Breckenridge *et al.*, 1954).

Case 1

A married woman aged 28 was first seen at the Royal National Throat, Nose, and Ear Hospital on June 24, 1947, complaining of right-sided nasal obstruction, an intermittent swelling in the right nasal cavity, a purulent nasal discharge, and considerable crusting with fetor. Some of the symptoms had been present for over two years. There was a large septal perforation, crusts in both nasal cavities, mucopus in the nasopharynx, and a nodular swelling of the right side of the palate. A radiographic opacity of the right antrum was present and antral lavage revealed pus and crusts. The W.R. was negative. On a tentative diagnosis of atrophic rhinitis, she was advised to use an alkaline nasal douche and a nasal paint of glycerin and glucose, night and morning, and this kept her relatively comfortable. As this diagnosis was not convincing, she was kept under close observation, attending frequently at short intervals, until on October 7 a large piece of necrotic bone, thought to be a sequestrum of the septum, was removed from the left side of the nose.

A few weeks later she was admitted to a hospital nearer her home because of acute maxillary sinusitis. This occurred

FIG. 1.—Case 1. Showing the external extent of the ulcer with necrotic bone in the margins.

FIG. 2.—Case 1. Showing the nodular enlargement of the palate.

FIG. 3.—Case 1. Showing the pleomorphic cellular reaction and the absence of focal necrosis and of necrotizing angitis. ($\times 230$.)

three times during the next fifteen months, necessitating her readmission on each occasion. These attacks were treated with penicillin and antral lavage, and in September, 1948, by a Caldwell-Luc operation on the right side. After this operation the right side of the nose and the tissues underlying it literally melted away, and an ulcer appeared which rapidly spread upwards almost to the margin of the right orbit. At this stage I saw her again, quite fortuitously, in my out-patient clinic at another hospital, where she was referred by her doctor. It was now evident that this ulcer was the external opening of a large fistula into the right nasal cavity, right ethmoidal region, and right antrum, and that its margins consisted of necrotic bone and of granulation tissue (Fig. 1). The mucosa on the buccal surface of the palate was thickened and nodular, although still intact (Fig. 2), but on palpation it was found that the bone of the hard palate had been almost completely destroyed. A diagnosis of malignant granuloma now sprang to mind, and, so far as confirmation is possible, this diagnosis was confirmed by biopsies from the edge of the ulcer and from the swelling on the palate.

Dr. I. Friedmann's report is as follows: "The histological appearances (Fig. 3) of this case are characteristic of malignant granuloma of the nose in so far as they consist of a chronic fibrous non-specific inflammatory granulation tissue infiltrated by pleomorphic inflammatory cells, including plasmacytes and lymphocytes. There are no giant cells present and there is no evidence of focal necrosis, frequently seen in similar cases. A small artery found in the biopsy specimen shows no evidence of necrotizing angitis. This histological picture virtually excludes all known forms of specific granulomatous reactions as well as neoplasm. There are possibly several histological types or variations of malignant granuloma of the nose. The most common type appears to be a pleomorphocellular granulation tissue as described in this case. In other cases one or more of the following morphological features have predominated: (1) histiocytes, (2) foreign-body giant cells, (3) extensive necrosis. One particular variety, the giant-cell granuloma, is frequently associated with necrotizing vascular disease resembling polyarteritis nodosa. The case here described appears to belong to the classical type as there was no sign of systemic vascular complications."

In spite of treatment with sulphonamides and penicillin, pieces of necrotic bone were daily extruded from the depths of the cavity, and later the palatal mucosa gave way. The patient was referred to Dr. M. Lederman, radiotherapist at the Royal Marsden Hospital, for irradiation, but after consultation it was decided not to risk a form of treatment which might itself cause bone necrosis. Large doses of potassium iodide together with a course of calciferol were given and the ulcer became cleaner and showed signs of healing. The horrible fetor disappeared and the steady necrosis and sloughing ceased. However, the improvement

was only temporary, and a few months later the condition again became noticeably active. Dr. Lederman then consented, with some misgivings, to try a course of deep x rays, and the very small dose of 300 r was administered between December 19, 1949, and January 21, 1950. A dramatic change followed. The margins of the ulcer became clean and a healthy skin-mucosal junction formed. The mucosal junction between the oral and nasal surfaces of the palate also healed. By April 12 there was no further evidence of activity, and the vast, hideous cavity gradually became lined with pink mucosa.

As the ulcer remained soundly healed, Mr. J. P. Reidy, early in 1952, began the difficult plastic reconstruction which is still in progress. In spite of four operations on the tissues of the nose and face, there has been no evidence of any return of the disease.

Comment

The natural history of malignant granuloma of the nose has not been precisely identified, and the histological picture itself has not been clearly established as a specific entity. Stewart's exhaustive review of the cases described up to 1930 was accompanied by a composite clinical description based on these records, but it is more than possible that some of them would not now be accepted as true cases of the disease. The lesion usually begins as an intranasal ulcerative process which soon appears on the face after having eroded the lateral wall of the nose or the anterior wall of the antrum. The facial tissues are progressively destroyed and bone necrosis with sequestration is a marked feature. The spread towards the pharynx is slower. Death usually results from cachexia, in anything from one to three years. The case reported here has followed the classical course, except for the end-result.

However, there is occasionally another type of case in which the necrotizing reaction remains confined within the nasal cavities and spreads over the surface of the mucosa. One such case has recently come under my care.

Case 2

A man aged 48 was first seen on October 26, 1954, complaining of pain in the nose for about four months. This pain followed a thyroidectomy. The teeth were thought to be the cause of the pain and had been extracted, but without relief. The right nasal cavity contained pus and crusts, and pus was found on antral lavage. On November 11 a granular area was noticed on the septum and a portion was removed for biopsy. This revealed a non-specific type of granulation tissue covered with a thick stratified squamous epithelium. The granular area increased in extent and a large ulcer appeared on the septum and also on the middle turbinal. On December 15 the patient was admitted and the antrum opened and inspected by the Caldwell-Luc approach. Macroscopically it appeared normal, and pieces

FIG. 4.—Case 2. Showing the similar pleomorphic reaction, but with an excess of histiocytes and plasmacytes. ($\times 750$.)

of tissue for biopsy were taken from the antral mucosa, the right middle turbinal, and the septum. The antral mucosa was normal, but (Fig. 4) "the nasal mucosa is densely infiltrated by large lymphocytes and histiocytes showing considerable irregularity of nuclear size and shape. There are numerous plasmacytes present, and frequent mitoses

are seen. The cartilage of the nasal septum has been eroded by the process" (Dr. I. Friedmann). Dr. L. W. Pagel concurred with this description, and both pathologists agree that this is a case of malignant granuloma. The distinctive feature of predominance of histiocytes and plasmacytes is a variation to which Dr. Friedmann has already drawn attention.

By January 8, 1955, destruction of the septum had occurred, but the process, although spreading rapidly within the nasal cavity, still shows no sign of involving the skin.

Discussion

Although it is possible that these two differing clinical pictures are associated with certain variations in the histological picture (Friedmann, 1955), the ultimate prognosis has hitherto been fatal in both types of case. Case 2 has been treated in a similar manner to Case 1, but it is as yet too early to say what will happen.

No rationale is claimed for the treatment given in Case 1, much less for the dramatic success with which it was attended. It was frankly a shot in the dark, entirely on an empirical basis of trial and error. The patient is apparently cured, presumably by the irradiation, as resolution followed immediately after it was given, and the disease had previously resisted, or relapsed after, other methods of treatment. The reluctance in trying irradiation naturally follows the knowledge that irradiation can itself cause, especially in bone, a similar necrotizing type of lesion. The end-result indicates that an almost absurdly small dose was the treatment of choice in this particular case, and would be well worth trying in other similar cases. In fact, at a meeting of the Section of Laryngology of the Royal Society of Medicine on December 3, 1954, Mr. Gilroy Glass reported two cases which were treated similarly and which have responded similarly. They had remained healed for about a year, up to the time of his report.

Summary

A case of malignant granuloma of the nose is described which has been cured by a very small dose of deep x rays. This is the first genuine case recorded in which the patient has not died of the disease.

In addition to the classical type of case with sloughing of the facial tissues there is another type which remains confined within the nasal cavities, spreading superficially in the mucosa.

The third pamphlet in a series on Food Hygiene has just been published by the Central Council for Health Education. This leaflet deals with refrigerator storage. It describes how the refrigerator should be used and cleaned, and what foods should have priority in it. A previous leaflet advised on food storage without a refrigerator, and another presented a "Shopping Quiz" for housewives, drawing attention to poor hygiene standards in food shops.

IMMEDIATE PARTIAL GASTRECTOMY FOR PERFORATED PEPTIC ULCER

BY

B. C. ROWLANDS, M.B., B.S., F.R.C.S.

Senior Surgical Registrar

AND

P. A. KING, M.B., Ch.B., F.R.C.S.

Formerly Surgical Tutor

University Surgical Unit, the Royal Infirmary, Sheffield

Between March, 1950, and December, 1951, five elective partial gastrectomies were performed at the University Surgical Unit for severe recurrent symptoms following simple closure of a perforated peptic ulcer. The simple closure antedated the ultimate resection by periods varying from six months to three years. Impressed with the inconvenience to the patients of disabling symptoms in the intervening period and of the increased technical difficulties at the time of the second operation, it was decided to treat certain selected cases of perforated peptic ulcers by immediate partial gastrectomy.

Some would consider that the treatment of a perforated peptic ulcer is a life-saving measure and that the simplest operation is all that should be attempted. Figures from Continental clinics support the contention that immediate gastrectomy is a safe procedure. Nuboer (1951) published a series of 131 immediate partial gastrectomies for perforated peptic ulcer with a mortality of 3.8%. Very low mortality rates are also revealed by certain Russian authors (Rozanov, 1953; Lidskii and Nurenberg-Charbiani, 1953). Lowdon (1952) performed partial gastrectomy without mortality in 51 consecutive cases of perforated peptic ulcer in patients between the ages of 20 and 70. These figures imply that in experienced hands the mortality rate from immediate partial resection can be expected to be no greater than that of simple suture.

The issue over which the various exponents of the major procedure are at variance is in the selection of the cases. In Nuboer's clinic "since 1943 partial gastrectomy has been done in nearly all cases of perforated ulcers. No regard is paid to the patients' age or duration of perforation." Nuboer justified this apparent lack of discrimination by suggesting on histological evidence that all the perforations, even in patients with a short history, were of a chronic nature. These findings, however, were not confirmed by Lowdon (1952) in some of his cases with a history of short duration. Forty (1951) quoted findings in 19 perforations examined histologically, in which no fewer than 15 were classified as being of an acute nature, and such findings imply that a critical assessment of each individual case is desirable. It would appear reasonable, therefore, to select individuals for immediate partial gastrectomy by estimating their probable prognosis after simple suture alone, the items of importance in such assessment being (a) the situation, appearance, and size of the perforation, (b) the duration and severity of the symptomatology prior to perforation, and (c) an appreciation of the statistical surveys of progress after peptic ulcer perforation.

Results

Between January, 1952, and June, 1954, 54 cases of perforated peptic ulcer were admitted under our care: 4 were treated conservatively with 2 deaths; 2 elderly patients with perforated gastric ulcer found to be unfit for resection were treated by simple suture, with 1 death; and 33 cases of perforated duodenal ulcer were treated by simple closure, with 3 deaths.

The following brief summaries describe the remaining 15 cases, which were treated by immediate partial gastrectomy:

Case 1.—Male, aged 65, with a two-year history of dyspepsia, perforated 16 hours before admission. Large perforation of duodenum with gross peritoneal soiling. Immediate partial gastrectomy; uneventful recovery.

Case 2.—Male, aged 60, with a long history of dyspepsia, perforated two hours before admission. Large perforation of anterior wall of first part of duodenum. Immediate partial gastrectomy; uneventful recovery.

Case 3.—Male, aged 55, with recent symptoms, perforated seven hours before admission. General condition poor. Perforated lesion found on distal third of greater curvature of stomach. Partial gastrectomy; developed paralytic ileus and renal failure; died on 11th post-operative day. Histology—benign gastric ulcer.

Case 4.—Male, aged 66, with recent dyspepsia and melaena, perforated 8 hours before admission. Perforation of anterior wall of stomach, with considerable peritoneal soiling. Immediate gastrectomy; general peritonitis and paralytic ileus; died on 10th post-operative day. Histology—chronic gastric ulcer.

Case 5.—Male, aged 64, with a long dyspeptic history, perforated six hours before admission. Large perforated duodenal ulcer, with gross peritoneal soiling; immediate gastrectomy; uneventful recovery.

Case 6.—Male, aged 64, with a four-year history of severe dyspepsia, perforated 15 hours before admission. Large perforation of pyloric antrum with early localization; uneventful recovery followed partial gastrectomy. Histology—gastric carcinoma.

Case 7.—Male, aged 60; previous gastro-entrostomy in 1933, perforated three hours before admission. Large perforated lesion just above the previous anastomosis seen at operation. Immediate gastrectomy; uneventful recovery. Histology—gastric carcinoma.

Case 8.—Male, aged 56; continuous dyspepsia since a previous perforation was successfully sutured in 1943. Perforated duodenal ulcer treated by immediate partial gastrectomy; uneventful recovery.

Case 9.—Male, aged 60, with a 20-years history of dyspepsia, perforated 12 hours before admission. Perforation in a stenosed duodenum treated by immediate gastrectomy; uneventful recovery.

Case 10.—Male, aged 42, with a history of two previous perforations, was admitted four hours after his third. Perforated duodenal ulcer treated by immediate gastrectomy; uneventful recovery.

Case 11.—Male, aged 71, with a 25-years history of dyspepsia, presented with a perforation and haematemesis. Partial gastrectomy for a large perforated duodenal ulcer; uneventful recovery.

Case 12.—Male, aged 56; long history; perforated eight hours before admission. Immediate partial gastrectomy performed in presence of perforated and stenosed duodenum; uneventful recovery.

Case 13.—Male, aged 44; eight years' dyspepsia, perforated three hours before admission. Perforated lesion of lesser curve dealt with by a Pauchet type of partial gastrectomy; uneventful recovery. Histology—chronic gastric ulcer.

Case 14.—Male, aged 59; recent symptoms. Large perforation of duodenum treated by partial gastrectomy five hours after onset of symptoms; uneventful recovery.

MAY 21, 1955

Case 15.—Male, aged 70, perforated three hours before admission. Very large perforation of duodenum treated by partial gastrectomy. Satisfactory recovery followed re-suture of a wound dehiscence on the seventh post-operative day.

Discussion

If the patient's general condition permits, a partial resection is the operation of choice in nearly all cases of perforated gastric ulcer. Such perforations, especially if chronic, are often difficult to suture, the amount of intra-peritoneal contamination is great, and containment of the infective material is unsatisfactory. The greater mortality following treatment by simple suture and toilet of patients with perforated gastric as compared with duodenal ulcers has been demonstrated by Chamberlain (1951) and Gilmour (1953). Another justification for routine immediate resection is the high proportion of carcinomas of the stomach which appear in the guise of simple gastric perforation. Thus Doll (1950) quoted 17 cases of perforated carcinoma of the stomach occurring in the eleven years 1938–48 in the Central Middlesex Hospital. Perforations were found at operation in 11 cases, but only 3 were recognized to be neoplastic, and 7 were discharged from hospital with the diagnosis of simple gastric ulcer. Kennedy (1951) quoted a five-year series of 111 acute perforations from the London Hospital which included seven cases of perforated gastric carcinoma. In the present series Cases 6 and 7, thought at operation to be of a simple nature, proved on histological examination to be malignant.

In the case of perforated duodenal ulcers the possibility of neoplasm is so rare as to be disregarded. The size of the ulcer, however, should be considered when deciding on the procedure to adopt. Simple closure is unwise where considerable cicatricial narrowing is present or in cases of large perforation, as simple closure may produce complete stenosis. The occlusion of a large duodenal perforation by an omental plug, although perhaps immediately successful, leaves an area of very imperfectly constituted duodenal wall which, in the continued presence of hyperchlorhydria, will inevitably re-ulcerate and perhaps re-perforate. Luer (1949) found that if the perforation was 1 cm. in diameter or more, the mortality rate following simple suture was more than double the rate in smaller perforations. The experience in this small series of cases suggests that radical operation in such emergency cases is no more difficult than in elective cases and that the subsequent smooth post-operative course is most satisfactory.

A history of previous perforation was taken as an indication for gastric resection if the case was in other respects satisfactory (Cases 8 and 10).

In either gastric or duodenal perforations the co-existence of haemorrhage increases the mortality rate (Avery Jones *et al.*, 1950). This dangerous combination is most satisfactorily dealt with by immediate partial gastrectomy, and in the present series was regarded as a definite indication if the patient's general condition allowed (Case 11).

The appearance of chronicity in a perforated duodenal ulcer may be simulated by inflammatory oedema, and in the absence of previous ulcer dyspepsia it may well be that the lesion is an acute one and immediate resection is unjustifiable: nor should duration of symptoms alone be taken as unequivocal evidence of chronicity. If the perforation is small, even with a long preceding period of dyspepsia, it may be, as contended by Forty (1951), that the patient has had a series of acute or subacute ulcers, each healing in turn. If, however, the perforation has the appearance of being in a chronic ulcer and the patient gives a well-defined period of disabling dyspepsia with perhaps previous hospital treatment and radiological confirmation of a chronic ulcer, immediate partial gastrectomy is justifiable.

The results of a follow-up study of 733 cases of perforation treated by simple suture are valuable in assessing the probable ultimate prognosis after perforation (Illingworth *et al.*, 1946). It was found that remission of ulcer symp-

toms after perforation was seldom of long duration, within five years 70% having relapsed and 50% developing severe symptoms. The prognosis was found to be worse in cases with a long antecedent history, whilst the incidence rate of major complications, particularly re-perforation and haematemesis, was 20% within five years of perforation.

When the series presented in this paper was started it was hoped that a critical selection of cases for immediate gastrectomy would eliminate the expected 20% of major complications and a proportion of the remaining cases which would be expected on the above statistical evidence to relapse. On making the selection we were influenced by the fact that the majority of patients seen in this hospital are industrial workers, miners, and others in whom the economic factor of loss of work is important and in whom prolonged dietary out-patient treatment is often impracticable.

In assessing fitness for immediate partial gastrectomy the patient's general condition was the main guide, and no arbitrary time interval since the onset of symptoms was laid down. For example, in Case 1, although the ulcer had perforated 16 hours previously, the patient was in excellent general condition and, following partial gastrectomy, made an uninterrupted recovery. A gross degree of peritoneal soiling was usually regarded as a contraindication to gastric resection, although in the first case in the series recovery followed gastrectomy in the presence of gross peritoneal contamination.

In no case did the technique of operation present any marked difficulty, and in general Nuboer's findings were confirmed. It was usually easy to free the duodenum, pylorus, and stomach from the inflamed and oedematous surrounding tissue. As Lowdon pointed out, the anterior duodenal perforation is usually unassociated with the technical difficulties so common with posterior and penetrating ulcers. In the majority of cases the closure of the duodenal stump was simple, although when dealing with perforated duodenal ulcers it was in most cases necessary to perform an open division and closure of the duodenum as the oedema of its walls and the size of the perforations prevented the application of a clamp distal to the ulcer. No case of leak from the duodenal stump occurred.

The two fatalities occurred early in the series, and in each case a considerable degree of peritoneal contamination accompanied the perforation. This subsequently led to a more cautious attitude in such cases, although an uneventful recovery followed immediate resection in Cases 1 and 5, in both of which peritoneal soiling was considerable. Tanner (1954) has reported similar successful cases of immediate gastrectomy performed in late perforation with frank pus in the peritoneal cavity.

The remaining cases all had a smooth post-operative recovery, the results encouraging us to continue the policy of performing immediate resection in selected cases.

Summary

Experience with immediate partial gastrectomy for perforated gastric duodenal lesions is recorded.

The operation was performed in carefully selected cases only.

The chief criteria for such selection in a patient fit for resection were (a) any perforated gastric lesion, (b) large perforations, (c) a history of previous perforation, (d) a long preceding history of ulcer dyspepsia, and (e) concomitant haematemesis.

Fifteen cases were selected for immediate gastrectomy in a series of 54 perforations dealt with over a period of 30 months. There were two fatalities.

The operation in no case presented any technical difficulty and the post-operative period was uneventful.

ADDENDUM.—Since June, 1954, a further 15 cases of perforated peptic ulcer have been admitted to the University

Surgical Unit. Four of these cases were dealt with by immediate partial gastrectomy without mortality.

We wish to thank Professor R. P. Jepson for his advice during the preparation of this short communication.

CONGENITAL ATRESIA OF THE BILE DUCTS

REPORT OF CASE TREATED SUCCESSFULLY BY CHOLECYSTOJEJUNOSTOMY

BY

RODNEY MAINGOT, F.R.C.S.

Surgeon to Royal Free Hospital and Southend General Hospital

John Thomson, of Edinburgh, first aroused interest in this condition by his careful analysis of 50 cases in 1892. Holmes (1916) collected 120 cases from the literature, described a large number of variations in malformations of the extrahepatic bile ducts, and concluded that about 16% of the patients could be amenable to surgical treatment. Ladd (1928) was the first surgeon to operate successfully upon a case of congenital atresia of the choledochus. Gray *et al.* (1948), in reporting two cases of their own which were successfully treated by cholecystogastrostomy, state that between 1928 and 1948 only 17 cases were recorded in the literature as being cured by surgical measures.

Durell and Halliwell (1952) described a case of congenital atresia of the common bile duct which was cured by cholecystogastrostomy, and remarked that surgical intervention had been successful apparently in only 21 cases up to 1949. Moore (1953) explored 31 cases of congenital atresia of the bile ducts and performed 8 anastomoses, only one of these patients surviving operation. Likewise, Greaney *et al.* (1954) explored 33 cases, 9 which were suitable for biliary-intestinal anastomosis, and 3 of which were cured. Gross (1953), in by far the largest series, records 146 cases: in 119 nothing could be done on abdominal exploration; in 27 the gall-bladder or the hepatic or common duct was available for anastomosis to the duodenum, and 12 of these were cured.

So far as can be ascertained from published articles, 38 cases of congenital atresia of the extrahepatic bile ducts have been successfully treated by surgery. The majority of the successful operations for this rare abnormality have been recorded by American surgeons. Durell and Halliwell (1952) gave an excellent account of the first case to be cured by cholecystogastrostomy in this country.

So far as I am aware the case described below is the first recorded account of a successful cholecystojejunostomy combined with jejunojejunostomy for atresia of the common bile duct to be published in the British literature.

Pathology

In this congenital abnormality one or more parts of the external biliary tract are either absent or exist as fibrous cords. The extent of such obliteration determines the operability of the case. It will be operable if the atresia exists in the lower portion of the hepatic duct or in the common duct, or if the gall-bladder and cystic duct communicate with the hepatic duct which is distended with bile.

The gall-bladder may be found in one of four pathological conditions: (1) it may be absent or atretic; (2) it may contain a small lumen which does not communicate with the ductal system; (3) it may be distended with white bile-mucocele; and (4) it may be normal or enlarged and contain normal bile, indicating that the blockage is in the common duct. The liver is enlarged, stained dark green, and diffusely nodular, portraying the picture of portal cirrhosis of the obstructive type. The edge of the spleen is usually palpable and portal hypertension is a common feature. Ascites may or may not be evident. Petechiae, extravasation of blood in the subcutaneous tissues, and cerebral haemorrhage have been observed in some of these cases.

Diagnosis

The clinical picture is similar in most cases. The outstanding sign is jaundice, which is present at birth or appears two or three weeks later. This is at first mild, the skin being merely tinted pale yellow, but gradually increases until at the end of a month or so it is intense and gives place to a greenish-yellow hue.

The congested cirrhotic liver at the same time gradually enlarges and feels unduly hard on palpation, its edge being rounded and firm. The notched margin of the spleen is frequently detected. The stools are white, putty-like in consistency, and acholic, while the urine is bile-laden and dark brown. It should be noted that the stools are always white from birth even though jaundice may not be noticed until the second or third week of life.

The icteric index varies in different infants and from day to day in the same patient, ranging mostly between 50 and 200; the blood picture shows a secondary anaemia; the red cells are not unduly fragile; there is no microspherocytosis; the clotting time is seldom elevated; the prothrombin time may be lowered; and the liver-function tests support a diagnosis of obstructive jaundice.

The condition may be confused with icterus neonatorum, erythroblastosis foetalis, jaundice of haemolytic sepsis, congenital syphilis, or congenital haemolytic anaemia. Every attempt should be made to arrive at a diagnosis within the first four or five weeks of life and not to delay exploratory laparotomy beyond the second month, as the majority of patients will die of liver failure within five months if the blockage is not relieved. It is a surprising fact, however, that a few patients possessing no extrahepatic ducts have lived to be 8 to 10 months old. The diagnosis can be arrived at by a process of elimination with a fair degree of certainty by the end of the first month of life, and sometimes earlier than this. In other words, the diagnosis is made by excluding other causes of jaundice and by proving that the infant under investigation is suffering from obstructive jaundice.

To-day, about 20 to 25% of these babies present conditions of the extrahepatic ducts which are correctable only by operative measures.

Operative Treatment

Pre-operative measures include the correction of dehydration, one or two small transfusions of blood, and the administration of vitamin K. Penicillin is given intramuscularly before and after operation.

The anaesthetic of choice is open ether. Satisfactory relaxation of the abdominal muscles cannot be obtained with local analgesia. The use of muscle relaxants is definitely contraindicated. There is a choice of two incisions: right

vertical epigastric muscle-split incision or Kocher's incision. Considerable difficulty may be experienced in determining the type of malformation present. The liver is enlarged and defies mobilization, the gall-bladder and the ducts (when present) are small, the anomalies show wide variations, and the operative field is highly vascular.

If the gall-bladder is present and the common bile duct cannot be seen, a wise manoeuvre consists in inserting a hypodermic needle into the fundus of the viscus and distending the gall-bladder with saline solution. When the cystic duct is patent and the common duct is present the fluid will distend the choledochus and bring it into view. In some cases of obstructive jaundice the lower end of the common bile duct is plugged with mucus or inspissated bile, and this method may be sufficient to produce displacement of the mucus-laden biliary sand and cause it to pass into the duodenum, thus relieving the obstruction.

Some surgeons practise operative cholangiography with the object of illuminating the existing ductal system. I have no special experience of this method of investigation for the type of case under discussion. Where, however, there is a definite stenosis of the common bile duct, although cholecystogastrostomy has often been practised for the relief of this condition, Ladd and Gross (1941) have no doubt that choledochoduodenostomy, when feasible, is a far superior operation in spite of its greater technical difficulty. According to Gross (1953), choledochoduodenostomy or hepaticoduodenostomy is the operation of choice when the lower end of the common duct is atretic or when only a nubbin of the hepatic duct is available for anastomosis to the intestine. I believe, however, that the mobile proximal loop of jejunum is more suitable for end-to-side union to the bile duct or gall-bladder than is the thick-walled pyloric segment of the stomach or the tethered duodenum.

Choice of Operation

The choice will in many cases depend upon the site and extent of the obliterative process and also upon the condition of the gall-bladder itself (see Table).

Conditions and Appropriate Operations

Condition Found at Operation	Operation of Choice
A Gall-bladder present; cystic duct communicates with main ducts; stricture lower end of common bile duct	(1) Cholecystojejunostomy plus entero-anastomosis (2) Choledochoduodenostomy (3) Cholecystoduodenostomy (4) Cholecystogastrostomy
B Gall-bladder functionless or absent; stricture lower end of common bile duct	(1) Choledochoduodenostomy (2) Choledochojejunostomy plus entero-anastomosis
C Extensive stricture of common duct, but hepatic duct patent and contains bile	(1) Hepaticojejunostomy plus entero-anastomosis (2) Hepaticoduodenostomy
D No extrahepatic ducts	(1) Longmire's operation

When choledochoduodenostomy is a feasible procedure the bulbous lower end of the common duct should be freed and divided, and a small short rubber tube or a piece of No. 8 catheter about 1.5 cm. long should be inserted upward toward the hepatic duct. An opening is made in the antero-superior wall of the first part of the duodenum, opposite the end of the duct, and the small segment of catheter is led through the hole into the lumen of the bowel. With the tube in place, a single row of closely and carefully applied interrupted mattress sutures of fine silk or "dek-natel," mounted on eyeless needles, is inserted so as to anchor the wall of the duct to the duodenum.

Hepaticoduodenostomy or hepaticojejunostomy is likewise performed with one row of interrupted mattress sutures, but after the latter operation an entero-anastomosis between the afferent and efferent limbs of the jejunum is carried out to divert the gastric and duodenal contents away from the vulnerable biliary tree.

When the gall-bladder obviously contains bile, as demonstrated by aspiration into a Record syringe, the organ may be anastomosed to the stomach, the duodenum, or to a loop of proximal jejunum with every hope of success. The operative technique of cholecystojejunostomy combined with jejunojejunostomy is described in the following report.

Case Report

The patient was a full-term male child born on October 8, 1951. He was normal at birth and weighed 7 lb. (3.2 kg.). Delivery was uneventful. The infant was breast-fed. Jaundice was noticed during the second week of life, the urine was dark brown, and the stools were white. No drugs had been administered. The parents and two other children were alive and well. There was no family history of jaundice, syphilis, or congenital deformity. The patient was admitted, under my care, to the Southend General Hospital.

On admission the infant was 1 month old and his weight 7 lb. 11 oz. (3.5 kg.). He was ill and apathetic, with jaundice of the skin and conjunctivae. No petechial haemorrhages or rashes could be seen, nor was there any evidence of sepsis of the skin or umbilicus. On inspection the abdomen was slightly protuberant and there were no distended veins. There was a moderate degree of hepatomegaly, as the rounded edge of the liver could be felt three fingerbreadths below the right costal margin. The spleen could not be palpated. A nystagmus was present, with no other abnormal neurological signs. The urine was a deep brown colour and contained bile salts and pigments. No urobilinogen was present. The stools were white and obviously contained no bile pigments. The value for haemoglobin was 5.6 g. per 100 ml. of blood (or 36%); the red cell count was 2,300,000; the colour index was 0.8; and leucocytes numbered 13,000 per c.mm. Red blood cells were of normal fragility, and 20 nucleated red cells were seen while counting 100 white cells.

The Wassermann and Kahn reactions were negative. The van den Bergh test gave a direct positive reaction and the serum bilirubin was 10.3 mg. per 100 ml. Blood grouping showed that parents and baby belonged to Group A and Rh positive.

A diagnosis of congenital atresia of the bile ducts was made. The infant's general condition was improved by two intravenous infusions of 120 ml. of blood, which raised the haemoglobin to 80%, and by the intramuscular administration of vitamins B and K.

Four days after admission to hospital the child's condition deteriorated, opisthotonos developed, and the nystagmus increased. The condition was diagnosed as an intracranial haemorrhage, and lumbar and ventricular punctures were performed. No cerebrospinal fluid was obtained on lumbar puncture and the ventricular fluid contained blood. The ventricular tap was repeated two days later and the fluid was blood-stained and xanthochromic. Six days later the circumference of the head had increased and bulging of the anterior fontanelle was present. The subdural spaces in each side were explored and 4 ml. of dark-brown blood was removed from the right side. As no further haemorrhages occurred, operation was carried out, under ether anaesthesia, on November 29, 1951.

Operation.—The abdomen was explored through a vertical right epigastric muscle-split incision which extended from the costal margin to 1 inch (2.5 cm.) below the umbilicus. Exposure revealed an enlarged cirrhotic dark-green liver. The spleen was larger and firmer than normal and a small amount of yellowish ascitic fluid was removed by aspiration. The tiny gall-bladder was tensely distended and the common bile duct ended in a bulbous nubbin above the duodenum. A hypodermic needle was inserted into the fundus of the gall-bladder and yellow bile was aspirated into a Record syringe, after which saline solution was forcibly injected to distend the minute ducts. The common bile duct ended abruptly about 2 or 3 mm. below the point

of entrance of the cystic duct. The fundus of the gall-bladder was mobilized; a long loop of the proximal jejunum was drawn upward in front of the transverse colon; and the apex of the loop was anastomosed to the full length of the gall-bladder by the side-to-side method, using two rows of interrupted sutures of the finest silk, mounted on eyeless needles. Portions of the jejunum proximal and distal to the stoma were anchored to the capsule of the liver to relieve any tension on the suture line. The operation was completed by performing a side-to-side jejunojejunostomy well below the previous anastomosis, with the object of diverting gastric and intestinal contents from the biliary tree. The individual layers of the abdominal incision were approximated with interrupted sutures of silk, and a small dressing was strapped over the wound.

Post-operative Progress.—Bile was noticed in the vomitus the night after the operation and in the stools three days later. During the next week the jaundice began to fade and the urine became lighter in colour. The liver was not palpable three weeks after operation. The wound healed soundly, jaundice entirely disappeared, no further haemorrhages occurred, the appetite rapidly improved, and the infant made an uninterrupted recovery. He was discharged from hospital six weeks after operation, weighing 9 lb. 2 oz. (4.1 kg.). The patient has been examined periodically during the last three years. When last seen he looked the picture of health and was developing normally.

Conclusions and Summary

A newborn child who has jaundice should be subjected to an exploratory operation shortly after a diagnosis of *obstructive* jaundice is made.

A search then must be made for any evidence of extrahepatic biliary passages which might be used to establish a free flow of bile into the intestinal tract.

Fully 20% of cases of atresia of the bile ducts can be cured by the performance of choledochenterostomy or cholecystoenterostomy.

The techniques of these operations are briefly discussed.

A case of congenital atresia of the common bile duct, which was successfully treated by cholecystojejunostomy combined with entero-anastomosis, is described.

Ambulance, a professional journal for ambulance and industrial first-aid personnel, has had its first issue. A development of the quarterly review published by the Institute of Certified Ambulance Personnel for their members. *Ambulance* is expected, while continuing to be the official organ of the Institute, to interest readers outside it. It will be on sale to the public (price 1s.) and be produced four times a year. Its aim is to encourage free expression of ideas, even if these do not represent the official views of the Institute, and its columns are open to any reader for discussion on any topic which concerns ambulance men and women. The theme of the first issue is industrial safety. An editorial suggests that "the first-aid arrangements made by industrial firms under the Factory Acts are capable of improvement if they are to safeguard workers under present-day conditions." Another article discusses the prospect of an industrial medical service being set up.

ATTEMPTED SUICIDE WITH METHYLPENTYNOL AND PERSOMNIA

BY

R. E. LOVELACE, M.B., B.S.

Lieutenant, R.A.M.C.

AND

A. I. ROITH, L.R.C.P.I., D.C.H.

Lieutenant, R.A.M.C.; Junior Specialist in Psychiatry
(From the Psychiatric Department, Royal Victoria Hospital, Netley)

Methylpentynol ("oblivon") is an unsaturated tertiary carbinol described by Margolin *et al.* in 1951. "Persomnia" is a synergistic combination of the open-chain ureides, carbromal and bromvaletone. Both these drugs have sedative and hypnotic powers, and, as well as being prescribed widely, are freely obtainable without prescription. The following case is described because there are still relatively few reports of overdosage with methylpentynol, and because this is the first reported case of attempted suicide with this combination of drugs.

Case Report

A soldier aged 38, weight 140 lb. (63.5 kg.), attempted suicide on February 6, 1955, by swallowing 25 capsules of oblivon (6.25 g. of methylpentynol) and about 75 tablets of persomnia (225 gr. (15 g.) of carbromal and 75 gr. (5 g.) of bromvaletone). These drugs were purchased from chemists' shops without prescription. The man was suffering from a severe reactive depression of two weeks' duration.

At 11.30 p.m. he began his attempt by taking oblivon, and continued with persomnia until he fell asleep. At 7.30 a.m. the following morning he was discovered unconscious on his bed, and tablets were found on the floor and in the bed. He was unresponsive to any stimuli. When seen by a medical officer at 8 a.m. he was in coma, and was at once transferred to hospital.

On admission at 9 a.m. he was found to be still comatose, but his colour, breathing, and pulse volume were satisfactory. Gastric lavage with sodium bicarbonate solution was performed and 20 mg. of amphetamine sulphate was left in the stomach. General supportive therapy was begun and he was started on intramuscular amphetamine. By 1.30 p.m. his coma had lightened, and by the following morning he was fully conscious. He was unable to recall anything from the time he took the drugs until he awoke in hospital on February 8. He was quite rational and was able to give a coherent account of himself. His only complaint was of headache. There was slight pyrexia, which was accounted for by bronchitis due to secondary respiratory infection. On February 11 he complained of pain in the left popliteal fossa, and this was found to be due to early thrombophlebitis.

The next day he was transferred to the psychiatric division of the Royal Victoria Hospital. The thrombophlebitis and residual bronchitis cleared up with penicillin. There was no apathy or ataxia, and he was left with only some depression relevant to his problems. During the next month he improved with sedation and psychotherapy.

Comment

Bourne (1954) and Lemere (1952) have reported cases of overdosage by methylpentynol, with recovery, in patients who had ingested respectively 6.25 g. and 8.75 g. The largest recorded overdose followed by recovery was 10 g. (Brown and Ellis, 1955). The only reported fatality appears to have followed a dose of 4.5 to 6 g. (Cares *et al.*, 1953).

Only one case of death from persomnia has been recorded (Coroner's Court, Bedford, 1952). This occurred in a woman

who swallowed over 200 tablets—800 gr. (52 g.). Hobart (1951) states that detoxication of the open-chain ureide sedatives is fairly rapid, and that 60–600 gr. (4–40 g.) have been taken in suicidal cases without harm.

Synergism between methylpentynol and barbiturates resulted in death in a man who took 9 oblivon capsules and 20 pentobarbitone sodium ("nembutal") tablets (*British Medical Journal*, 1955). Although it appears from our case that methylpentynol and persomnia do not potentiate each other, the possibility of an additive effect might be considered.

Finally, we would agree with Glatt (1955), who said with reference to methylpentynol, "It is regrettable that members of the public should still be able to purchase large quantities of this drug so easily without a prescription, in spite of the advice of the Pharmaceutical Society; it should be supplied only on a prescription." On the other hand there are no indications for placing special restrictions on the sale of persomnia, but note should be taken of a recent report in the English literature of a purpuric eruption caused by carbromal (Borrie, 1955).

Summary

A soldier aged 38 attempted suicide by swallowing 25 capsules of oblivon and 75 tablets of persomnia. He was suffering from reactive depression. He recovered on routine treatment. This is the first reported case of attempted suicide with this combination of drugs.

Medical Memoranda

Recurrent Abortion Associated with a Bicornuate Uterus

A successful outcome to a pregnancy in one horn of a bicornuate uterus is by no means a rarity, but the problem of how best to advise a patient with such a developmental abnormality of the uterus after four successive abortions may be difficult to solve. This is illustrated by the following case.

CASE REPORT

When first seen by me at Farnborough Hospital in 1949 the patient was a healthy woman aged 28. Her general medical and family history contained no features of relevance. Menstruation had begun at 15, and periods of six days' duration were occurring regularly at 26-day intervals. Her first four pregnancies all terminated in abortion, and the details may be summarized as follows.

The first pregnancy, in 1943, ended in abortion at two months and was followed by evacuation of the uterus under general anaesthesia. A diagnosis of "subseptate uterus" was made, but a hysterogram some six months later was reported as "indefinite," as the dye was not retained.

The second pregnancy, in 1946, terminated in abortion at 10 weeks. The patient was receiving weekly injections thought to have been of progesterone, and it was on the day after the third of these that the abortion occurred.

The third pregnancy, in 1949, lasted nearly 14 weeks, and it was at this time that the patient first came under my care. When the second period was due there had been three small painless vaginal blood losses on consecutive days. She allowed a week to elapse before reporting to the clinic, and a pregnanediol estimation at the time revealed no evidence of progesterone deficiency. When the third period would have been due vaginal loss recommenced. She was admitted to hospital, and, in spite of complete bed rest, abortion occurred two weeks later. Evacuation of the uterus followed, and on examination under anaesthesia an indentation could be clearly felt in the position of the fundus. A finger passed through the open cervical canal identified a projection into the uterine cavity, the retained products of conception being found in the left horn.

The fourth pregnancy occurred in 1951, and the patient was seen after she had had seven weeks' amenorrhoea. She stated that one week previously a small red blood loss per vaginam had been noted, and this had been followed by a slight pinkish discharge every morning. Some days later, at the time when the second period was due, a further small fresh blood loss occurred, but with complete rest in bed and 2 gr. (0.13 g.) of phenobarbitone daily for seven days this symptom was not repeated. The time when the next period would have occurred was estimated and complete bed rest was again the regime adopted. Nothing untoward occurred. Progress appeared to be satisfactory until the 22nd week of pregnancy, when backache and a watery vaginal loss were followed by complete abortion. A male foetus was passed which was normal on inspection. Macroscopically the placenta showed no abnormality.

Eight months later a hysterosogram was undertaken. One and a quarter hours after $\frac{1}{2}$ gr. (22 mg.) of "omnupon" had been administered hypodermically, an intrauterine injection of "viskiosol six" was given. The x-ray picture obtained is reproduced. The patient was naturally anxious about the outcome of any future pregnancies, and I advised that a further attempt might be made.

Three months later she began her fifth pregnancy. As had been previously arranged, she was admitted to hospital for complete rest in bed at the times when her periods would normally have been due. Progress was uneventful until the 26th week, when she was readmitted to hospital complaining of backache and watery discharge. These symptoms, however, were not apparent after admission, and three days later she returned home.

At 36 weeks the foetal position was left sacro-anterior. Maturity and the presentation of breech with extended legs were confirmed radiologically. No attempt at external cephalic version was made, and elective caesarean section was decided upon. The operation was performed three weeks later. Foetus and placenta were found to be occupying the left horn of the uterus and were delivered through a longitudinal incision in this horn, breech extraction of a female infant being achieved with no difficulty. The right horn of the uterus was hypertrophied and about the size of a 10-weeks pregnancy. A thick muscular projection extended from the indent in the fundus down to the level

Radiograph showing uterus bicornis unicollis.

of the internal os. The child appeared normal in all respects and weighed 5 lb. 12 oz. (2.6 kg.). Maternal and infant progress was uneventful.

COMMENT

In an attempt to assess what the chances of a successful conclusion to a fifth pregnancy would be I was influenced by the writings of Malpas (1938) and Eastman (1950). These authors estimated mathematically the "spontaneous cure rate"—that is, the chances of successful pregnancy—following any given number of successive abortions. Their calculations included both those abortions resulting from accidental or fortuitous factors and also those in which a recurrent cause was present. The figure arrived at by Malpas for the chance of successful pregnancy following four consecutive abortions was 6% and that of Eastman under 2%.

In the case here reported there was a most definite causative factor for the abortion, failure of approximation of the Müllerian ducts having led to the condition of uterus bicornis unicollis. The mathematical chances of a fifth pregnancy succeeding seemed very slight indeed. The decision to advise the patient to make a fifth attempt was taken because of the fact that the duration of each pregnancy had increased, abortion occurring at 8, 10, 14, and then 22 weeks. This suggested that each successive hypertrophy of the pregnant horn of the uterus made it more capable of containing the next pregnancy, and it was hoped that if this sequence were maintained a viable foetus might result. In this decision I was influenced, too, by the keenness of the patient herself to try again. Another alternative was to perform an abdominal metraplasty, but it was decided to await the outcome of this further attempt.

It is an established fact that when pregnancy occurs in one horn of a uterus the other undergoes hypertrophy and a decidual reaction occurs. Occasionally the non-pregnant horn continues to menstruate, and this bleeding at the time of a period from a pregnant bicornuate uterus is not necessarily indicative of threatening abortion. However, in this case the losses were followed by abortion on too many occasions for this symptom to be ignored, and thus rest over the time when the periods were due was regarded as important.

I am indebted to Mr. R. C. Thomas for permission to report this case, and to Mr. D. Lindsay and Mr. K. G. Seager for their helpful advice.

Purpura following Manipulation of the Spine

The patient, a milk tester aged 42, is well known to me, as he has suffered for years from a contact eczema of the forearms. I have therefore had frequent occasion to inspect his skin, and before the episode described below he had not shown any purpuric manifestation.

On June 3, 1954, he was driving a motor-cycle combination with his head turned sideways to view a field of wheat, when he hit a small obstruction in the road. The jar was not excessive. Two hundred yards further on he tried to dismount, but found that he was unable to do so because of pain in his back. With considerable difficulty he got home and retired to bed. I saw him the next day and found him almost completely immobilized, with the now common syndrome, "the acute back."

On June 5 I asked an orthopaedic surgeon to see him on a domiciliary visit and he diagnosed, "joint lesions at L 3-4 joint on the left side, and the L 4-5 joint on the right side." These he mobilized by forward pressure on the left side of the third and on the right side of the fourth lumbar vertebra, with suitable positioning to lock the neighbouring joints. There was some relief of pain from this manoeuvre.

On June 6 I was called to see him as a rash had appeared on both lower legs. The rash was a florid petechial one, extending from his toes up over his thighs. There was a large effusion into the right knee-joint and bilateral effusion into both ankles.

He was admitted to the skin ward of the Gloucester General Hospital for observation, where the rash and joint symptoms subsided over the next ten days.

Since that date I have seen another patient who was manipulated by an osteopath for a cervical lesion, and who exhibited two patches of purpura on the shoulder in the skin area supplied by nerves arising from the vertebral apertures manipulated. Blood, fragility, and clotting tests in this patient were all normal and his rash faded within two days.

The orthopaedic surgeon who manipulated the first patient told me that he had seen transitory eruptions following manipulation, but nothing of the magnitude of the case described. I make no suggestion about the mechanism of this phenomenon, but think it worth reporting as yet another cause of purpuric eruptions.

I thank Mr. J. Bourdillon for his orthopaedic care of this case, and Dr. R. E. Bowers for his advice and for admitting this case to his dermatological beds for observation.

Clinical Assistant, Skin Department,
Gloucester Royal and Cheltenham General Hospitals

The Adrenal X-Zone in Kwashiorkor

Although information is available concerning the morphological changes in the human adrenal before and after birth, nothing is known of the function of the foetal X-zone of the cortex, which is most concerned in these changes. Anencephaly is the only condition definitely known to be associated with changes in the development and disappearance of this zone. Consequently the report by Gillman and Gillman (1951) that this zone persists in African infants dying of kwashiorkor is of great interest, since it would suggest a new approach to the physiology of this zone. As a first step in this direction it was necessary to confirm, if possible, the original observation.

The adrenals from seven cases of kwashiorkor in African children between the ages of 1 and 4 years were examined by methods used previously (Stoner, Whiteley, and Emery, 1953). They were compared with the adrenals from 19 other African children dying from a variety of causes, and with the adrenals from a larger series of English children (Stoner *et al.*, 1953). The behaviour of the foetal X-zone appeared to be the same in all three groups. No evidence of its persistence in the cases of kwashiorkor was found, and, so far as could be ascertained from these small groups, the rate of involution of the foetal X-zone after birth in the African adrenals was the same as in the English series and equally unaffected by systemic disease.

We have been prompted to report this negative observation since, with modern methods of treatment, fatal cases of kwashiorkor are becoming infrequent, and the original claim of Gillman and Gillman has now been reiterated in two reviews (Lanman, 1953; Baar, 1954).

Reviews

PSYCHO-ANALYTICAL TECHNIQUE

The Technique of Psycho-analysis. By Edward Glover, M.D. (Pp. 404+x. 35s.) London: Baillière, Tindall and Cox. 1955.

Neither Freud nor any of the early pioneers in psycho-analysis ventured to write a full exposition of its technique. Perhaps they were acting on Bernard Shaw's cruel epigram, "He who can does; he who cannot teaches"; but more probably they were daunted by the endless ramifications of an enormously complex subject. The second generation of psycho-analysts were less restrained, and after the First World War several books appeared on technique. One recalls a very poor one in 1920 by Paul Bousfield, a fairly good one in 1922 by David Forsyth, and an excellent one in the same year by de Saussure. Then followed a series of six lectures by Edward Glover in 1928, which were published as a supplement to the *International Journal of Psycho-Analysis*. Since that time Dr. Glover has severed his connexion with other psycho-analysts. This has doubtless given him more independence, but has its own peculiar disadvantages.

The present book is made up of three parts. The first, longest, and most essential one consists of a greatly expanded version of the lectures just mentioned. The second is a record of a lengthy questionnaire Dr. Glover carried out in 1936-8 among British psycho-analysts. The main conclusion emerging from it is the extraordinary difficulty of formulating questions with sufficient precision to elicit comparable replies of value from different analysts. The third part is a reprint of three thoughtful essays that were published in the *International Journal* in 1931, 1937, and 1954 respectively.

The book is written in an easy, fluent, and vivid style, and is packed with the author's characteristic shrewd wisdom. Although ostensibly addressed to students, it can be read with profit by every practising psycho-analyst. So many detailed issues are raised in it that it would need a long technical essay to evaluate them properly, and this no doubt will happen elsewhere. In the meantime it can be hailed as a contribution of value to a difficult topic, and recommended to those who are directly concerned with it. It is well produced and has an excellent index.

EPSOM COLLEGE

Epsom College Register, 1855-1954. Edited by T. R. Thomson. (Pp. 620; illustrated. 31s. 6d.) Oxford: University Press for Old Epsomian Club. 1955.

Timed very accurately to anticipate the visit of Her Majesty, whose demonstration of her interest in the centenary of the College has gratified the whole of our profession, this *Epsom College Register*, as a labour of love on the part of Dr. T. R. Thomson and of the Old Epsomian Club, reflects the greatest credit on all concerned in its production, including the Oxford University Press. The introductory chapters, which are in fact a brief history of the school in its first hundred years of existence, should prove intriguing to the medical profession at large as well as to the considerable Epsomian section of it, and also to those of the general public who are education-minded. That the College has deserved well of the profession, so many of whose sons it has educated, especially by its provision of free places for those boys (and girls) left in straitened circumstances by early parental death and other causes, is a truism which there is no need to labour here. That it urgently needs financial help to carry out an essential programme of improved buildings and other amenities is equally true. The Council has for some months striven unceasingly to convince the medical profession of this, with a degree of success not as yet by any means commensurate

with its truth. The production of this admirable volume may help to persuade those who chance to read it that the enterprise and vision of the Council really do deserve generous support. Of the *Register* itself it can be reported that it is well worthy to take rank among the best of the similar products emanating in recent years from public schools of similar standing. It is a splendid monument to the patriotism and piety of the Old Epsomian Club.

HENRY ROBINSON.

MODERN TRENDS IN OPHTHALMOLOGY

Modern Trends in Ophthalmology. Third series. Edited by Arnold Sorsby. (Pp. 346+xiv; illustrated. 65s.) London: Butterworth and Co., Ltd. 1955.

The purpose of a book such as this is to enable its reader to keep in touch not only with recently consolidated gains in knowledge but also with current trends in thought and experiments in technique through which the advances of the future may accrue. This volume, the third of its series, follows the general lines of its predecessors. Its 28 chapters divided into six sections cover such a diversity of subject-matter as to make a general appraisal difficult; the value attached to each section will vary with the interests, experience, and familiarity with the literature of each individual reader, but each section is not without interest, and the general balance is good. Those surgically inclined will welcome the chapters on corneal and retinal operations and on surgical technicalities, and another giving a clear exposition of the management of vertical squint. In the diagnostic and clinical fields are excellent and well-illustrated articles on, among other subjects, slit-lamp fundus microscopy, binocular ophthalmoscopy, and tonography; while particular recognition may be accorded to chapters on the nature of malformations and on the criteria of genetic affections, and to the section on social ophthalmology dealing with the problems of the blind and visually handicapped. Current views in relation to ocular pharmacology, collagen diseases, allergy, virus diseases, and the fitting of contact lenses are among other subjects discussed.

Some of the sections are so short and of such little apparent value or interest as to make the reviewer wish that they had been omitted to allow of the "selected bibliographies" having been made less selective; for example, in one chapter in which 36 or so authors are quoted in the text, only 12 references are appended. It is also perhaps unfortunate that in certain directions, particularly in an article on retrolental fibroplasia, and even allowing for the inevitable time-lag between writing and publication, the book's titular claim to modernity can hardly be upheld. Nevertheless this volume, excellently produced and well illustrated and indexed, will go a long way in helping to keep the ophthalmologist abreast of the times and in touch with the modern trends of his specialty.

A. J. B. GOLDSMITH.

RECENT ADVANCES IN TREATMENT

Modern Treatment Yearbook, 1955. Edited by Sir Cecil Wakeley, Bt., K.B.E., C.B., LL.D., M.Ch., D.Sc., F.R.C.S., F.R.S.E., F.R.S.A., F.A.C.S., F.R.A.C.S. With 36 contributors. (Pp. 344+viii; illustrated. 25s.) London: For Medical Press by Baillière, Tindall and Cox, Ltd. 1955.

The Modern Treatment Yearbook, which comes of age in this twenty-first publication, is designed to keep the practitioner informed on the practical application of the latest research in medicine, using the latter term in its widest sense. Though the emphasis is on therapeutics, the yearbook includes more than a bare description of recent advances in treatment, for it recognizes that it is impossible to describe treatment adequately without defining the condition to be treated, which often involves some discussion on aetiology and diagnosis. It thus provides what is essentially an annual refresher course in medicine given by 36 physicians and surgeons, mostly chosen from those working in London or its environs. A great diversity of subjects is covered

in these 36 well-chosen articles, including, for example, the new insulins, Bornholm disease, blood-vessel grafting, temporal arteritis, growing pains, and prolonged labour. Though the book is a small one comprising only 344 pages, and though it is packed full of concise information, it is nevertheless eminently readable, even by an exhausted practitioner at the end of a long day. Instead of the tabulated instruction so popular in many current American therapeutic works of reference, each contribution in this book consists of a well-written short essay summarizing in excellent English, in simple terms, and with much wisdom the present state of our knowledge on a large number of subjects of current interest in which advances have recently been made.

This is a very good book indeed, and it was a most encouraging and unusual experience for the reviewer to find that there was nothing in it he could not understand.

D. M. DUNLOP.

GALEN

Galen of Pergamon. By George Sarton. (Pp. 112; illustrated. \$2.50.) Lawrence, Kansas: University of Kansas Press. 1954.

English literature of the history of medicine is poor in reliable works on Galen and has very few translations of his writings. This is a serious deficiency. Hippocrates is at best a shadowy figure who may well have written nothing, and every member of the so-called "Hippocratic" collection is of disputable date and authorship. Most of them come from a world lit by a misty half-light of scholarship. But Galen is a real and very human figure, one of a world and circle familiar to philosophical historians. To them Galen's use of the experimental method is as well known as Harvey's, perhaps better. Moreover, it was the translation into Latin of Galen's works, and specially of his anatomical works, that set medicine on its modern scientific path, signposted by observation and experiment. Hitherto the only full account of Galen in English was in a scattered series of pleasantly readable papers by the late Dr. Joseph Walsh which are, unfortunately, not easily accessible. Thus Dr. Sarton in this handy little volume opens to English readers what is almost a new chapter in the study of ancient medicine.

Galen, as Dr. Sarton tells us, was a Greek of Asia Minor who studied at many centres in the East Mediterranean—then under complete Roman control. He spent several years at Alexandria. His writings are the chief source of our knowledge of the great medical school there. His most active and creative years were spent at Rome, where he was physician to Marcus Aurelius (Emperor, 161–180) and tutor to his son Commodus (Emperor, 180–192). He must have been very familiar with the Latin tongue, but his writings are all in Greek, the scientific lingua franca of his time. Of all this Sarton gives a concise and excellent account, wisely treating lightly the differences between the over-written ancient "medical sects," the tedious and unclear exposition of which has repelled many readers of medical history. Sarton's booklet provides also good summaries of Galen's various activities, as anatomist and physiologist, as clinician, and as philosopher, with sections on his character, style, bibliography, and translation. Altogether a useful and well-timed little book.

CHARLES SINGER.

GYNAECOLOGY

Gynecology: Diseases and Minor Surgery. Compiled and edited by Robert J. Lowrie, M.A., M.D., F.A.C.S. Foreword by Claude E. Heaton, M.D. (Pp. 852+xix; 775 illustrations, 19 in colour. £8 2s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1953.

This work on gynaecology, the first of two volumes, is described as representing the culmination of many years of effort of 79 contributors from 30 medical schools and other institutions in the United States, Canada, and Great Britain.

The book, which is generously illustrated, covers the subject of gynaecology with considerable thoroughness, even including matters which seem more appropriate to undergraduate teaching. To remind graduate readers that

the cervix is also called the "neck of the womb" seems unnecessary, as are two illustrations showing how a digital examination of the pelvic organs is carried out. Also, a number of opinions are expressed which will not be accepted in this country. For example, in the chapter on infertility there is the statement that "donor insemination is a needed and rewarding medical service"; even in America this statement is probably no longer acceptable now that an American judge in Chicago has ruled that, "except where donor and recipient are married to each other, artificial insemination is illegal and constitutes adultery on the part of the mother . . . and the children fathered by anyone but the mother's husband are illegitimate" (*British Medical Journal*, 1954, 2, 1555). On a lighter level, it must be pointed out that the use of gin, 1–2 oz., for dysmenorrhoea is not "so highly regarded by the English School." There are some surprises, too: for example, a section describing in considerable detail the "Kenny" treatment in acute poliomyelitis. The claim is made in the foreword that due consideration has been given "to the role of the psyche" in gynaecological disorders, yet there is no separate chapter about this extremely important subject.

This book contains much wisdom: nevertheless its form and cost will not commend themselves to many in this country.

C. S. RUSSELL.

CRANIAL HYPEROSTOSIS

Hyperostosis Cranii. By Sherwood Moore, M.D. (Pp. 226+x; illustrated. 75s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1955.

The syndrome of obesity, facial hirsuties, and frontal hyperostosis described by Morgagni and re-described by at least three other writers has been known to physicians for nearly two centuries. Dr. Moore has collected practically all the available information on this condition, to which he has added studies of his own.

He subdivides the syndrome into five types and elaborates the whole affair into something which, in the reviewer's opinion, is more complex than the facts justify. It is also suggested that frontal hyperostosis causes headache, fatigue, muscular weakness, nervousness, depression, diplopia, epileptiform seizures, impairment of memory, and other alarming symptoms. These features may have occurred in patients with frontal hyperostosis, but the evidence that they are caused by it is exceedingly uncertain. As regards the aetiology, the author's own words are: "The theory is advanced that hyperostosis and its syndrome are the manifestation of an endogenous intoxication traceable to aberrance in some unknown phase of the function of reproduction." It will be news to most doctors that cranial hyperostosis has social, economic, and palaeopathological aspects.

Although Dr. Moore's book does not throw any new light on Morgagni's syndrome, it must remain a valuable source book for those wishing to explore the subject; the bibliography runs to 315 titles.

A. M. COOKE.

Doctor to the Islands, by Tom and Lydia Davis, is an account of a young doctor, born and brought up on the Cook Islands, who returns from New Zealand to his old home as medical officer. Tom Davis is a self-confident and critical young man. He credits his predecessors with little knowledge and the administration of the Islands with a lack of interest in local welfare which is hard to believe. None the less the problems facing a doctor on the Cook Islands and on others in Polynesia, and the various methods adopted to try to solve them, make interesting reading, as do "Dr. Tom's" excursions into politics on behalf of the islanders. Medicine is not the only topic in the book, however, for Tom Davis took back to Rarotonga with him a New Zealand girl he had married and she has included her account of social life and conditions there. As husband and wife have written alternate chapters in the book the result is rather disjointed. For those who like sailing yarns the last few chapters give a lively story of a Pacific crossing in a small yacht at the worst time of the year. *Doctor to the Islands*, which is published by Michael Joseph, costs 15s.

BRITISH MEDICAL JOURNAL

SATURDAY MAY 21 1955

DEFENCE AGAINST ATOM BOMBS

On August 6, 1945, soon after 8 a.m., an American Superfortress bomber released an atomic bomb over the centre of the Japanese city of Hiroshima. More than 4 square miles (10 square km.) of the city were destroyed. The city centre was dominated by a number of reinforced concrete buildings owned by banks, department stores, and other commercial enterprises, while outside the centre lay a densely packed zone of small wooden workshops and lightly constructed dwellings. The destruction was due partly to blast and partly to fire, which took firm hold of the city about an hour after the attack and burned unchecked for days.¹ The population of Hiroshima was something under 300,000—or about the size of Coventry, though more straggling.² The population was considerably swollen at the time of the bombing by war workers and military establishments. It is believed that an alert had been sounded before the bomb was dropped but had been "relaxed." The number killed will never be precisely known; it is often estimated at 70,000–80,000, with about an equivalent number of injured. However, the Hiroshima city authorities placed the final toll of immediate and delayed deaths as 210,000 to 240,000.³ The civil defence services, if they attempted to function at all, were overwhelmed by a disaster the scale of which was completely unforeseen. A photograph in a book published in 1953 by a committee of the National Research Council of Japan conveys more forcibly than any words the plight of the survivors. It shows⁴ a group of more or less seriously injured people the day after the disaster, lying in the open, without shelter or shade, without food or water, without hope or comfort. Yet five miles distant was relatively undamaged terrain from beyond which might have come mobile medical and rescue teams and supplies—had they existed to meet a disaster on this scale.

Doubtless the efficiency of atomic weapons has been greatly increased since 1945, and estimates of the destructive power of the hydrogen bomb in particular are too well known to need recapitulation. However, it is at least uncertain if the most powerful weapons would be used in any new war. Smaller, though locally more highly destructive, atomic weapons have recently been developed, such as guided missiles, and projectiles that can be fired from an 11-in. (30-mm.) gun.⁵ While it may be true that a small number of hydrogen bombs released over selected areas in Britain might paralyse defence and rescue work, this is unlikely unless an attack with smaller weapons were to be successfully developed. The lessons of Hiroshima and Nagasaki are therefore still relevant to our own civil defence, and they point to the need for an efficient civil defence service. Neglect to provide one cannot be excused on the ground that it might be rendered useless by a hydrogen bomb attack.

An important investigation on atomic bomb injuries in relation to the type of protection has recently been reported by two American workers,⁶ who analysed the case histories of 5,136 persons injured at Hiroshima and interviewed 1,207 uninjured persons who had been exposed to the bombs. All these survivors reported that they had been within a radius of 13,120 ft. (2½ miles, or 4 km.) from the ground-centre of the explosion. Excluded from the analysis were a small number of uninjured persons within this distance, who were in tunnels or in air-raid shelters. Of the injured, more than half had mechanical injuries—lacerations and contusions—but remarkably enough no fractures were encountered. A. A. Liebow, S. Warren, and E. de Coursey⁷ had earlier reported that, among the survivors of Hiroshima seen two months after the bombing, only 4.5% had fractures. They attributed this low figure to the fact that only those who were able to move escaped the flames. Some time elapsed—perhaps one hour—between the explosion and the spread of the fires. Burns afflicted 45% of the injured. All except three of these were due to flash and not to fire; most were confined to the extremities and were of second or third degree. Radiation effects were suffered by 34%; they were usually moderate, as might be expected in a group of patients who had survived several weeks to months after exposure. The absence of blast injuries was another unexpected finding. Those near enough to be thus injured must have been killed in this or some other way.

Unexpected, too, and with an important bearing on our own problems of civil defence, were the results of the analyses in relation to the class of protection.

⁴ — *ibid.*, 1953, p. 22, Tokyo.

⁵ Hunter, C. G., and Wedd, G. D., *Med. ill. (Lond.)*, 1954, 8, 754.

⁶ Reynolds, M. L., and Lynch, F. Y., *Publ. Hlth Rep. (Wash.)*, 1955, 70, 26.

⁷ Liebow, A. A., et al., *Amer. J. Path.*, 1949, 25, 853.

Of those people who were indoors or in heavy buildings at the time of the explosion 80-88% suffered mechanical injuries, as against 28% of those in the open. Moreover, the most severe mechanical injuries were in the people who were indoors or shielded out of doors. Doubtless the percentage of people remaining alive to tell of their experience was greater indoors than out, but those who were preserved indoors suffered injury from flying glass and debris, falling walls, and the like. The investigation clearly shows that severe mechanical injuries in each distance zone increased with increasing protection, and were incurred in one-half to two-thirds of the injured persons who were indoors in buildings of either light or heavy construction.

What are the lessons to be learnt from this survey? Clearly an investigation of the effects on survivors of an atomic explosion cannot give a true picture of the effects on the whole exposed population. Nevertheless, such an investigation can yield information of the utmost value for the planning of civil defence and rescue. Thus, if the interpretation of the low incidence of fractures in survivors is correct, probably a great many lives could be saved if people immobilized by injuries were removed to safety before the widespread fires get under way—about one hour after the explosions at Hiroshima and Nagasaki. In a western city, with a much lower proportion and density of timber construction, this interval might well be increased. The analysis of the injuries in relation to the type of protection affords, perhaps, the most unexpected finding; it seems clear that satisfactory protection can be given only by a structure built or adapted for this purpose, in which the risk of flying glass, plaster, or other debris is reduced to a minimum. Finally, there is the lesson of the flash burns, which injured about 45% of the survivors. Of all the atomic bomb hazards, that from heat flash is most easily avoided. Indeed, the thinnest layer of light-coloured fabric is sufficient to protect against it. Moreover, the moment that elapses between the light flash and the heat flash may be sufficient to enable those caught in the open to protect themselves from the latter. Evidently instruction in civil defence should be directed to the general public as well as to defence service personnel.

BANNING OF HEROIN

The quantity of heroin (diacetylmorphine) that the Home Office has authorized to be manufactured in the U.K. this year is 150 kg. Some of this may be exported, though none has yet been. In 1954 the amount manufactured was 198 kg., and of this the authorized quantity exported was 27 kg. The amount

medically prescribed was perhaps something like 100 kg., since some might have been put into stock and some used for the manufacture of nalorphine. The number of doses to which this weight is equivalent would seem to be at least several million in a year. The drug is therefore commonly prescribed in Britain; and, since its universally known dangers of causing addiction would allow its prescription only after particularly careful thought, those doctors who claim that for some cases it has no satisfactory substitute would find many of their colleagues in agreement with them. Moreover, they cannot be accused of taking unnecessary risks with such a drug, for the number of addicts in this country is trifling. About forty are known to the authorities, and the strict control over supplies of the drug makes it most improbable that the true total can be much greater. The decision to ban its use altogether may therefore have been taken a little hastily, especially since a possible alternative exists which could be tried—namely, a ban on the export of the drug.

Repeating the Government's decision to prohibit the manufacture and export of heroin after December 31 next "except for small quantities for purely scientific purposes," Lord Mancroft¹ said that the ban was made in order to give effect to a resolution adopted by the Economic and Social Council of the United Nations, that the advice of the appropriate statutory bodies was taken, and that adequate supplies of a perfectly good substitute were available. In taking this step the British Government is falling into line with the great majority of the United Nations members—many of which have never had trouble with addiction to heroin—including Canada, Australia, New Zealand, and the U.S.A., and indeed only France, Belgium, and Italy have not yet agreed to a ban on manufacture or import. Those countries where the drug is prohibited are apparently satisfied with the consequences of this, several of them after some years' experience. Nor did opinion in Britain seem to be much different until fairly recently, and the monograph on heroin was omitted from the *British Pharmacopoeia* in 1953. The *National Formulary* contains no preparation of heroin; the introductory notes in the present edition² state that "its use could with advantage be reduced and reserved for parenteral administration." When the view was advanced in these columns two years ago³ that in order to help to free the world from its thousands of heroin addicts the advantages of prohibiting its manufacture in

¹ House of Lords Hansard, Vol. 192, No. 48, Col. 595 (April 27).

² *National Formulary*, 1955, British Medical Association and Pharmaceutical Society of Great Britain.

³ *British Medical Journal*, 1953, 2, 196.

⁴ *Ibid.*, 1953, 2, 338.

⁵ Fifth Report of Expert Committee on Drugs Liable to Produce Addiction, *Wld Hlth Org. techn. Rep. Ser.*, No. 95, 1955.

Britain outweighed the disadvantages, Dr. A. H. Douthwaite's disagreement with that opinion⁴ was left unsupported. But since then opinion has hardened, no doubt in part because clinical experience with the newer synthetic analgesics has increasingly shown that they do not meet the needs of some cases, and that heroin alone can do so. Incidentally, addiction to pethidine, according to the World Health Organization, is now reaching alarming proportions.⁵ The B.M.A. considered the matter last year in response to a request from the World Medical Association, and the Council agreed that the medical profession should not be deprived of the use of this drug. As Dr. R. Hale-White points out elsewhere (p. 1277), this is a sufficient refutation of the opinion expressed in the House of Lords by Lords Mancroft and Haden-Guest that the whole medical profession is behind this Order. Further opposition to it is evident in motions sent in by B.M.A. Divisions (published in the *Supplement* this week at p. 242) for debate at the Annual Representative Meeting in June. Opinion seems on the contrary to favour the continued prescribing of the drug. All this, combined with the fact that the drug is widely prescribed with relatively little ill effect, suggests that alternative means should be sought for preventing the abuse of heroin. Surely the Government might well try authorizing production for home use only and place a ban on exports.

DENTAL CARIES

In 1947 a group of research workers from the United States and Canada met at the University of Michigan⁶ to discuss the mechanism of dental caries. Last year the World Health Organization sponsored a seminar during which the aetiology of dental caries was discussed. From 1945 to 1951 the Royal Swedish Medical Board⁷⁻⁹ carried out far-reaching experiments into the cause of dental caries. All agree that the prime factor in the cause of dental caries is the concentration of acid in the mouth and the length of time it is present on the tooth surface. Acids are produced by the fermentation of carbohydrate foods. Most of the food is swallowed; much that remains on the tooth surfaces is quickly washed away by saliva, and some of the acid produced by fermentation is efficiently neutralized. But small areas on the tooth surface are sheltered from the forces of mastication and the stream of saliva, and food stagnates there. When fermentable particles of food lodge in these areas several times a day and, owing to their sticky nature, remain there for some time, these particular sites on the tooth surface become carious. The total

quantity of fermentable carbohydrates consumed is therefore subsidiary to the frequency with which they are taken, their time relationship with other foods, and their physical consistence.

Experiments and observations show that dental caries is increased by impaired salivary flow, by a lowered buffer capacity of the saliva, or by an increase in the frequency of taking sticky fermentable carbohydrate foods into the mouth; it is decreased by the avoidance of such foods, reducing the frequency with which they are eaten, alteration of the consistence of the food so that it does not stick to the teeth, or by introducing specific enzyme inhibitors into the mouth. Although tooth structure has some influence on whether caries occurs or not, the decisive factors are usually conditions on the tooth surface.

The findings of the Medical Research Council's recently published report¹⁰ on "The Effect of Sugar Supplements on Dental Caries in Children" cause no surprise. Extra sugar was given with their meals to test groups of children in three areas in England, but the control groups were not without considerable amounts of sugar and other fermentable carbohydrates, for both groups took their full sweet, sugar, and jam ration in two areas and breakfast cereal and bread *ad lib.* in all three. Both test and control groups, therefore, had sugar and wheat flour products, and both showed much the same amount of dental caries. Such alteration in percentage of sugar in a meal has been shown in animal experiments^{11 12} to have little effect on dental caries, and in the Swedish experiments sugar was shown to have the least effect when taken with other foods. The number of children taking part in the M.R.C. experiments was small, and the authors state on page 30 of the report, referring to the largest of the three studies: "The small number exposed to risk prevents any definite conclusions being drawn. . . ." It is surprising to find, however, that the extensive Swedish experiments have not been mentioned.

NEW TESTS OF HEARING

The eight years which have followed the publication in 1947 of the report on hearing-aids and audiometers¹ by the Electro-Acoustics Committee of the Medical Research Council have witnessed notable advances in the functional investigation of hearing. For example, the methods of speech audiometry prescribed by the committee have enabled otologists to measure accurately not only the essential handicap of the deaf subject—namely, his inability to understand the spoken voice—but also the extent to which this handicap can be corrected by means of hearing-aids and otherwise. In addition to these improvements in the measurement of hearing loss, the qualitative analysis of it has also been the subject of important developments. Thus in 1948 M. R. Dix, C. S. Hallpike, and J. D. Hood,² of the Medical Research Council's Otological Research Unit, demonstrated for

¹² Wakeman, E. J., et al., *ibid.*, 1948, 27, 489.

the first time that the phenomenon of loudness recruitment, first described by Fowler, of New York, and considered by him to be a general characteristic of "nerve" deafness due to lesions of any of the cochlear nervous elements, was in fact pathognomonic of lesions of the hair cells of Corti's organ. By contrast, in cases of deafness due to lesions of the cochlear nerve fibres, loudness recruitment was characteristically absent or incomplete. As a result of this work, now widely confirmed, tests for loudness recruitment have become valuable in making the important clinical distinction between end-organ deafness and nerve-fibre deafness.

Results of comparable clinical value have also accrued from the work of J. D. Hood³ on cochlear fatigue and adaptation. Hood carried out a number of exact studies of the deafening effect on the normal human ear of prolonged exposure to pure tones, and he was able to show that this deafness underwent an abrupt increase when the stimulus intensity exceeded a certain critical level. Hood was also the first to give a clear account of the phenomenon of cochlear adaptation, a particularly elusive variety of deafness which occurs during and immediately after the application of a sustained sound stimulus. Its rapid disappearance on removal of the stimulus makes the phenomenon exceedingly difficult to investigate, and its demonstration was possible only by means of an ingenious test carried out during the application of the stimulus.

The clinical importance of cochlear adaptation and of the methods since developed for its measurement lies in the fact that it undergoes a striking increase in cases of deafness due to disease of the neural elements of the cochlear apparatus, in particular the hair cells of Corti's organ. Thus it comes about that in cases of deafness of obscure origin clinical investigation of cochlear adaptation provides valuable evidence of whether or not the cochlear end-organs are affected.

As might be expected, these delicate methods of investigation of the functional state of the cochlear end-organs are beginning to prove of exceptional value in the investigation of the early stages of its derangement by disease or injury, and a notable example has recently been provided by the work of L. Rüedi⁴ and others,⁵ of Zurich. These workers have used them for investigating the effect of vitamin A in protecting the cochlear end-organs from injury by prolonged pure-tone stimulation. In Rüedi's experiments a group of normal subjects were exposed to prolonged pure-tone stimuli of high intensity, and the critical intensity level was determined. Repetition of the tests after a period of high vitamin-A intake revealed a marked increase in the critical level, indicating an increase in the resistance to injury of Corti's organ. Functional changes of this kind could not be revealed by any of the usual tests of cochlear function, such, for instance, as pure-tone audiometry carried out according to the usual technique. The successful use by Rüedi and his colleagues of these new methods of investigation of cochlear function, therefore, gives grounds for the hope that otologists elsewhere will find in them an equally valuable instrument for the investigation of the early stages of cochlear disease or injury.

HEALTH SERVICES IN NORTHERN IRELAND

The report¹ of a committee set up by the Government of Northern Ireland "to advise on criticisms and suggestions made by members of both Houses of the Northern Ireland Parliament about the operation of the health services" is summarized in this week's *Supplement*. Two out of three members of the committee, the chairman of which was Mr. H. G. Tanner, have been closely associated with the development of hospital and health services in Great Britain. Such criticisms of the health service as have been voiced in the Northern Ireland Parliament seem mainly to have been directed to the system itself—not to any laxity or maladministration which may have occurred, but to the possibility of such occurrence should the good sense and restraint which have hitherto characterized the service be diminished. The main complaint is that parliamentary control over health services is ineffective, and that too much power is in the hands of nominated bodies or corporations which cannot readily be called to parliamentary or governmental account.

In Northern Ireland there has been a devolution of responsibility which does not obtain in Great Britain. The Ministry of Health and Local Government is not empowered itself to provide health services, but only to promote or secure their provision and co-ordination, which it does mainly through a Hospitals Authority and a General Health Services Board. The Ministry has thus a less positive role in administration than the Ministry of Health in England, and parliamentary critics have complained of the Hospitals Authority in particular as autocratic in dealing with hospital management committees and hospital staffs, and as stultifying local initiative. The Tanner Committee scarcely subscribes to these criticisms. It finds that the Hospitals Authority has shown itself energetic, that it has many achievements to its credit, and that there is no foundation for any charge of irresponsibility or extravagance. Nevertheless, it agrees that its relationship with the Ministry is anomalous, and that the position both of the Authority and the General Health Services Board in regard to the Ministry should be that of agent to principal. The system which has been found successful in Great Britain should be adopted in Northern Ireland.

A large number of detailed recommendations are made by the committee, but so far as general medical services are concerned their effect would be to alter the position very slightly. One recommendation concerning consultants is that their contracts should be reviewed at regular intervals; another is that distinction awards should no longer be made by the Authority but preferably by a single committee having jurisdiction over the whole of the United Kingdom, to which Northern Ireland advisers should be attached. But in general the report presents a picture of the health services of Northern Ireland—where there has been greater freedom to incur capital expenditure than in England and Wales and Scotland—as in a state of vigorous and continuous growth.

INBORN DEFECTS OF THE RENAL TUBULE

Fanconi attributed the syndrome popularly associated with his name to a genetically determined defect of the renal tubule. It is only recently, however, that attempts have been made to relate this syndrome to a number of hitherto distinct metabolic lesions, whose underlying cause appears to be a failure in function of the proximal tubule.¹⁻⁴ This part of the kidneys is concerned in the reabsorption of water, glucose, amino-acids, phosphate, bicarbonate, calcium, and possibly potassium, so that a wide variety of single or multiple biochemical abnormalities may be predicted as likely to follow disordered function here. The best-known single defect is renal glycosuria, but renal diabetes insipidus also occurs occasionally, and is characterized by extreme polyuria which is insensitive to posterior pituitary extract. Amino-aciduria occurs in hepato-lenticular degeneration (Wilson's disease) and in congenital cystinuria. It has been suggested that cirrhosis of the liver in the former results from the drain of amino-acids, though it is possible that both the hepatic and the renal lesions are secondary to the accumulation of copper. Faulty reabsorption of phosphates leads to vitamin-D-resistant rickets, while hyperchloraemic acidosis (Albright's syndrome) may be the result of a failure to reabsorb bicarbonate, with a compensatory increase in chloride reabsorption. Idiopathic hypercalcaemia has also been reported, though hypopotassemia has not been recognized as a single defect. Theoretically any combination of defects might be expected, but so far only a few are well defined. Glycosuric rickets appears to be a specific entity, though in many cases amino-aciduria has not been looked for. Glycosuria has been noted in some patients with Wilson's disease. The triple resorptive defect of glucose, phosphate, and amino-acids occurs in the classical Fanconi syndrome, and it is interesting that in some of these patients also the metabolism of water, bicarbonate, and potassium may be disordered; cirrhosis of the liver is a well-recognized complication. Cystinosis, in which cystine is deposited in the tissues, is usually considered to be a variant of the Fanconi syndrome, and may be accompanied by glycosuria and hypophosphataemia.

Although these diseases were originally found in children, a number of cases have been reported in adults^{5,6}; many of these were originally termed Milkman's syndrome because of the pseudo-fractures and osteomalacia. They are presumably milder forms of the inherited defect, though it is conceivable that acquired lesions or some other inborn error of metabolism may be responsible. It is important to realize that these conditions do not give rise to renal failure in the accepted clinical sense except occasionally as a

terminal complication, and death usually results from dehydration, acidosis, or intercurrent infection. The limited necropsy material from cases of the Fanconi syndrome has invariably shown degenerative changes in the proximal convoluted tubule. The absence of phosphatase from this part of the kidney led to the view that deficient phosphorylation is responsible for the faulty reabsorption.^{7,8} However, E. M. Darmady has recently shown, by painstaking micro-dissection of individual nephrons from two cases, that the proximal tubules are abnormally short and are joined to the glomerulus by a thin "swan-like" neck.⁷ Further work on other examples of the group, using both histochemical and histological techniques, will be awaited with much interest. There is no doubt that the new classification will help to clarify many defects which are at present obscure. Prognosis has already been improved by the introduction of measures designed to counteract the metabolic disturbances. Massive doses of vitamin D, alkalinizing regimes, and the replacement of water and potassium are all important, and there is some experimental evidence that methyltestosterone may have a beneficial effect on renal tubular function.⁹

NEW LOOK IN PHYSICAL MEDICINE

Taunts of therapeutic empiricism and false pathological conceptions based on therapy have in the past often been directed at the specialty of physical medicine. Some degree of empiricism is probably inevitable in a specialty which has grown up slowly over the course of centuries, so that many of its methods are surrounded by an aura of traditional sanctity, and Dr. W. S. Tegner,¹ in his Samuel Hyde Memorial Lecture, scrutinizes ruthlessly the scientific basis of most of the treatments which are still being used in orthodox departments of physical medicine. He refutes absolutely the conception of a specialist in physical medicine being concerned only with therapy: in point of fact he must be a skilful diagnostician in view of the wide range of disorders from which his patients may be suffering. In addition, he is in the best position to undertake the long-term planning and management of chronic disorders of the locomotor system, such as rheumatoid arthritis. Tegner admits the strong suggestive influence of many physical treatments, and proceeds systematically to destroy some popularly held misconceptions on massage, electrical currents, ionization therapies, ultra-violet light, and various forms of heat treatment. He favourably reviews the recent experiments which have put short-wave therapy on a sound scientific basis and, conversely, have failed to show that microwave therapy and ultrasonics have advantages compensating for their expense and danger. He criticizes the use of such meaningless jargon as "tonic effects" and "removal of waste products and metabolites," and also the multiple names by which a single mode of treatment may be known—for

example, constant current, direct current, or galvanism, all of which mean the same thing. Finally, he commends the newly developed electrodiagnostic techniques as examples of the recent scientific trends in physical medicine and as excellent research weapons.

At the annual meeting of the British Association of Physical Medicine last year Drs. A. C. Boyle, A. T. Richardson, and R. Doll contributed to a symposium on "The Scientific Approach."² They discussed in more general terms the imperative necessity of applying a statistical scrutiny to all new forms of therapy before they are accepted, and of reviewing as soon as possible all the classical methods still in use. In each case three questions had to be answered: "Is this treatment of value?" "Of how great a value?" "And with what type of patient?" None of these speakers eschewed the use of "placebo" remedies, provided that the physician was perfectly clear about the nature of his prescription and chose an inexpensive and harmless method of achieving the desired result. Another point made by all the contributors to this discussion was the importance of understanding the natural history of the disease being treated, and of realizing the potentiality it had for spontaneous remissions. Doll, speaking from the statistician's point of view, once again emphasized the dangers of "general impressions" in therapeutics, and the pitfalls in using theoretical considerations in developing a new approach rather than the essential test of "Does it work?" Specialists in physical medicine have often been challenged to subject their techniques to scientific validation, and it is a healthy sign that they should now be critically examining the methods by which the specialty can achieve its objects of restoring the patient to health and of making a useful contribution to medical research.

GENETICS OF CONGENITAL HEART DISEASE

Large-scale studies of the families of children with congenital heart disease have been published only in the last few years. Before then selected individual families had been reported. For example, G. C. Walker and L. B. Ellis¹ recorded the case of a father and four of his eight children all with signs of patent ductus arteriosus, and M. Campbell² recorded signs of auricular septal defect in three generations. In neither of these families was there full post-mortem or operative confirmation of the nature of the lesion. In addition, genetic factors are known to play a part in the causation of certain syndromes with which congenital heart disease may be associated. For example, situs inversus, partial or complete, is in some cases at least due to recessive genes,^{3,4} and cardiac malformations in addition to dextrocardia are commonly present in this condition. Congenital heart lesions are also often found in association with arachnodactyly, which is usually due to a dominant gene.

In 1953 T. McKeown and his colleagues⁵ gave an account of the family histories of 437 children with congenital heart disease who had been born in Birmingham between 1940 and 1949. They found a small but definite increase in the incidence of congenital heart disease among the brothers and sisters of these index cases. Their estimate of the general incidence at birth

was 3.2 per thousand, but among the 352 sibs born after their index cases six were affected, five of whom were also index cases in the series. It was noteworthy that in the two fraternities with two affected children in whom the precise lesion was known the pair of affected sibs had the same lesion, in one pair transposition of the great vessels, in the other a ventricular septal defect. Non-cardiac malformations did not occur with undue frequency in sibs. In only two instances were the parents first cousins, and in both the malformation was dextrocardia with transposition of the viscera. This year P. E. Polanyi and M. Campbell⁶ have reported on the families of 386 children attending Guy's Hospital. Their findings are similar. Of 635 sibs whose condition was known, 9 had congenital heart disease, and 6 of the 265 born after the index case were affected. Here, too, there was a tendency for the affected sibs within a fraternity to have the same or similar lesions. While Polanyi and Campbell thought that the incidence they found of non-cardiac malformations among the sibs (2%) was unduly high, it is doubtful if this is really so. In only three instances were the parents first cousins, and in one of these the child was one of the few patients with transposition of viscera.

Specific types of congenital heart disease are evidently apt to be concentrated in certain fraternities, but the risk of subsequent children having congenital heart disease is not high and of the order of 1 in 50. If simple genetic factors are at work they must have a low penetrance, and this is supported by the finding that usually only one of a pair of monozygous twins is affected.

It is desirable for genetic analysis to break down congenital heart disease into specific types. This will become possible as more operations are performed on cases of congenital heart disease, making exact diagnosis possible. R. C. Anderson,⁷ of Minneapolis, Minnesota, has made just such a study of 105 families in which the index case was proved at operation to have patent ductus arteriosus without other cardiac defects (four other children were excluded because of a known maternal history in pregnancy of rubella). Of 145 sibs born after the index case, two had patent ductus arteriosus and one of these also had coarctation. Since the general incidence of patent ductus arteriosus is almost certainly less than 1 in 5,000, Anderson's data show a familial concentration. None of the sibs in this series had any type of cardiac or non-cardiac malformation. All of the four probably monozygous twins of index cases were unaffected.

There is no convincing evidence that maternal age or birth order or season of birth affects the incidence of congenital heart disease. Sex, however, plays a part; coarctation of the aorta occurs mostly in males and patent ductus arteriosus mostly in females. Polanyi and Campbell⁶ show that aortic stenosis, Fallot's tetralogy, and transposition of the great vessels also occur predominantly in males.

EMERGENCIES IN GENERAL PRACTICE

TREATMENT OF SEVERE ASTHMA

BY

A. MARGARET C. MACPHERSON, M.D., F.R.C.P.

Physician, Elizabeth Garrett Anderson Hospital for Women

The development of the first really severe attack of asthma is an alarming event for the patient, for the patient's friends, and, at times, for the doctor. Usually there has been some previous evidence of an asthmatic tendency which may have amounted to little more than discomfort. Then an attack of tightness in the chest lasts longer than usual, increases in severity, and the patient's efforts become concentrated simply in trying to breathe out the air which overfills his lungs. Any attempts his relatives or friends make to help are of little avail and their distress at standing by and watching his gasping respirations only too often adds to the patient's alarm. It is in this atmosphere that the doctor finds himself. Successful treatment depends to a great extent on the tacit assumption that the attack can and will be treated successfully. It is rare for an asthmatic attack to be fatal, unless it occurs in elderly patients, or is complicated by other conditions, such as spontaneous pneumothorax, or unless wrongly treated by respiratory sedatives.

Much depends on the way in which the situation is handled. The doctor must be prepared to give up time to the patient's treatment, and time spent in initial treatment is time saved in the long run. The patient will usually have found the position which gives greatest relief, either sitting forward in bed or sitting up in a chair.

Antispasmodic Treatment

Treatment of the bronchospasm should be begun at once. It is rare that adrenaline is unsuccessful, provided it is given correctly, and it is important to give it with care when first used. Once the patient appreciates its use he will look forward with confidence to its benefits during subsequent attacks; if it is used inadequately it may need much persuasion and perseverance on the next occasion to overcome his prejudice against it.

A dose of 5 minims (0.3 ml.) of adrenaline, 1 in 1,000, is given hypodermically. If this dose does not give relief after 10 minutes, adrenaline should be injected at the rate of 1 minim (0.06 ml.) a minute, keeping the needle *in situ*, until the spasm is relieved. In this way large doses of adrenaline can be given without ill effects.

In those cases in which adrenaline is ineffective, aminophylline can be given. It is best administered by intravenous injection, the contents of one ampoule containing 0.25 g. in 10 ml. of water being injected slowly. This can be repeated after four hours, and if necessary the dose can be doubled provided the total of 20 ml. is given slowly. Intravenous treatment may usefully be supplemented by giving the aminophylline in a rectal suppository. This is a convenient way of maintaining some antispasmodic action over a prolonged period and is particularly useful for administration at night.

Antihistamine drugs are usually of little help in relieving severe asthmatic attacks.

Sedatives

During the acute stage sedative treatment is usually inadvisable. As the attack passes off, small doses of sedative can be given to calm the patient and to help ward off another attack. Phenobarbitone in $\frac{1}{2}$ -gr. (32-mg.) doses is usually effective. Opium derivatives and large doses of barbiturates

are contraindicated. The patient's life may depend on his respiratory efforts, and depression of the respiratory centre, particularly by the use of morphine, may prove fatal.

Oxygen

If there is marked cyanosis, oxygen will often help the patient. It should be given with a B.L.B. mask or "polymask." The administration of oxygen, however, may distress the patient more than benefit him, as the application of anything over the mouth or nose may increase the sense of suffocation, and the very suggestion of oxygen may be associated in the patient's mind with the terminal stages of severe illness.

A.C.T.H. and Cortisone

A.C.T.H. and cortisone are on occasions of definite use in treating asthma, but, with our present knowledge, they should be used with caution. A.C.T.H. and cortisone are given in doses of 100 g. in divided doses six-hourly during the first 24 hours and continued, with reduced dosage if possible, for three or four days; cortisone can be given by mouth. There is no doubt that in many instances this treatment will give definite relief. If, however, the treatment has to be repeated, its results, using the same dose, may be disappointing and an increased amount will be required to produce the same effect. Large doses and more continued treatment are not without danger to the patient. At the present time it is probably advisable to withhold these remedies, giving them only when there is urgent need. They are usually called for in treating elderly patients with emphysema who are in great distress and in danger of developing cardiac failure, and also in cases in which the acute attack is prolonged and is developing into status asthmaticus.

Status Asthmaticus

If the attack becomes prolonged, with no remissions, and extends over a period of several days and nights, the condition then is indeed a difficult one to treat. It is advisable whenever possible to remove the patient from home surroundings, preferably into a hospital. The atmosphere of a hospital ward, with efficient nursing and the knowledge that there is always medical help at hand if required, will do much to quieten the patient. Continuous treatment with aminophylline can be carried out if required by slow intravenous drip, using 0.5-1.5 g. of aminophylline in a litre. At this stage the patient is often suffering from some degree of dehydration, since the continued breathlessness has made drinking and eating difficult or almost impossible. By giving aminophylline intravenously, the necessary fluid can be supplied, and it may be useful to use 5% glucose-saline as the vehicle for the drug. The patient should also be encouraged to take sips of water by mouth. When cyanosis is marked, an oxygen tent may be necessary. Cortisone or A.C.T.H. may be required and should be given if other treatments have been tried and failed, or, as already indicated, should be given to patients with severe emphysema or cardiac failure.

Treatment after the Attack

As soon as the attack has been controlled, it becomes necessary to take steps to prevent another attack developing. A small dose of sedative such as phenobarbitone, $\frac{1}{2}$ gr. (32 mg.) two or three times during the day will often quieten the patient. The first evidence of recurrence of wheezing or tightness in the chest should be treated immediately. An

injection of adrenaline, 3 to 5 minims (0.2 to 0.3 ml.) should be given at once. The earlier this is done, the more likely it is to ward off a fresh attack. If it is not possible for the doctor to give the injection immediately, it is often advisable for suitable patients to be taught how to give the injection to themselves. When this is not feasible, ephedrine, $\frac{1}{2}$ gr. (32 mg.), or isoprenaline, 20 mg., can be taken in tablet form, isoprenaline tablets being dissolved slowly under the tongue. Atomizers may be used to give adrenaline or isoprenaline by inhalation. Many of the proprietary preparations for the treatment of asthma contain one or other of these drugs together with phenobarbitone. Aminophylline suppositories given in the early part of the night may help to prevent an attack in the early hours of the morning. Some patients find antihistamine preparations beneficial, if taken as soon as the first symptoms of spasm are noticed. Expectorant mixtures containing potassium iodide and ammonium carbonate relieve those patients who have difficulty in coughing up sputum after an attack and are of particular use for patients who have chronic bronchitis complicated by asthma.

It is now recognized that one of the most successful treatments in controlling the incidence of attacks and in controlling an attack in its early stage is breathing exercises. If the patient conscientiously practises those exercises which encourage proper diaphragmatic breathing and full expiration, he will be able to reduce the number of attacks and also can often abort an attack. The breathing exercises can be combined with postural exercises when there is evidence of localized chronic infection in the bronchial tree.

Prevention of Pulmonary Infection

Care should be taken to detect pneumonic lesions during the period after an asthmatic attack, particularly in those patients who suffer from chronic bronchitis. During an asthmatic attack, bronchi or bronchioles may become plugged with thick mucous secretion, with resultant segments of collapsed lung beyond. Usually re-expansion takes place, but at times the collapsed portion of the lung becomes infected and prompt treatment with antibiotics is indicated if this complication is suspected.

Next article on Emergencies in General Practice.—"Post-partum Maternal Collapse," by Miss Josephine Barnes.

Refresher Course Book.—Copies of the second volume of collected articles from the Refresher Course for General Practitioners published in the *Journal* are still available at 25s. (postage 1s.) each. The volume contains 60 articles, all of which were revised by their authors for publication in the book. The first volume is now sold out and out of print. Copies of the second volume may be obtained from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller.

PRACTICAL ADVICE ON HEARING-AIDS

In a lecture at the Institute of Laryngology and Otology, London University, on April 29 Mr. J. CHALMERS BALLANTYNE, assistant director of the audiology unit of the Royal National Throat, Nose, and Ear Hospital, discussed the indications for advising a hearing-aid, the choice of a suitable instrument, and the way to get the best results from it.

The ability of a deaf person to hear with an aid, said Mr. Ballantyne, was determined very largely by the type, as well as the degree, of his deafness, and it was essential to have a clear understanding of the differences between the two broad types of deafness—perceptive (or "nerve") deafness and conductive (or "middle-ear") deafness. The hearing apparatus had two parts, a perceiving apparatus and a conducting apparatus. The perceiving apparatus consisted

of the end-organ of hearing itself—that is, the organ of Corti—and the acoustic nerve and its central connexions. The conducting apparatus consisted of the external auditory canal, the middle ear, and the Eustachian tube. It also included the fluids of the inner ear. Its function was to conduct sound-waves from their source to the end-organ, amplifying them to some extent as it did so. Perceptive deafness resulted from any lesion in the perceiving apparatus, while conductive deafness was due to lesions in the conducting apparatus. The two types of deafness could nearly always be distinguished from one another by a careful history, a thorough clinical examination, and a single tuning-fork.

Indications for the Use of Hearing-aids

There were very few deaf people who could not derive some benefit from using an aid, continued Mr. Ballantyne, and it was much better to start using one too early than too late. When deafness was purely conductive in nature, as in early cases of otosclerosis and in suppurative disease of the middle ear, the perceiving apparatus was normal. In theory, all that was required to allow such a patient to hear normally was to amplify sounds to such a degree that they would reach the normal perceiving apparatus at a normal degree of loudness. In practice also, the necessary amplification could usually be provided by an electrical hearing-aid.

When deafness was purely perceptive, as in the deafness following meningitis or the deafness of old age, the problem was much more complex. Amplified sounds reached the abnormal perceiving apparatus with the same degree of loudness as in the normal ear, sometimes even louder. But they were distorted sounds, often uncomfortable and sometimes painful. And it was characteristic of perceptive deafness that, beyond a certain point, the ability to understand speech became reduced and not enhanced by further amplification. On the other hand, many patients suffering from perceptive deafness could derive real benefit from an electrical aid.

Construction of Electrical Aids

Since the second world war the design and construction of electrical hearing-aids had improved enormously. Aids consisted of three parts: a microphone, an amplifier, and a receiver. The microphone converted sound energy into electrical impulses; the amplifier amplified the sounds; and the receiver converted the electrical impulses back into sound energy.

The Amplifier.—Most electrical aids used a system of thermionic valves, the power required by this system being provided by two batteries. A low-tension battery warmed the filaments in the valves, and a high-tension battery provided the power for the amplification. Many commercial firms are now substituting the so-called "transistor" valve for the thermionic valve.

The Receiver.—There were three different types of receiver: the insert receiver, the flat receiver, and the bone-conduction receiver. The insert receiver fitted into the ear itself and was by far the most commonly prescribed. It should be made to measure for each individual user. It could be used even in the presence of active middle-ear discharge, provided that the ear was cleaned regularly by simple aural toilet and the insert kept free from discharge. An external otitis might result in a few cases, when the use of an insert must be discontinued, at least temporarily. The flat receiver was worn with a headband. It was large, uncomfortable, and now rarely prescribed. Leakage of sound was almost invariable, with consequent "howling." The bone-conductor receiver also caused considerable discomfort by the presence of a headband, but it might be indicated in some cases of aural discharge with external otitis. In a very limited number of cases of conductive deafness, not exceeding 2% of all hearing-aid users, it might give a very good performance. One commercial firm now produced a bone-conductor receiver carried on a spectacle frame.

Choice of an Aid

The choice, continued Mr. Ballantyne, lay between the Government aid and a commercial one. The "Medresco" aid (the name being derived from Medical Research Council) was a duo-pack aid—that is, the batteries were carried separately from the microphone and amplifier. Its designers intended to produce an efficient aid, at the lowest possible cost, and of value to the greatest possible number of deaf persons. In these objects they had largely succeeded. The size of the batteries was perhaps the greatest single disadvantage of the Government aid, for they were large and undoubtedly cumbersome. On the other hand, they lasted much longer than smaller batteries and were cheaper to produce. And much smaller batteries were available, at the patient's own expense, which could be used with the Government aid (*low tension*: Ever Ready B119, Siemens S119, Drydex D.H.519; *high tension*: Ever Ready D18, Siemens S18, Drydex D.L.14). Improvements to the Medresco aid were gradually being made, and a smaller model should be available before very long. The aid itself was issued free to any deaf person considered by an otologist to be likely to benefit from its use. It was obtainable at any hearing-aid distribution centre, where repairs were also available. Batteries could be replaced at any hospital.

Commercial aids were nearly all of the mono-pack type—that is, the batteries were included with the microphone and amplifier. They were lighter in weight, less conspicuous, and much more comfortable to wear. In some, but by no means in all, said Mr. Ballantyne, the performance also was better than that of the Medresco. Their great disadvantage was, of course, the cost, which varied roughly from £15 to £35 for thermionic-valve aids, and was approximately £20 more for "transistor" aids. Maintenance and repairs added considerably to the burden. The choice of a commercial aid should be made only after trying several under all the normal conditions of the patient's life. The aid should be tried not only at home but in the office, church, theatre, and the like.

The National Institute for the Deaf had an approved list of manufacturers and was always ready to offer advice on this matter. Test reports were also made on commercial aids by members of the Medical and Scientific Committee of the Institute.

It was claimed for the newer transistor aids that maintenance costs were considerably reduced, since only one battery was needed, with a working life of up to 200 hours. But their ability to withstand hard, constant wear remained to be proved.

It was often advisable to consult an agent who stocked a variety of makes before making a final decision.

The Wearing of an Aid

Many deaf persons were opposed to the idea of wearing an aid. It advertised their disability, so they thought. Little did many of them realize how much more obvious it was when they refused to wear one. In women the aid could easily be worn without any sign of its presence. The receiver could be hidden by an appropriate hair-style, and the lead likewise made invisible. In children the various parts of the aid could be distributed by means of a home-made harness, details of which were obtainable from the Deaf Children's Society. All children, the speaker continued, should be provided with the smaller mono-pack type of aid, but this ideal was not yet attainable.

A person with only a mild or moderate degree of deafness might need an aid only for hearing at a distance, as in a church or theatre. Many otosclerotics heard better in noisy surroundings than in quiet rooms—the phenomenon of "paracusis." In the noisy surroundings of certain occupations they therefore found an aid unnecessary and uncomfortable. Most other users, depending on professional or social necessity, should wear their aids all day.

When there was only a slight difference in the degree of deafness in the two ears the aid should be worn in the better ear. This meant less amplification and therefore less distortion, which in turn meant less battery consumption and less expense. The deaf person with an aid should sit as near as possible to the speaker. The further away he sat, the greater was the amplification needed and the more uncomfortable the background noise became. In a theatre, concert hall, or conference room the deaf person should sit as near as possible to the centre of the hall or table. With practice, an aid could be used quite satisfactorily with a telephone, and some commercial firms made a special adapter for this purpose.

Rehabilitation

It was impossible to over-emphasize the importance of careful instruction in the use of a hearing-aid. It was not enough to hand it "over the counter," so to speak, and expect the deafened person to hear immediately. Many an aid had been relegated to the bottom drawer within a month or so through failure to realize this.

Nor did the doctor's duty end there, for other "aids" to hearing might be needed to obtain full benefit, and every possible clue to the meaning of speech must be utilized. Auditory training taught the patient to distinguish, or discriminate, the many complex sounds of speech. And visual training, better known as lip-reading, enabled him to fill in the many visual clues to the pattern of speech.

Finally, said Mr. Ballantyne, many patients asked whether the continued use of a hearing-aid would cause deterioration in their hearing. Most patients who used aids suffered from a progressive deafness, but there was no evidence whatsoever that the use of an aid would, *per se*, affect the hearing adversely.

THE QUEEN AT EPSOM COLLEGE

The Queen and the Duke of Edinburgh visited Epsom College on Friday afternoon, May 13, and inspected the buildings and grounds. The visit took place almost exactly 100 years after Her Majesty's great-great-grandfather, the Prince Consort, opened the College on June 15, 1855. The skies were uncertain, but the picturesque red brick buildings of the College standing in 90 acres of Epsom Downs framed a very happy occasion. The Queen, who is the College patron, was welcomed on arrival by General Sir Robert Haining, Lord Lieutenant of the County of Surrey, who presented the High Sheriff (Colonel the Hon. Guy Cubitt) and the Mayor of Epsom (Councillor Langston), and the Mayor in turn made other local presentations. Then, with the Royal Standard flying above the school buildings, the Queen inspected a guard of honour formed of the combined cadet corps. Lord Webb-Johnson, President of Epsom College, presented Dr. Henry Robinson (treasurer), Mr. R. W. Raven (chairman of the College council), Air Marshal Sir Lawrence Pendred (president of the Old Epsomian Club), and Mr. H. W. F. Franklin (headmaster). Accompanied by the last-named, Her Majesty and the Duke of Edinburgh made a leisurely and informal tour of the school, visiting the boys' rooms, the chemistry, physics, and biology laboratories, watching the pupils at work at the benches—Epsom was one of the first public schools to install such laboratories in the early 'seventies—the natural history museum, the art school, the carpenters' shop, and the assembly hall, where members of the dramatic society were giving a performance of *Twelfth Night*, with a very spirited Malvolio. The royal party next visited the chapel, where a surpliced choir of some 40 boys sang an anthem. The sporting and athletic side of the College was also in evidence—on the cricket pitch, and in the fives court (near which the remains of an early Bronze Age man were discovered a few years ago), the gymnasium, and the rifle range. A pause was made at the sanatorium, a building of modern design, with 58 beds, operating theatre, and

x-ray apparatus; here the royal party were received by the medical officer and the resident matron. The whole tour lasted an hour and a half, after which tea was taken in the headmaster's house in the company of the ladies of the College and the prefects. Before leaving, the Queen and the Duke planted trees in commemoration of the College centenary.

Epsom's Links with Medicine

Epsom College was founded 100 years ago by John Probert, who was a member of council of the then

The Queen in the Biology Laboratory.

The Queen with the Headmaster of Epsom College, Mr. H. W. F. Franklin. (Photos by Bippa.)

Provincial Medical and Surgical Association, afterwards the British Medical Association, and one of the first presidents of the Metropolitan Counties Branch. It was originally known as the Royal Medical Benevolent College, though it was never intended that it should be exclusively for doctors' sons or for boys intending to be doctors. About one in three Epsomians enter the medical profession, and the centenary register shows this to have been roughly the proportion throughout its history. But the College has always had a special claim upon the charities of the medical profession. Out of its complement of 350 boarders and 150 day boys, 62 at present are Foundation scholars, all sons of members of the medical profession in necessitous circumstances, most of them orphans; those who need it have everything paid; others are helped according to their needs. Further, in addition to 25 leaving scholarships available for boys studying medicine, scholarships are awarded to Epsomians every year by nine London teaching hospitals. Like other public schools, Epsom College has found it difficult to modernize its buildings and equipment out of its ordinary financial resources, and a centenary appeal, of which readers of this journal have already been reminded, has been made for not less than £150,000 in order that the school may "embark with confidence on a second hundred years of vigorous life and useful service to the community." Such an appeal cannot need many words of commendation to members of the medical profession.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM

ANNUAL CONGRESS: LONDON, APRIL 28-30

This year's meeting of the Ophthalmological Society of the United Kingdom, held under the presidency of Mr. O. GAYER MORGAN at the Royal Society of Medicine, was most successful. From a wide variety of subjects discussed, four have been chosen for summary here. First, the clinical aspects of retinal vein thrombosis, the subject of Mr. Gayer Morgan's presidential address; secondly, the use of "diamox" (acetazolamide) in glaucoma; and, lastly, two examples of modern ophthalmic techniques—the intraocular injection of air, and the use of radioactive isotopes in tumour diagnosis.

Retinal Vein Thrombosis

The seriousness of thrombosis of the retinal veins, said Mr. GAYER MORGAN, lay in the fact that it produced permanent visual disability in such a large proportion of cases. In the eye the close proximity of the arterioles and veins in the optic nerve and at their crossings made it possible for sclerosis of retinal arterioles to involve the adjacent walls of the veins. While in the kidney, the heart, and the brain the main factor leading to thrombosis was slowing of the blood stream in the arteries, in the eye the veins were affected more as a result of involvement of the common adventitia than because of stagnation, in spite of there being often concomitant arterial disease.

Treatment in the past had resolved itself into a review of the general health and the use of vasodilators. But now, said the president, it seemed that anticoagulants had a useful part to play in the treatment. They might prevent extension of the clotting or promote recanalization. There was also the possibility of using them prophylactically in cases of threatened venous thrombosis. One of the essentials for the rational use of anticoagulants was the recognition of the prethrombotic state. Patients with two good eyes often delayed attending until complete thrombosis had occurred, but those who had lost the sight of one eye from a previous thrombotic episode came up immediately they noticed their symptoms and so treatment could be started in the prethrombotic period. The ultimate outlook varied. There

might be absorption of the blood and reappearance of normal vision and an apparently normal vein; or a narrow and sheathed venous vessel might persist with many new collaterals, but even in this latter case there was no loss of field, so the blood supply to the retina must be adequate.

Mr. Gayer Morgan then described four cases which he had himself observed carefully over a period of time. From these he concluded that if anticoagulants were to be really useful they should be administered when a retinal vein was found to be dilated, when extravasation of blood was minimal, and while visual acuity was still good.

Action of Diamox in Glaucoma

Mr. E. S. PERKINS opened the symposium by discussing the clinical aspects. Diamox had a quick action, he said, and might reduce the ocular tension in all types of glaucoma. After a few days' use it might become less effective, but combined with miotics there was an additive effect. In a series of many varieties of glaucoma he had found the tension was reduced and kept so in 48% of cases; it was reduced but failed to remain within normal limits in a further 38%; while in 14% it was unaffected. Diamox was used initially in doses of 500 mg. at once and 250 mg. six-hourly, and later reduced to 250 mg. twice or thrice daily. Its chief use was as a pre-operative drug, particularly in acute congestive glaucoma, but it was disappointing as a therapeutic measure in patients with long-standing congestive attacks. The side-effects consisted of diuresis, nausea, vomiting, and paraesthesiae in the limbs. Mr. Perkins also discussed the possible modes of action of diamox. The drug was known to inhibit the enzyme carbonic anhydrase, and he described experiments showing that this enzyme is present in iris and ciliary tissue.

Dr. J. GLOSTER described experiments designed to measure the extent and rate of change in intraocular pressure induced by diamox when given intravenously to rabbits in a dose of 50 mg. per kg. of body weight. Intraocular pressure was continuously measured manometrically, and blood-pressure readings were also taken. In general, the intraocular pressure was reduced by 3 to 5 cm. of water in 15 minutes in the rabbit and the effect began two to three minutes after the administration of the drug.

Dr. M. LANGHAM, from his observations on the entrance of fluorescein into the eye, believed that the rate of flow of aqueous was reduced after the injection of diamox. There was no evidence that the drug produced an increase in permeability of the blood-aqueous barrier, as shown by measuring the accumulation of ascorbic acid and fluorescein in the eye before and after its use, nor was there any evidence to suggest that it acted by decreasing the resistance to drainage. Studies on the pH of aqueous humour and its ionic content did not answer the question of whether diamox acted specifically on the formation of aqueous humour by neutralizing carbonic anhydrase in the eye, or whether the results on intraocular pressure were of a secondary non-specific character.

In the discussion Professor G. P. SOURDILLE and Mr. A. PALIN gave some interesting clinical experiences with diamox in glaucoma. Dr. DOROTHY CAMPBELL showed how the plasma sodium and the degree of diuresis varied with the changes in intraocular pressure after the use of diamox in patients with glaucoma, and Sir STEWART DUKE-ELDER summarized the present standing of the drug.

Use of Air in Ophthalmology

Mr. H. B. STALLARD said that the intraocular injection of air had been used in ophthalmology therapeutically for the treatment of tuberculous iritis, diagnostically as an aid to the location of intraocular foreign bodies and intra-orbital neoplasms, but chiefly to help in the anatomical replacement following operations. After cataract extraction air was injected into the anterior chamber to re-form this and to keep the iris and vitreous face away from the wound; following cyclodialysis for glaucoma, air checked bleeding,

re-formed the anterior chamber, and kept the fistulous tract open; after the operation for retinal detachment air in the vitreous restored the normal anatomical position of the retina; it was of value in the operation of keratoplasty to keep the bed of the transplant away from the iris and lens; and in the division of anterior synechiae air could be used to put the synechiae on the stretch and facilitate intraocular instrumentation. Air was compressible, continued Mr. Stallard; it produced a spring-like pressure, its site in the eye could be controlled by posture, and it was absorbed over a period of four to eight days. These were the properties which made it so useful in ophthalmology. The dangers attending its use, air embolism and the production of glaucoma, were almost negligible. Sterilization of the air was achieved by autoclaving a syringe with the plunger withdrawn.

Radioactive Isotopes

Mr. ANTHONY PALIN and Dr. R. C. TUDWAY read a paper on the use of radioactive isotopes in the diagnosis of intraocular tumours. The technique had practical importance because it was often difficult to distinguish clinically between malignant and non-malignant neoplasms in the eye. However, the excess take-up of such isotopes by most actively growing tumour tissue had now been amply verified. The authors used radioactive phosphorus (P^{32}) which with its short-range beta emissions appeared to give significant findings on the Geiger-counter. Adult patients were given 1 millicurie of radioactive phosphorus in water, sucked through a straw, and 24 hours later Geiger-counter readings were taken by a medical assistant or technician who had no knowledge of the site of the tumour. These readings were taken in the various meridians of the affected eye, and controls were taken from the symmetrical meridians in the fellow eye. The statistical error of the method was plus or minus 15%. In general (save in very small or very posterior tumours) the significant difference between the two eyes was taken as 40% or over. The cases of malignant tumour which the authors had studied showed a significant differential reading, and there was only one case, which had a low total, and therefore unsatisfactory, count, where the results of the method were misleading. In the discussion it was pointed out that the results did not depend on pigmentation of the tumour but rather on hyperactive cell metabolism; that most of Mr. Palin's cases were clinically suspect before the test was used; that, in the acute stage, uveitis might produce a misleading result; and that the method as at present developed was not of value in gliomata in young children.

Reports of Societies

RADIOACTIVE ISOTOPES

SYMPOSIUM AT ROYAL SOCIETY OF MEDICINE

[FROM A SPECIAL CORRESPONDENT]

Looking back over the past decade of clinical experience with artificial radioactive isotopes, one gets the impression that many people were apt at first to be too enthusiastic about the part this new tool would play in therapy and diagnosis. It was clear, however, from the tone of all the speakers at the symposium arranged by the Section of Medicine at the Royal Society of Medicine on April 26, that work with radioisotopes is now entering a period of more balanced assessment and comparison with other methods.

ABC of Radioisotope Therapy

The therapeutic uses of radioisotopes depend upon the fact that when the atoms of an unstable element disintegrate they emit radiations capable of destroying the tissues through which they pass. These radiations are of three kinds: (1) Electrons, or beta particles, which penetrate up to

about a millimetre of tissue; (2) gamma rays, which are electromagnetic radiations of rather shorter wavelength than x rays and which penetrate several centimetres of tissue; and (3) alpha particles, emitted only by the heavier elements and having a penetrating power much less than that of beta particles. Each unstable isotope emits radiations with a characteristic penetrating power and each has a characteristic rate of disintegration. The "half life" of different isotopes varies from a fraction of a second to millions of years.

A radioisotope is handled by the body in the same way as the naturally occurring stable isotope. Moreover, radioisotopes can be measured in minute amounts by means of their radiations. If, therefore, a substance normally present in the body is labelled by adding to it a negligible amount of the corresponding radioactive material, we can follow the way in which the substance moves about the body or is metabolized. This may be done either by measuring the radioactivity in serial samples of body fluids, or, as with some of the radioiodine tests of thyroid function, by measuring the gamma radiations with a detector outside the body. This is the basis of the increasing number of clinical tests in which a radioisotope is used.

Methods of Localizing the Dose

If a radioisotope with suitable properties can be brought into or near a tissue it may be possible to destroy that tissue without undue damage to near-by organs. In a sense, this new branch of radiotherapy can be regarded as an extension of the older technique of local irradiation by implanting radium or radon seeds. But, owing to the wide choice of radioisotopes now available, it has been possible to devise other more satisfactory methods for achieving a local effect.

Dr. E. E. POCHIN (U.C.H., London), opening the discussion, dealt in broad outline with the principles underlying these methods. The surface of the body might be irradiated by local application of a beta-ray emitter, he said, instancing the extensive use of P^{32} in surface applicators for the treatment of superficial lesions of the skin. A solution of radioactive material could be injected directly into the lumen of a hollow viscus or introduced inside a rubber bag. Both these methods had been used for irradiating superficial tumours in the mucosa of the bladder. Another way was to inject the radioactive material as a colloidal suspension into a solid tissue. In the colloidal state, most of the injected material was retained at or near the injection site. Colloidal gold¹⁹⁹, for example, had been used in a variety of malignant tumours.

A more promising use of radiogold lay in the treatment of malignant effusions, continued Dr. Pochin. If colloidal radioactive gold were injected into the peritoneal cavity, it was rapidly deposited upon the peritoneal membrane. From this position malignant metastases were irradiated by beta radiations. However, since the beta rays of Au^{199} were of low penetrating power, the damage to the metastatic deposits was confined to a thin shell over their surface, unless they were very small. This might help to explain why radiogold appears to have no useful effect in some cases, while in others it led to marked improvement.

If small radioactive colloidal particles were injected intravenously they would accumulate in the reticulo-endothelial system and irradiate selectively those organs which contain a high proportion of R.E. cells. This principle had been tried in the treatment of the reticulosos and of a few primary tumours of the liver (using radioactive colloidal gold). If, however, large particles, 30 to 50 microns in diameter, were injected intravenously, they were arrested in the lung capillaries, whence they might irradiate the lungs selectively. If the injection could be made by cardiac catheter into one pulmonary artery, the irradiation could be localized in one lung. The first attempts to develop this method had been made with carbon particles coated with radioactive gold. But this had the disadvantage that distant organs might be damaged by the gamma rays of Au^{199} .

Metabolic Localization

Perhaps the most spectacular, and certainly the most successful, therapeutic use of radioisotopes, went on Dr. Pochin, was based on what might be called "metabolic localization." If the radioactive material was given internally in the form of a chemical substance which naturally accumulates within a particular organ or tissue it might be possible to achieve a high and uniformly distributed radiation dose without undue irradiation to the rest of the body. The two most promising examples of this were the use of radioiodine (I^{131}) in the treatment of thyroid disease and of P^{32} in the treatment of polycythaemia vera. The thyroid concentrated iodine to such an extent that the intensity of radiation delivered to the thyroid from a dose of I^{131} might be several hundred times as great as the radiation to the rest of the body. For this reason it was always possible to destroy selectively a normal or overactive thyroid gland by means of radioiodine. At present it would be fair to say that radioiodine provided a useful alternative to surgery and the antithyroid drugs in selected cases of Graves's disease and toxic nodular goitre. Radioiodine was simpler and less unpleasant to the patient than either of the former methods, and it entailed no immediate hazards. There was, however, still a possibility that carcinoma might arise in those parts of the thyroid which had been irradiated but not destroyed. No cases of cancer of the thyroid attributable to radioiodine had yet been reported among the many hundreds treated and followed for five years or longer. But most people agreed that, until more experience had accumulated, radioiodine should be used in the treatment of the non-malignant thyroid only if the patient was past middle age or if there was appreciable risk from other forms of treatment.

In malignant disease of the thyroid radioiodine was the treatment of choice if there were metastases which had the power to concentrate iodine. Generally, the tumours most likely to concentrate radioiodine were the most highly differentiated.

Concluding his remarks, Dr. Pochin stressed the great possibilities for the further development of radioisotope techniques. While it was probable, he said, that new methods would be introduced, whereby better local radiation effects could be obtained in tissues, of equal importance was the gradual improvement in methods of selecting patients. This was also one of the points stressed by the next speaker, Professor Smithers.

Experience at the Royal Marsden Hospital

Professor D. W. SMITHERS gave a brief survey of the results of work with radioisotopes over the past four years at the Royal Marsden Hospital (formerly the Royal Cancer). This survey included, among many other topics, the diagnostic use of I^{131} in thyroid disease, studies of the blood circulation by means of Na^{24} , measurement of red blood cell volume with red cells labelled by Cr^{51} ; and the therapeutic uses of I^{131} in thyroid carcinoma, P^{32} in polycythaemia, and colloidal gold in malignant effusions.

With regard to the therapeutic applications of radioisotopes, said Professor Smithers, in some cases there was already enough experience to show that the new treatment had something useful to offer the patient for whom previously there was little else. This was certainly true of radioiodine in the treatment of iodine-concentrating metastases from a thyroid carcinoma. To a lesser extent it seemed true also of Au^{199} in the palliative treatment of malignant effusions, but it might be several years before it became possible to pick out with any confidence those patients most likely to derive benefit from this treatment. In other cases, as, for instance, the infiltration of prostatic tumours with Au^{199} , doubts about the wisdom of increasing tissue tensions in malignant disease even with radioactive materials had held back workers in Britain until the results of trials by others were available. Again, artificial radioisotopes had in a few cases been adopted because they had some slight practical advantage over the older methods. Such was the case with tantalum¹⁸² wire, which

appeared to be superior to radon seeds in the treatment of superficial tumours of the bladder, and with implants of gold¹⁹⁹ grains, which might supersede radon seeds in the treatment of some types of tumour.

Professor Smithers showed two films—one demonstrating the therapeutic uses of isotopes by surface, intracavitary, and interstitial application; the other the treatment of a young woman with malignant disease of the thyroid, a tracheotomy, and metastases in the neck nodes and lungs. This patient was treated by radioiodine. The tumours all regressed, and nearly six years after the treatment she was in normal health, with no clinical or radiological evidence of disease. Professor Smithers was careful to point out that this was an exceptional case.

Radioisotopes in the General Hospital

The last speaker, Mr. N. VEALL (Guy's Hospital), discussed the value of radioisotopes in diagnosis and research. He stressed the fact that radioisotope techniques were applicable in almost every branch of medical research, and quoted several examples to show how some of the methods developed for research had been adapted for routine clinical use. It was now possible for diagnostic tests to be carried out in the smaller hospitals, since the necessary equipment for most of the established procedures involved a capital expenditure of less than £200. When the volume of work justified such a course specialized equipment was available for carrying out particular tests on a mass scale. In some hospitals, for instance, hundreds of radioiodine tests of thyroid function were performed each year.

Another speaker asked whether every general hospital should be allowed to embark on work with radioisotopes, or whether it ought to be restricted to a few large centres. Mr. VEALL was rather of the opinion that the apparatus needed for many diagnostic tests was now so cheap and so simple to operate that any medical centre wishing to use it should be encouraged to do so. However, Professor SMITHERS pointed out that when isotopes were used for treatment adequate facilities must be available if only to ensure, among other things, proper precautions against radiation hazards by everyone concerned and for the disposal of radioactive wastes. He thought it would be uneconomical to have more than a limited number of radiotherapeutic centres throughout the country; and therapy, at least with internally administered isotopes, would tend to be confined to the larger medical centres.

LOCAL MEDICAL SOCIETIES

Manchester Medical Society

Some of the difficulties in diagnosing ankylosing spondylitis, and their bearing on treatment, were stressed by Dr. J. SHARP, lecturer in rheumatic diseases at Manchester, at a meeting of the Section of Medicine on March 23. In the majority of spondylitis patients referred to a special clinic for x-ray treatment, said Dr. Sharp, the disease conformed strictly to the generally recognized picture, and 70% of them were much improved by deep x-ray therapy. In the remainder, the disease had unusual features, and of these only 31%, a very significantly smaller proportion, derived similar benefit from treatment. There was evidence that the difference in the effects of treatment was due to inclusion in the "atypical" group of some patients with rheumatoid arthritis affecting the spine, of others with psoriatic arthropathy with spinal involvement, of a few with Reiter's disease, and of some who had developed a form of spondylitis following repeated and prolonged attacks of rheumatic fever, and that these conditions were usually unresponsive to x-ray therapy. Further, immobilization usually had an adverse effect in ankylosing spondylitis, while it was often helpful in these other conditions. About a third of the patients in the "atypical" group did not seem to fit into any of these categories, and Dr. Sharp suggested that other, as yet unrecognized, conditions might be represented.

Nova et Vetera

GLOUCESTERSHIRE ROYAL HOSPITAL

This year the Gloucestershire Royal Hospital celebrates the bicentenary of its foundation, and on May 3 the occasion was honoured by a visit of the Queen and the Duke of Edinburgh. A thanksgiving service was held on May 8 in Gloucester Cathedral.

In 1754 certain benevolent people in the city and county of Gloucester decided to form a charity to found and endow the Gloucester General Infirmary for "the cure of the sick and lame of any County or Nation, who are destitute of the means of support." The ample pecuniary return so quickly made to the appeal on the first formation of the charity in 1754 enabled the promoters of the scheme to act with promptitude. The conclusion being formed that the erection of a new building would be the most satisfactory course, land called the Talbot Ground near the South Gate was purchased, on which the present buildings now stand.

To prevent delay in offering to the poor the advantage of the charity, the Crown and Sceptre Inn, Westgate Street, was purchased for the sum of £300, fitted up as a temporary hospital, and opened for the immediate reception of patients on August 14, 1755. To mark this occasion an inauguration service was held in Gloucester Cathedral, followed by a dinner at the Bell Hotel, both being attended by most of the leading persons in the county and city.

On July 18, 1761, the new building, which had been erected at a cost of £6,200, was publicly opened after a service at the cathedral and a dinner at the King's Head Hotel, presided over by Sir Onesiphorus Paul. At that time the four principal wards in the new building were named "Beaufort," "Berkeley," "Benson," and "Talbot," and the total beddage was 116.

The Old Infirmary (the Crown and Sceptre Inn) was sold in 1765. In 1813 the Squirrel Inn and other property adjoining the Infirmary on the south side was purchased for £1,000, and in 1827 the south wing to accommodate 54 patients was erected at a cost of £4,745, thus increasing the number of beds to 170. In 1877 the hospital was established as a training school for nurses, and since that date many thousands of students have received their training and gained their certificates through the excellent teaching facilities provided.

In 1878 another institution in Gloucester, called the Gloucestershire Eye Institution, was closed and all the cases were transferred to the General Infirmary. The Infirmary thereupon, under an arrangement with the Eye Institution, created an ophthalmic department, and the hospital became known as the Gloucestershire General Infirmary and Eye Institution.

On June 23, 1909, on the occasion of the visit of H.M. King Edward VII to the Royal Agricultural Show held in Gloucester, it was made known in the reply to the address of the Gloucester Corporation that His Majesty had been graciously pleased to accede to the request of the hospital committee to use the prefix "Royal," in the name of the Institution, "in recognition of the admirable work done by those responsible for its management, and the devoted and successful efforts of its staff in the prevention and alleviation of human suffering," and thereafter it was called the Gloucestershire Royal Infirmary and Eye Institution.

In July, 1948, the hospital was taken over under the National Health Service Act, and the newly appointed group management committee decided that the other hospital in the city, known as the City General Hospital, previously administered by the local authority, should become part of the Royal Hospital, and the two are now one unit, known as the Gloucestershire Royal Hospital.

C. J. ADAMS,
House Governor.

Army Pathology

SIR,—In his interesting annotation on Army pathology (*Journal*, April 30, p. 1087) Major-General A. Sachs omits all mention of one of its most notable contributions to medicine—namely, the first clear account of the pathology of syphilitic aortitis. In 1875, Francis H. Welch, Assistant Professor of Pathology at Netley, gave a paper at the Royal Medical and Chirurgical Society entitled "On Aortic Aneurysm in the Army and the Conditions Associated with It." The paper was published in the *Medico-Chirurgical Transactions* in 1876.¹ Welch showed that aneurysm was due not to strain, as usually supposed, but to a diseased condition of the aortic wall which preceded dilatation. He gave an accurate account of the macroscopic and microscopic features of the aortic lesion, and distinguished it from atheroma. By reference to the medical history sheets of soldiers dying from aneurysm, he was able to show conclusively that a high proportion had been treated for syphilis, a fact difficult to prove in civilian cases before the advent of the Wassermann reaction.

It is evident that syphilitic aortitis had not escaped notice at Netley before Welch's time. For Myers, in his *Essay on Diseases of the Heart among Soldiers*,² mentions that Dr. Aitken had recognized aortitis in cases of aneurysm and had regarded it as syphilitic. Prior to this, a good deal of inquiry had been directed to the cause of aneurysm in soldiers, and the widely accepted explanation was that it arose from a hypertrophied heart ejecting blood with excessive force. The cause of this cardiac hypertrophy was supposed to be tight clothing and accoutrements, combined with strain, alcoholism, and other factors.

Though Welch's classical paper received inadequate recognition at the time, and his views were disputed, to-day it is generally accepted as the pioneer account of syphilitic aortitis. Both Allbutt and Osler so regarded it, and historians of cardiology such as Herrick, and Willis and Dry, have paid proper tribute to Welch's work. The centenary of Army pathology warrants some reference to it.—I am, etc.,

Classification of Breast Cancer

SIR,—Anyone who is concerned about the present unsatisfactory state of affairs in assessing the treatment of breast cancer will readily agree with Mr. Michael Harmer's plea (*Journal*, March 26, p. 790) for a standardized internationally accepted scheme of clinical staging. That such an anatomical yardstick is necessary in comparing the results of any form of treatment of malignant disease will be agreed by all. Unfortunately, however, in breast cancer the problem is not quite as simple as this.

For any system of staging to be of real value, accurate information regarding the involvement of regional nodes must be available. Clinical determination of axillary node involvement is incorrect in about 20% of cases with enlarged glands and 40% of cases with impalpable glands; and although routine histological examination of these glands gives a more accurate assessment even this may fail to reveal small metastases unless serial sections are cut.¹ In the majority of patients supraclavicular gland involvement is based entirely upon clinical examination, and the state of the internal mammary nodes is ignored. Thus any system of classification of breast cancer based entirely upon

clinical staging can only be an approximate guide to prognosis.

An attempt to present a more accurate classification was made by grouping cases according to both clinical stage and histological grade.² The Manchester staging system and the method of grading introduced by Patey and Scarff³ were used: the results are shown in the diagram.

It is evident that each stage contains representatives of three types of tumour, each bearing a different prognosis. Grade III cases are seen to account for many of the failures in Stage I, and Grade I cases for the successes in the more advanced stages. It is postulated that the histological grade of malignancy provides a measure of the probable extent of the growth, those of low grade tending to remain localized to the primary site and those of high grade tending to metastasize early. This may compensate, to some extent, for the omissions and errors which may arise in the clinical assessment of glandular involvement.

We agree that an international method of staging breast cancer is urgently required, but we feel that to use a system of clinical staging alone in comparing the results of treatment would be to neglect the most significant denominator of all—namely, the inherent degree of malignancy of the cancer cells. Such a course, in our opinion, would only serve to increase the confusion that already exists.—We are, etc.,

Anxiety Neurosis

SIR,—However much I lack the urge to effort for common welfare, I cannot let Dr. Ronald A. B. Rorie's article (*Journal*, April 30, p. 1062) pass in silence. I fear the silence, hence my attempt to combat it. As you see from the article, Dr. Rorie occupies an important position in the practice of objective medicine—that is, "real" medicine—and the article is "from a thesis submitted to the University of St. Andrews for the degree of doctor of medicine." So its shortcomings—if any—are worthy of examination.

In his second paragraph he says: "The family doctor . . . through lack of training has not the knowledge, and too often not the inclination, to attempt to deal with the obviously neurotic patient." I would humbly ask, without knowledge how can the family (or any other type of) doctor deal with the neurotic patient, so why throw in the slurring words about the lack of inclination? With reference to paragraph five, would Dr. Rorie to-day like to name the medical schools—in Britain—that attempt to supply the opportunity to obtain the aforesaid necessary "knowledge"? I do not ask Dr. Rorie to place these schools in order of merit. With reference to paragraph seven, how does Dr. Rorie propose to rectify the persisting Victorian disapproval? Does he suggest that it is the G.P.'s job? With reference to paragraph ten, which begins, "It is obvious that if the general practitioner refuses, consciously or otherwise . . ." Please, please Dr. Rorie how can the G.P. refuse unconsciously (=otherwise)? This brings us back to the G.P.'s faulty teaching and (I hope) forces us to consider who is responsible for it.

In his last paragraph but one Dr. Rorie says there is a very strong case for a "small psychiatric unit" in all general hospitals. I could not agree more with this modest requirement, which nevertheless may not come into action for a long time yet because the time lag is at the very top—that is, in the medical schools—as Dr. Rorie himself says. Another reason is that the "small psychiatric unit" will carry, or force, a good deal more with it—for example, there is just as much need for psychiatric

social workers, men and women, as there is need for midwives, district nurses, and such others as the welfare officers of local authorities. These trained (when they are trained) people need not be quite as expensive as registered medical practitioners, but in the effectiveness of their particular jobs of work can be just as useful.

Meanwhile, such ideas carried into co-operative effort will set free your G.P. and you will have every right to demand that he (or she) should be fully trained in knowledge of the job he has to do. The giving of a "merit award" to a G.P. worthy of it might be easily as practicable as the administration of merit awards in the present circumstances to other parts of the medical profession. Finally, if this country wants the general medical practitioner to survive, his training policy cannot be allowed to remain in the state indicated by paragraph five of Dr. Rorie's article. How can anyone expect a "doctor" to become interested in a part (an abnormal part) of real life that he is without adequate knowledge of? Even though I appear to see some related matters in a way not covered by Dr. Rorie's article, I sincerely congratulate him on it.—I am, etc.,

Mansfield.

JOHN McNAMARA.

Psychosomatic Appendicitis?

SIR,—Dr. J. W. Weston (*Journal*, May 7, p. 1158) states that he has had recurrent attacks of mild appendicular colic, and apparently has made a self-diagnosis on the assumption (a prevalent mistake) that pain produced in the appendix is situated in the right iliac fossa. That tenderness and, secondarily, pain in the right iliac fossa do occur in both the inflammatory and obstructive types of appendicitis is well recognized—if the appendix is in the normal site. But the excitation of pain in that situation is produced not in the appendix: it is caused primarily by stimulation of the somatic nerve afferents of the parietal peritoneum, and not by "overaction of the sympathetic." Since the appendix, like the rest of the gut, has a bilateral nerve supply through the autonomic system, it necessarily follows that pain produced in any part of the intestine will be situated in the midline and at a definite site—epigastric, umbilical, or hypogastric—depending on the embryonic position of the segment of gut at fault. On the other hand, pain produced in a bilateral organ (or tissue) is always unilateral, since the innervation is unilateral—e.g., kidney, testis, arm, leg, etc.

Dr. Weston would be wise to "wonder" a little longer and to consider other possible causes for his attacks of "sharp stabbing pain localized to the right iliac fossa" before having his appendix removed.—I am, etc.,

Dundee.

F. R. BROWN.

Ban on Heroin

SIR,—Your report under the heading "Medical Notes in Parliament" in the *Journal* of May 7 (p. 1163) makes me write to you again on this subject. You have published several letters in which the ban on heroin is deplored for one reason or another. The writers of these, and the host of doctors who are in agreement with their views, must think that the Association has taken no action in the matter, if Lord Haden-Guest can assume that "the whole medical profession, so far as could be ascertained, was behind the Order" and Lord Mancroft can say "the vast weight of evidence was in favour of the move."

The Association received last year from the World Medical Association a questionnaire on the subject of the ban on the manufacture of heroin. This was referred to the Science Committee, who recommended as follows: "That the World Medical Association be informed that it is the duty of the Government to legislate against misuse of heroin, but the medical profession should not in any way be deprived of the use of this or any other drug which may assist in the treatment of patients." This resolution was endorsed by the Council of the Association in November, 1954. Seeing that the overwhelming majority of medical men are members of the Association the statements of Lord Haden-Guest

and Lord Mancroft were singularly uninformed. Lord Haden-Guest, being a doctor, should have found out the Association's view on the matter before making such a statement.

This is not the first time that the opinion of the Association has been entirely ignored by the Central Health Services Council in recommendations to the Minister, which seems strange seeing that the chairman was recently President of the Association. I am sure it would give satisfaction to members if the Association's views were made clear, possibly by the Public Relations Officer, on occasions such as this when the Government takes a decision contrary to the expressed view of the Association.

I wish someone would inform me what the "perfectly good substitute is" for heroin—to use Lord Mancroft's words. Is it something known to the Central Health Services Council and the Members of the House of Lords but kept hidden from the small fry in whose hands is the treatment of the patients of this country? Or is it "physeptone"? If the latter, Lord Mancroft is in error in his description of this drug.—I am, etc.,

London, N.W.1.

R. HALE-WHITE.

SIR,—One appreciates the good intention behind the ban on heroin, but there are certain aspects of this matter which cannot help causing concern. It is clear from the correspondence in the *Journal* and elsewhere that there is no complete substitute for heroin, and such is my own experience. If there was a substitute, then no one would object at all to the ban, and it is obvious that the Government has been misinformed on this point. As it is, legislation will be brought into effect which will have the direct result of condemning some citizens to suffer pain which could be relieved by this drug. A few people will be asked, therefore, to make this sacrifice for the good of a supposedly larger number of their fellow creatures. Such a policy invokes a principle which has always been regarded as unethical and unacceptable to British Medicine, for it is the same principle under which the Germans carried out their much discussed experiments on human subjects. We have fought strongly to preserve the right to prescribe drugs of doubtful value, and I can only hope that the same effort will be made to preserve heroin until a genuine substitute is available. The fundamental function of clinical practice is to relieve suffering, and no weapon employed to this end should ever be banned, even for the most cogent socio-economic reason.—I am, etc.,

Barnton, Midlothian.

A. G. DONALD.

The Changing Face of Medicine

SIR,—I was highly interested to read Dr. C. P. D. Grant's splendid contribution, "Youth Looks at General Practice" (*Journal*, April 30, p. 1049) and your comments (p. 1075), and I entirely agree when he calls the N.H.S. a system "designed to undermine incentive and initiative," a system in which a list of "heads" has to be built up to provide a living wage, a system in which "the G.P. can very easily degenerate into a rather apathetic kind of sorting clerk."

Is it not worth while to learn from excellent insurance schemes working in other countries which provide a system without lists and capitation fees? They offer individual services rendered by G.P.s and paid for according to an approved national scale of fees. Minor surgery, treatment of fractures, suitable laboratory investigations, some physiotherapy, all within the capacity of the G.P., could easily be done in G.P. surgeries and paid for accordingly. What an incentive for the G.P. to treat the patient and not to transfer them much too readily to overcrowded out-patient departments. It would mean saving of money and working time for patients sent to such departments, relief of overworked out-patient department personnel, saving of salaries and manpower of nurses so short in supply, clerks, secretaries, physiotherapists, porters, etc. Costs for ambulances and hospital cars would be greatly reduced.

Specialists' services could be changed to bring at the disposal of patients specialists not only for domiciliary visits but also for consultations in their own consulting-rooms, where certain treatment could be provided. Patients would be pleased to have their self-chosen specialist, who would be paid according to an approved scale of national fees.

By abolishing lists and capitation fees I, as a middle-aged G.P., could envisage an easier entry of the young generation into general practice.—I am, etc.,

Finchley, N.3.

H. SIMON.

SIR,—My own reactions to eighteen months in general practice differ slightly from those expressed in Dr. C. P. D. Grant's excellent article "Youth Looks at General Practice" (*Journal*, April 30, p. 1049) and Dr. G. F. G. Marshall's letter (*Journal*, May 7, p. 1153). My feeling has been that the many differences between hospital work and general practice all spring from the fundamental one that in hospital jobs we were one of many who played a part in the treatment of the individual patient, whereas in general practice we are alone in representing the medical profession to him. I was just as conscious of these differences as Drs. Grant and Marshall, but I cannot agree with them that this experience of itself constituted an adverse criticism of the undergraduate curriculum.

There is no alternative, as I see it, to the ironical fact that to learn general practice one must first become a general practitioner. One's ingenuity in the application of general principles of both medicine and common sense was certainly taxed to a degree at first, but I never found my basic knowledge so lacking as to be in fear of making a serious error. Occasional reference to a picture book of skin rashes and a small handbook of prescribing was of particular help at first. Harvey Cushing once wrote that every patient presented two questions: first, what can be learnt from him, and secondly what can be done for him. How true to the newcomer to general practice! I personally found the problem of explanation to constitute the greatest difficulty, especially in the giving of a judicious forecast as to the course an illness might take and its likely duration. One can so easily be held to account for any unexplained sequelae when one lives in patients' midst.

Drs. Grant and Marshall both allude to the question of satisfaction of work in general practice. As Dr. Grant says, the tendency to apathy to clinical matters and over-concern with "the practice" as a business entity is a real danger as years go by. This can hardly be conducive to happiness, as no doubt Osler would have told us. I am hesitant in agreeing with the stress which Dr. Marshall lays on the approval earned of patients as a central, reliable source of satisfaction. It is pleasant indeed to bask in the knowledge of this state, and yet, if we do, it is all too easy with time to cease self-criticism and for our clinical standards consequently to fall. As I see it, we can only be sustained in our relative intellectual isolation by keeping alive the scientific approach to problems nurtured in our hospital days by continued reading, especially of symposia which review current thought. As in other facets of life, we have to live on a vision, and much effort is constantly required if it is to remain bright in our minds. It is in this sphere, and the occasions on which my patients have derived benefit in advice or treatment as a direct result of my reading, that I have found the greatest satisfaction of all.

Such an approach, as the mainspring of our thought and work, can do much to help us restore the prestige of general practice to its rightful place in medicine and our own self-respect as professional men. Dr. Grant's suggestions about the introduction of general-practitioner clinical assistantships, and access to x-ray departments and pathology laboratories, would help greatly in this motive, and I very much hope will be introduced in due course. George Eliot epitomized this approach in her *Middlemarch*: "I should never have been happy in any profession that did not call forth the highest intellectual strain, and yet keep me in warm contact with my neighbours. There is nothing like

medicine for this: one can have the exclusive scientific life which touches the distance, and befriend the old fogies of the parish too."—I am, etc.,

Heswall, Cheshire.

D. S. CRAIG.

SIR,—I feel that many of the statements in Dr. C. P. D. Grant's article "Youth Looks at General Practice" (*Journal*, April 30, p. 1049) should not go unanswered. I qualified just before the late war and have been in practice some seven years, five of these in my own single-handed practice, and feel sure that his attitude on many things is not typical of the less senior general practitioner.

He complains of the "volume of trivial complaints." The only objective study on this point that I have seen¹ considered a disease serious when it embodied a major threat to life or livelihood. On this basis, in a London practice of over 3,000, 16% of diagnoses were of serious disease, and the work involved in dealing with these patients was 43% of the total work in the year. In my experience much disease that does not embody such a threat is serious enough to the patient, and difficult and interesting to treat. As for "trivial illness," much serious illness begins in this way, much is a symptom of serious underlying psychological or social trouble which the good doctor must treat, and the remainder gives a good opportunity for health education of a valuable kind.

Dr. Grant deplores "the cessation of clinical control of patients removed to hospital under the National Health Service." What does he suppose happened to these patients prior to 1948? If they did not in fact go to hospital, could they afford to pay doctors and nurses to look after them elsewhere, and were the doctors satisfied that all the resources of medicine were available for their patients in these circumstances? Surely the truth about the increased demand for hospital beds is that now millions of people have a family doctor who never had one before, and that much chronic illness which before was endured in silence is now diagnosed and treated.

I agree very much with Dr. Grant that family doctors should be able to get many investigations done without referring the patient to hospital. (It seems that the co-operation of the Northern Ireland Hospitals Authority puts us in Northern Ireland in a privileged position in this respect.) Much more co-operation between hospital and general practice would be of great advantage to both—and to the patient; but many general practitioners would feel that their work lay in their practices rather than in doing hospital work described as "routine" and not needing "very advanced or specialized knowledge." Many general practitioners seem to feel that because they do not work in hospital they are cut off from all that is really interesting and important in medicine. This mistaken attitude has its origin in methods of medical education; the student has to be taught about disease largely as it is seen by specialists in hospitals. Lay misconceptions about medicine are reinforced, and the drama of the operating theatre, the laboratory, and the x-ray departments has come to be regarded as the occupation of every medical man who does a worthwhile job. This produces the attitude of mind which causes Dr. Grant to refer to "the malingerers and neurotics—the pests, the 10% hard core of every doctor's list." It is true that even to-day the undergraduate receives inadequate training in psychological medicine, but that does not justify the description of sick people as pests and malingerers.

However thankful we may often be for the resources of our hospitals and the wisdom of our specialists the practice of medicine is coming more and more into the patient's home. An emergency tracheotomy or intubation for laryngeal diphtheria was a dramatic event, but prophylactic immunization is preferable. Lobectomy for bronchiectasis, or localization and removal of a complicating brain abscess, are remarkable and admirable processes; but prevention of pertussis and early treatment of pneumonia are more acceptable to the patient. Cardiac surgery can mean new life for a cardiac cripple; good general practice in many cases could forestall the development of rheumatic carditis. These are only the most obvious instances; and every year medical progress increases the possibilities of the family doctor's work.

Dr. Grant speaks of "the young practitioner, excluded from the hospital and committed to his desk by the system. . . ." Desks were not unknown previously, and a careful history taken behind one by a doctor who knows his patient as a person often gives more useful information

than a sheaf of special investigations. I prefer to think of the family doctor not as excluded from the hospital but as having the great opportunity of living among his patients, observing them in health and disease, in their homes and at their work, following the natural history of each condition from origin to cure, or as it accompanies each patient to the inevitable end, however long delayed. The opportunities for clinical work and even for research in general practice are very great. Exceptional men have taken advantage of this in the past, and will again in the future. This needs saying again and again, because there is a fashion now for thoughtless general practitioners to belittle their work and to bemoan their "loss of status." I am in complete agreement with Dr. Grant's final sentence: "... taken seriously and practised conscientiously it [general practice] is the most difficult specialty of all."—I am, etc.,

Belfast.

REFERENCE

¹ Backett, E. M., et al., *British Medical Journal*, 1954, 1, 109.

SIR,—Your report (*Journal*, April 30, p. 1045) of the 1954 presidential address to the Edinburgh Obstetrical Society by Dr. Clifford Kennedy states, "and then two years in the Services, when the mind of the doctor, so far as things medical are concerned, might in the average case be a complete vacuum." Surely this is an *ex cathedra* statement which in fairness to the Services, and the Army, in which I served, in particular should not be allowed to pass unchallenged.

In the first place, doctors, like other people, are called up to meet the needs of the nation, and not specifically to further their personal ambitions. Secondly, despite this fact, experience shows that if any show professional leanings or initiative their place in the professional orbit of the Service is assured. Lastly, I feel sure that the number of Service medical officers who, on transfer to part-time service, can honestly say that they have derived little or no benefit professionally during their time in the Forces must be very small.—I am, etc.,

London, S.W.1.

MALCOLM ROBINSON.

Difficulties of Child Adoption

SIR,—Dr. P. M. Fea's letter (*Journal*, April 30, p. 1096) indicates a grave lack of appreciation of the many problems involved in child adoption, and the consequent need for safeguards to protect the child from unwise placement and the adoptive parents from the tragedy of failure. The suggestion that the unwanted child must "justify its existence" implies that the child has incurred a debt to society only to be discharged by the satisfaction of the emotional needs of others, whether these be suitable or not as adoptive parents. The adoption societies are at the present time in a position to select from many applicants. Far from having "an unfounded suspicion" of would-be adopters, experience has shown that there are many considerations other than the fact that a couple may be "kindly disposed." So long as there are younger couples wanting a child it does not seem unreasonable that 40 is usually the upper age limit for adoptive parents.

Some emotional disturbances are exhibited by a proportion of adopted children, and such disturbances are often intensified when the parents are elderly, and particularly when the child reaches adolescence. Children are normally placed in infancy, when they have the best chance to settle in their new home. The later the age of adoption the greater is the chance of behaviour disorders. Dr. Fea, and others who are concerned with these questions, would find that they are discussed by Kornitzer¹ and the Home Office report on adoption.²—I am, etc.,

Beckenham.

Measles

SIR,—Your leading article (*Journal*, April 23, p. 1018) deprecates the prophylactic use of sulphonamides and penicillin as routine treatment of measles. During the January–March epidemic this practice has had approximately 50 cases of true measles, ranging from 1 year to 7 years, and in all cases we prescribed sulphonamides or penicillin. There was only one instance of complication, which was in a child of 5 years who developed bronchopneumonia and right-sided otitis media: this case occurred when the mother had not followed our instructions to give the prophylactic treatment.

It would be interesting to know the incidence of complications with or without prophylactic treatment. It appears that there is a definite place for routine prophylactic treatment in measles, starting in the pre-rash stage as soon as the catarrhal symptoms appear and there is a history of recent measles contact. I wish to thank my principal, Dr. R. G. Wigoder, for permission to record these results.—I am, etc.,

London, S.E.6.

J. F. LUND.

The Foot as a Half-dome

SIR,—I was especially interested in Dr. J. McKenzie's article (*Journal*, April 30, p. 1068) in which he compares the foot to a half-dome, as it is a concept that I myself found most useful in explaining the mechanics of the foot. But why does he, in common with so many others, describe the forefoot as being pronated when the foot has adopted a "flat-footed" attitude? When the foot is allowed to collapse from the active fully arched posture into a resting or flat-footed attitude, no movement of the forefoot takes place relative to the ground, for it remains plantar grade throughout. Hence it is certainly not pronated relative to the ground. But in this position the back part of the foot has "rolled in" into a valgus or everted position, and since the forefoot has not moved it must now be in a position of inversion in relation to the rest of the foot, and inversion is synonymous with supination. In the flat-footed stance the forefoot is thus supinated relative to the back part of the foot. Thus the change from the fully arched to the relaxed flat-footed posture is brought about primarily by rotation about an antero-posterior axis of the front and back parts of the foot in opposite directions. It is for this reason that I like to refer to the foot in the relaxed posture as being "unscrewed" rather than flat, and "screwed up" when it adopts the fully arched active position.—I am, etc.,

London, S.E.1.

T. T. STAMM.

Influenza

SIR,—Even in the face of an epidemic of influenza it is well-nigh impossible these days to differentiate such cases from other respiratory viral infections without routine serology in every case, as suggested by Dr. John Fry (*Journal*, February 19, p. 478). It is equally impossible to assess the true incidence of pulmonary opacities without radiological investigation of the chest in every case, and, for many reasons, that cannot normally be countenanced.

In the first half of 1953 (influenza virus A year) the Army Chest Centre, Connaught Hospital, Bramshott, was asked to deal with the overflow of mild cases of upper respiratory tract infection from other hospitals. Five hundred cases were admitted as upper respiratory tract infection between January 15, 1953, and May 5, 1953. Every case had a radiograph of the chest on admission, and the incidence of pulmonary opacities was most revealing. Routine serology (see Table) was carried out in all such cases and in random cases amongst the remainder. The cases were classified as follows: infectious mononucleosis, 6; rheumatic fever, 1; rubella, 1; tuberculous primary pleural effusion, 1 (A. and A.F.B. isolated on culture); transverse myelitis, 1; herpetic stomatitis, 1; malaria, malignant tertiary, 1; scarlet fever, 1.

The remaining 487 cases were then divided into the following groups, which are as defined by Stuart-Harris¹ but with certain modification. The figures in parentheses give the number with pulmonary opacities: *Group One*.—Common cold, 8. *Group Two*.—Bacterial sore throat, 112 (1). *Group Three*.—Febrile catarrh with exudate, 47 (4). *Group Four*.—An influenza-like illness with (a) no evidence of catarrh, 51 (1); (b) minimal catarrh, 67 (16); (c) marked catarrh, 202 (44). All groups were easily recognized, and therefore the high and accurate incidence of pulmonary abnormalities demonstrable on routine radiological examination of the chest in every case on admission is of particular interest—for example, Group 3 plus Group 4 (a), (b), and (c): 65 out of 367 cases, or 17.71%; Group 3 plus Group 4 (b) and (c)—that is, all cases with catarrh: 64 out of 316 cases, or 20.2%—that is, 1 in 5; Group 4 (b) and (c); 60 out of 269 cases, or 22.3%—that is, more than 1 in 5.

	Total Cases	Serology Tested	Influenza "A"	Influenza "B"	"Q" Fever	Psittacosis L.G.V. Group of Viruses	Streptococcus MG	Agglutinins	Negative Serology
Group 1	8	—	—	—	—	—	—	—	—
" 2	112	7 (1R)	—	—	—	—	—	—	7 (1R)
" 3	47	10 (4R)	—	—	—	—	—	—	10 (4R)
" 4(a)	51	6 (1R)	2	2	—	—	—	—	2
" 4(b)	67	24 (16R)	7 (3R)	3 (3R)	—	2 (2R)	—	—	12 (8R)
" 4(c)	202	61 (43R)	16 (10R)	12 (9R)	1 (1R)	2 (2R)	—	—	30 (21R)
Total	487	108 (65R + 1R AWOL)	25 (14R)	17 (12R)	1 (1R)	4 (4R)	—	—	61 (34R)

R=With radiological changes. The case who went A.W.O.L. did not have serological tests carried out.

These results are of outstanding interest because such a rate of pulmonary complications demonstrable on chest radiography is by no means generally recognized. Such results would be of special significance to those with Service experience, who know that anyone with a febrile illness of at least one day's duration is likely to be admitted to hospital. The radiological changes were those found in respiratory virus infections but are not diagnostic of, or peculiar to, any one virus. The term "adhesive bronchial pneumonia" is both descriptive and accurate and should replace the term "aspiration pneumonia," which is apt to be so readily used in such cases.

These brief remarks are part of a paper on the subject of upper respiratory tract infection which it is hoped to publish in the *Journal of the Royal Army Medical Corps* in due course. The authors of this work include Captain C. H. Jones, R.A.M.C., and Captain J. G. Elliott, R.A.M.C.—I am, etc.,

Hindhead, Surrey.

Exchange Transfusion in Haemolytic Disease of the Newborn

SIR.—The article by Drs. William Walker and Sheila Murray on the treatment of haemolytic disease of the newborn (*Journal*, July 17, 1954, p. 126), claiming a mortality rate of 2%, and reiterated in a further article by Drs. Walker and G. A. Neligan (*Journal*, March 19, p. 681), cannot be allowed to pass without comment.

Admirable as is the work of the Durham school on this subject, they lay themselves open to the criticism that by ignoring stillbirths when computing their mortality rate they have rendered their figures worthless, since all of the worst risks will have been eliminated before birth, and the mortality rate for the less severely affected liveborn infants becomes unfairly bettered. Furthermore, in the matter of

excluding the deaths of several of the liveborn infants in the 1955 report, it would seem that the liveborn mortality rate is also questionable. For example, two of the infants (K. and P.) amongst the group III cases, whose death was not attributable to haemolytic disease, had cord blood Hb values of 8.0 g.%, while one of them (K) had a serum bilirubin value of 15 mg.%. This alone, according to Dr. Walker's own published standards, should signify a severe degree of disease, severe enough *per se* to cause the death of many infants. Yet he has excluded them from the mortality figures on the grounds of double pathology. He has included in his mortality figures a much less severely affected infant (H.) in group III whose cord Hb value was 10.3 g.% and bilirubin only 1.9 mg.%. To the critical observer such inconsistencies render the figures quite unacceptable, but one might well ask what should or should not be included on the grounds of double pathology, because who is to judge just where to draw the line? It is a simple matter, by excluding cases on the grounds of other causes of death, to make one's mortality rate just what one likes. Indeed, the post-mortem results of many of Dr. Walker's cases showed just exactly nothing, or ? heart failure. Hence, if the necropsy revealed nothing, the death was presumed as due to haemolytic disease; if any other pathological cause can be found, haemolytic disease is excluded.

The only really scientifically honest way to arrive at approximate mortality figures is to include all stillbirths and all neonatal deaths of infants whose erythrocytes show a positive direct Coombs test. This may be difficult in the case of macerated stillbirths, but we have in this hospital counted all stillbirths (after 28 weeks) of infants whose mother's serum contained abnormal antibodies. Usually the presumption of incompatibility becomes almost a certainty when the previous history is consulted or there has been an undoubted change in maternal antibody titre. The stillbirth rate by this means may be slightly too high, but the figure must be closer to the truth than that obtained by ignoring these cases.

It is unfortunate that these British workers have decided to write off their erythroblastic stillbirths as irretrievable on evidence which is not even statistically significant.¹ Premature induction of labour, as a means of saving at least a proportion of these affected infants, has been banned on unacceptable evidence. The incidence of kernicterus in premature infants is reputed to be higher than in mature babies, and this is also debatable. It is more probable that it is not prematurity itself which contributes to kernicterus, but the way in which the babies are treated and handled. Evidence to substantiate these remarks is shortly to be published, and the plea is advanced to those interested workers to keep an open mind before accepting the dictum that "premature induction of labour has no routine place in the management of this disease."—I am, etc.,

Subiaco, Western Australia.

Coal-workers' Pneumoconiosis

SIR.—I have read with great interest and appreciation Drs. J. C. Gilson and G. S. Kilpatrick's article on coal-workers' pneumoconiosis (*Journal*, April 23, p. 994). They have given a lucid summary of a difficult social and therapeutic problem. They discuss the nature of chest pain in these cases, and I would like to quote some of the symptomatology I have elicited from Durham miners with pneumoconiosis.

Assessment of pain is always difficult, and especially so when the question of pension is involved. When one has excluded the more obvious causes of pain such as strain, cough fracture, or pleurisy, there remain a number of more obscure cases which often present some of the following features. The pain may be retrosternal, in either pectoral region; or be right across the front of the chest, and is often related to effort. In character it may be constrictive. If this is the only history obtained, cardiac ischaemia cannot

be ruled out without an E.C.G. before and after exercise. But usually the pain presents other features. For instance, it may be periodic, coming on for a few days or weeks at a time, though not continuously present. When the man is having a bad period the pain may not be related to exertion, but may occur in bed at night or while sitting in the armchair. When related to exertion the pain may be relieved by rest, but often persists for hours before this occurs. During the periods of remission the miner may be capable of considerable exertion. The pain is often associated with dyspnoea, more rarely with wheeze.

What such pain is due to is not clear. I have seldom attributed it to cardiac ischaemia because there are so frequently atypical features. Emphysematous bronchitis may get similar pain, but it seems a much more dominant feature in pneumoconiosis. Perhaps repeated undiagnosed pleuritis are related to the cause. I should be interested to learn if the above description of chest pain in pneumoconiosis fits in with the findings of Drs. Gilson and Kilpatrick.—I am, etc.,

Sunderland.

Chlorpromazine

SIR.—The report by Dr. J. R. Tasker (*Journal*, April 16, p. 950) of a fatal case of agranulocytosis, due to chlorpromazine, clearly puts the drug in a new category. My note (*Journal*, April 23, p. 1034) concerning the use of the drug in a few cases of severe and otherwise intractable vomiting of whooping-cough was by then already in the process of printing, and it invited the obvious rejoinder by Dr. J. H. Owen (*Journal*, May 7, p. 1155).

The fact remains that whooping-cough is at present in this country one of the chief killing diseases of childhood, with an impressive respiratory morbidity in later adult life. Chlorpromazine, as a drug powerfully effective in controlling the paroxysms and vomiting of this potentially lethal and disabling illness, is worthy of a controlled group trial in a selected number of severe cases as short-term therapy. The general practitioner will see but few cases of this type even in an epidemic. If this correspondence stimulates a more extensive investigation, it will have served its purpose.—I am, etc.,

London, S.E.13.

HOWARD REEVE.

Cyst Formation Following Hernia Repair

SIR.—It would be a pity to allow Mr. G. T. Watts's rather sweeping condemnation of the method of hernia repair by skin implant (*Journal*, May 7, p. 1156) to pass unchallenged. I have used the method now for 10 years, restricting it to difficult cases where a satisfactory repair from the tissues locally available appeared impossible—recurrent herniae, incisional herniae, about 100 cases in all—and have been very pleased with it. I have had no cysts, no serious sepsis, and few recurrences. In many of the cases the defect was large and the implant was the only bar to recurrence—for example, a man who had a hole blown in his abdominal wall by the discharge of a 12-bore sporting gun at a range of one yard (0.9 m.). In one case I had to reopen the abdomen three years after repairing a ventral hernia and was impressed by the thick shining tendon-like tissue which had replaced the skin implant.

The development of cysts implies that the skin has been placed under conditions which allow the survival of epithelial elements. I think the way to avoid this is to make sure that the skin is sutured everywhere under full tension in all directions, and especially that no little folds or loose corners are left at the edges of the implant. This is difficult and time-consuming and makes the operation a little tedious. I suspect that some of the cysts that occur may be due to modifications of the method introduced in a misguided attempt to make it easier or quicker. I am sure that if used only for the sort of case I have indicated, and carried out with care, the method will be found more successful than the alternatives of repair by fascia lata or by the implantation of some foreign body.—I am, etc.,

West Hartlepool.

Natural Childbirth

SIR.—This subject, whenever it is discussed, invariably discovers ardent adherents, equally passionate dissenters, and much confusion between antenatal exercises, antenatal preparation for pregnancy, labour, and the puerperium, and relaxation exercises. Would it not be wise to admit that there is little to be said for antenatal exercises in relieving the discomfort and shortening the duration of labour, but that they do prepare the woman for the very valuable exercises she will, if she is wise, practise after delivery?

Antenatal preparation has, of course, a great deal to be said in its favour, for the average primigravida is sublimely ignorant of the problems ahead, has probably acquired a great deal of horrific and incorrect information about the pangs of labour, the travail of childbirth, and so on from friends and relatives, who become surprisingly sadistic at such times, and is almost certainly scared about some aspect of pregnancy, in particular labour. Intelligent advice and correction on all these matters is obviously part of good antenatal preparation for natural childbirth, but what is "natural childbirth"? Presumably it means an unassisted delivery with no pain, at most only discomfort, and this question of pain is really what all the correspondence is about.

Dick Read's contribution to the problem is his reiteration of the well-known fact that tension begets pain, or, rather, lowers the pain threshold; and the essence of natural childbirth is preparation for a natural process. Not every woman can be assured of freedom from discomfort when she is having a baby any more than when she is having a tooth drilled. Her appreciation of pain can, however, be lowered by previous preparation, pain-relieving drugs, or frank anaesthesia, and the first may be enough or the last necessary. The experienced general practitioner is perfectly well aware of this, and when looking after a young primigravida he first gains her confidence, explains the problems she must face, and, in fact, with continuing supervision does everything to relieve tension and anxiety. When she goes into labour his steady voice and confident assurance are powerful and continuous aids towards "natural childbirth." Unknowingly he may induce a state bordering on hypnosis, and with some cases a completely painless labour follows. The essential factor is surely the confidence the woman has in her attendant, and obviously antenatal preparation must encourage it. Relaxation exercises, conducted by the one who will attend the woman in labour, are all to the good, and good relaxation between contractions may be ensured, but it is useless to promise every woman a labour free from pain, and analgesics should never be withheld even by the most enthusiastic "naturalists."

Perhaps if we remember the disservice done to women by referring to "pains," by the publicity given to such items as gas to relieve the anguish of labour for every woman, "trilene" now safe for midwives, and so on, and tried rationally to present the problem, and promote relaxation fairly and try to relieve tension, natural childbirth might and could be more commonly achieved, even in highly organized maternity units.—I am, etc.,

Pembury, Kent.

E. D. GRASBY.

Ante-partum Haemorrhage

SIR.—Mr. Frank Stabler's excellent paper on this subject (*Journal*, May 7, p. 1145) will be of great value to the general practitioner in the out-patient management of this condition. I would venture to disagree, however, with one of his recommendations. My colleagues in the pathological laboratory have impressed upon me the importance of providing a sample of blood for cross-matching before the administration of dextran or any of the other plasma substitutes; and in cases where the restoration of blood volume is necessary merely as a preliminary to blood transfusion we have found it is usually preferable to use normal saline rather than dextran. In domiciliary conditions it may sometimes be difficult to obtain a blood sample and then to put

up a dextran transfusion, and for that reason I would suggest that normal saline should be used as a stopgap measure. Although the saline is rapidly excreted from the circulation in normal circumstances, in the collapsed patient it seems to produce temporary improvement for about an hour, which should usually give sufficient time for a flying squad to reach the patient with blood.—I am, etc.,

Worcester.

J. A. CHALMERS.

Injection Technique

SIR,—I am grateful to Dr. John Richards (*Journal*, April 30, p. 1092) for drawing attention to the value of stretching the skin when giving injections. That is a point I omitted to mention (*Journal*, April 9, p. 909), and the benefit of which I had not fully appreciated. But surely, apart from assisting penetration of the skin by the needle, does it not supply a further illustration of Pavlov's dictum, that whether the stimulus be pain, touch, temperature, or stretching, the body can only respond to, or sense, one stimulus at one time? Stretching of the skin may be felt during an injection instead of either the touch of the needle or the pain of its prick. The more the skin is stretched, the stronger will be the stimulation of the stretch-sensing nerve endings, and the greater the chance that stretch-stimulation will override and prevent appreciation of pain-stimulation. A quickly given injection affords time for appreciation of one stimulus only—the dominating stimulus. Make sure when giving injections that the dominating stimulus is the pleasant one—stretch or touch—not the unpleasant one of pain.

Based on this principle, here is another simple but effective dodge. When injecting children in the arm, instruct the mother to stroke or rub the child's leg. The dominating stimulus observed by the child is the touch on the leg; the minor stimulus, pain in the arm, escapes its observation—provided the pain stimulus in the arm is reduced from a major to a minor stimulus by employing the procedure which I described in my letter.—I am, etc.,

K. D. SALZMANN.

Diphtheria Immunization in Guernsey

SIR,—In 1937 an epidemic of diphtheria started in the autumn, reached its peak in the winter and autumn of 1938, and subsided in 1939. In 1938 the Guernsey Board of Health proposed that there should be a law for the compulsory immunization of all children between 1 year of age (afterwards changed to 2 years) and 10 years of age, without any conscience clauses for exemption. Exemption could be obtained for ill-health, previous attack of diphtheria, or a negative Schick test, subsequently all children to come under the law on reaching the age of 2 years. The *Projet de Loi* was passed by the States of Guernsey in June, 1938; this was confirmed by Order in Council in March, 1939.

A campaign for voluntary immunization was carried out until the law came into force, and 40% of children under 15 years of age had been inoculated by January, 1939; by the end of 1939, 7,600 children (76%) had been inoculated. A large number over the age of 10 years had been immunized voluntarily. In 1940 approximately 8,000 children out of the 10,000 under 14 years of age were evacuated to Britain, and in June the island was occupied by the Germans. Supplies of A.P.T. and T.A.F. could no longer be obtained, and immunization was suspended until liberation in May, 1945. Then all children between the ages of 2 and 7, which covered the war years, not previously immunized, came under the compulsory law. Subsequently all children in Guernsey come under the law as they become 2 years of age, and in practice more than 95% of these children are immunized. Children not traced, children who come to live here after 2 years of age or exempted for ill health, account for the remainder. Free voluntary reinoculation is offered, and since 1945 approximately 40% have accepted this. The injections are carried out by the local medical practitioners. No serious ill effects from the injections have been reported.

When the law was proposed in 1938 there was considerable opposition, but since the war this has died down, and even individual objection on principle is very rare, although pressure has to be brought on a certain number of parents due to their inertia.

I give below the numbers of notified cases of diphtheria for the years 1897 to 1954, with the population at certain years.

Year	Notified Cases of Diphtheria	Population	Year	Notified Cases of Diphtheria	Population
1897	35	37,242	1927	33	
1898	122		1928	61

Grange, Guernsey.

ROWAN REVELL.

POINTS FROM LETTERS

Analgesia for Tooth Extraction

MR. HERBERT CAIGER (Banstead, Surrey) writes: The following simple method of securing almost painless extraction seems worth putting on record. A dentist in Kimberley used it when extracting a lower molar of mine some 60 years ago. . . . I used it very frequently for 20 years in country practice in South Africa, where dentists were not always available. Swabs of cotton-wool are soaked in a mixture of equal parts of tinct. aconit. and chloroform and applied, one on the inside and one on the outside of the gum, for about three-quarters of a minute, with a larger dry swab covering each. The numbing and burning sensation produced almost completely obliterates the pain of extraction. This simple technique . . . is available without an anaesthetist; it is less painful to the patients than injection into the gums, and probably less costly; and available when more modern methods are perhaps not so. If possible, the tinct. aconit. used for the mixture should be made with rectified spirit like that in the *Pharmacopoeia* of 1885—not like the later tincture made with weaker spirit and mixing less perfectly with the chloroform.

Speaking Up

DR. J. B. GURNEY-SMITH (Redhill) writes: I read with considerable interest the two recent letters on this subject and venture a few observations. I agree with Dr. J. Hamilton Mellroy (*Journal*, April 2, p. 853) in his plea for instruction in voice production for medical students. Comparatively few in our profession are blessed with polished articulation, as is apparent after attending a sectional discussion of any medical society. Medicine is one of the three great learned professions, and it is obvious that a doctor is liable to be involved in situations requiring public utterances from time to time. I feel no doctor, however learned he be, should be invited to deliver lectures and addresses unless he knows how to "deliver the goods." As an Anglican lay-reader, who frequently conducts services and preaches in churches of varying size and of diverse acoustic properties, I can vouch for my views. I would like to pass on two simple tips which are very important—that is, (1) look at the back row in speaking and then everyone in between will hear, (2) maintain an even volume of tone throughout the delivery. How many speakers and even clergy drop their voices at the ends of sentences and so one misses the last few words, which may be vital.

Obituary

JOHN LOWE, C.B.E., M.C., M.D., F.R.C.P.

Dr. John Lowe, medical secretary of the British Empire Leprosy Relief Association and honorary secretary of the International Leprosy Association, died suddenly in London on May 13.

Born at Handsworth, Birmingham, in 1898, John Lowe attended King Edward's School, Birmingham. After service in the first world war, during which he won the M.C. in France, he studied medicine at Birmingham University, graduating M.B., Ch.B. in 1922. A year later he went out to India as a medical missionary in the Leprosy Home at Dichpalli in the Nizam's Dominions. While there he obtained the M.D. for a thesis on malaria. In 1931 he joined the leprosy research department at the Calcutta School of Tropical Medicine, and became head of the department in 1935. For a number of years he acted as assistant editor, and later as editor, of the *Indian Medical Gazette*. During the second world war he was appointed professor of tropical medicine and director of the School of Tropical Medicine at Calcutta. For his work on leprosy he was awarded the Kaiser-i-Hind Gold Medal in 1944.

In 1946 Lowe retired from his appointments in India and in the following year, after obtaining the M.R.C.P., went out to Nigeria. He first worked under the British Empire Leprosy Relief Association, and later under the Nigerian Government at the Leprosy Research Centre at Uzuakoli in the Eastern Province. His energies were chiefly directed towards finding an improved form of treatment for leprosy. He was the first to publish satisfactory results with the oral administration of diamino-diphenyl sulphone. This was found to be effective, safe, and easily administered, while inexpensive enough to be used in wholesale mass treatment. It is now adopted as the standard treatment for leprosy in most countries throughout the world. Lowe published many papers, chiefly on leprosy. He was a clear thinker, writer, and speaker.

Lowe was appointed C.B.E. in 1953, and in spite of impaired health he continued to work in Nigeria till he came home in 1954. In that year he was elected F.R.C.P. and was appointed medical secretary of the British Empire Leprosy Relief Association, and undertook also the honorary secretaryship of the International Leprosy Association. But his work was hampered by repeated heart attacks, and in the end it was from one of these he died. He is survived by a widow and two sons, both medical men.

E. M. writes: Dr. Lowe has added much to our knowledge of leprosy, and sufferers from that disease in India, Africa, and indeed throughout the world owe him a debt of gratitude. His death is a sore loss in the field of leprosy research, a field in which there are all too few first-class workers. Low had the true scientific spirit—the desire for truth and the power of self-criticism. While not seeking undue credit for himself, he was always quick to give credit to others whom he considered worthy. In research he was a good colleague to work with. Though sometimes deliberate in getting off the mark, he lost no time once he got going, and threw himself with energy and thoroughness into whatever he had undertaken.

Sir ARTHUR MACNULTY writes: May I be allowed to pay a tribute to my friend and colleague Dr. John Lowe? He was well known as a specialist in tropical diseases, his work in this field at the Calcutta School of Tropical Medicine being outstanding. He did much research in leprosy, and

from 1947 to 1954 was in charge of the research unit of the leprosy settlement at Uzuakoli, Nigeria. The British Empire Leprosy Relief Association were glad to welcome him back as their medical secretary, and as chairman of the medical committee of the association I found his counsel and help invaluable. He had done much research on the treatment of leprosy by sulphonamides, and was investigating the use of B.C.G. in prophylaxis of the disease. In spite of ill-health, he battled on, working indefatigably in the campaign against leprosy, although he knew the price might be his own life. I often exhorted him to rest and take more care of himself. His reply invariably was that he preferred to die fighting. He had his wish, and, after a noble and well-spent life, no one could have been better prepared when the summons came to leave this world.

ETHEL CASSIE, O.B.E., M.D., D.P.H.

Dr. Ethel Cassie, who died at her home at Freeland, Oxfordshire, on May 7, was one of the architects of the maternal and child health services of the country. She was 72 years of age. She was best known as the senior medical officer for maternity and child welfare at Birmingham, but her earlier work will be remembered also in Scotland, where she opened the first child welfare centres in Edinburgh more than 40 years ago. Her 22 years in Birmingham brought to the services of that city a more than national repute for the high quality of the administration and practice of maternal and child health work.

Ethel Wiseman was born on September 3, 1882, at Dalhousie, Punjab, India, the eldest child of Frederick Wiseman, of the Indian Civil Service. Her father's early decision that his first child should become a doctor remained unaltered when the first child was a girl, and Ethel Wiseman entered the Edinburgh School of Medicine for Women in 1901. She graduated M.B., Ch.B. in 1906, obtaining the Dorothy Gilfillan Prize as the most distinguished woman student in the university examination, and took the D.P.H. of the Scottish Royal Colleges in 1907. She married Alexander Cassie, a science tutor, in 1907, but the marriage was not finally successful and they parted in 1920. Alexander Cassie died in 1933. Ethel Cassie commenced general practice in Edinburgh in 1908 and was appointed visiting physician to the Hospital and Dispensary for Women and Children. She became medical officer of health of the county and boroughs of Clackmannanshire in 1915 (substituting for the medical officer of health, who was on war service) and assistant medical officer for child welfare in Leith in 1918. In 1921 she was appointed senior medical officer for maternity and child welfare in Birmingham, first under Sir John Robertson and later under Dr. H. P. Newsholme, and continued in this post until her retirement for health reasons in 1943. She proceeded to the M.D. in 1923, and in 1926 gained the Jessie Macgregor Prize for Medical Women, awarded by the Royal College of Physicians of Edinburgh for "the best record of original work in the science of medicine."

It was the quality of originality that made Ethel Cassie outstanding in health administration. She was not one to wait for a lead from others, but rather to give the lead and explore new fields. It was on her advice that the first premature baby unit in this country was opened at the Sorrento Maternity Home in Birmingham 24 years ago. Her understanding of the needs and difficulties of foster children and illegitimate children led to the adoption of special schemes for their care in Birmingham many years before their needs were high-lighted by

the Curtis Committee. Much of her pioneer work has later been embodied in Government circulars to local authorities. She published in 1929 a textbook on maternity and child welfare and contributed also to other publications, but she was not prolific either as a writer or on the platform, preferring always to translate her thought into action rather than words. Her administrative ability and wisdom, coupled with a lively knowledge of clinical medicine, brought her wider responsibilities than local authority work. She was a member of the Departmental Committee on Maternal Mortality appointed by the Minister of Health in 1928, which issued its classic reports in 1930 and 1932. She was appointed O.B.E. in 1941, and in the following year became a member of the Minister of Health's Advisory Committee on Mothers and Young Children. In 1944 she was appointed a member of the Royal Commission on Population, and those who knew her well would discern her influence in its report issued in 1949. Later she took part in initiating a Ministry of Health survey of the growth of infants and young children, but increasing ill-health compelled her to relinquish active work in 1951. Her death will recall to many how much the present high standard of maternal and child health in this country owes to her, not only through her leadership in local authority work but through the stimulus of her constructive thought over a wide field. There was indeed truth in the ancient form of words appointing her—"our trusty and well-beloved Ethel Cassie"—to the Royal Commission in 1944, "reposing great trust and confidence in your knowledge and ability."—K. M. H.

Dr. GEORGIE I. BRODIE writes: With the death of Dr. Ethel Cassie there passes one of the most outstanding and colourful personalities in the field of maternity and child welfare. As her deputy in Birmingham I was privileged to learn from and to be inspired by her. From near and far her pioneer work in the sphere of maternity and child welfare was renowned. Closely working with her, I was daily aware of the bases of that renown. Hers was the mind of a builder, and to the edifice she constructed in Birmingham she brought many talents, not the least of which were a clarity of mind, a singleness of purpose, and a capacity to imbue others with enthusiasm for improving the lot of mothers and children. All workers in the maternity and child welfare field owe much to her for making a model administrative service, which has been copied here and abroad, and rarely improved upon. To her ability as a medical officer Dr. Cassie added a wide range of interests. She was recognized as a connoisseur of old furniture and china. She travelled widely, was a voracious reader, and an interesting conversationalist. Her charm was never more evident than in her own home, where she entertained so delightfully, and those of us who were privileged to enjoy her friendship and hospitality will for long feel the loss of a stimulating and endearing personality. The maternity and child welfare service will always owe a debt of gratitude to Dr. Cassie for her outstanding ability and pioneer work.

J. R. HUTCHINSON, M.D., D.P.H.

Dr. J. R. Hutchinson died on May 6 at Chalfont St. Giles, Buckinghamshire, aged 75. He had retired from the Ministry of Health in 1947 after 36 years' service in the epidemiological divisions of the Local Government Board and the Ministry of Health, of which he became a senior medical officer.

James Randal Hutchinson studied medicine at Owens College, Manchester, and graduated M.B., Ch.B. with honours in 1902. He was awarded the Bradley scholarship for clinical surgery, but was soon attracted to preventive medicine, and took the D.P.H.

of Manchester in 1904. His first contribution to public-health literature consisted of papers on the eyesight of Blackburn schoolchildren, which were published in the medical officer of health's annual report for 1907. In 1908 he became senior assistant to that great character Dr. James Niven, medical officer of health of Manchester, and two years later was himself appointed medical officer of health of Wigan. These were busy times and places for a man interested in communicable diseases. He published reports on outbreaks of scarlet fever at Crumpsall in 1909, typhoid from ice-cream in Manchester in 1910, and smallpox in Wigan in 1911. Throughout the period he was intimately concerned with the clinical care of the infectious diseases and particularly tuberculosis, and in 1911 he proceeded M.D., his thesis having dealt with "the presence of typhoid bacilli in enteric fever and afterwards." In this connexion it is interesting to note that in 1943 he published in the *British Medical Journal* a paper on the value of phage typing in the investigation of outbreaks of paratyphoid fever.

Hutchinson was in his 32nd year when, in 1911, he joined the medical inspectorate of the Local Government Board, and he was responsible for several of the reports to the Board which are classic examples of the descriptive epidemiology of that period. He became a master of the subject of the local authority's responsibility for the control of infectious diseases and was typical of that small but strong body of local-government-trained men who provided the backbone of the newly formed Ministry of Health, in which he rose to the post of senior medical officer. He had a fine gift of appraisal and criticism and was a trenchant critic of loose theorizing, sloppy argument, and tendentious conclusions. His fastidious mind was well suited to the pursuit of epidemiology and was matched by his personal characteristics in a remarkable way. His very many friends in the public health service will remember this precision—how neatly the bows on his bespoke shoes were tied and how the bowler hat gave place to the boater on the same day in May each year; how his car was always spotless, and there was rarely a weed in his lawn. These qualities made him a challenging teacher but also a comfortable and loyal companion. One knew where one was with Randal Hutchinson and could rely on his facts and on the soundness of his judgment. Perhaps his most characteristic work was the "Report of the Committee on Vaccination, 1926" which remains as a memorial. His swan song was a historical note on "The Prevention of Smallpox in England," published as an appendix to the Chief Medical Officer's Report, 1946.

Dr. Hutchinson was married and is survived by his widow, to whom we extend deep sympathy in her loss.—W. H. B.

CORNELIUS A. GRIFFITHS, F.R.C.S.

With the death of Mr. Cornelius A. Griffiths on May 7 Cardiff has lost a notable surgeon of the old school. He was 90 years of age. Cornelius Albert Griffiths was born at Merthyr in 1865. He studied medicine at Bristol, where he gained the Martyn Memorial Scholarship in Pathology in 1888 and the Sanders Scholarship in 1889, and at St. Bartholomew's Hospital, London. With the foundation of the University of Bristol still many years ahead and the University of Wales not yet empowered to grant medical degrees, he sat the London Conjoint examination and qualified

in 1889. He then held house appointments at Bristol General Hospital, and from 1890 to 1893 was medical tutor in the Bristol Medical School. In the latter year he obtained the F.R.C.S., and took the post of resident medical officer at the old Swansea General and Eye Hospital. In 1894 he settled at Cardiff and a few years later was appointed honorary assistant surgeon to the Cardiff Infirmary, and surgeon and honorary secretary of the Cardiff branch of the Surgical Aid Society. Later, he became honorary consulting surgeon to the Porth and Maesteg cottage hospitals. During the first world war he worked as a surgeon at the 3rd Western General Hospital, with the rank of major in the R.A.M.C., and after the war he became honorary surgeon to King Edward VII Hospital, now the Cardiff Royal Infirmary. He was a member of the British Medical Association for 65 years, and a justice of the peace for Cardiff for over 30 years.

We are indebted to Professor LAMBERT ROGERS for the following appreciation:

At 90 years of age the death of Mr. Cornelius Griffiths removes from us the last survivor of a little group of octogenarian and contemporary members of the consultant staff of the Cardiff Royal Infirmary. In the last few years they have dropped away one by one: first Mr. Geary Grant, consulting surgeon, then Dr. Cyril Lewis, consulting physician, and Sir Ewen Maclean, at one time President of the Royal College of Obstetricians and Gynaecologists, and professor of obstetrics and gynaecology, and now Mr. Cornelius Griffiths, who outlived them all and who had been a consulting surgeon for many years. Often his slightly stooping, spare figure with its slow, deliberate, and measured tread was to be seen walking along one of the main streets of Cardiff, stick in hand, cigar in mouth, and a soft round hat on his head. Recently his memory had been failing and he would not always recognize whoever addressed him; and more recently still he had been missing from his accustomed haunts and confined to his house. His actions were always deliberate, unhurried, and gentle, as was his operating, for he was a neat, bloodless, precise, and careful operator whom it was a pleasure to watch at work. While he was no great contributor to the literature of his subject, Cornelius Griffiths was a painstaking, careful practitioner of it and was one of that great band of provincial surgeons in this country who, true to high ideals, have done so much to enhance the prestige of British surgery and the high standard of surgical work in the hospitals of our land. His death, like his living and all that he did, appears to have been gentle and dignified. He was revered and respected in Cardiff and South Wales, where he had an extensive consulting practice. He had been retired for so many years that the younger surgeons of to-day knew him not.

A. J. WILSON, M.D., F.R.C.P.Ed.

Dr. A. J. Wilson, who died suddenly on April 30 at the age of 56, was a well-known physician in the Midlands. At the time of his death he was the senior honorary physician and honorary physician in charge of the electrocardiographic unit at the Coventry and Warwickshire Hospital, Coventry.

Arthur James Wilson was born at Whitehaven, Cumberland, on April 3, 1899. From St. Joseph's College, Dumfries, he entered Edinburgh University to study medicine at the age of 16, graduating M.B., Ch.B., with first-class honours, in 1921. A brilliant student, he acquired many prizes and distinctions, including the Wightman Prize in clinical medicine in 1920 and the Pattison Prize in clinical surgery in 1921. He proceeded to the M.D., with honours, in 1928. Obtaining the M.R.C.P.Ed. in 1936, he was elected a Fellow of the

College four years later. After graduation Wilson held appointments as house-physician at the Coventry and Warwickshire Hospital and as senior house-surgeon at Salford Royal Hospital, before returning to Coventry to become honorary anaesthetist at the Coventry and Warwickshire Hospital. For a short period he was engaged in general practice in partnership with the late Dr. W. H. Lowman. In 1927 he was appointed assistant physician to the Coventry and Warwickshire Hospital, and was made honorary physician in 1929. He was also honorary physician to the Manor Hospital, Nuneaton, for many years. Always ready to take an active part in the local affairs of the British Medical Association, he often showed cases of clinical interest to meetings of the Coventry Division, of which he was honorary secretary in 1927-8. Besides being a member of the board of management of the Coventry and Warwickshire Hospital for many years, and chairman in 1931-2, he also served as vice-chairman of the medical committee of the hospital from 1944 to 1946, being chairman in 1946-7.

Dr. C. S. APPELYARD writes: As one of his oldest friends and a fellow student, I would like, on behalf of my medical colleagues, to give our appreciation of the well-known "A.J.," as he was affectionately called. His services were unrelenting to his hospital and to his patients. We of the profession owe him a great debt of gratitude for his kindness to and care of ourselves, our wives, and families. Himself a bachelor, he was a man of unassuming character, devoted entirely to his profession. He had been working for 16 years suffering from a painful affliction which was much graver than any of us realized. He died in harness at the age of 56 as we had always known him, the same unassuming and very gallant gentleman. His loss will be lamented by his many patients and old friends.

HARRY J. RAE, M.C., M.B., D.P.H.

Dr. Harry J. Rae, who died on May 8, was until 1952 medical officer of health of the then joint public health service of the North-East of Scotland. He was 69 years of age.

Harry James Rae was born at Aberdeen on January 30, 1886, and received both his scholastic and university education in that city. He obtained the M.A. in 1907 and completed the medical curriculum, with honours, in 1911. After holding various hospital appointments and undertaking the course for the Diploma in Public Health he was appointed in 1914 to a vacancy in the school medical service of the County of Aberdeenshire. In 1915 he became the chief tuberculosis officer for that county, but shortly afterwards joined the R.A.M.C. and served in the first world war with a field ambulance unit in the Middle East. For war service he was awarded the Military Cross. On demobilization he returned to the duties of tuberculosis officer, which post he held until he became, in 1925, medical officer of health for the county. The medical officer of health of the city of Aberdeen was then the late Dr. J. Parlange Kinloch, and a partnership between city and county was established with the object of avoiding redundancy in all health service projects. Facilities available in the city health department became available for the county authority, and particularly so when legislation was anticipated and the poor law hospitals in the city of Aberdeen were taken over by the city council. When Dr. Parlange Kinloch was appointed chief medical officer in the Department of Health for Scotland in 1928,

Rae was appointed medical officer of health to the City of Aberdeen and was at the same time made head of the public health department of Aberdeen University. In view of the increased facilities which had become available the county council, in order to maintain the liaison, made an approach to the city council, and Rae was maintained in office as the county medical officer of health. In a short time a similar arrangement was made with the county council of Kincardineshire, and a joint public health service for the North-East of Scotland became a reality. It was due to Rae's untiring efforts that this project was so successful. To write reports for, and to attend the meetings of, no less than three major local authorities obviously required a man of great capacity and initiative. The pattern of the joint north-eastern public health arrangement was examined by deputations from various health authorities in other parts of Scotland and England, and many were the laudatory comments on such an arrangement.

Despite his immense amount of local authority work, Rae took a most active interest in the teaching of the undergraduates and of the postgraduates for the Diploma in Public Health. He was an active member of the Scottish branch of the Society of Medical Officers of Health and the Sanitary Association for Scotland. With the introduction of the National Health Service (Scotland) Act, 1947, the administrative control of hospitals was removed from the local authorities, but this seemed in no way to lighten the duties of the medical officer of health, though it did lessen the need for a joint public health service. In appreciation of his many years of service Rae was allowed to continue in office for a year after he was due to retire. He was appointed an Honorary Physician to King George VI in 1950, and in 1952-3 he was an Honorary Physician to the Queen. In 1953 he became a city councillor. When the British Medical Association held its Annual Meeting at Aberdeen in 1939 he served as a vice-president of the Section of Public Health and Hygiene.

He is survived by his wife, two sons, Captain Harry J. Rae, Royal Signals, and Dr. William Rae, of Aberdeen, and two daughters, Mrs. Agnes Clark, of Coupar Angus, and Dr. Isobel Margetts, of Nottingham.

H. A. MACEWEN, O.B.E., M.B., D.P.H.

Dr. H. A. Macewen, formerly a senior medical officer of the Ministry of Health, died at his home at Innellan, Argyllshire, on April 17 at the age of 74.

Hugh Allan Macewen was born on May 21, 1880, the second son of the late Sir William Macewen, F.R.S., Regius Professor of Surgery in Glasgow University, and a Past President of the British Medical Association. Hugh Macewen was educated at Glasgow Academy and at Glasgow University, where he graduated M.B., Ch.B. in 1905. In the following year he took both the Cambridge D.P.H. and the D.P.H. of the English Royal Colleges. After acting as resident medical officer at Bethesda Hospital, Hamburg, and in several Glasgow fever hospitals, he decided on a career in administrative medicine, becoming assistant medical officer of health for Stirlingshire and Dunbartonshire. A brief tenure of a similar post in Cumberland followed, and then, in 1910, he became medical officer of health for Fife and Kinross. In 1911 he was appointed medical inspector for the Local Government Board, London, and in 1920 he joined the staff of the Ministry of Health as medical officer, proceeding later in the same year to deputy senior medical officer and in 1924 to senior

medical officer, a post which he filled with distinction until his retirement in 1941. During this period at the Ministry, especially prior to and during the early part of the second world war, he did very valuable and pioneer administrative work, about which an appreciative article was printed in the *Medical Officer* in 1941. From 1941 to 1942 he acted as temporary medical superintendent of Ballochyle emergency hospital, Ayrshire. During the course of his career he wrote a number of papers on public health subjects, and the first edition of his useful book on *Food Inspection* was published in 1910, the year in which he was elected a Fellow of the Royal Society of Edinburgh.

Macewen was a kindly man, rather shy and retiring, but having a courteous and friendly disposition, which made him a charming host. His home at Innellan overlooked a beautiful stretch of the Firth of Clyde, which gave him much interest and pleasure in his later years. Many people, especially the young, found him a wise counsellor. He set himself high standards and was essentially upright and extremely conscientious. In 1925 he married Dr. Barbara Cunningham, to whom he was ever devoted and whose admirable care sustained him during his last distressing illness.—H. B. K.

The death occurred at Bishop Auckland on March 4 of Dr. D. B. CAMA, who had practised in the county of Durham for many years. Dhun Boman Cama was born in Bombay on April 27, 1883, a member of a distinguished Parsee family, and received his early education in Bombay. He then studied medicine in Edinburgh, taking the Scottish triple qualification in 1911. After gaining early experience in general practice he settled at Witton Park, Co. Durham, in 1917, and in 1932 moved to Bishop Auckland, where he soon won the affection of his patients. He is survived by his widow, a daughter, and two sons. His elder son, Dr. Leonard Cama, carries on the medical practice.

J. C. writes: Strenuous work during the second world war severely affected Dr. Cama's health, but, combating ill-health with great fortitude, he continued in practice until 1951. His work exemplified the highest traditions of medical practice, and his skill, tireless efforts, and great kindness won the affection of all his patients. A man of few outside interests, he most enjoyed the company of his family and his friends, and his hospitality was renowned.

Lieutenant-Colonel H. G. L. HAYNES, who had lived and worked in Brentwood since 1920, died there on April 1, aged 77. Horace Guy Lankester Haynes was born at Evesham on June 18, 1877, and from the Grammar School there he entered Epsom College with a scholarship. From Downing College, Cambridge, where he was an exhibitioner, he went on to the Westminster Hospital, qualifying in 1903. After holding house appointments at the Westminster Hospital and the Children's Hospital, Shadwell, he was in general practice at Marksfield, Leicestershire, from 1908 until the outbreak of war in 1914. He served first in the 84th Field Ambulance and later commanded with great distinction the 2/2 London Field Ambulance, 56th Division. He was a keen Territorial and in 1932 was awarded the Territorial Decoration. Lieutenant-Colonel Haynes settled in Brentwood in 1920, where he was a prominent citizen until his death. For 25 years he was medical superintendent of Middleton Hall, a private mental home in Brentwood. During this time he not only managed the home, but was always willing to give his expert opinion and advice to the general practitioners of the town. It was during those years that he took a keen interest in the work of the British Medical Association, being president of the Essex Branch in 1926-7 and chairman of the Mid-Essex Division from 1930 to 1933. He attended a number of Annual Meetings as the representative of his Division. He also held office in

the Romford Medical Society and the Royal Medico-Psychological Association, of which he was an honorary member. During the last war he was appointed chairman of the Ministry of Labour and National Service Medical Board, and he continued to serve in that capacity until early this year.

M.R. writes: Colonel Haynes was a quiet, retiring man, difficult to know well, and slow to make friends. To those who had his friendship he was a delightful companion, full of reminiscences, with a puckish sense of humour. He was keenly interested in sport, especially rugby and cricket, and had an astounding memory for batting and bowling averages, and of famous victories and defeats of the years gone by. He was a regular habitué of Twickenham and Lord's, and enjoyed taking his friends with him and regaling them with his pungent comments on the game and his memories of the "good old days." Colonel Haynes had four sons, whose careers in medicine and the Services he watched with great pride and satisfaction. The loss of his youngest son in the Navy during the last war was a blow from which he never completely recovered. To his widow and three surviving sons his friends extend their sympathy.

Colonel ALFRED SPITTELER, who served in the Indian Medical Service for some thirty years, died at Beckington, Somerset, on April 11 at the age of 82. Born on June 10, 1872, Alfred Spitteler graduated M.B., C.M. at Madras University in 1897 before coming to London to continue his medical studies at University College Hospital. He took the D.P.H. of the English Royal Colleges in 1900 and the London Conjoint diploma five years later. Having decided to join the Indian Medical Service, he entered Netley as a probationer in March, 1900, and later in the same year was posted to India, where he served as medical officer to a number of regiments, and also as a specialist in public health. From 1902-4 he was on active service in Somaliland, being awarded the East Africa General Service medal with the Somaliland clasp. He left India for Mesopotamia early in 1915 as a member of a detachment of the Indian Expeditionary Force, and was mentioned in dispatches in the following year for distinguished service in the field. Later he served in Kurdistan, and in 1920 was again mentioned in dispatches, and in the same year he was appointed O.B.E. and promoted to lieutenant-colonel. After a further period of service in India he was for a few months in 1927 A.D.M.S. and civil administrator at Aden, being granted the brevet rank of colonel. Back in India in the following year, he retired from the I.M.S. in 1929, and came to England to settle in the West Country. For several years he was chairman of the Callington branch of the British Legion and was county commissioner for Cornwall of the Boy Scouts. During the second world war, from 1943 to 1945, he was medical officer to troops and officer commanding a camp reception station at Ilfracombe. He is survived by his widow, formerly Miss Louisa E. Dore, whom he married in 1904, and by whom he had two sons.

Mr. K. B. BELLWOOD, consulting surgeon to the ear, nose, and throat department of Bedford General Hospital, died suddenly on April 17 at his home at Bedford. He was 64 years of age. Kenneth Benson Bellwood was born at Middlesbrough on October 21, 1890, and from Sir William Turner's School, Redcar, he entered Pembroke College, Cambridge, in 1909, taking the Natural Sciences Tripos in 1912. Going on to St. Bartholomew's Hospital with a Shuter clinical scholarship, he qualified M.R.C.S., L.R.C.P. in 1914, graduating M.B., B.Chir. three years later. After qualification he held the appointment of midwifery assistant at St. Bartholomew's Hospital before entering the Royal Navy for service in the first world war. He was appointed O.B.E. in 1919 for his contribution to the war effort, and in the same year became surgeon in charge of the ear, nose, and throat department of the Royal Naval Hospital, Chatham. In the following year, on his return to civilian life, he became house-surgeon to the ear, nose, and throat depart-

ment at St. Bartholomew's. In 1921 he took the F.R.C.S. and for a short time held the appointment of surgeon to the Seamen's Hospital Society at Albert Dock Hospital. Deciding to enter general practice, he went into partnership with the late Mr. W. H. Miller at Bedford, where he began to specialize as an oto-rhino-laryngologist. In 1930 he was appointed ear, nose, and throat surgeon to the Bedford County Hospital, where he built up the excellent department that exists to-day. Bellwood never spared himself, and the strain under which he worked may have influenced the course of the illness from which he eventually died. He was appointed consultant surgeon in 1948. Still in harness when his last relapse occurred a few weeks ago, he appeared to be making good progress towards recovery when he died quite suddenly and without distress. His death has saddened his many friends and old patients, who loved him for his modesty and kindness. His colleagues held him in great respect, and in 1938 he was elected president of the Bedfordshire Branch of the B.M.A. He married Miss Florence V. Cooper in 1921, and she survives him together with two daughters. A great family man, he was never happier than when surrounded by his children and grandchildren.

Dr. J. MEADMORE CROCKER, who was in practice at Bingley, Yorkshire, for over 50 years, died at the home of his daughter at Eldwick, near Bingley, on April 14, five days after his 89th birthday. James Meadmore Crocker was born at Wetherby, Yorkshire, on April 9, 1866, the eldest son of Dr. James Crocker, and studied medicine at Leeds, qualifying M.R.C.S., L.R.C.P. in 1890. He then entered into partnership with his father, who had settled at Bingley in 1871, and took over the whole of the practice when Dr. James Crocker died in 1903. After 46 years of devoted service to his patients he retired from general practice in 1936. He held many local medical appointments, including those of police surgeon, factory surgeon, public assistance medical officer, and public vaccinator. For nearly half a century he was medical officer to the Morton Banks Infectious Diseases Hospital at Keighley until he relinquished the appointment in 1948, and he had been a member of the honorary medical staff of the Bingley Hospital since its foundation in 1891. During the first world war he was in charge of the medical side of Morton Banks Hospital, with the rank of major in the R.A.M.C. He came out of retirement on the outbreak of the second world war in 1939 to take over his old practice when his successor, Dr. W. A. Lochhead, was called up for service in the R.A.M.C. There were no trams or omnibuses at Bingley when Dr. Meadmore Crocker first started in practice there, and his visits to patients were made on horseback and later in a gig, until in 1907 he became the first doctor in the town to own and drive a motor-car. He is survived by one son and one daughter.

Dr. P. C. RAIMENT, who died suddenly at Cheltenham on April 20 at the age of 74, had had an interesting career. Born on August 24, 1880, Percy Charles Raiment received his medical training at the London Hospital Medical College, qualifying M.R.C.S., L.R.C.P. in 1908. After holding the appointments of assistant house-surgeon at Huddersfield Royal Infirmary and senior house-surgeon at the East Suffolk and Ipswich Hospital, he settled in practice at Brook Green, in West London, in 1910. Becoming a member of the British Medical Association in the following year, he soon took an active part in its affairs. He was assistant honorary secretary of the Kensington Division from 1912 to 1915, and one of the representatives of the Division at the Annual Representative Meetings held at Liverpool in 1912 and at Aberdeen in 1914. The first world war, in which he served as a captain in the R.A.M.C. attached to the 6th South Lancashire Regiment, provided a dividing point in his career. Entering the R.A.M.C. from general practice, he returned to civilian life as a student once again, this time at Oxford. He entered University

College, and matriculated in 1919 at the age of 38. Two years later he obtained the B.A., with a first class in the Honours School of Natural Science, and in 1924 he proceeded to the M.A. In 1923 he was appointed senior demonstrator of biochemistry at Oxford, and in the same year he published *A Laboratory Handbook of Biochemistry*, a work written jointly with Mr. G. L. Peskett. Dr. Raiment was awarded a research scholarship by the British Medical Association in 1925-6 for work on the significance of the changes in the inorganic radicals of the blood in cases of chronic rheumatism, gout, and allied diseases, the research scholarship being renewed for 1926-7. He left England in 1928 on his appointment as professor of physiology in Cairo University, but he held the appointment for only two or three years, and on his return to England he retired from medical work.

Dr. J. F. RAMSDEN died at his home at Alverstoke, Hampshire, on May 1 after a long illness. He was 40 years of age. John Fletcher Ramsden was born on June 14, 1914, and was educated at Berkhamsted School and at Birmingham University, where he graduated M.B., Ch.B. in 1939. He then became assistant to Dr. Peter Dawes, at Feckenham, Worcestershire, but left there to serve as a surgeon-lieutenant in the R.N.V.R. during the second world war. In 1946 he became senior house-surgeon at the North Staffordshire Infirmary, Stoke-on-Trent, and in the following year joined Drs. N. L. Russell and D. C. Mackenzie in general practice at Gosport. In spite of illness in 1950, he carried on bravely for another three years, but his state of health caused him to give up work entirely in 1953. He had a most attractive personality and was beloved by his patients and by everyone with whom he came into contact. He is survived by a widow and two children, both of school age.

L. H. G. M. writes: Those of us who studied with John Ramsden in the nineteen-thirties at the Birmingham Medical School knew him to have a terrific sense of fun. Although he had great wit, he coupled this with a nature so kind and generous that he had scores of friends. On May 1 Rammy died, just short of his 41st birthday. His illness had lasted five years, and the courage he showed throughout it was seen at its best in the latter months, when his sense of humour remained unchanged and a visit to his sick-room filled one with admiration and humility. Such courage in adversity was greatness indeed. He leaves a widow and two children, to whom our deepest sympathies go in their grief.

Dr. W. NUNAN, who was well known in Bombay until his retirement from practice there in 1935, died in London on May 3 aged 75. William Nunan was born in Limerick on January 26, 1880, and was educated in Limerick and at Clongowes Wood College, Kildare. He studied medicine at Trinity College, Dublin, graduating M.B., B.Ch., B.A.O. in 1905, and proceeding to the M.D. in the following year. His brother, Sir Joseph Nunan, K.C., was at Trinity College at the same time. After some years of practice in an Irish country town Dr. Nunan went to Bombay, where he was appointed police surgeon in 1911 and coroner four years afterwards. He was also administrative medical officer of the Bombay Port Trust. Always interested in medico-legal matters, Dr. Nunan was appointed professor of medical jurisprudence and toxicology at the Grant Medical College, Bombay, in 1919, and he was an examiner in his subject to the University of Bombay. Though he led a busy life as physician and teacher, he found time to take a very active part in the life of the community, and in 1932 he was awarded the Kaiser-i-Hind medal for social and general work in India. When he returned to this country in 1935 Dr. Nunan became interested in psychiatry, and from 1946 to 1948 he worked as a psychiatric specialist in the Ministry of Pensions in Southampton and Portsmouth. Later he was appointed psychotherapist at the Tavistock Clinic. He was the author of a book entitled *Lectures in Medical Jurisprudence*, and he wrote a number of articles on psychiatric subjects, particularly on the use of suggestion as a remedial agent.

H. S. K. L. and H. G. D. write: The death of Dr. R. D. MOORE, whose obituary was printed in the *Journal* of April 30 (p. 1099), has brought to an end a life which exemplified all that was best in rural medical practice during the first part of this century. Churchdown was a small village when he settled there in 1900. Having acquired the nucleus of a practice from a doctor who had up to that time regularly visited the village from a near-by town, he was one of the first to realize the value of a motor-car to a rural practitioner. He quickly built up a practice extending over a very wide area. His stories of those pioneering days were most amusing: to stop at the foot of the Cotswolds to apply a handful of road dust to the belt drive of his car was a commonplace. He retired from practice in 1934, but continued to live in, and to take a keen interest in, the affairs of the village in which he had worked for so long. During the second world war he contrived to join the Home Guard as a combatant, again with the rank of major, and later he helped one of his former partners as medical officer to a rocket anti-aircraft battery. He remained at Churchdown until, because of failing sight, he decided to settle with his daughter and son-in-law in Kent, where he continued to make his life useful in spite of increasing blindness. During his early days he was a keen and good golfer, but cricket was the game he loved most throughout his life. He missed few county matches, and his holidays were usually found to coincide with Test matches. Few doctors can have left behind them so much affection among both patients and colleagues, an affection well earned. No effort was too great where the good of the sick was concerned, and he frequently drove patients to the hospital out-patient department in his car, remaining with them throughout the consultation to lessen their apprehension, and taking them home afterwards. His cheerfulness and constant optimism were a great inspiration to all who knew him, but his affable manner concealed a remarkable ability to recognize serious illness when he encountered it. It is still said of him that his presence alone could effect a cure, and his memory is cherished in many a home.

Mr. J. F. BALLARD, director of the Boston Medical Library, who died on May 15 aged 76, was well known to medical librarians in this country. James Francis Ballard joined the staff of the Boston Medical Library as a messenger boy in 1892 and became assistant librarian (the highest paid position in the library) in 1909. In 1927 the title of his post was changed to director. Ballard was actively interested in library affairs all his life. In 1937-8 he was president of the (American) Medical Library Association. He devised the modern classification of the Boston Medical Library (third edition, 1948) now used in a number of medical libraries throughout the world and translated into Japanese and Spanish. An authority on early medical literature, he wrote the *Catalogue of the Medieval and Renaissance Manuscripts and Incunabula in the Boston Medical Library* (Boston, 1944), a scholarly record of one of the best collections of its kind. In 1920 Ballard was sent abroad by the China Board of the Rockefeller Foundation to purchase a medical library for Peking Medical School, and on his return he was commissioned to establish a medical library for the new University of Rochester School of Medicine. At the time of his death he was consultant to several medical libraries, including the Armed Forces Medical Library, Washington. In 1942, when he had completed 50 years' service, a life-sized head-and-shoulders plaque of Ballard was unveiled in Boston Medical Library. During his service of over 62 years this medical library has grown from modest beginnings to become the third largest in the United States. James Ballard was a most genial person, who had many friends all over the world. Those who had the pleasure of meeting him at the first International Congress on Medical Librarianship in London, 1953, will be particularly sorry to learn of his passing.

Medico-Legal

FATAL REACTION TO PENICILLIN

Another death from allergic shock due to penicillin was the subject of a coroner's inquest on April 22. The case before the Westminster coroner, Dr. H. N. Stafford, was of a woman, aged 72, who was receiving penicillin treatment for furunculosis of the left hand. She had previously received several injections of penicillin, and on April 19 her medical practitioner, Dr. G. K. C. Rettie, gave her an injection of crystalline penicillin, 500,000 units, into the left deltoid muscle. About five minutes afterwards the patient became flushed and had difficulty in getting her breath. In spite of remedial measures she died within the next five minutes. Dr. Keith Simpson, consultant pathologist, carried out the post-mortem examination. He reported that a vein in the arm was transfixed during the injection, and this would result in a reaction to penicillin likely to be dangerous to life. There was no error of technique, but an unfortunate mishap. He gave the cause of death as allergic shock following penicillin injection. The coroner returned a verdict of death from misadventure.

CYANIDE POISONING OF BABY

The death of a baby from poisoning due to hydrocyanic acid gas and from dysentery was the subject of an inquest on March 1 before the Oldham Deputy Coroner, Mr. H. Armistead. According to the baby's father, Mr. A. E. Hall, the family moved house on February 25. Before moving into their new house their furniture was disinfected by the Oldham Housing Department. Among the furniture was a pram, and the baby, 9-month-old Alana Hall, was put in it at about 7 p.m. and quickly fell asleep. Later in the evening she became restless, but did not awaken. Between 9 and 10 p.m. Mr. Hall noticed that she was rather pale and had trouble with breathing. On admission soon afterwards to the Oldham Royal Infirmary she was found to be dead. During the last few days before death she had suffered from diarrhoea. After the furniture was moved into the new house, the family, with the exception of Mrs. Hall, appeared to be affected unpleasantly. Mr. Hall suffered from a severe headache, and their 2-year-old daughter was sick. The pet budgerigar died after being taken into the house.

Mrs. Hall stated that there was a small tear in the leather upholstery of the pram. The budgerigar had been in the same room as the baby.

Mr. H. Lancashire, a disinfectant employed by the Oldham Corporation, said that he loaded the large removal disinfecting van with furniture, including the pram, and drove it to the Croftbank cyanide operator. After the disinfecting had been carried out he drove it to the new house and helped to unload the contents. He gave the family the usual instructions about ventilation, "getting plenty of fresh air into the house, etc." Since this case written instructions were now being left with new tenants.

Mr. N. T. Pickering, employed by the Croftbank Chemical Company as a cyanide fumigation operator, said he carried out the fumigation by the pot generation method—a mixture of 4 lb. (1.8 kg.) of water, 3 lb. (1.4 kg.) of sulphuric acid, and 2 lb. (0.9 kg.) of sodium cyanide. When fumigation was complete, he carried out the usual tests after ventilating the van. As there was plenty of breeze he did not set the fan in operation inside the van. The tests indicated that the air was clear. In answer to a question from the coroner, he said the gas could get into the pram upholstery through any tear and then come out gradually.

Post-mortem examination was carried out by Dr. C. H. Adderley, group pathologist to the Oldham Hospitals. In his opinion the cause of death was dysentery caused by *Shigella sonnei* and hydrogen cyanide poisoning. Dr. J. B. Firth, director of the North-western Forensic Science Laboratory, found traces of cyanide in the organs of the dead body, and also in the body of the budgerigar.

A verdict of accidental death was returned.

The Services

A Supplement to the *London Gazette* has announced the following awards:

Second Clasp to the Territorial Efficiency Decoration.—Majors F. A. Edwards, T.D., and B. L. McQuillan, T.D., R.A.M.C.

First Clasp to the Territorial Efficiency Decoration.—Majors F. A. Edwards, T.D., B. L. McQuillan, T.D., and A. D. Stoker, T.D., and Captain H. W. Wykes, R.A.M.C.

Territorial Efficiency Decoration.—Majors (Honorary Lieutenant-Colonels) R. W. Fairbrother and R. B. Lumsden, Major E. Grey-Turner, M.C., Captains (Honorary Majors) C. Cockburn, C. W. A. Kimbell (retired), and N. Macmichael (retired), and Captain H. W. Wykes, R.A.M.C.

Universities and Colleges

ROYAL COLLEGE OF PHYSICIANS OF LONDON

At a quarterly comitia of the College held on January 27, with the President, Sir Russell Brain, in the chair, the following candidates, having satisfied the Censors' Board, were elected Members of the College:

J. C. Barker, M.B., A. W. Beard, B.M., W. C. Boake, M.B., H. G. T. Bridge, B.M., Stephanie J. Carter, M.B., H. D. Chalke, L.R.C.P., A. Coady, M.B., A. T. Cook, M.B., Captain R.A.M.C., L. Cudcowitz, M.D., D. W. Davies, M.B., Pamela A. Davies, M.B., Felicity C. Edwards, B.M., M. R. E. Evans, M.B., H. A. Fleming, M.D., E. G. Galea, M.B., Mary A. Le C. Hills, M.B., W. A. Hudson, M.B., R. B. Hunter, M.B., H. K. Ibbertson, M.B., K. V. Jones, M.B., Captain R.A.M.C., W. I. N. Kessel, M.B., J. W. Lance, M.B., J. H. Lawrence, M.B., D. W. Levy, M.B., Elizabeth A. Martin, M.B., S. Mattingly, M.B., W. K. Newton, M.B., D. W. Piper, M.B., J. C. Pond, M.B., E. J. Ross, M.B., G. F. M. Russell, M.B., M. Sandler, M.B., E. P. J. Silberstein, M.B., K. S. Somers, M.B., C. E. Stroud, M.B., G. S. Wakefield, M.B., R. T. T. Warwick, B.M., W. C. Watson, M.B., Rose A. J. Whelaw, M.B., W. H. Wolfenden, M.B., Joan F. Zilva, M.B.

Licences

Licences to practise were conferred upon the following 71 candidates who had passed the final examination in medicine, surgery, and midwifery of the Conjoint Board and who had complied with the by-laws of the College:

J. R. Akers, N. M. Bailey, G. C. W. Baker, Margaret A. Barrie, G. D. Blackledge, J. P. Booth, P. S. Boulter, H. J. Bradley, A. T. Brown, Elizabeth A. Burns, Enid J. Cartwright, Joan E. Chaffers, Evelyn B. Clayton, V. E. Crapnell, Hilary J. Crawford, D. R. Crockett, Sheila R. Crosland, I. I. Dainow, D. J. Davies, J. G. Davies, Ann Davis, G. H. Daw, J. A. Dew-Jones, G. S. Dormand, L. W. S. Eyears, W. J. Fessel, Phyllis M. Flcury, J. J. Fryatt, R. H. S. Gibbs, R. C. Giles, J. N. Godlee, S. A. Greenhalgh, R. L. Hargrove, Sheila C. Hay, W. T. Henry, I. Janota, Jona Jones, P. H. Johnson, A. N. Kalra, H. W. Kirkpatrick, J. K. M. McKay, Dorothy M. Mahabir, E. Mallett, A. G. Matheson, Maryrose E. Mears, P. H. Merry, D. M. G. Murphy, G. A. Naylor, M. J. O'Neill, J. E. Pearson, Jane Platnauer, D. J. H. Prosser, Margaret A. Riddell, Muriel I. Riegelhaupt, K. P. Robinson, C. R. Salmon, A. N. Sargent, A. A. Shaikh, D. J. Sils, G. C. Spackman, J. D. Spink, F. Summers, G. G. Temple, E. R. Thomas, L. F. Thomas, D. J. Thornton, Ailsa M. Thurgar, M. D. A. Vickers, A. W. Ware, Gladys M. L. West, J. P. M. Williams.

Diplomas

Diplomas in Medical Radiodiagnosis, in Pathology, and in Tropical Medicine and Hygiene were granted, jointly with the Royal College of Surgeons of England, to the successful candidates whose names were printed in the report of the meeting of the Royal College of Surgeons of England in the *Journal* of December 25, 1954 (p. 1556).

Diplomas in Laryngology and Otology, in Anaesthetics, and in Ophthalmology were granted, jointly with the Royal College of Surgeons of England, to the successful candidates whose names are printed below in the report of the meeting of the Royal College of Surgeons of England.

Other Diplomas in special subjects were granted, jointly with the Royal College of Surgeons of England, as follows:

DIPLOMA IN CHILD HEALTH.—R. S. Bull, J. A. Kay.
DIPLOMA IN INDUSTRIAL HEALTH.—A. J. Essex-Cater, W. N. Taylor.
DIPLOMA IN MEDICAL RADIOLOGY.—C. F. Baxter, C. Bissyllas, K. N. H. Low, Helen M. Mellor, J. W. Logan.
DIPLOMA IN PSYCHOLOGICAL MEDICINE.—V. N. Bagadia, B. C. Bignold, Maatjie V. Buhrmann, H. W. Conran, L. D. J. Coore, D. Davis, R. Doherty, T. Gallia, R. A. Gelfer, S. Goldin, B. Gordon, M. G. Jovanoudera, A. F. Johnston, M. H. B. Joyce, W. A. Ker, R. D. Laing, R. P. Michael, P. McK. Middleton, Marjorie A. Morgan, J. G. Neville, J. Pisani, P. K. Ray, G. H. Renton, E. A. Ritchie, D. H. Ropschitz, A. J. E. Rowe, R. Sander, C. P. Seager, R. V. Shirvaikar, H. J. Stott, J. L. Swift, L. Tarlo, J. F. Thomson, D. L. Walker, Eva Waller, J. S. Whitley, W. E. J. Wilson, E. A. M. Wood.
DIPLOMA IN PUBLIC HEALTH.—N. K. Bharucha, Nulece Cassels, Joan M. St. V. Dawkins, R. C. Greenberg, M. Husain, D. M. O. Lowry, H. R. Miller, J. P. J. O'Keefe, Hla Kyaw Pe, G. W. Piper, G. H. G. Poole, J. D. Russell, W. J. Wigfield.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council of the College held on February 10 with Sir Harry Platt, President, in the chair, the Handcock Prize was awarded to P. S. Boulter (Guy's Hospital).

A Fellowship in the Faculty of Anaesthetics was granted to R. W. Milner (Jamaica).

Diplomas of Membership were granted to P. R. Holt and to the other successful candidates whose names are printed above in the report of the meeting of the Royal College of Physicians of London held on January 27 as recipients of the L.R.C.P.

A Diploma in Industrial Health was granted, jointly with the Royal College of Physicians of London, to Z. Khan; in Psychological Medicine to D. L. Walker; and in Public Health to I. H. Seppelt, in addition to the other successful candidates for these diplomas whose names are printed above in the report of the meeting of the Royal College of Physicians of London.

At a meeting of the Council of the College held on March 10, with Sir Harry Platt, President, in the chair, the second Lady Cade Medal was awarded to Squadron Leader Peter Howard; the Hallett Prize to D. Singh (Patna); the Handcock Prize was presented to P. S. Boulter (Guy's); and Paul E. Copus (Cardiff High School) was awarded the twenty-fourth Macloghlin Scholarship.

Vital Statistics

Marriages and Divorces in 1953

In England and Wales in 1953 there were 344,998 marriages, giving a rate of 15.6 persons married per 1,000 population. This rate is lower than any since 1945, when it was 18.7. London and the South-eastern region had the highest marriage rate with 16.7, and the Eastern region lowest with 13.4. On the other hand, London and the South-eastern region had the lowest birth rate with 14.1 per 1,000 population; the Northern region had the highest birth rate with 17.5. Many more marriages were celebrated in March than in any other month (56,840). The distribution of marriages is now affected largely by the date of Easter and the end of the income-tax year. The least popular month was November with 15,475 marriages. The commonest age for marriage continued to be 23 for men and 21 for women. 71 youths aged 16 were married and 1,725 girls of that age, while 248 men and 47 women aged 80 or over got married; 6 of these men were aged 90 or over. The divorce rate continued to fall, there being 29,736 divorces and 590 annulments. The commonest age group for both men and women to have their marriage dissolved was 30 to 34 years. 6,530 boys and 6,534 girls were adopted under the Adoption of Children Acts. Of the 8,787 confinements which resulted in multiple births, 8,703 were of twins, 83 of triplets, and 1 of quintuplets.—*Registrar-General's Statistical Review of England and Wales for 1953*, Tables, Part II, Civil, 1955, H.M.S.O., 5s.

Week Ending May 7

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 575, whooping-cough 1,850, diphtheria 4, measles 19,492, acute pneumonia 499, acute poliomyelitis 24, dysentery 862, paratyphoid fever 9, and typhoid fever 3.

Infectious Diseases

In England and Wales during the week ending April 30 the largest falls in the number of notifications of infectious diseases were 5,888 for measles, from 28,425 to 22,537, 174 for dysentery, from 1,053 to 879, and 148 for acute pneumonia, from 688 to 540, and the only large rise was 110 for whooping-cough, from 1,658 to 1,768.

The largest decreases in the incidence of measles were 825 in London, from 2,614 to 1,789, 791 in Essex, from 2,098 to 1,307, 733 in Yorkshire West Riding, from 3,303 to 2,570, 653 in Warwickshire, from 2,708 to 2,055, 411 in Middlesex, from 1,953 to 1,542, 374 in Surrey, from 1,345 to 971. The number of notifications of scarlet fever was 461, being 6 fewer than in the preceding week, and there were no large fluctuations in the local trends. The largest vari-

ations in the trends of whooping-cough were an increase of 30 in Kent, from 64 to 94, and a fall of 72 in Middlesex, from 146 to 74. 9 cases of diphtheria were notified, 5 fewer than in the preceding week; of these, 3 were notified in Kingston-upon-Hull C.B. and 2 in Liverpool C.B. 6 of the 15 cases of paratyphoid fever were notified in Durham (Sunderland C.B. 4).

19 cases of acute poliomyelitis were notified, and these were 8 more for paralytic and 5 more for non-paralytic cases than in the preceding week. The largest returns were London 4, Kent 4, Somersetshire 3, Yorkshire West Riding 3 (Leeds C.B. 2).

The number of notifications of dysentery fell below 1,000 for the first time for 11 weeks. The largest centres of infection were Lancashire 329 (Blackburn C.B. 45, Liverpool C.B. 45, Oldham C.B. 44, Manchester C.B. 34, Blackpool C.B. 27, Salford C.B. 25, Middleton M.B. 24, Worsley U.D. 16); Durham 110 (Easington R.D. 34, Seaham U.D. 18, Gateshead C.B. 16); London 75 (Stepney 19, Southwark 11); Yorkshire West Riding 66 (Rotherham R.D. 15, Leeds C.B. 12); Northumberland 43 (Newcastle-upon-Tyne C.B. 19); Leicestershire 37 (Leicester C.B. 27); Yorkshire North Riding 30 (Middlesbrough C.B. 30).

In Scotland the number of notifications of dysentery fell from 323 to 296. The largest returns were Glasgow 158 and Edinburgh 38.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1946-54 are shown thus ----, the figures for 1955 thus —. Except for the curves showing notifications in 1955, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Health of Eire in 1953

The annual report of the Department of Health of Eire for 1953-4 shows that the birth rate during 1953 was 21.1 per 1,000 of the population, being 0.8 below the rate for 1952. It was the smallest rate since 1942, but was above the rates for 1930-41. The infant mortality rate was 39 per 1,000 live births and was the lowest rate ever recorded in Eire, being 2 below the rate for 1952 and 8 below the average of the five years 1948-52. The death rate was 11.8 per 1,000 population, being 0.1 below the rate for 1952. The death rates for 1952 and 1953 were exceptionally low. The death rate varied between 12.1 and 15.3 between 1930 and 1951.

A further decline was recorded in the death rate from tuberculosis. This rate has fallen steadily from 124 per 100,000 population in 1947 to 40 in 1953, but it is still much above the level of mortality in England and Wales (20) and Scotland (26). The number of persons treated by the tuberculosis service was 36,037, a rise of 2,198 on the total for 1952. Since 1949 the number of persons treated has increased each year by 2,000-3,000. 6,602 new cases of tuberculosis came under the notice of the health authorities, a decrease of 193 compared with 1952. The deaths from infectious diseases in 1953 included 476 from influenza, 185 from gastro-enteritis (under age 2), 59 from whooping-cough, 35 from measles, 33 from poliomyelitis, 3 from scarlet fever, and 3 from diphtheria.

The cost of the local health services has risen rapidly from £5½m. in 1947-8 to over £11m. in 1953-4. During this period the proportion paid by the Exchequer has risen from 16% to 50% of the total. Grants from the Hospital Trust Fund during the year amounting to nearly £4m. were made for construction and maintenance. The sweepstakes held on the Cambridgeshire, Grand National, and Derby resulted in over £1½m. being paid to the funds of the Hospital Trust Board.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending April 30 (No. 17) and corresponding week 1954.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Medical News

St. John "Save-a-Life" Week.—In many parts of England, Wales, and Northern Ireland May 21–28 will be the St. John Ambulance Brigade's "safe-a-life" week. During this week units of the Brigade will give life-saving demonstrations at works canteens, seaside beaches, swimming-baths, and other places of popular resort. They will be concentrating on the Holger-Nielsen method of artificial respiration. According to figures for England and Wales given by the Brigade, in 1953 1,107 persons lost their lives through accidental drowning and "nearly 1,000 more through asphyxia and electric shock." The Brigade hopes, through its "save-a-life" week, to increase the chances of recovery of those involved in such accidents. The week is being inaugurated by a meeting at the Chapter Hall, St. John's Gate, Clerkenwell, on May 21, at which the speakers will be Lieutenant-General Sir OTTO LUND and Lady MOUNT-BATTEN.

Delayed Effects of Hiroshima Bomb.—Less than a year after an atomic bomb was dropped on Hiroshima in 1945, the U.S. Atomic Bomb Casualty Commission was established in Japan and began collecting data on the results of the explosion. In an interview given to the regional editor of *U.S. News and World Report* and published in that magazine on May 13, Dr. ROBERT H. HOLMES, director of the Commission, summarizes the results of what is now almost a 10-year follow-up on the inhabitants of Hiroshima. The positive findings, according to Dr. Holmes, are an increased incidence of leukaemia (103 cases) and of cataract. In addition 15 microcephalic children were born to women who were in the early stages of pregnancy at the time of the explosion, but, Dr. Holmes stresses, "no genetic effects thus far have been observed among the first generation of offspring from exposed parents." The microcephalics represented, he points out, a developmental defect *in utero*, not a genetic effect. Immediately following the dropping of the bomb, there was evidence of infertility among the survivors, "but so far as our data indicate this was a transient phenomenon, and, as the general health of the individual improved, the fertility reappeared." Dr. Holmes said that the commission were studying the possibility of premature ageing and an increased incidence of cancer, but it was too early for any definite conclusions on these questions.

Society of Chiropodists.—"One Hundred Million Feet" were referred to as the problem of the chiropodists at the annual dinner of the Society of Chiropodists at Park Lane Hotel, London, on May 13, with Mr. John H. HANBY, the president, presiding. Mr. T. T. STAMM, proposing the toast of the profession of chiropody, said that chiropodists were now united in a single body recognized by the State, and with recognized standards of training and ethics. Having attained this position it must now be their purpose to develop it in the public interest. Chiropody's function was not just to provide comfort but to improve function and keep feet on the road. The chiropodist was an essential member of the orthopaedic team. Mr. Stamm summed up by saying that the profession of chiropody should now have three main aims: to work to restore foot function, to retain its independence, and to increase its contact with the medical profession. Mr. HANBY, replying to the toast, stressed particularly the chiropodist's role in prevention among schoolchildren and, at the other end of the scale, in making the aged mobile. The latter was an urgent problem, and, as to the former, there were too few chiropodists in the school health service. Mr. J. R. HALL proposed the toast of the guests, on behalf of whom Dr. W. S. C. COPEMAN replied.

Harveian Society of London.—The legal profession was well represented at the Buckston-Browne-Gray-Hill dinner, held on May 13 at the Royal College of Surgeons. Sir

FRED PRITCHARD, Q.C., proposing the toast to the Harveian Society of London, spoke of the value of friendships formed through intercommunication of two great professions. Some much-needed reforms to-day could come about only if the law and medicine worked together to secure them, with the object of common service in mind. Nearly everybody agreed that the rules which affect present-day laws about insanity should be overhauled. Neither profession could revise the rules alone, but the law and medicine together should see to it that the rules were revised in a way which would be of advantage to the community. Responding to the toast, Mr. A. DICKSON WRIGHT, the president of the Harveian Society, supported the idea that the law and medicine should collaborate more closely, and mingled humorous and serious remarks about both professions in a way entirely his own. The health of the guests was proposed by Dr. D. GERAINT JAMES, and Mr. H. EDMUND DAVIES, Q.C., Recorder of Cardiff, replied.

Eighth World Health Assembly.—At the opening session on May 10, Dr. IGNACIO MORONES PRIETO, Mexico's Minister of Health and Welfare, was elected president of the Assembly. Dr. S. AL WAHBI (Iraq), Dr. J. GRATZER (Austria), and Sir ARCOT MUDALIAR (India) were elected vice-presidents.

U.S.A. Poliomyelitis Inoculation Programme.—On May 13 the U.S. Public Health Service cleared over four million doses of Salk poliomyelitis vaccine, and inoculation in the United States has been resumed. Meanwhile President Eisenhower has accepted the Department of Health and Welfare's recommendation that distribution of the vaccine should continue on a voluntary basis. While there is a shortage of vaccine, inoculation will be limited to children between the ages of 5 and 9. A report from Denver, Colorado, states that the parents of two unrelated children who had been inoculated with Cutter vaccine have developed paralytic poliomyelitis. Dr. FLORIO, the city health director, is quoted as saying: "It is definitely possible that these parents contracted polio from their children."

Sex Hormones.—Last autumn representatives of the B.M.A., the Pharmaceutical Society, and the Royal College of Nursing discussed the dangers inherent in the general availability of sex hormones without prescription and what measures of control were needed. As a result of these discussions the following statement was issued by the council of the Pharmaceutical Society and published in a recent issue of the *Pharmaceutical Journal* (April 16, p. 288):

Some time ago in view of reports of the misuse of sex hormones for the suppression of lactation and the treatment of menopausal conditions the British Medical Association approached the Society to discuss whether any control should be imposed on their distribution and enquiry was made as to the practice of pharmacists in response to requests for such products. This showed the need for some regulation of the supply of sex hormones and after consideration it was agreed that the appropriate course would be for the matter to be the subject of advice to pharmacists by the Council of the Society. Accordingly the Council have decided to advise pharmacists not to supply sex hormones or their preparations unless satisfied that the customer is obtaining them on medical advice. This does not apply to cosmetic preparations containing hormones which are at present the subject of separate consideration.

American Grants for Leukaemia Research.—The Robert Roesler de Villiers Foundation (of New York) will shortly make grants-in-aid in support of research on leukaemia. Investigators in the United Kingdom who are interested should apply to the Regius Professor of Physic, University Department of Medicine, Tennis Court Road, Cambridge, before June 15. During the year 1955, awards of not more than \$1,000 (about £350) will be made to any one research worker.

Medical Candidates.—The names of two other medical candidates for Parliament have been announced, in addition to those mentioned in the *Journal* of May 7 (p. 1149) and May 14 (p. 1230). They are: WILLIAM STANLEY RUSSELL

THOMAS, Brecon and Radnor, Liberal (1919). Barrister-at-law, Lincoln's Inn. M.P. for Southampton from 1940 to 1945. Deputy Chairman, London Liberal National Party, 1937–45. Member, Select Committee on Public Petitions, 1942–4. Member, Select Committee on National Expenditure, 1944. JESSE DICKSON MABON, Renfrewshire West, Labour and Co-operative (1954).

Sir James Learmonth, Regius Professor of Clinical Surgery at Edinburgh, is visiting Strasbourg University from May 21 to 25 under the Foreign University Exchange Scheme.

COMING EVENTS

Polish Medical Association in Great Britain.—Annual meeting on May 28 and 29 at 18, Queen's Gate Terrace, London, S.W.7. Dr. J. CZEKALOWSKI will speak on "The Newer Approach to the Virus Problem." Full details of programme from hon. secretary, Polish Medical Association, 14, Collingham Gardens, London, S.W.5.

Concert in Aid of Lord Horder Centres for Arthritics.—IRENE KOHLER and the London Philharmonic Orchestra at the Royal Albert Hall on June 2 at 8 p.m. Programme and tickets (21s. to 2s.) from the Hall or the usual agents.

NEW ISSUES

British Journal of Ophthalmology.—The new issue (Vol. 39, No. 5) is now available. The contents include:

GENERALIZED CHOROIDAL SCLEROSIS. COURSE AND MODE OF INHERITANCE. Arnold Sorsby and J. B. Davey.
OCULAR CHANGES IN THE BLOCH-SULZBERGER SYNDROME (INCONTINENTIA PIGMENTI). J. Graham Scott, A. I. Friedmann, M. Chittiers, and W. J. Pepler.
PRELIMINARY REPORT ON THE USE OF CONTRAST MEDIA IN ORBITAL RADIOGRAPHY. J. W. Cowie and J. S. Groves.
VARIATION OF FIXATION DIRECTION WITH COLOUR OF FIXATION TARGET. D. H. Fender.
CLASSIFICATION OF ANGIOID STREAKS. R. J. McWilliam.
OPHTHALMIA NODOSA DUE TO CATAPILLAR HAIRS. J. A. Corkey.
DIBENZYLINE IN GLAUCOMA. John Primrose.
ABNORMAL FUNDUS REFLEXES AND RETINITIS PIGMENTOSA. R. P. Crick.

Issued monthly; annual subscription £4 4s.; single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Archives of Disease in Childhood.—The new issue (Vol. 30, No. 150) is now available. The contents include:

ON THE PROGNOSIS OF CRETINISM. David Lawson.
THE ABSORPTION OF SHORT-CHAIN FATS BY PREMATURE INFANTS. Selma E. Snyderman, Soledad Morales, and L. Emmett Holt, jun.
A STUDY OF CEREBRAL PALSY IN THE CHILDHOOD POPULATION OF EDINBURGH. T. T. S. Ingram.
CONGENITAL PNEUMONIA AND PNEUMONIA IN THE NEONATAL PERIOD. Kr. Harnaes and K. H. Torp.
HAEMOGLOBIN AND RED CELLS IN THE HUMAN FOETUS: II. THE RED CELLS. Elizabeth P. N. Turnbull and James Walker.
HAEMOGLOBIN AND RED CELLS IN THE HUMAN FOETUS: III. FOETAL AND ADULT HAEMOGLOBIN. Elizabeth P. N. Turnbull and James Walker.
BLOOD FORMATION IN INFANCY: PART III. CORD BLOOD. John Marks, Douglas Gairdner, and Janet D. Roscoe.
THE USE OF COBALT IN SOME COMMON ANEMIAS OF CHILDHOOD. B. L. Cole.
THE DETERMINATION OF BLOOD PRESSURE IN INFANTS BY THE FLUSH METHOD. John Reinhold and Michael Pynt.
CIRCULATING BASOPHILIC LEUCOCYTE COUNTS IN THE NEWBORN. Ross G. Mitchell.
THE EVALUATION OF THE EOSINOPHILIC RESPONSE TO CORTICOTROPHIN AND CORTISONE IN THE NEWBORN INFANT. James W. Farquhar.
THE EFFECT OF DISEASE AND INJURY ON THE ADRENAL CORTEX OF STILLBORN AND NEWBORN INFANTS. F. A. Langley and J. C. Burne.
A CASE OF GALACTOSAEMIA WITH SPECIAL REFERENCE TO MENTAL DEVELOPMENT. P. R. Clay and C. T. Potter.
THE AMINO-ACIDURIA IN GALACTOSAEMIA. D. C. Cusworth, C. E. Dent, and F. V. Flynn.
A STUDY OF THE GENETICS OF GALACTOSAEMIA. A. Holzel and G. M. Komrower.
A FAMILIAL TUBULAR ABSORPTION DEFECT OF GLUCOSE AND AMINO-ACIDS. Joseph Luder and Wilfrid Sheldon.
A CASE OF HYPOTHYROIDISM WITH NEPHROCALCINOSIS. Jean M. Naylor.
METASTATIC TUBERCULOUS ABSCESSSES. F. J. W. Miller and Maureen Cashman.
BILE PERITONITIS IN INFANCY. Pamela A. Davies and A. Elliot-Smith.
SUPERFICIAL GANGRENE OF THE SKIN IN CHICKENPOX. R. S. Illingworth and R. B. Zachary.
SUBACUTE AND CHRONIC INTUSSUSCEPTION IN INFANTS AND CHILDREN. Duncan Macaulay and Thomas Moore.
GANGRENE OF THE EXTREMITIES IN TWO AFRICAN INFANTS. Lorna G. Macdougall.
A CASE OF FIBROMA OF THE LEFT VENTRICLE IN A CHILD OF 4 YEARS. Ursula James and Margaret H. Stanfield.
FAMILY PERIODIC PARALYSIS IN A MENTALLY DEFECTIVE BOY. Thomas A. Corstoun.
PELLAGRA IN AN ENGLISH CHILD. G. W. Hickish.

Issued six times a year; annual subscription £3 3s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, May 23

BRITISH ASSOCIATION OF SPORT AND MEDICINE.—At Middlesex Hospital Medical School, 8 p.m., Mr. Philip Wiles: Athletic Injuries as Seen in the Hospital.

LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., special university lecture in pathology by Dr. R. J. Huebner (Bethesda, U.S.A.): Newly Recognized Respiratory Viruses and the Search for Diseases which they Cause.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. A. C. Corcoran (Cleveland): Current Developments in Hypertension.

Tuesday, May 24

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. W. N. Goldsmith: Skin Lesions in Metabolic Disorders.

LONDON AMATEUR BOXING ASSOCIATION.—At 69, Victoria Street, S.W., 8 p.m., Mr. A. Rugg-Gunn: Eye Injuries.

NATIONAL BOOK LEAGUE.—At 7, Albemarle Street, W., 7.30 p.m., Professor J. Z. Young, F.R.S.: Memory.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor H. G. Hanley: Surgery of Male Subfertility.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Physiology Lecture Theatre, 5 p.m., Dr. A. C. Corcoran (Cleveland Clinic, Ohio): Evaluation of Anti-hypertensive Drugs.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C., 5.15 p.m., Cushny Memorial Lecture by Professor R. A. McCance, F.R.S.: Metabolism and Renal Function in the First Few Days of Life.

WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY.—5 p.m., Almoth Wright Lecture by Lord Stamp: Action of Bacterial Enzymes on Immunizing Antigens.

WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY.—5 p.m., Almoth Wright Lecture by Lord Stamp: Action of Bacterial Enzymes on Immunizing Antigens.

WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY.—5 p.m., Almoth Wright Lecture by Lord Stamp: Action of Bacterial Enzymes on Immunizing Antigens.

Wednesday, May 25

BIRMINGHAM MEDICAL INSTITUTE: SECTION OF PSYCHIATRY.—8 p.m., Dr. J. D. Sutherland: Psychotherapeutic Provisions in a National Health Service.

EUGENICS SOCIETY.—At Royal Society, Burlington House, 5.30 p.m., Dr. J. A. H. Waterhouse, Ph.D.: Twins and Genetics.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Localized Diseases of the Collar.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. J. Anderson: General Aspects of Erythroblastosis and its Impact on Pathological Processes.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor T. N. A. Jeffcoate: Pruritus Vulvae.

Any Questions ?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Deposit of Tartar on Dentures

Q.—Could you please advise on the cause and removal of a deposit on my dentures which resists the commercial cleaning solutions? It forms a minute, spreading, fawnish-white coating over the plastic of the dentures, especially in the interstices of the teeth. If I retain the dentures in my mouth overnight for three or four nights the deposit at once gets the upper hand. If the deposit is "tartar," what is tartar? Where does it come from? What is the best way to prevent its deposition? Does its appearance depend on the pH of one's saliva? Will anything dissolve it from the dentures?

A.—The deposit on the dentures is probably "tartar." The mode of deposition of this tartar or calculus is still undetermined, though much work has been done on it. The saliva contains a very high concentration of calcium and phosphorus, and their stability may depend on the colloids also present in the saliva. It has been postulated that the low tension of carbon dioxide in the mouth, with consequent loss of carbon dioxide from the saliva, causes precipitation of calcium salts. It is thought that the presence of carbon dioxide is important in maintaining a high concentration of calcium salts in the saliva. The pH of the saliva is very variable, largely depending on the carbon dioxide content, and there is no obvious correlation of figures for salivary pH and tartar deposition from one individual to another.

The tartar deposit tends to be greatest opposite the openings of the salivary ducts, and forms on the natural teeth and to some extent on dentures. There is at present no known way of stopping this deposition and recourse must be had to its physical removal. Brushing the dentures each day with a soft brush and soap should keep them well polished and free of tartar, but if the surface of the dentures loses its polish tartar deposits may be more marked. It would be as well, if the deposit continues, to get the dentures repolished, as this helps to prevent further deposition.

Serology in Herpes Zoster

Q.—What is the present status of the complement fixation test performed on the patient's serum in the diagnosis of herpes zoster? Has any other diagnostic test been designed for this purpose? Have any of these tests been carried out on a series of normal individuals? Has it definitely been established that herpes zoster is due to a virus? What is the evidence for this? Please give references.

A.—Serological tests for herpes zoster are difficult to perform because the antigen used in the test consists of vesicle fluid collected from cases of varicella or zoster during the early stages of the eruption. The limitations of such a test are considerable. However, a number of investigations carried out some years ago indicated that the serum from patients convalescent from zoster fixed complement in the presence of zoster or varicella vesicle fluid antigen.¹ In one or two cases increases in antibody titre were detected. Furthermore, these serological tests indicated a very close relationship between the two viruses. The sera from normal individuals usually have a lower antibody titre or are clearly negative, but the findings in both cases must be related to the titre after the onset of infection.¹

The great difficulty about varicella and zoster viruses is that they cannot be grown in the ordinary culture media used in virology. But recently Weller has managed to propagate both viruses in tissue culture.^{2,3} This development may lead to the production of a diagnostic antigen. Another

test of some practicable value is the examination of scrapings from vesicular lesions for the presence of multinucleate epithelial cells and intranuclear inclusion bodies. These cytological changes are commonly found in both zoster and varicella, but they cannot be distinguished one from the other nor from similar lesions seen in herpes simplex infections. However, herpes simplex virus can be grown quite readily in the laboratory, which helps to distinguish the two if the need arises.

The virus aetiology of zoster is based on two main findings. The disease has been reproduced in human beings by direct inoculation of vesicle fluid.⁴ In some cases typical varicella has resulted (usually in children) or a local vesicle has developed. Natural cases of varicella in children resulting from an adult with zoster are well recognized.⁵ Secondly, the virus has been grown in tissue culture from vesicle fluid, and the actual causative agent, the virus elementary bodies, has been seen in vesicle fluid under the electron microscope.⁶

Ultrasonic Vibrations and Gall-stones

Q.—I have heard that it is possible to disintegrate gall-stones *in situ* by directing ultrasonic waves on them. Has this therapy in fact been used with any success?

A.—A number of physical studies have been made in the attempt to disintegrate calculi, both urinary and biliary, by ultrasonic vibrations. The results have been discussed by Mulvaney.¹ Up to the present only partial disruption of the calculi has been achieved and that only under conditions which are quite impracticable clinically. Even if disintegration of gall-stones in the gall-bladder could be achieved clinically, it would seem inadvisable to carry this out, as the small fragments resulting would be more of a danger to the patient than the larger gall-stones from which they are derived, owing to the likelihood of their passing into and obstructing the common bile duct.

Psychiatric Treatment of Adult Enuretic

Q.—What can psychiatric treatment offer a man of 26 who is a persistent bed-wetter, and has on that account ruled out the possibility of marriage?

A.—It is improbable at this age that enuresis is the result of a primary emotional disturbance. In children the opposite is the case, but those with emotional problems tend to get better with time or with treatment, leaving a residue of cases where the cause is constitutional and biological rather than psychological. It is likely that the patient belongs to this group, and inquiry should be made about the depth of his sleep, for if he sleeps very heavily dextro-amphetamine taken at bedtime may result in his being awakened in time by the discomfort in his bladder. The dose required may vary from 2½ to 30 mg. If there is a history of precipitancy of micturition by day, he should be tried on propantheline bromide ("probanthine") 15 mg. at bedtime. Nocturnal epilepsy is less likely as a cause, but inquiry should be made about disturbance of his bedding, biting of his tongue, and whether attacks have occurred by day.

Although it would be unwise to promise it, it is nevertheless true that some of these patients are cured by marriage. The most probable explanation lies in their being disturbed during the night by the movement of the other occupant of the bed. This, added to bladder discomfort, may be sufficient to awaken the deep sleeper.

There may of course be an emotional reaction which is secondary to the enuresis but which requires treatment. If the patient has ruled out marriage as a possibility, it

sounds as if this may be the case. Enuretics often marry, and women will frequently accept the burden involved with patience. Psychotherapy in such a case would not affect the enuresis, but might encourage a more hopeful and resolute acceptance of the disability. Such psychotherapy should be on the level of discussion and counselling, and extensive procedures should not be required.

Sensitization to Streptomycin

Q.—In the case of a person who is administering streptomycin by injection and has become sensitized to the drug, as evidenced by dermatitis of the hands, is there any likelihood of this sensitization disappearing spontaneously while contact with the drug is maintained? Full protective technique is observed, and it is presumed that the absorption of the drug occurs by inhalation.

A.—In our experience sensitization to streptomycin, acquired by handling the drug, does not disappear spontaneously while contact with the drug is maintained. If the patient ceases contact with the drug, the dermatitis may clear up, but fresh contact is apt to result in a fresh outbreak. Of course, it must be determined that the sensitization is indeed to streptomycin. The simplest technique for determining this is to inject 25 to 100 micrograms in 0.1 ml. intradermally. If the patient is sensitive erythema appears, which may be observed at 6, 12, or 24 hours after the injection. The actual dose given should depend on the severity of the symptoms. The higher dose may produce some general exacerbation if the patient is very sensitive, but the test should not be regarded as negative unless the full dose of 100 micrograms has been given. Desensitization is feasible although a little tedious. The technique is described by Crofton.¹ Clinical details and the frequency of this form of sensitization have been described by the Ministry of Health² and by Crofton and Foreman.³

Olfactory Hallucinations

Q.—A close relative of mine, aged 28, complains that her clothes emit obnoxious odours due to some naphthalene which was once used in her clothes cupboards. The cupboards have since been cleaned to her satisfaction, but she still complains that people in buses, theatres, and shops can still smell her clothes, even at a distance. She is convinced that when people smoke or sniff they do so because of her, and as a result is loath to go out. Neither I nor anyone else can smell anything abnormal. Could this condition be due to any nasal or other physical condition, or should she be referred for a psychiatric opinion? The patient is the neatest of persons and fastidious to a degree. What treatment is advised?

A.—This patient should certainly be referred for a psychiatric opinion. The symptoms described could not be solely due to any nasal or other physical condition, since she undoubtedly seems to misinterpret the behaviour of others. It is all very suggestive of the onset of schizophrenia. The first thing, however, would be to have a competent psychiatric opinion before deciding what treatment should be adopted. To suffer from olfactory hallucinations, coupled with other misinterpretations, at the age of 28 is unlikely to be due to a depression, although such symptoms can occur in involutional melancholia, nor are any other symptoms of depression described in this case.

Treatment of Warts

Q.—I would be grateful if you would tell me what you consider the best treatment for warts.

A.—Treatment of infective warts may be radical, and this is indicated when they are single or few and in sites where they are for one reason or another troublesome. The best radical measure is careful curettage under local analgesia, the wart being shelled out and the cavity being swabbed with

phenol or trichloroacetic acid. Cautery, diathermy, caustics, freezing, and radiotherapy are used to the same end but are more crude, lack the precision of curettage, and are not without dangers.

The oedematous warts occurring at the anus, and on the vulva or prepuce, may be associated with local discharges. Effective treatment of the discharge will usually clear the warts. Otherwise they are commonly responsive to a single or repeated painting of podophyllin resin (25% in 90% spirit).

Multiple plantar warts and mosaic warts often clear after soaking the part in 3% formalin for ten minutes at night for six weeks. In general, desiccating measures which cause some desquamation of the skin and antiseptics have some value, as for instance sulphur and resorcin pastes for flat warts, but most other treatments are probably effective only through suggestion. Wart charming is an effective remedy in the hands of the few.

Nervous instability with sweating and greasiness of the skin predisposes to warts and their spread, and this probably accounts for their high incidence in children. The manner in which remedies are prescribed and presented is important. For the great variety of measures employed in this field the reader may consult textbooks.

Toxicity of Rotenone

Q.—I should be grateful for information on the chances of dermatitis or toxic effects in a factory where girls are engaged in packing an insecticide containing 0.5% powdered rotenone. The percentage has recently been raised from 0.25%. No physical ill effects have ever been found with the latter concentration, but there is, of course, some escape of the powder into the air. The methods adopted to prevent any ill effects consist in the use of an industrial vacuum cleaner and the provision of light fabric face masks.

A.—Rotenone is the active principle of derris root and also of various tropical plants of the genus *Lonchocarpus*. Information about derris root can be obtained in the earlier editions of the *British Pharmaceutical Codex*, but not in the 1954 edition. References to rotenone are to be found in *Occupational Diseases of the Skin* (2nd edition) by Schwarz, Tulipan, and Peck, pp. 413-14. A paper by Haag¹ deals with toxicological studies of *Derris Elliptica*. It is said that derris dust if inhaled in sufficient quantity will produce fatty degeneration of the liver. Rotenone is a sensitizer, and dermatitis has been reported amongst workers who make and use spray solution containing it.

It would be useful to know the other ingredients of the powder containing 0.5% rotenone. Some of the so-called "inert" powders which have been used as vehicles, such as kaolin and talc, are known to produce pulmonary fibrosis.

Packing of powders is commonly done under exhaust ventilation, and if this is efficient there should be no need for the workers to wear respirators.

Treatment of Uterine Hypoplasia

Q.—What is the treatment of sterility due to uterine hypoplasia?

A.—Uterine hypoplasia is frequently diagnosed as a result of an impression gained during bimanual examination, and this is unreliable evidence no matter how skilled the observer. As a rule the diagnosis requires examination under anaesthesia, measurement of the uterus, and diagnostic curettage. To justify a diagnosis of uterine hypoplasia, the overall length of the uterus should be 2½ in. (6.3 cm.) or less, and the endometrium should be thin and should show an unstimulated appearance on microscopic examination. The uterine index—that is, the length of the cavity of the body of the uterus relative to the length of the cervical canal—is difficult to measure accurately, and, in any case, is not so informative as was once believed. Uterine hypoplasia is usually manifested by a late menarche, although this symptom by itself is of little significance.

Amenorrhoea or infrequent menstruation is also to be expected; a scanty regular loss is not necessarily indicative of hypoplasia.

However, even if uterine hypoplasia is proved to exist, there is no evidence that the condition *per se* lowers fertility, despite the general statements to the contrary which are found in most gynaecological textbooks and in monographs on infertility. Why should it? A small cavity with ill-prepared walls does not prevent conception, as the frequent occurrence of tubal pregnancy proves. It might, however, favour abortion. The only circumstance in which uterine hypoplasia is associated with infertility is when it is the result of inadequate ovarian function. In such case the uterus can be made to grow to normal size with oestrogen, but this does not raise fertility and the effect is only temporary. For the real cause of the sterility is failure of the ovary to produce ova, so treatment should be directed to the establishment of ovulation, even though the results are generally unsatisfactory. If uterine hypoplasia occurs despite normal ovarian function, then it is presumably because the uterus is unresponsive to ovarian hormones. It is the target organ which is at fault, the fault being unknown but allegedly inherent. In that case treatment with oestrogens is not likely to affect the uterus at all.

A critical, some may say hypercritical, outlook leads to the conclusion that uterine hypoplasia is more often a convenient label than a proved state; and that when it is present its treatment is either unnecessary or is doomed to failure unless its cause can be traced and corrected.

Methylpentynol in Pregnancy

Q.—*I should be glad to know whether there is any danger in expectant mothers taking methylpentynol before visiting the dentist, especially when they are going to have gas.*

A.—There are no reports in the literature to suggest that methylpentynol is dangerous for expectant mothers. It is destroyed in the body very much like ordinary alcohol, and the ill effects of too much methylpentynol resemble the effects of too much alcohol.

Treatment of Bee Stings

Q.—*What is the best treatment for bee stings? I am a member of a bee club and have been asked for advice.*

A.—Bee stings may result in a local reaction due to the injected bee-venom, a more generalized allergic reaction, or both.

The sting should be gently removed. Local therapy consists in the application of an antihistaminic ointment: various alkali solutions are also of help—for example, soap, sodium bicarbonate, methylene blue, weak ammonia, or calamine. For the milder urticarial reactions an antihistaminic drug, preferably one that does not cause drowsiness, ephedrine, or a combination of these two should be given. For the severe allergic reactions, angioneurotic oedema, severe dyspnoea, collapse, or unconsciousness, 1:1,000 adrenaline should be given in doses of 5–10 min. (0.3–0.6 ml.) and repeated as necessary. Some sensitized bee-keepers have found taking a small dose of ephedrine prior to handling the bees a means of reducing the severity of their reactions. All might well be advised to carry with them ephedrine and an antihistaminic to take as soon as they are stung, while the more severely affected should carry isoprenaline.

"Desensitization" or hyposensitization presents a series of difficult problems which are well discussed by Mueller and Hill, of Boston.¹ Isolated successful cases have been recorded, but it is not known for a series of patients what proportion would be adequately protected nor for how long the protection is likely to last once the injections are stopped. Bee-venom antigen is available from commercial firms, but skin testing and hyposensitization should be advised and carried out by an expert, for the antigen is a potent one. As in the treatment of hay fever, the dosage depends on the degree of sensitivity and even in skilled hands carries some risk of untoward reactions occurring. One

might expect the results to be similar to those of hyposensitization to hay fever and other immediate wealing allergies. The writer hesitates to advise hyposensitization except in individual cases and only when undertaken by experts.

Sparks from a Silk Shirt

Q.—*When I wear a leather corset and an artificial silk shirt the crepitations and sparks of static electricity are observed on removal of the shirt. Are such sparks sufficient to ignite ether or petrol?*

A.—The only safe answer is yes, though the risk of ignition of dangerous vapours by the crepitations and sparks alone is probably small and would require the co-existence of various other favourable factors. Nevertheless, in these kind of circumstances no avoidable risk, however slight, should ever be incurred. The conditions described in the question are particularly favourable to the development of static charges of high potential.

It has long been known that the ordinary movements of an anaesthetist, or other person in an operating theatre, can build up in himself a high charge of static electricity. Should he then approach or handle an object of lesser electric potential a spark will be formed sufficient to ignite or explode any dangerous vapour in the vicinity. This is known to be the explanation of many disasters that have occurred. If ordinary movements can do this, how much more so will the relatively violent ones described in the question? Silk is considered to be specially dangerous, and other fabrics may be little less dangerous. The risk of such accidents is much accentuated by the use of footwear made of ordinary non-conductive rubber or other similar material and also by furnishing operating rooms with non-conducting floor coverings such as linoleum.

Specific Desensitization to Foods

Q.—*An asthmatic child has been advised to avoid milk, fish, eggs, cheese, chocolate, and nuts. As it will be difficult to provide such a diet, can you please advise me whether it would be worth undertaking specific desensitization, and, if so, how should it be done?*

A.—Specific desensitization to foods is not advised. Neither oral nor parenteral "hyposensitization" have been proved to be effective, and both methods are considered by most authorities to be ineffective. Complete elimination from the diet and re-testing by ingestion every six months or so is the accepted treatment of proved food allergies.

The writer, however, would emphasize the great importance of not eliminating from the diet of any asthmatic (child or adult) any food unless it has been shown beyond doubt that its ingestion, even when introduced into the diet in a hidden or unsuspected form, repeatedly precipitates asthma.

Correction.—In the Parliamentary report on the consumption of welfare foods (*Journal*, May 14, p. 1228) the word "tons" (of dried milk) should read "tins."

Books of "Any Questions?"—The second and third volumes of "Any Questions?" are available, price 7s. 6d. (postage 6d.), from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller. Each contains some 200 selected expert answers, and the third volume a cumulative index to the three published books.

THE NATURAL HISTORY OF ANAEMIA ASSOCIATED WITH PROTEIN MALNUTRITION*

BY

A. W. WOODRUFF, M.D., Ph.D., F.R.C.P., D.T.M.&H.

Wellcome Professor of Clinical Tropical Medicine, University of London, at the London School of Hygiene and Tropical Medicine; Physician, Hospital for Tropical Diseases, University College Hospital, London

During the past three decades it has become clear that protein malnutrition is a major cause of death and disability throughout the Tropics. Its severest effects are on infants and young children, but there are reasons for believing that older children and adults, and particularly pregnant women, are affected by it. The term "protein malnutrition" has been discussed by Platt (1953); its meaning is wider than simple dietary protein deficiency, and includes disturbances produced primarily by under-feeding but aggravated by zymotic agents and infection which may convert borderline nutrition into malnutrition.

The study on which these lectures are based began in 1950 in Nigeria when I was confronted with a number of severely anaemic pregnant women. Anaemia in pregnancy is common in Nigeria and throughout the Tropics, and difficulties were encountered in finding an effective remedy for it. Similar difficulties were experienced by Napier (1940) in treating anaemia in pregnancy in India. Earlier work (Woodruff, 1951) has indicated that protein malnutrition plays an important part in the causation of this anaemia, and there is prevalent in Nigeria, as in the Tropics generally, the disease variously known as malignant malnutrition, kwashiorkor, and fatty liver disease. This has recently been referred to as the protein malnutrition syndrome in childhood. It is associated with an anaemia, and, in view of this, further investigations were undertaken to answer the question whether the anaemia in protein malnutrition in childhood is similar to or different from that encountered in pregnant women. There were obvious similarities between both sets of patients in that they were living on poor diets; in the children there was a special demand for protein imposed by the growth of their own body, and in the pregnant women a similar demand imposed by the foetus.

In considering the anaemias associated with protein malnutrition it is necessary to take into account many facts relating to the persons affected, their disease, and their environment. Thus the local foods are of obvious importance; so are the parasites and other causes of locally prevalent diseases, and the habits and social customs of the people.

*Being the text of the Goulstonian Lectures delivered before the Royal College of Physicians of London on February 23 and 25, 1954.

The patients were all studied at hospitals associated with University College, Ibadan, Nigeria, a town which has grown rapidly during the last 50 years and in which the social and economic conditions prevailing have previously been described (Woodruff, 1951).

Although poverty plays a part in the causation of malnutrition, Trowell *et al.* (1954) have drawn attention to the fact that malnutrition often depends more on the type of crops grown in the patients' neighbourhood than on monetary wealth. Thus in a cassava-growing region wealthy people may live on an unbalanced and poor cassava diet. Certainly the parents of grossly malnourished children often are sufficiently well off to wear costly clothing. Taboos are important causes of malnutrition in some regions. Thus in Western Nigeria a common taboo prohibits the eating of eggs, so although hens are numerous no use is made of the valuable source of protein their eggs supply.

Methods of Investigation.—The haematological methods used were standard and have previously been described in detail (Woodruff, 1951). The electrophoretic studies of plasma proteins were made with paper as described by Flynn and de Mayo (1951). Reticulocyte ripening was studied by the method described by Nizet and Robschey-Robbins (1950).

ANAEMIA AND MALNUTRITION IN PREGNANT WOMEN

These patients, numbering 45, all complained of lassitude and weakness, and many of dyspnoea. Only two gave a history of having had soreness of the tongue. The most outstanding clinical findings were hepatomegaly and splenomegaly. The liver was palpable in 30 and the spleen in 32 cases. In 10 the liver reached 3 in. (7.5 cm.) or more below the costal margin, and the spleen did so in nine. Subcutaneous oedema was present in 10 cases and ascites in one. No evidence of cardiac failure was found to explain the hepatosplenomegaly or oedema. A trace of albumin was present in the urine of several patients, but there were no casts.

The haematological findings for 40 patients are shown in Table I; in the remaining five cases either the patient was first seen in convalescence or full haematological indices were not obtained. It is apparent that these anaemias are of considerable severity; about 50% are normocytic, 25% macrocytic, and 25% microcytic, as judged by the mean corpuscular volume (M.C.V.). The mean corpuscular

TABLE I.—Haematological Values at Initial Examination in 40 Cases of Anaemia in Pregnancy

Type of Anaemia	Haemoglobin (g. per 100 ml.)		Red Blood Cells (millions per c.mm.)		M.C.V. (cu. μ)		M.C.H.C. (%)		Reticulocytes (% of R.B.C.)	
	Mean	Range	Mean	Range	Mean	Range	Mean	Range	Mean	Range
Macrocytic (M.C.V. > 95 cu. μ) (11 cases)	6.93	5.18-8.70	2.23	1.81-2.90	102.76	95.30-120.40	30.33	26.60-33.30	4.51	1.2-9.5
Normocytic (M.C.V. 82-95 cu. μ) (19 cases)	5.55	4.62-9.18	2.00	0.89-3.98	86.88	82.30-93.46	33.04	26.20-38.00	4.49	0.5-16.5
Microcytic (M.C.V. < 82 cu. μ) (10 cases)	6.66	4.14-9.62	2.60	1.38-3.36	74.26	57.70-81.81	33.47	28.60-37.68	3.30	0.5-6.0

haemoglobin concentration (M.C.H.C.) in the majority of cases is satisfactory, and evidence of iron deficiency was infrequent.

Reticulocyte counts at initial examination averaged 4%, indicating that the marrow was active, and this was borne out by microscopical examination of the marrow films, which with two exceptions showed macronormoblastic hyperplasia. In two cases Ehrlich megaloblasts were present. Dr. D. S. Ridley has kindly examined the marrow films and reports that the principal features are: (1) the cells are larger than normal, but not so large as those of the megaloblastic series, the pronormoblasts being 15-21 μ and early normoblasts up to 17 μ in diameter; (2) normal coarsely marked nuclei are found; (3) there is premature haemoglobinization; (4) primitive forms predominate in relation to the scanty late normoblasts; and (5) erythropoiesis is active.

The sickle-cell trait was found in only six cases, thus this abnormality could not be held responsible for the characteristics of the anaemia.

The gastric juice was examined in 39 cases, and histamine-fast achlorhydria was found in 11. Among these 11 patients were the two with megaloblastic marrow.

Schumm's test was positive in 21 cases, so that in these there was a haemolytic process at work. Fairley *et al.* (1938) described such a process in pregnant women suffering from nutritional macrocytic anaemia, and in his cases, too, there was hepatomegaly. Fairley thought it probable that this haemolytic process was initiated by malaria, but continued in the absence of an overt infection. Such a mechanism may be at work in these cases, although haemolytic anaemia in liver disease has been described by Davidson and Fullerton (1938) and by Coleman (1948), and this affords another possible basis for this feature.

In 1950 it was suspected that the anaemia in these cases might respond to liver extract, vitamin B₁₂, or folic acid, for it is associated with a macronormoblastic marrow in which the cells are sometimes difficult to distinguish from megaloblasts. Megaloblastic anaemia in pregnancy has been reported in the Tropics by many workers, and Wills (1931, 1932, 1933), Manson-Bahr (1951), and others have found it to respond to specific haemopoietic substances. Vitamin B₁₂ in doses of 100 and 120 μ g. failed, however, to bring about a reticulocyte crisis or improvement in the haematological picture. Maximal doses of liver and of folic acid also failed. The therapeutic failure of vitamin B₁₂ is understandable in the light of estimations of the vitamin in the serum which Dr. G. I. M. Ross has kindly carried out in five cases, the concentrations ranging from 470 to 1,000 μ g. per ml. The normal range was found by Mollin and Ross (1952) to be from 100 to 720 μ g., with a mean of 358 μ g. per ml. of serum. Thus the values in these women were all normal or slightly above normal.

In macrocytic, normocytic, and microcytic groups iron administered before delivery failed to evoke a reticulocyte crisis or haematological improvement. In one of the cases the M.C.H.C. was as low as 26.6%. Five of the patients improved spontaneously after delivery without treatment. In others, however, this tendency towards spontaneous remission was absent.

The problem, therefore, was of an anaemia often of considerable severity, occurring late in pregnancy, refractory to treatment with iron, folic acid, liver extract, and vitamin B₁₂, and associated with a macronormoblastic marrow and hepatosplenomegaly.

Investigations Concerning the Cause of the Anaemia

Role of Helminths

Of the many questions posed by this anaemia one of the first is whether parasites such as intestinal worms are important aetiological factors. Accordingly stools were searched in all cases; ova of *Ancylostoma duodenale* were found in 14, and ova of *Ascaris lumbricoides* in 34. Treating both worm infections did not, however, influence the anaemia. In many of the cases the infection was light, only very few ova being present. Infection with *A. lumbricoides* is not recognized as a cause of anaemia, though the nutritional demands of this parasite have to be met from the patient's diet and may aggravate any malnutrition present. Infection with *A. duodenale*, where present, no doubt aggravated the anaemia, but the extent to which it did so was probably small, for the characteristics of the anaemia in infected and non-infected persons were similar.

Malaria

One or more blood films from the patients were examined on admission, and subsequently whenever there was fever. Patients found to have overt malaria were excluded from the study. Ibadan is, however, in a highly malarious region, and probably all the patients had been infected in the past but their infections had been adequately dealt with by their immune processes. Malaria may have played a part in the causation of the anaemia and malnutrition, but there is abundant evidence that other very important factors were also at work. Thus patients, and particularly pregnant women, with malarial parasites in the blood and anaemia not uncommonly failed to improve haematologically when given adequate antimalarial treatment.

In well-nourished persons, even when severe anaemia is caused by malaria, the anaemia improves rapidly after adequate antimalarial treatment has been instituted. To one of the pregnant women in this series 600 mg. of mepacrine had been given empirically daily for three days before she was seen for the purpose of this study. Her haemoglobin content was 5.03 g., and her total plasma protein level 5.93 g. per 100 ml. (albumin 1.95 and globulin 3.45 g. per 100 ml.). During the subsequent eight weeks she was delivered, received 2 pints (1.1 litres) of blood by transfusion and 0.9 g. ferrous gluconate daily for three weeks, yet at the end of this period her haemoglobin level was unchanged. She was given a supplement of 4 oz. (113 g.) casein daily, and in two weeks the haemoglobin had risen to 6.2 g., and the total plasma proteins to 7.08 g. per 100 ml. (albumin 3.11 and globulin 3.60 g. per 100 ml.). In cases such as this it is clear that conditions other than malaria are important in preventing recovery from the anaemia.

Significance of the Hepatomegaly

The next question is, what is the significance of the hepatomegaly: is it possible that it is related to the anaemia? Syphilitic disease of the liver was excluded, as the Kahn test, performed in 36 cases, gave a positive result in only one case.

A biopsy of the liver was taken in 42 of the 43 patients, and histological examination showed fatty infiltration in about a quarter of these, and in almost all an increase in fibrous tissue. The fat, when present, was usually in the peripheral portions of the liver lobules, but in some cases it was irregularly distributed; it was never gross, but simulated that seen in mild cases of fatty liver disease in malnutrition of childhood (Woodruff, 1951). The fibrous tissue was

increased in the portal tracts and also occurred diffusely between liver cells. Staining with Wilder's silver method showed that reticulin, instead of being a fine strand between parenchymal cells, was thicker than normal and in multiple strands, often appearing like teased-out rope or lacework. In most cases the cytoplasm of the parenchymal liver cells was thin, vacuolated, and stained badly; in some cells only filaments of cytoplasm were present. Biopsies were repeated after treatment in eight cases, and the late Dr. W. Silvera (who kindly examined the sections) found that in the second specimens the cytoplasm invariably stained better than in the first, and fat where originally present had diminished or disappeared. No change in reticulin was, however, noted. Dr. D. S. Ridley has stained several of these sections for glycogen and found this greatly increased. Certainly the cells are not filled with their normal complement of healthy cytoplasm.

This liver damage has much in common with that found in children suffering from protein malnutrition, and is also similar to that which can be produced in animals by feeding them on diets low in protein and adequate in carbohydrate or fat. Accordingly the question arose whether the anaemia in these cases is the result not of deficiency of a specific haemopoietic factor but of protein, and whether protein malnutrition causes the liver damage and both contribute to the production of anaemia.

Plasma Proteins

The plasma proteins were estimated chemically in 34 cases. The mean values are shown in Table II, from which it will be found that the albumin fraction is reduced and the globulin fraction increased as compared with normal

TABLE II.—Plasma Proteins (g. per 100 ml.) in 34 Cases of Anaemia in Pregnancy

	Total Protein	Albumin	Globulin	Fibrinogen	A/G Ratio
Mean	7.37	3.15	3.76	0.46	0.84:1
Range	4.9-8.7	1.9-4.1	2.6-4.9	0.1-1.2	0.48-1.48:1

Mean of 11 older children, adult males, and non-pregnant females with protein malnutrition and anaemia	25.72	8.99	15.64	12.58	37.07
Normal average:					
Ricketts <i>et al.</i> (1949)	60.30	4.00	9.70	12.80	13.20
Taylor <i>et al.</i> (1949)	64.10	4.10	7.70	11.40	12.70
Mean of 12 patients with malaria (Taylor <i>et al.</i> , 1949)	55.90	6.80	8.10	13.70	15.30
Mean of 7 patients with cirrhosis of liver and ascites (Ricketts <i>et al.</i> , 1949)	35.20	4.20	7.20	7.70	35.70

values. Serum was examined electrophoretically in nine cases to determine the type of globulin responsible for the increased amounts present. Typical electrophoretic patterns are shown in Figs. 1 and 2 and may be compared with that from a healthy Syrian woman living in Ibadan (Fig. 3). The mean values of the various protein fractions are summarized in Table III and compared with figures from other patients studied and with those of healthy persons, patients with malaria, and patients with cirrhosis of the liver.

It is clear from a review of the literature on the plasma proteins in malaria (Maegraith, 1948) that in this disease the albumin is reduced and the globulin increased. It is not clear, however, which globulin fraction becomes increased. Taylor *et al.* (1949) infected 12 healthy volunteers with malaria and permitted them to have five to eight paroxysms of fever. The electrophoretic protein patterns before and after the experiment are shown in lines 5 and 6 respectively in Table III. The albumin fraction decreased by 14.5%, the α_1 globulin increased by 62%, and the γ globulin by 19%. Similar changes have been reported by Ganzin (1954).

There is a large literature on the changes in the plasma proteins which may occur in liver disease. The figures given in Table III are those obtained by Ricketts *et al.* (1949) in seven patients with hepatic cirrhosis and ascites, and it is seen that there is nearly three times the normal amount of γ globulin present. The serological changes in the pregnant women fit in most readily with the interpretation that they were brought about by liver damage and to some extent also by malaria.

The position thus far, therefore, was that these women were anaemic, they were not suffering from deficiency of any known specific haemopoietic factor, and the anaemia appeared not to be caused by the presence of parasites but was associated with liver damage and altered levels of various protein fractions in the blood. The next question which arose was whether there was any evidence that the patients' diets were deficient in protein. Answering this was fortunately facilitated by the fact that the hospitals at Ibadan, like the great majority of those in tropical Africa, do not provide patients with food except in special cases. Food must be brought by relatives or friends, who visit the hospital thrice daily for this purpose. It was thus possible, by weighing and charting the food brought, to obtain an indication of what the patients eat in their homes. In 1950 this was done in 13 cases, and the protein, carbohydrate, and calorie content estimated. The mean daily protein consumption worked out at approximately 50 g., and the total calories provided about 2,000. Miss M. W. Grant, of the Department of Nutrition at the London School of Hygiene and Tropical Medicine, has carefully

FIG. 2

Figs. 1 and 2.—Protein pattern obtained by electrophoresis of serum of two of the patients with anaemia in pregnancy. In this and in subsequent similar diagrams figures under Alb. indicate percentage of albumin present, those under α_1 , α_2 , β , and γ the percentages of the various globulin fractions.

FIG. 3.—Protein pattern obtained by electrophoresis of serum of a healthy Syrian woman living in Ibadan.

checked the diets and these figures, and considers that the values were probably all over-estimated by as much as 30%, the reason being that the water content of the flour used in Ibadan is greater than the figure given in the tables used. Even so, the protein content of the diets was just over half that usually recommended for pregnant women, whereas their calorie value appeared to be adequate. This fitted in with the appearance of the patients, who were fairly well covered. In 1953 more accurate dietary data were obtained, not only by weighing and recording food eaten but by collecting representative samples for analysis. The exact counterpart of food eaten by the patients was placed in a container, aliquots were dried and brought back to this country, and Professor B. S. Platt kindly had these analysed. With the data obtained from these analyses and the records of the patients' diets Miss M. W. Grant and Miss Dare have been able to estimate accurately the calorie, protein, fat, and carbohydrate values of the diets. These are shown in Table IV, and support the suggestion that the

44/53	976	27.4	32.1	143.6
Adolescents:				
36/53	1,132	30.3	35.2	173.4
48/53	1,432	37.2	45.0	219.3

earlier figures were over-estimates. Thus the mean daily protein intake was 36.4 g. The calorie value was adequate for patients lying in bed.

In the League of Nations *Report on the Physiological Basis of Nutrition* (1936) it is recommended that women between the fourth and ninth months of pregnancy should have 1.5 g. protein per kg. body weight. For the women in this series this would have been 77.3 g. per day. In 1950 the Committee on Nutrition of the British Medical Association recommended that at least 14% of a pregnant woman's calories should be supplied by protein. Thus by either of these standards the women in this series were living on a diet grossly deficient in protein.

A further question which now suggested itself was whether the patients who developed anaemia were those who had an excessive demand on their already poor supplies of dietary protein. This arose from the fact that there seemed to be an extraordinary proportion of twins born of the women studied. Accordingly the obstetric history of the patients was gone into. Much of this has previously been reported (Woodruff, 1951), but, in brief, it has been found that among 45 women studied there was one twin pregnancy in five pregnancies. Ross (1952) states that the ratio throughout the world is 1 in 90. In the United States of America among white persons it is 1 in 88, and among coloured citizens 1 in 67; among Africans in Rhodesia, where Ross was working, the rate is 1 in 35. At Ibadan in 1953 the ratio in 1,000 consecutive hospital deliveries was found to be 1 in 20. Twin pregnancies therefore were four times as common among the anaemic women as they were in non-anaemic pregnant women delivered in hospital at Ibadan. This suggests that those who have heavy nutritional demands imposed by twin pregnancy and are living on this deficient diet are more likely to develop anaemia than are women bearing only one child. The people of Nigeria recognize

that to bear twins imposes a greater risk to maternal health than does a single pregnancy, and for this reason have an elaborate ritual following their birth. It is considered that evil spirits are brought by the twins and are responsible for this ill-health. Two wooden idols are therefore made, into which it is hoped the spirits will enter, thus preventing harm to mother or children. As in much folklore, there is some basis for the belief, for certainly anaemia in pregnancy with its associated risks to health is more common among women bearing twins.

Cytological Appearances

There seemed, therefore, to be good evidence that this anaemia was associated with protein malnutrition and with liver damage. Further, this liver damage was of the kind

TABLE V.—*Cell Diameter and Thickness (in μ) in 34 Cases of Anaemia in Pregnancy*

* Whitby and Britton (1950). † Larsen (1948). ‡ Price-Jones, Vaughan, and Goddard (1935).

reported by Himsworth (1950) in animals deprived of protein and given adequate calories in the form of fat or carbohydrates—namely, diffuse fibrosis and fatty infiltration. Larsen (1948) found that in patients with acute or chronic liver disease the red blood cells have an increased diameter but diminished thickness. Thus the ratio of their diameter to their thickness is greater than normal. Glynn, Himsworth, and Neuburger (1945) have also reported this type of red blood cell in rats suffering from hepatic disease induced by methionine deficiency. The next question therefore was whether the cells in these cases were also broader and thinner than normal.

Their characteristic appearance in thin films suggested that they were. The cells were larger than those of microcytic anaemia, yet they had the pale, vacuolated appearance of those found in that disease. Trowell has called them "foam" or "bubble" cells, and many resemble target cells. There is polychromasia due to the slight increase in reticulocytes and there is also well-marked anisocytosis—a point which is brought out by the wide base of the Price-Jones curves in such cases.

Price-Jones curves were constructed in 36 cases. A shift to the right was present in 24 cases, to the left in only two, and a centrally placed curve was found in 10 cases. In all cases the base was broader than normal. Normal values and the figures obtained from these curves are summarized in Table V. The mean cell diameter (M.C.D.) was increased

FIG. 4.—The ratio of red blood cell diameter to thickness in 36 women with anaemia in pregnancy. In all but five cases this ratio is greater than the average in health—that is, the cells are thinner than average.

even in most cases which were microcytic when classified according to the M.C.V. It was greater than normal in 15 cases, and in the upper half of the normal range in 15 cases. The standard deviation (σ) of the M.C.D., which Larsen (1948) finds is constantly raised in liver disease, was also raised in all cases. The range was 0.51-2.79 μ . The mean corpuscular average thickness (M.C.A.T.) was below normal average in 34 cases. Haden (1935) has shown that normally the diameter of the red blood cell is 2.4-4.2 times its thickness, and that when the diameter is more than 4.2 times the thickness the cell is abnormally thin. The diameter-thickness ratio in the pregnant anaemic women is shown in Fig. 4; it will be seen that in 13 cases the cells were pathologically thin, and in all but five they were thinner than average.

Response to Treatment

In view of the evidence of protein malnutrition, five patients were given daily supplements of 2-4 oz. (56.5-113 g.) casein after a control period of 10 days. This was followed by steady improvement without the development of a well-marked reticulocyte crisis (Fig. 5). In these cases, and in others in which improvement took place on a good diet only, the haematological improvement was invariably accompanied by increase in plasma albumin and by the albumin-globulin ratio becoming less abnormal. In Table VI the values in nine cases before and after treatment are shown and attention is drawn to the fact that albumin has increased in every case.

There is a further important piece of evidence suggesting that protein malnutrition causes liver damage in pregnant women. Following the demonstration of what appeared to be liver damage due to protein malnutrition in anaemic

FIG. 5.—Improvement in haematological values in anaemia in pregnancy following treatment with casein. Rectangles labelled A and G indicate albumin and globulin values respectively.

mothers, Silvera and Jelliffe (1952) at Ibadan examined the livers of infants who died within a few hours of being born of malnourished mothers. They found that in several instances the infant's liver was grossly infiltrated with fat and even contained an increased amount of fibrous tissue. This fatty infiltration and fibrosis is of very great interest in that it cannot have been caused by parasites. In two instances vascular or congestive damage arising during childbirth could be excluded by the fact that the two mothers from whose infants the specimens were obtained were delivered by caesarean section. A nutritional cause was the only one likely. It appears that in tropical parts some infants may be born with the handicap of a damaged liver.

Comment

The evidence thus far therefore suggests that anaemia in pregnant women in Nigeria might be associated with protein malnutrition and liver damage, in some cases no doubt aggravated by parasitic infection. Further, this malnutrition is more likely to develop in those who have heavy demands on their protein supplies. If this hypothesis is correct, then the anaemia of these pregnant women and that of children and non-pregnant adults suffering from protein malnutrition ought to have much in common, and to test the hypothesis a comparison was made of the anaemia in these three types of patients.

ANAEMIA ASSOCIATED WITH PROTEIN MALNUTRITION IN EARLY CHILDHOOD

This series of nine children were studied by courtesy of, and with much help from, Dr. A. Tompkins. All presented with classical clinical manifestations of protein malnutrition or kwashiorkor. They were oedematous, each had a dermatitis and liver damage, and eight had ascites. Their hair, instead of being crisp and curly as it should be in Africans, was soft and straight. One might ask how children are allowed to become so ill, and the answer to that question in part lies in local folklore and superstition. The child affected is commonly believed to be possessed of a spirit or devil, and the advice of an indigenous practitioner is first sought. His usual treatment is to tie the head of a snake, lizard, or rat on to the patient, and it is only when this has failed that help is sought from a hospital or a medically qualified person. Thus we have another example of how ignorance and spurious beliefs play a part in the causation of this disorder.

The age at which this florid clinical condition occurs varies considerably, but the commonest is some months after the cessation of breast-feeding; this takes place much later than in Europe, usually between the ages of 2 and 3 years. At this time the child is given a diet of starchy gruels high in carbohydrate and relatively low in protein. Though the disease is commonest at

this age, it may occur in a modified form at any time in childhood, and it seems probable that a variety of it is found in adult life. The ages of the children in this series ranged from 2½ to 6 years. In two of the cases the illness had started after the mother had left the child in the care of a grandparent while she was preoccupied with a later addition to the family. This is not uncommon history, and it is probable that the grandparent, by reason of age or incapacity, is unable to provide more than the cheapest and most readily available foods. These are cassava, yams, and maize, all of which are rich in carbohydrate and poor in protein.

Anorexia was usual, and this is an important symptom as it leads to aggravation of the dietetic deficiency. Oedema, when it first appeared, often affected the most dependent parts of the body, and therefore the side on which the child had been lying during sleep (Fig. 6). Later all the subcutaneous tissue becomes oedematous, and in addition to ascites there may be pleural or pericardial effusions.

FIG. 6.—Unilateral oedema of face following sleep in child suffering from protein malnutrition.

FIG. 7.—"Crazy-pavement" dermatosis in an African child suffering from protein malnutrition.

ference with the nutrition of the superficial layers which results from the oedema beneath pressing on capillaries and restricting blood supply. In addition to this "crazy-pavement" dermatosis, however, there may be generalized depigmentation of the skin and hair, which, instead of being the normal black of the African child, assumes a light-brown colour. Nagchaudhuri and Platt (1954) have investigated this and found that there are chemical changes in the pigment in the hair of these cases. Such generalized depigmentation was present in one case.

In this group of nine children with oedema and skin changes the liver was palpable in seven, the greatest distance below the costal margin being 1½ in. (3.7 cm.). The spleen was palpable in only two cases; in one of these it was just tipped on inspiration, and in the other it was 1 in. (2.5 cm.) below the left costal margin.

Results of Investigations

Haematological Values

Detailed haematological observations were made in six cases. The bone marrow was uniformly macronormoblastic, but megaloblasts were not found and sickling was not detected in any of the six cases.

The haematological indices at initial examination are shown in Table VII. The anaemia, it will be noted, is well

Mean	8.16	3.12	82.76	32.29	8.04	1.58

marked, though not severe. Schumm's test was negative in all six cases. The M.C.V. is on the low side of the normal range in most cases, but the M.C.D. is abnormally increased in four cases and at the upper limit of the normal range in one case. The M.C.A.T. is below the normal range in all but two cases. There is little evidence of iron deficiency, the lowest M.C.H.C. being 30%. The Price-Jones curves showed a shift to the right in four cases, and in two the curve was centrally placed; in all it was flatter than normal. The standard deviation of the M.C.D. was increased just as it was in the pregnant women, the mean being 0.916 and the range 0.369–1.513. The values for the ratio of cell diameter to thickness in these cases are shown in Fig. 8, from which it is obvious that the cells are very much thinner than normal. This anaemia is therefore orthochromic and, as judged by cell volume, normocytic, but on the basis of cell diameter it is macrocytic. The cells, however, like those of the pregnant women, are thinner than normal and the ratio of cell diameter to cell thickness is increased.

Parasites

Particular attention has been paid to examination for parasites in these as in all cases in the study. Ova of *A. duodenale* were not found in the stools of any of these children, but in two cases ova of *A. lumbricoides* were found. Blood films were examined for malarial parasites both on admission and subsequently whenever there was fever; in two cases *Plasmodium falciparum* rings were found on admission. Trowell, Davies, and Dean (1952) find that those affected by kwashiorkor usually harbour some parasites, but the same syndrome may occur in the absence of parasitic infections. The findings in this series support this statement.

FIG. 8.—The ratio of red blood cell diameter to thickness in six children with anaemia and protein malnutrition. In five cases the cells are pathologically thin.

Plasma Proteins

The plasma proteins were estimated in five of the six cases, and the values obtained, together with the corresponding haemoglobin and red blood cell counts, are shown in Table VIII. In three cases the figures obtained after treatment are also given. By comparison with normal values the albumin fraction before treatment is low and the globulin fraction greater than normal in all but two cases, so that there is a striking inversion of the albumin-globulin ratio. The albumin, it will be noted, increased with treatment. This increase is most marked in the first case, where after eight weeks' treatment with a good diet and a supplement of 56 g. milk protein daily the figures approximated to those at the lower end of the normal range.

The colloid osmotic pressure of the plasma in these cases is shown in Table VIII, the figures for Case 61/53 being obtained during convalescence. These pressures have been calculated from the formula propounded by Keys (1938), who in a series of 40 normal young men found the range to be from 247 to 342 mm. water (Keys *et al.*, 1950a). Thus the values were lower than normal in all four cases in which they were calculated before treatment. The development of oedema is dependent on several factors, of which the plasma colloid osmotic pressure is only one. In nephritis with hypoproteinaemia, Muntwyler *et al.* (1933) found that oedema usually developed when the plasma colloid osmotic pressure dropped below 160 mm. water, and that patients with pressure above this figure had no oedema. His findings accord well with those in this series in which all the patients had gross oedema and a plasma colloid osmotic pressure below 160 mm. water when first observed. The oedema became less with treatment; when the second reading was obtained, it had disappeared altogether from Case 30/53 and in Cases 37/53 and 42/53 was just perceptible.

Electrophoresis of the Plasma Proteins

In view of the abnormal globulin values found in these children the question again arose as to what globulin fraction predominated.

Serum was examined electrophoretically in five cases, a typical curve being shown in Fig. 9; the combined results obtained are shown in Table III and are compared with those in normal serum. Electrophoresis confirmed that in all these malnourished children the albumin fraction was grossly reduced and the α₁ and γ globulin increased. In cirrhosis of the liver the reduction in albumin and increase in β and γ globulins closely parallel the changes in these malnourished children.

FIG. 9.—Protein pattern obtained by electrophoresis of serum of child with protein malnutrition and anaemia.

In Taylor's malaria experiment (Taylor *et al.*, 1949) the increase in γ globulin was proportionately less, and that of α₁ globulin proportionately greater, than in the children or in cirrhosis. It is of course difficult to compare Taylor's experiment with malaria in volunteers and the findings in these children, who probably had been chronically infected most of their lives. Nevertheless, if the changes were due only to malaria one would expect them to be of the same qualitative kind as in Taylor's experiment. Again, the interpretation which, though provisional, best fits the facts is that the increase in γ globulin is the one that is associated with liver damage and the increase in α₁ globulin is brought about as part of the development of immunity to malaria. Liver damage, malaria, and a low-protein diet probably all contribute to the low albumin values.

Liver Pathology

Liver was obtained for histological examination in all cases. In two this was at necropsy, in the remainder by biopsy. The outstanding features were infiltration with fat and some increase in fibrous tissue in the portal tracts and between the parenchymal cells as in the pregnant women.

Response to Treatment

Regarding treatment in these cases, there is general agreement that best results are obtained with well-balanced diets rich in protein. On admission, therefore, all the patients were given a balanced diet and a 50 g. supplement of casein daily. It was not possible to observe the children during a control period before giving them this diet, as their condition on admission was critical. This was emphasized by the fact that two of them died within a few hours.

The responses of these cases were similar to one another, and in brief this meant a gradual improvement in the clinical condition over a period of weeks or months and a coincident rise in haemoglobin and plasma protein levels. As in the pregnant women, no marked reticulocyte crisis occurred, and this is understandable if there is a deficiency of protein rather than of specific haemopoietic substances. The anaemia would thus be unlike that present in pernicious and similar anaemias, where microquantities of a haemopoietic substance are deficient, the other requirements of haemoglobin production being available. Here it is probable that the materials from which haemoglobin is made are defective or deficient, and this can be corrected only gradually.

The slowness of the therapeutic response in malnutrition and undernutrition has been commented on by many workers. Keys *et al.* (1950b), reviewing the literature on starvation during and after the two world wars, state that the plasma protein level in malnourished persons given a liberal diet increases at only a slow rate. This is understandable on the basis of work done by Elman *et al.* (1942), who from experiments on dogs found that a deficiency of 1 g. of plasma protein is equivalent to one of approximately 30 g. of body protein. Thus by computing the plasma protein deficit and multiplying by 30 a rough indication of the total body protein deficit can be reached. In protein-deficient dogs Elman *et al.* noted that, although infusion of

plasma or amino-acids temporarily raised the plasma protein level, it was only after the total body protein deficit had been replaced that permanent elevation of plasma protein level occurred. On the basis of the plasma protein values and the estimated plasma volume the mean total initial body protein deficit in children in this series can be computed as approximately 450 g. per child. According to the League of Nations (1936) standards the mean daily protein requirement for growth and metabolism of those children worked out at 41 g. It is thus clear that, with these large deficits to make good, a diet containing more than 41 g. of protein daily would be needed for a considerable period before normal plasma protein values could be obtained and maintained.

Reticulocyte Ripening

The rate at which reticulocytes ripened was studied in two children. In the first the estimations were made at an interval of three weeks, during which the haematological values of the plasma proteins had not changed significantly. The rate at which reticulocytes ripened also remained virtually constant, the percentage present in the blood diminishing by increments of 0.5 and 0.6 per hour respectively. In the other case estimations were made at the beginning, in the middle, and at the end of a six-week period, during which the haemoglobin level had risen from 8.88 g. to 10.80 g. per 100 ml., and the plasma protein level from 4.97 g. (albumin 0.71 g.) to 5.94 g. (albumin 1.29 g.) per 100 ml. The successive rates at which reticulocytes ripened also improved, the percentage present in the blood diminishing by increments of 0.5, 0.6, and 1.0 per hour. Similar results were obtained in three pregnant women. In one whose plasma proteins had not changed significantly during three weeks the percentage of reticulocytes present in the blood decreased by 0.4 per hour at the beginning and at the end of the period. In two others whose plasma proteins had respectively improved from 7.45 g. (albumin 2.22 g.) and 6.62 g. (albumin 2.23 g.) to 7.9 g. (albumin 2.80 g.) and 7.53 g. (albumin 2.62 g.) per 100 ml., the rate of reticulocyte ripening also improved. Before treatment the percentage of reticulocytes in the blood decreased by increments of 0.64 and 0.5 per hour respectively, and after treatment in each case by increments of 1% per hour.

Nizet and Robscheit-Robbins (1950) have shown that in dogs with simple anaemia the reticulocytes ripen at the normal rate, but in those with anaemia and hypoproteinaemia ripening is delayed. They found that this delay can be overcome by adding various amino-acids or plasma proteins to the suspension, and conclude that the red blood cell at the reticulocyte stage is able to incorporate plasma proteins into itself or synthesize proteins from amino-acids. Thus if the plasma proteins are abnormal or deficient, some disturbance may take place in the ripening of reticulocytes and therefore in the formation of the mature red cell. These workers state that it is at present not clear whether man is ever subjected to protein depletion severe enough to bring about this effect. The present investigations in children and adults suggest, however, that in protein malnutrition of the kind here being discussed the disturbance is sufficient to delay reticulocyte ripening.

Comment

These children with protein malnutrition therefore have an anaemia. They have histological evidence of liver damage, there is gross abnormality of their plasma proteins with reduction in albumin and increase in globulin, and there is evidence of arrest in the ripening of reticulocytes. The condition responds slowly to a good diet rich in protein.

Thus protein malnutrition and anaemia occur in acute or subacute forms during two phases of life in which growth is rapid: in children when the growth is that of their own body, and in pregnant women when it is that of the foetus. The question arises as to what extent protein malnutrition occurs in association with anaemia at other times of life, and, if it occurs, what are the characteristics of the anaemia.

ANAEMIA AND PROTEIN MALNUTRITION IN OLDER CHILDREN AND ADULTS

Of 21 anaemic older Nigerian children and adults studied, all complained of lassitude, weakness, and inability to carry on with their work; most of them also complained of dyspnoea. In 15 the abdomen was distended by hepatomegaly, splenomegaly, or ascites. In most instances the swelling was of considerable extent, as can be seen from Fig. 10. The liver was palpable in 13 cases and the spleen

FIG. 10

FIG. 11

FIG. 10.—Older child with ascites and cirrhosis of the liver. FIG. 11.—The ratio of red blood cell diameter to thickness in 19 older children, adult males, and non-pregnant females suffering from anaemia and chronic protein malnutrition.

in eight. The liver was 3 in. (7.6 cm.) or more below the costal margin in four cases; the spleen reached for a similar distance in three. In 11 patients there was ascites, and in 10 clinically detectable oedema. One patient complained of sore tongue. Some fever was present from time to time in most cases, but there were periods of several weeks without any rise in temperature.

Results of Investigations

Haematological Findings

The initial haematological values in 17 of these cases are summarized in Table IX; four are excluded as complete haematological investigation was not possible in these cases. Once again the anaemia was well marked, there was no great tendency to hypochromia, the M.C.D. was increased, and the M.C.A.T. diminished in almost all cases. The bone marrow was macronormoblastic, but megaloblasts were not found. Schumm's test was positive in three cases.

The Price-Jones curves were displaced to the right in all but two of the cases, in which they were centrally placed. The curves were broader than normal in all cases. The ratio M.C.D./M.C.A.T. is shown in Fig. 11, and it is apparent that in almost all cases the cells were thinner than normal.

Here, then, were a set of anaemias of considerable severity and almost all associated with hepatosplenomegaly, ascites, or oedema, and a macronormoblastic bone marrow. It was again important to exclude sickle-cell disease and parasites as causes of anaemia, and accordingly appropriate searches were made.

Parasites and the Sickle-cell Trait

Of the 17 cases subjected to detailed haematological studies the sickle-cell trait was present in one-fifth. The characteristics of the anaemia in these cases were similar to those of the others in which the trait was not present, and sicklaemia was accordingly thought not to be an important aetiological factor. Cases of anaemia in which overt malaria were found have been excluded.

Ova of *Ancylostoma duodenale* were found in the stools of eight patients, and ova of *Ascaris lumbricoides* in five, a double infection being present in three. The faeces were free from helminthic ova in seven cases. In a further case the only parasite found was *Taenia saginata*, which can be discounted as a cause of anaemia; in yet another, fatal case a single *A. lumbricoides* was found at necropsy. In most of the cases the infections were light as judged by the number of eggs present in the faeces. It is unlikely that a light infection with *A. lumbricoides* plays an important part in the causation of protein malnutrition or anaemia. If to the three cases in which this parasite alone was present are added the seven without intestinal parasites, and the one infected with *T. saginata* only, it will be seen that in 11 of the 21 cases intestinal parasites could be excluded as a cause of the malnutrition and anaemia. In more than half of the patients, therefore, it seemed unlikely that parasites were playing a part in the causation of the disease at the time of their admission to hospital.

Plasma Proteins

Analysis of the plasma proteins both chemically and electrophoretically gave similar results to those found in the children and pregnant women, the albumin invariably being reduced and the globulin greatly increased. The values in

TABLE X.—Plasma Proteins (g. per 100 ml.) in Older Children, Adult Males, and Non-pregnant Females

	12 Patients		7 Patients (Means)	
	Means	Range	Before Treatment	After Treatment
Total protein	6.07	3.93-7.30	5.84	6.34
Albumin	1.96	0.62-3.34	1.94	2.49
Globulin	3.82	2.49-5.02	3.64	3.60
Fibrinogen	0.29	0.14-0.50	0.26	0.25
A/G ratio	0.46/1	0.13/1-0.66/1	0.55/1	0.71/1
Haemoglobin	—	—	6.08	7.71

12 cases are shown in Table X, in which figures obtained before and after treatment are also given. In each of the cases the albumin content improved after treatment with a high-protein diet.

A curve typical of those obtained by electrophoretic separation of the serum proteins in the series is shown in

Fig. 12. Mean values estimated electrophoretically in 11 cases are shown in Table III. In these older children and adults the albumin deficit, and the amount of γ globulin present, were greater than in either of the other groups. This and the advanced liver changes found suggested that malnutrition was of longer standing in cases in this group than in the children and pregnant women.

One point which is clearly brought out by the figures is that the total protein value may give little indication of the disorganization which may be present in the various constituents. Thus one patient's plasma proteins amounted to 7.30 g. per 100 ml., but in that total there was only 1.87 g. albumin compared with 5.02 g. globulin. In an oedematous young male adult who died shortly after admission the figures were: total 5.48 g. (albumin 0.62 g., globulin 4.86 g.) per 100 ml. serum.

Proteins in Ascitic Fluid

The electrophoretic pattern of the proteins in ascitic fluid and the rate at which fluid accumulated were determined in two cases. It was found that in one approximately 4.6 g.,

FIG. 13.—Frozen section of liver from a child who died at the age of 8 with cirrhosis of "hobnail" type. Note fibrous strands and fatty infiltration. The fat appears black in the photograph. (Stain Sudan III and haematoxylin. x35.)

and in the other 7.5 g., of protein were being lost into the fluid daily. Thus the onset of ascites in one of these malnourished persons may constitute a serious drain on protein supplies. In one case the rate of production of fluid fell from 200 ml. to 80 ml. daily after the institution of a high-protein diet. No emphasis is placed on this observation in a single case, but it fitted in well with the hypothesis that protein malnutrition was the most important factor in the causation of the ascites.

Liver Histology

Specimens of liver were obtained either by biopsy or at necropsy in all cases. Again, either fat or fibrosis was a constant finding, and in two cases cirrhosis was gross and

advanced. In one child who died at the age of 8 the liver was found at necropsy to be of the typical "hobnail" type, and in addition to being cirrhotic it was also grossly infiltrated with fat (Fig. 13). Such changes are almost certainly later chronic manifestations of the process which is seen in its early acute form in younger children and pregnant women.

One adult male who died had a primary carcinoma of the liver in addition to gross cirrhosis. On the primary nature of this growth the late Dr. W. D. Silvera and Dr. D. S. Ridley were agreed.

Hippuric Acid Excretion Test

In view of the histological and naked-eye evidence of liver damage obtained it is hardly surprising that abnormally small quantities of hippuric acid were excreted after the usual test doses of 6 g. sodium benzoate had been given. In the five cases in which this was done the mean amount of hippuric acid excreted in four hours and expressed as benzoic acid was 0.946 g., range 0.471-1.973 g. Harrison (1947) considers values below 2.5 g. to be abnormal.

Response to Treatment

In this group treatment was even more difficult than in the children or pregnant women. In general the results were poor, but small increases in haemoglobin with coincident improvement in plasma albumin were usually obtainable after the patient had been on a good diet with a supplement of casein for at least two weeks. In those having a treatable infection, such as ankylostomiasis, the outlook was more favourable. The remainder, however, all had advanced chronic liver disease and belonged to a class of patient notoriously unresponsive to treatment. The evidence pointed to the disease in these cases having reached an irreversible stage. Three of the patients died within a few weeks of admission to hospital; all had grossly cirrhotic livers.

DISCUSSION

There is, therefore, evidence that anaemia in some African older children, adult males, and non-pregnant females may be associated with chronic protein malnutrition and liver damage, and this anaemia has the same characteristics as that found in young children and pregnant women. This type of disease is very much more common in the Tropics than in temperate regions. When it occurs it seems to be more chronic than that in children and pregnant women, and unless there are aggravating parasitic factors it is even less amenable to treatment.

Thus protein malnutrition may develop in acute form in childhood and in pregnancy, both periods of rapid growth. It may occur at other times in chronic form if there is a prolonged drain on protein supplies. Some individuals are probably always bordering on this state of malnutrition, and this might be expected to affect their growth and development and to disturb their metabolic and physiological processes. Thus it has been shown by Burke, Harding, and Stuart (1943) that protein deficiency in pregnancy may lead to a low birth weight of the infant. In Nigeria infants born of women with anaemia weigh, on an average, 2 lb. (0.907 kg.) less than those of healthy women (Woodruff, 1954). Platt (1939) has shown that in malnourished children there is a stunting of growth; the growth curves begin to fall away from normal at 6 months of age, and full physical development may never take place. Anaemia and liver damage appear to be other aspects of this malnutrition syndrome.

There is another way in which the disease may manifest itself on a large scale in the Tropics, and this is in

the development of gynaecomastia. Several of the male patients in the series suffered from this, and it is a common condition in Africans, Trowell (1948) finding 25 (5%) of 500 East African railway workers so affected. Figs 13 and 14 are photographs of two of the patients

FIG. 14

FIG. 15

Figs. 14 and 15.—Gynaecomastia, probably resulting from liver damage caused by protein malnutrition.

studied. In these cases once again liver biopsy showed fatty infiltration or fibrosis. It seems that the gynaecomastia results from damage which renders the liver incapable of inactivating oestrogens normally produced, and this damage also is probably caused by prolonged protein malnutrition. Disturbances of this kind illustrate the gross changes in bodily functions which may occur in the syndrome.

CONCLUSIONS

This study indicates that the natural history of anaemia associated with protein malnutrition may briefly be summed up as follows:

Evolution of Nutritional Macrocytic Anaemia Associated with Liver Damage

Among certain communities children may be born with livers already damaged by maternal malnutrition. If they survive they again pass through a period following weaning during which the demand for protein imposed by growth is greater than the supply, and the liver is liable to be damaged. At these times an anaemia and other signs of malnutrition may develop. The anaemia is associated with a macronormoblastic marrow and with red cells which are broader and thinner than normal. Many succumb while passing through this stage in childhood; others recover, but probably the majority of these latter are left with some hepatic damage and fibrosis. Nevertheless the functional reserve of the liver is such that, in spite of this, the patient manages until he or she passes through a period in which demands for protein are again in excess of the available supply. In women this state may occur in acute form during pregnancy, foetal growth being the precipitating factor. In adult males and non-pregnant females the disease is less common, but when seen in hospital practice in Nigeria it usually represents a late stage of a chronic process. It develops if the diet is markedly and chronically deficient in protein, and particularly if parasites impose an additional drain on deficient supplies of nutrients. In these cases one of the factors in the causation of the anaemia may be that haemoglobin in its production can draw on plasma proteins, as has been shown by Whipple (1948), and thus when these proteins are abnormal or deficient the production of haemoglobin may be affected. In these cases abnormality, as distinct from deficiency, of plasma proteins may arise from the production of antibodies containing protein, or from liver disease, it being established that the liver plays an important part in protein synthesis.

The characteristics of protein malnutrition in Nigerians are similar whether it occurs in childhood, in pregnancy, or in adult life unassociated with pregnancy. In many cases the disease starts in early life, or even in intrauterine life, and progresses as it is aggravated during periods of growth or deprivation until finally it ends in advanced hepatic cirrhosis with all its concomitant haematological and other features. This stage may even be reached in childhood.

Many of the clinical and pathological states considered in this work are gross and unlikely to be encountered in Great Britain. Nevertheless they provide an insight into the function of various organs and tissues, and into processes which may affect the body in a less florid form in the temperate zones in conditions—such as nephrosis, exudative dermatoses, burns, alcoholism, and cirrhosis of the liver—resulting from non-nutritional causes.

Finally it should be added that Dr. Goulston clearly wished these lectures to illustrate disease processes, for he directed that they should be read "on some dead body, if possibly it can be procured, which shall then and there be dissected for the diseases treated of, and shall afterwards be buried." It is hoped that this study of the natural history of anaemia associated with protein malnutrition may have applications which extend beyond the syndrome seen in the Tropics to disease processes encountered in other regions of the world.

I am grateful for help and co-operation received from many persons while carrying out this work, particularly from Professor A. Brown, Mr. J. B. Lawson, Dr. A. B. Tompkins, and Dr. K. Mellanby. To Professor B. S. Platt I am indebted for much helpful criticism. For technical assistance I wish especially to thank Mr. L. E. Pettitt, Mrs. A. Walshe, and Miss I. Florence.

This work would not have been possible without a generous grant from the research funds of the Hospital for Tropical Diseases, London.

A plea for more enlightened treatment of criminals was made by Sir DAVID HENDERSON in the Morison lecture on "Society and Criminal Conduct," which he delivered last December at the Royal College of Physicians of Edinburgh. He declared that further research must be devoted to the causation and motivation of abnormal conduct. By the time criminal behaviour had been fully established it was often irremediable. The law must be sufficiently elastic to take cognizance of all the data, hereditary, physical, and social, surrounding criminal behaviour. Society must take care that the law is not merely a system of revenge. "We may extol the reformatory outlook, but the spirit of revenge and retaliation, of hate and anger, and resentment, has its roots dug deep." His analysis of 150 "lust cases" shows the difficulty of reconciling the legal with the medical approach; a disturbing feature of homosexual cases was the inconsistency of the sentences imposed. Of 129 reprieved murderers, 112 had made a satisfactory readjustment to society. The 150 lust cases showed 81 sane, 17 insane, 26 defective, and 26 psychopathic. Sir David said he had come to believe that abnormality and unsoundness of mind could not be accepted as synonymous. Abnormality demanded an individual approach which could be effected only through clinical research. There was a close parallel between mental illness and the disorders that resulted in crime; both were best treated at a preventive level.

EXPRESSION OF THE SICKLE-CELL GENE IN AFRICA

BY

G. M. EDINGTON, M.D., D.C.P., D.T.M.&H.

Specialist Pathologist, Medical Research Institute, Accra, Gold Coast

AND

H. LEHMANN, M.D., Ph.D., F.R.I.C.

Senior Lecturer in Chemical Pathology, St. Bartholomew's Hospital, London

It has always been difficult to reconcile the accepted theory of the inheritance of sickle-cell anaemia with the facts found in Africa. Neel (1947, 1949) and Beet (1949) concluded that the sickle-cell gene was harmless in the heterozygote but produced sickle-cell anaemia in homozygotes. Although the sickle-cell trait has been found to be present in 20, 30, and even 40% of individuals in some African peoples, the anaemia is considered to be rare in adults. In infants, however, it has been found to occur with a frequency which falls well within the range of the expected incidence of homozygotes (J. and C. Lambotte-Légrand, 1951; Foy, Kondi, and Brass, 1951; Vandepitte and Louis, 1953; Hutton, 1953; Welbourn and Raper, 1954). Nevertheless one of us stated: "I do not believe that in Uganda we could have overlooked sickle-cell anaemia present in all homozygous carriers of the trait. Even if they had died in early infancy, it would have been such a 'slaughter of the innocents' that it could not have escaped our attention" (Lehmann, 1952).

A high incidence of the trait in an adult population with a low incidence of sickle-cell anaemia could be explained most easily by the early death of affected infants. Such a removal of the gene, however, before the age of procreation should lead to a fall in the sickling incidence. Neel (1953) has suggested that the high incidence of the trait found in certain peoples might be explained either (a) by a very high rate of mutation from the gene for normal haemoglobin to that for haemoglobin S, sufficient to replace the loss by death from sickle-cell anaemia, or (b) by a reproductive advantage over the normal or non-sickling homozygote conferred on the heterozygote by the haemoglobin S gene balancing the disadvantage of the anaemia in S homozygotes—the theory of balanced polymorphism. Neel thought that there was some evidence of an increased mutation rate in his family studies in the U.S.A.; but Vandepitte (1954), in the Belgian Congo, could find no evidence of a mutation rate sufficient to replace the loss of S homozygotes in infancy. Balanced polymorphism has been proposed as a possible mechanism for the maintenance of congenital anaemias by Haldane (1949) and for the survival of the sickle-cell trait by Beet (1946, 1947), by Raper (1949), and particularly by Brain (1952a, 1952b). They all suggested that the sickle cell might be more resistant to tropical parasites, particularly the malaria parasite.

Allison (1954) was the first to report very striking differences in the degree of incidence of malaria parasites in sicklers and non-sicklers, though his work has been challenged by Moore, Brass, and Foy (1954). Recently Raper (1954) has reported a statistically significant difference in the degree of parasitaemia of sickling and non-sickling children during the second year of life.

There exists, however, yet a third possible explanation of the high incidence of the S gene which can be added

to those described. If it was found that some healthy African adults were homozygous for the S gene, it would explain in part why sickle-cell anaemia is not found with the expected frequency in adults and why the trait is inherited more often than one would expect if all the homozygotes died in early infancy. One of us (Edington, 1953) was struck by the histories given by patients suffering from sickle-cell anaemia in the Gold Coast. Symptomatically these patients improved with advancing years. One patient aged 44 had been free from crises for nine years and had had six children, three of whom were alive and well; another, aged 39, was suffering from sickle-cell anaemia but had five children who were all alive and well. In view of the discovery, however, of modified sickle-cell anaemia in individuals heterozygous for S and another inherited abnormality of haemoglobin (sickle-cell-thalassaemia, sickle-cell-haemoglobin C disease, sickle-cell-haemoglobin D disease; see Itano, 1953a) there was a possibility that these patients were not the true S homozygotes, as electrophoretic analyses of the haemoglobins had not been performed.

Electrophoretic Tests

Until recently the study of the genetics of sickling depended on the testing of whole families for the presence or absence of the sickling character in the red cells and on the clinical condition of those showing sickling; the diagnosis of homozygosity and heterozygosity was subject to considerable doubt. With the introduction of electrophoretic tests on haemoglobin there is now no reasonable doubt that, subject to certain rare exceptions, a determination of the genotype can be made by means of a single test on the blood of an individual, and need not depend on a study of the rest of the family. Normal non-sickling persons show as a rule 100% of haemoglobin A, and in any case no haemoglobin S. Heterozygous sicklers have both types of haemoglobin, while homozygous sicklers have mainly haemoglobin S, together usually with a varying amount of persistent foetal haemoglobin (haemoglobin F) but no haemoglobin A.

There is very strong evidence that genes for haemoglobins A, C, D, E and G, and S belong to a series of multiple alleles, so that all homozygotes and all heterozygous combinations of them can be diagnosed electrophoretically, except that haemoglobins D and S are indistinguishable, as they have the same electrophoretic mobility. Homozygous haemoglobin D (never yet found) could certainly be distinguished by the absence of sickling, but SS and SD can be separated only by solubility measurements. Haemoglobin S is much less soluble in the reduced state than haemoglobin D; thus SS and SD can be separated by their different solubilities. To establish the claim that an individual is a homozygote for haemoglobin S, electrophoretic and solubility studies are therefore necessary. As S homozygotes also possess foetal haemoglobin, a possibility arises that individuals with sickle-cell-thalassaemia disease (SAF) could be mistaken for S homozygotes (SSF).

As Itano (1953a, 1953b) has pointed out, the solubility of the haemoglobin of an SS individual depends on the proportion of F being present; thus the solubility of haemoglobin from an S homozygote with a high proportion of persistent F may be within the same range as the solubility of the haemoglobin of a patient with sickle-cell-thalassaemia disease, in whom the proportion of S is high and that of F moderate and A low. If the amount of A is small—up to 8.2%—it may escape detection by electrophoresis (Singer and Fisher, 1953). Thus a sickle-cell homozygote with a high percentage of foetal haemoglobin and a sickle-cell-thalassaemia individual may not be differentiated by electrophoresis (though this will be exceptional), and the solubility of the two haemoglobin mixtures may be within the same

range, the upper range for that seen in SS homozygotes. If such a finding is made the only recourse is still the family study. However, thalassaemia has never been found in the Gold Coast, in spite of an exhaustive search. This was stimulated particularly by a high incidence of target cells (Edington, 1953).

We have recently conducted a survey of Gold Coast Africans for abnormal haemoglobins (Edington and Lehmann, 1954), and were particularly interested in trying to discover whether in such an investigation symptomless homozygotes for the S haemoglobin could be found. Of the 200 individuals examined, 38 were sicklers, and two of these were homozygous for the S gene (which incidentally would be the expected incidence for homozygotes).

Case 1

J. A. S., a plethoric African man of the Gã tribe aged 40, reported to the out-patient department of the Gold Coast Hospital complaining of epigastric pain occurring about half an hour after meals during the last six weeks. Previous history, family history, physical examination, and laboratory and radiological investigations revealed no abnormality apart from sickling of the erythrocytes and that the patient was symptomatically relieved by alkalis. He had had three children, one of whom, a son aged 22, was alive and well. A boy aged 14 had died of dysentery and a girl aged 7 of "measles." When the analysis of the haemoglobin revealed that J. A. S. was an S homozygote further investigations were made. On direct questioning he admitted that he had suffered from "rheumatism" in childhood. At the age of 8 he had had attacks of pain in the larger joints of the limbs accompanied by fever; these attacks occurred about ten times in that year and gradually lessened in frequency and severity until they ceased at the age of 18.

Laboratory Investigations.—Urine: no sugar, bile, albumin, casts, or urobilin. Kahn test negative; van den Bergh negative; serum bilirubin, 0.3 mg. per 100 ml.; haemoglobin (Grey wedge), 13 g. per 100 ml.; red cells, 4,600,000; reticulocytes, 1.2%; white cells, 5,400; P.C.V., 43%; sickling of the erythrocytes—no filamentous forms noted; thin film and differential count revealed no abnormality apart from the presence of scanty target cells (less than 4%).

Case 2

E. B. A. D., a well-built man of the Akwapim tribe aged 30, reported to the out-patient department of the Gold Coast Hospital complaining of a "rash." He was suffering from a mild neurodermatitis which cleared rapidly with treatment. Analysis of the haemoglobin revealed that he was an S homozygote.

On direct questioning he admitted that he had suffered from attacks of pain in the larger joints which had begun at the age of 12 and were worse in the rainy season. During these attacks his eyes were yellowish and his urine was highly coloured. The attacks were never severe, and ceased at the age of 25, when he stopped playing football—to which game he attributed the illness. His parents were dead, cause unknown. He is married with one child alive and well. Physical examination revealed no abnormality. Neither the liver nor the spleen was palpable.

Laboratory Investigations.—Kahn test negative; serum bilirubin, 0.7 mg. per 100 ml.; haemoglobin (Grey wedge) 15.5 g. per 100 ml.; red cells, 4,860,000; reticulocytes, 1%; white cells, 4,600; P.C.V., 48%; no abnormality detected in the thin film. Urine: urobilin present in a dilution of 1:2.

Investigation of the Haemoglobins

The chemical investigation of the two bloods showed all the features usually considered typical of sickle-cell anaemia. Fig. 1 shows the electrophoretic pattern of the haemoglobin of both individuals—a single band in the S position. Both bloods contained foetal haemoglobin determined by alkali denaturation (Singer, Chernoff, and Singer, 1951). The

FIG. 1.—The blood of J. A. S. and E. B. A. D., two Gold Coast Africans, is compared by paper electrophoresis with a blood containing as a "marker" A and C haemoglobins. Both individuals show a single band in the S position. Foetal haemoglobin was found by chemical means, but it does not separate on paper electrophoresis from A or S haemoglobin. The haemoglobins are photographed unstained (for detailed technique see Lehmann and Smith, 1954).

solubility of the haemoglobins determined after Itano (1953b) certainly for the first individual fell well within the range of the solubilities found by that author only in sickle-cell anaemia (<0.44 g./l. of 2.24 M phosphate buffer).

	% Alkali-resistant (Foetal) Haemoglobin	Solubility in g./l. of 2.24 M Phosphate Buffer
J. A. S.	5.2	0.15
E. B. A. D.	24.2	0.50

The second individual shows a high foetal haemoglobin and the solubility is within the range for that seen in both sickle-cell anaemia and sickle-cell-thalassaemia disease (0.44–0.90 g./l. of 2.24 M phosphate buffer). It has already been pointed out that the possibility of finding the sickle-cell-thalassaemia disease in the Gold Coast can be disregarded, and so far as the major argument of this communication is concerned it may be stated that from the accepted point of view both sickle-cell homozygotes (SSF) and sickle-cell-thalassaemia individuals (SAF) should be suffering from anaemia.

It thus seems that, at least in the Gold Coast, the homozygous inheritance of the S gene can be a benign condition which would be missed in ordinary clinical and haematological investigations and which may be detected only by the analysis of the haemoglobin.

The Sickle-cell Trait

While it has been shown that every sickle-cell haemoglobin homozygote need not suffer from a severe disease, it cannot, on the other hand, be taken for granted that the heterozygous condition will always be entirely harmless and express itself solely as a trait rather than as a disease. Haematuria due to pathological lesions in the kidney and ascribed to the presence of the sickle-cell trait has been described in American negroes (Harrison and Harrison, 1952). Vernier (1955) summarizes 35 reports of one-sided renal haemorrhage in sickle cell individuals, most of them sickle cell trait carriers.

We have recently seen in Accra a girl of the Gã tribe, aged 18, suffering from haematuria, whose haemoglobin on electrophoretic analysis revealed the presence of the trait—that is, of both normal and sickle-cell haemoglobin. No history of previous illness was given and the physical examination revealed no abnormality. The results of the laboratory investigations were as follows. Urine: numerous red blood cells present; a few of them were abnormally shaped, but no definite sickle cells were seen. Culture was sterile and guinea-pig inoculation was negative. Serum bilirubin, 1.2 mg. per 100 ml.; direct van den Bergh test negative. Hb, 12.3 g. per 100 ml.; red cells, 4,320,000; reticulocytes, 2.8%; white cells, 8,100; P.C.V., 33%; sickling positive. A peripheral blood film showed many target cells with an occasional poikilocyte and polychromatic red cell. The alkaline phosphatase and thymol turbidity were within normal limits. The haematuria cleared within a few days, but no follow-up was possible. It cannot be claimed that the presence of the trait was definitely responsible for this girl's symptoms, but in view of the reports in the American literature it must be considered in the differential diagnosis of the condition.

The sickling phenomenon may certainly play a part in the terminal phases of other diseases where the picture of the crises can be seen at necropsy without evidence of previous acute episodes (Thoma, 1953). At the present moment it is not clear whether these crises, which are not uncommon in the Gold Coast (Edington, 1951, 1955), occur most often in the S homozygote, in the heterozygote for S and normal haemoglobin, or in the individual bearing the S gene in combination with some other abnormal haemoglobin. In an attempt to elucidate this problem we have recently begun to examine electrophoretically the blood of all subjects coming to necropsy, and the crisis has been noted in one woman suffering from sickle-cell haemoglobin C disease. In addition, however, the blood of another woman (K.L.), who presented at necropsy the typical features of the crisis, revealed on electrophoretic analysis the presence of the trait only (normal and sickle-cell haemoglobin) (Fig. 2), as is described in detail below.

FIG. 2.—The blood of K.L., who died in sickle-cell crisis, is compared by filter-paper electrophoresis (for details see Lehmann and Smith, 1954) with a "marker" blood from an individual heterozygous for A and C haemoglobins. The haemoglobin of K.L. shows bands in the S and A position. K.L. is heterozygous for A and S haemoglobins.

Crisis in a "Sickle-cell-trait Carrier"

K.L., an African woman of the Gã tribe aged 23, was admitted to the Maternity Hospital, Accra, in a comatose condition. Shortly after admission she died following the expulsion of a hydatidiform mole. She had had one previous child, who had died in infancy. No history of previous illnesses was obtained from the relatives. The patient had been ill for two weeks with fever. Substernal pain and cough had been noted during the last week and she was thought to be three months pregnant.

Necropsy Report.—The body was that of a well-built plethoric African female. The sclerae were slightly jaundiced. There was frothy mucus in the trachea and the lungs were congested and grossly oedematous (795 g.). Heart: the left ventricle was hypertrophied; no lesions of the myocardium, valves, or coronary arteries were noted (320 g.). The liver was congested (1,975 g.). The spleen was enlarged, rubbery in consistency, and dark blue in colour (495 g.). The cut surface was dark red and did not bleed on section. The uterus was enlarged to the size of a three-months pregnancy. No abnormal blood clot was present and the placental site appeared macroscopically normal. The remaining abdominal organs exhibited intense pallor and the kidneys were oedematous. The sternal marrow was dark red and dry. The brain was pale and the vessels contained watery blood. The heart's blood showed sickling on direct examination, and electrophoretic analysis of the haemoglobin revealed the presence of sickle and normal adult haemoglobins (Fig. 2).

Histological Examination.—All organs were fixed in 10% formol saline and transferred to formol sublimate saline before embedding. **Liver:** The sinusoids were congested and contained numerous white blood cells; the Kupffer cells were distended and contained numerous sickled erythrocytes; free iron-containing pigment was present in the Kupffer cells and periportal parenchymal cells. **Haemofuchsin** was not detected; a little malarial pigment was present. **Spleen:** There was gross congestion and haemorrhage and the sinuses were stuffed with sickled cells; the Malpighian corpuscles were widely separated and com-

pressed; the germinal centres were hypertrophied and surrounded by a narrow rim of lymphocytes; traces of free iron-containing pigment were present; a reticulin stain showed interruption of the normal reticulin pattern in the areas of haemorrhage. **Uterus:** Tags of placenta were adherent and a marked polymorphonuclear infiltration with small abscesses was present. **Lung:** The smaller vessels were congested with sickled erythrocytes. The alveoli showed gross oedema and heart failure cells were present. **Kidney:** An occasional hyalinized glomerulus was noted, and there were occasional casts in the collecting tubules. Thrombosed vessels were not noted and no free iron was present. Apart from a normoblastic hyperplasia seen in the sternal marrow no other abnormality was noted in the remaining organs.

Comment.—The gross pathology of the spleen and the histopathology of the liver and spleen were those found in the sickle-cell crisis. Mild haemolysis was also probably present, as shown by the presence of jaundice, iron pigment in the Kupffer cells, and a normoblastic hyperplasia of the sternal marrow. This was probably not of long standing, as there was only a little free iron in the spleen, and none in the kidney. Undoubtedly a septicaemic element was also present, and it is difficult to decide what part this played as an eventual cause of death. It is considered that the terminal crisis was probably initiated by the septicaemic condition and was directly responsible for death.

Discussion

Two Gold Coast Africans, to all intents and purposes healthy, have been found to be homozygous for the sickle-cell gene. Previously it had been thought that most patients suffering from sickle-cell anaemia died in childhood, and it was difficult to explain the high incidence of the trait in certain communities because of this belief. At the present time the mortality occurring in S homozygotes is not known, but it is possible that a considerable number reach adult life, procreate, and lead relatively normal lives. One of us (G.M.E.) has now observed over 50 patients suffering from sickle-cell anaemia, and the prognosis, in the Gold Coast at least, is by no means gloomy. Many of these patients have improved with the passing years and are able to lead useful and normal lives. It is too early yet to venture an opinion on the fertility of these patients, as the majority were children when first seen and have not yet reached the age of marriage, but from the histories obtained in the older patients it is not expected that fertility would be greatly impaired. The survival of the relatively healthy homozygote may be a potent factor in maintaining a high incidence of the trait in certain peoples.

On the other hand, there is no doubt that sickle-cell anaemia is the cause of considerable mortality, the exact extent of which is unknown, and in this communication it has been suggested that the trait itself may be by no means harmless. It is impossible to say to what extent procreation by S homozygotes helps to balance the mortality caused by the sickling phenomenon, but this possibility must be taken into account, in addition to the possible protection afforded by the trait against malaria and a possible high mutation rate of the S gene, when discussing reasons for the persistent high incidence of the trait in certain African and Indian peoples.

Summary

Of 200 individuals examined in the Gold Coast, 19% showed sickling and two (1%) were found to be homozygous for S haemoglobin. They were adults not suffering from sickle-cell anaemia, yet chemically their haemoglobin was indistinguishable from that of such patients.

A sickle-cell crisis is described in a woman heterozygous for sickle-cell and normal haemoglobin.

These findings, and their bearing on the current theories on the expression of the sickle-cell gene and its population dynamics, are discussed.

OSTEOMALACIA IN VON RECKLINGHAUSEN'S NEUROFIBROMATOSIS

METABOLIC STUDY OF A CASE

BY

PAUL D. SAVILLE, M.B., M.R.C.P.

J. R. NASSIM, B.M., F.R.C.P.

F. HARWOOD STEVENSON, M.D., M.R.C.P.

LILY MULLIGAN, B.Sc.

AND

MARGARET CAREY, B.Sc.

From the Royal National Orthopaedic Hospital, London

Von Recklinghausen's neurofibromatosis is a hereditary and familial disease. It is characterized by lesions of skin, nerve, and bone. Skeletal abnormalities are said to occur in 7% of cases (Gould, 1918; Reuben, 1934). The commonest abnormality is scoliosis (Hagelstam, 1946; Fairbank, 1951). There may be overgrowth or undergrowth of individual bones, while neurofibromata may erode the bones from the periosteum or cystic changes may occur in bone.

Apart from neurofibromatous affection of bone, the occurrence of osteomalacia in association with neurofibromatosis has been reported too often to be a chance finding. Gould (1918) reported typical histological findings of osteomalacia in five cases of von Recklinghausen's disease which he examined *post mortem*. He gave no indication of the aetiology. Since then further cases have been reported but without full metabolic investigations. Merklen and Israel (1934) described a case of von Recklinghausen's disease with general rarefaction of bone and Milkman's syndrome. Milkman's syndrome is now generally believed to be invariably due to osteomalacia. Nørgaard (1937) described many radiological abnormalities of the skeleton in two cases.

In Fig. 3, Case 1, of his article it can be seen that the x-ray film of the pelvis shows a pseudo-fracture through the left inferior pubic ramus and another through the superior pubic ramus. The patient was 22 years old, and an x-ray film one year previously showed no pseudo-fracture. This patient then was undoubtedly suffering from osteomalacia. Hernberg and Edgren (1949) reported the case of a woman aged 32 with neurofibromatosis of skin and multiple pseudo-fractures (Looser-Milkman syndrome). She had a serum inorganic phosphorus of only 2 mg. per 100 ml. with normal calcium, and was given 11 million units of vitamin D in twelve weeks with no apparent effect until eight months later, when healing occurred. They suggested that this might be a "parallel phenomenon" to von Recklinghausen's disease or raised resistance to vitamin D. Since then knowledge of the pathogenesis of osteomalacia and rickets has advanced, and it is now clear that these cases are due to a hereditary abnormality of the renal tubule. Dent (1952) described two cases of osteomalacia in von Recklinghausen's disease which he considered to be due to resistant rickets (Types I and II respectively). Fraser and Nordin (1953) reported a case which they felt was due to resistant rickets. Swann (1954) also reported several cases of this syndrome.

We are recording a further case in which the opportunity was taken to make metabolic studies on varying doses of vitamin D, proving conclusively that this disease falls into the group known as resistant rickets. In addition, biopsies were made from affected bone, and the results of these are also reported.

Case History

The patient was a man aged 55 who for seven months before admission had increasingly severe backache, made worse by coughing and sneezing. More recently he noticed aching pain in his shoulders, left ankle, and left foot. Walking was almost impossible. His general health was satisfactory, but he had always had a "weak bladder" and passed urine every 1½ hours by day, and two or three times at night. He had had no relevant past illnesses, apart from "fits" as a child. His father and paternal grandmother had had neurofibromatosis.

Examination revealed a stunted little man with typical skin lesions, both pigmentation and tumours, covering the trunk, head, neck, and limbs. The right leg was 1½ in. (3.8 cm.) shorter than the left, and all the muscles below the right knee were partially atrophied. There was a tarsal equinovarus deformity of the right foot. He gave the impression of being of rather low intelligence, and was virtually illiterate.

Investigations.—Haemoglobin, 98% (14.5 g. per 100 ml.); W.B.C., 6,750 (normal differential count); E.S.R., 3 mm. (Wintrobe). Urine: normal cytology; sterile on culture, no albumin or sugar. Serum calcium, 9.9 mg. per 100 ml.; phosphorus, 2.2 mg. per 100 ml.; alkaline phosphatase, 14.5 King-Armstrong units; potassium, 5.3 mEq/l.; alkali reserve, 29 mEq/l.; blood urea, 37 mg. per 100 ml.; plasma protein, total 6.9 g. per 100 ml. (albumin 3.2 g., globulin 3.7 g.). Urea clearance, 63% of normal (uncorrected). Glucose-tolerance test, normal, rising from 70 to a maximum of 151 and back to 70 mg. per 100 ml. in two hours. Sugar appeared in the urine at the height of the curve. Paper chromatography of urine: No aminoaciduria; superglycine pattern present, which we have come to associate with osteomalacia in the adult (C. E. Dent). X-ray examination showed multiple fractures of ribs ("There is an opacity in the right lower zone which on lateral view is seen to be below the diaphragm, which is tented up over it.") There was some kyphosis and some demineralization of the

spine. "The tibiae and fibulae are markedly porotic. There is a cystic appearance at the upper and lower ends of the left fibula and the upper ends of the tibiae. There is a pseudoarthrosis at the lower end of the left fibula, resulting in valgus deformity of the ankle. There are pseudofractures through the lower third of the shaft of the left tibia and neck of right femur." Fat balance: On 80 g. intake there was 93% absorption over twelve days. The patient required four daily doses of 700 mg. of ascorbic acid orally before he was "saturated."

Pathological Report.—Biopsy specimens were taken from the left femur and left fibula, including the pseudoarthrosis, and also a chip from the tibia in the region of the pseudo-fracture, three months after treatment. *Resected portion of fibula:* The specimen consisted of a length of fibular shaft approximately 2 in. (5 cm.) in length. The upper part was reasonably normal in its external appearance, while the lower part was irregular in contour and ended as one surface of a pseudoarthrosis. Histologically the lower part of the bone was extremely osteoporotic, and its periosteal surface was deeply indented by irregular masses of mucoid fibrous tissue. Degenerated cartilage and fibrocartilage covered the surface of pseudoarthrosis. The upper part of the bone was slightly osteoporotic; excessive amounts of osteoid tissue could not be demonstrated in either situation. *Biopsy from tibia:* Sections showed that the localized rarefaction evident clinically at the site of biopsy (an "Umbauzone" of Looser) was the result of resorption of bone. Haversian spaces were greatly enlarged: there was some irregular new formation of bone, including some periosteal new bone. There was no evidence of excessive amounts of osteoid tissue on the surface of either the compact or the trabecular bone.

Metabolic Procedure.—The patient was admitted to the metabolic ward at the country branch of the Royal National Orthopaedic Hospital. He was not confined to bed, but allowed to sit in a chair. The metabolic regime and the collection of excreta followed the methods advocated by Albright and Reifenstein (1948). Urine was collected in three-day and six-day periods. Food was prepared by the dietitian in the metabolic unit kitchen. Bulk supplies of meat, biscuits, and homogenized milk were used. Bread was made in the unit from unfortified flour.

In these metabolic charts the intakes are measured vertically downwards from the baseline marked O. Positive balance is indicated by the fact that the rectangles showing urinary and faecal output fall below this baseline—that is, excretion is less than intake; and negative balance when they reach above the baseline—that is, excretion is greater than intake.

Distilled water was used throughout. The diet was analysed twice during the balance. The patient was on this diet eight days before balance studies were recorded.

The diet contained; calcium, 813 mg. per day; phosphorus, 1,184 mg.; nitrogen, 12.55 g. Three litres of distilled water was given daily. Balance data for calcium, phosphorus, and nitrogen for six consecutive six-day periods are shown in the Chart. The following points will be noted:

Six-day Periods 1-3.—Patient was given 0.25 mg. (10,000 units) calciferol daily. Faecal calcium was equal to dietary intake with low normal urine calcium. The slightly lowered faecal calcium in period 3 is exactly accounted for by slightly lowered faecal nitrogen, and is therefore due to variation in faecal collections. The net balance for calcium was negative. Phosphorus and nitrogen balance was positive.

Six-day Periods 4, 5, and 6.—Patient was given calciferol 10 mg. (400,000 units) daily by mouth. This resulted in a steady decrease in faecal calcium with a slight rise in urine calcium, bringing the patient into strongly positive balance for calcium and phosphorus. The rapidity of this response shows that the dose of calciferol was unnecessarily high. With the improvement in the calcium and phosphorus balance the serum inorganic phosphorus rose from 2.6 mg. to 3.6 mg. per 100 ml.

Discussion

Osteomalacia results from under-saturation of body fluids with respect to calcium and phosphate ions. This leads to a failure to precipitate calcium salts in the organic matrix of bone. It is manifested by a lowered serum calcium or inorganic phosphorus, or both, with demineralization of bones. The latter may be generalized or localized in the pseudo-fractures described by Looser, and which Albright and Reifenstein (1948) considered to be pathognomonic of osteomalacia.

Osteomalacia can occur from a variety of conditions which, by one means or another, lower the ionic product of calcium $\times$ phosphorus. These are now considered in relation to our own patient.

1. Dietary.—Deficiency of calcium salts or vitamin D. Our patient's diet contained a high proportion of bread and cheese containing adequate calcium salts, and was in fact deficient only in ascorbic acid, and even this had caused no signs or symptoms of scurvy.

2. Absorption Defect.—The commonest cause of osteomalacia in this country is steatorrhoea. The patient gave no history of bowel abnormality. A 12-day fat balance showed 93% of fat absorption on a daily intake of 80 g., during which time metabolic studies showed him to be in negative calcium balance. Moreover, a normal urine calcium excretion virtually excluded a diagnosis of steatorrhoea.

3. Renal Acidosis.—The patient did not have acidosis. Urine calcium was not high. He did not have aminoaciduria.

4. Resistant Rickets Group—Renal Tubular Defect with Hypophosphataemia.—Balance studies show that on a normal intake of calcium and phosphorus, and despite 0.25 mg. (10,000 units) of calciferol daily, he still failed to maintain a normal serum inorganic phosphorus and was in negative balance for calcium, mainly due to high faecal excretion. The positive balance for phosphorus was accounted for by the positive nitrogen balance. On administration of 10 mg. (400,000 units) of calciferol daily, the patient went into strongly positive calcium and phosphorus balance, and the serum inorganic phosphorus rose from 2.4 to 3.7 mg. per 100 ml. He has since been maintained on half of this dosage of calciferol, with remission of all symptoms and healing of his pseudo-fractures.

This type of balance chart is highly characteristic of cases of resistant rickets in adults or older adolescents. The total lack of response to 10,000 units of calciferol daily is quite unlike other types of osteomalacia, which are

particularly sensitive to these small doses (Bauer and Marble, 1932). On the other hand, the immediate and considerable improvement in calcium and phosphorus balance on massive doses of calciferol indicates that osteomalacia is present but "resistant" to doses of calciferol which would cure other types of the disease than resistant rickets. It has been shown by Bauer, Marble, and Claflin (1932) that normal subjects on large doses of calciferol will show a prompt improvement in absorption of calcium and phosphorus, but, unlike osteomalacics, there is an equally great increase in urinary calcium and phosphorus, so that the calcium and phosphorus balance is not improved. In our case the marked improvement in calcium and phosphorus balance on high doses of calciferol confirms that the patient was suffering from osteomalacia.

The histological criterion of active osteomalacia is the presence of excessive osteoid disposed as wide bands of pale staining tissue on the surface of both compact and trabecular bone. In the present case, although evidence of osteomalacia had been clear, the absence of this histological feature at the time of biopsy after three months of high dosage with vitamin D indicates that remineralization of osteoid had been effected.

Summary

Metabolic balance studies on a case of von Recklinghausen's neurofibromatosis with osteomalacia is presented.

The association of the two diseases is noted, and proved cases previously mentioned in the literature are quoted.

The aetiology of the osteomalacia is shown to be a renal tubular defect, presumably congenital, which brings it into the group of diseases usually known as resistant rickets.

Bone biopsy showed that there is osteoporosis as well as osteomalacia. The cystic appearance of bone is due to combined osteoporosis with deep indentation of bone by mucoid fibrous tissue originating from the periosteum. There was no histological evidence of osteomalacia at the time of biopsy, presumably as a result of treatment.

We wish to thank Dr. James Dow for referring this case to us; Mr. John W. Woolen for the serum analyses and fat balances; Miss Patricia Carroll for her help in the routine chemical investigations; and the nursing staff of the metabolic unit for their care of the patient during the prolonged periods involved in these balances.

POST-OPERATIVE STAPHYLOCOCCAL ENTEROCOLITIS DURING ANTIBIOTIC THERAPY

BY

B. J. FOWLER, F.R.C.S.

Lately Senior Surgical Registrar, Derby

Staphylococcal enteritis during antibiotic therapy is now of clinical importance. An antibiotic-induced intestinal bacterial vacuum in the recipient renders conditions very suitable for colonization by resistant staphylococci (Smith, 1952). Though chlortetracycline ("aureomycin") and oxytetracycline ("terramycin"), the most potent producers of an intestinal bacterial vacuum, have normally been incriminated, chloramphenicol, and penicillin and streptomycin together, have also been blamed. Zischka (1950), quoted by Herrell *et al.* (1953), even described a case following sulphaguanidine therapy. Parenteral administration has also produced the condition (Reiner *et al.*, 1952; Fairlie and Kendall, 1953; Herrell *et al.*, 1953). The normal post-operative increase in adrenocortical hormones may account for the infection gaining a hold, even in some cases without the aid of antibiotics (Herrell *et al.*, 1953). It seems justifiable to differentiate staphylococcal enteritis from post-operative pseudo-membranous enteritis; Prohaska *et al.* (1954), Dearing and Heilman (1953), and Pettet *et al.* (1954) are also of this opinion.

Cross-infection is the main factor in its causation. Cases have been described by Kramer (1948), Reiner *et al.* (1952), Dearing and Heilman (1953), Gardner (1953), Terplan *et al.* (1953), Wakefield and Sommers (1953), Hay and McKenzie (1954), Choremis *et al.* (1954), Williams (1954), Spink (1954), Bowie (1954), and Fairlie and Kendall (1953).

Three further cases are now recorded.

Case 1

A small, ill woman aged 68 had a strangulated femoral hernia repaired, 4 cm. of severely affected ileum being returned to the abdomen. She received 1 g. of streptomycin and 300,000 units of aqueous procaine penicillin intramuscularly twice daily for 4½ days. The streptomycin totalled 9 g. The wound suppurated and local infection increased over the next two days. The pus was not cultured. Her general condition deteriorated. Oral chloramphenicol, 0.5 g. six-hourly, was begun at 10 a.m. on the sixth day after operation. Two days later the wound was only slightly inflamed, and her general condition had so improved that provisional arrangements for her return home were made.

However, the next day she vomited several times and had severe diarrhoea. Her throat was red and sore. Chloramphenicol was stopped, a total of 6.5 g. having been given. She deteriorated with vomiting, diarrhoea, and circulatory collapse, and died ten days after operation.

At necropsy, otherwise healthy small and large intestines were full of a creamy and practically odourless light-yellow fluid. Acute infantile gastro-enteritis was simulated. This observation led to culture of the fluid, which gave a growth of coagulase-positive staphylococci insensitive to penicillin, sulphathiazole, streptomycin, chloramphenicol, and chlortetracycline. It was concluded that staphylococcal enteritis caused death.

Case 2

A man aged 35 with Crohn's disease received pre-operatively 26 g. of succinylsulphathiazole in 5½ days and streptomycin 2 g. and 1 g. on the two days before operation.

Right hemicolectomy was performed. Post-operatively he received 300,000 units of "distaquaine" and 0.5 g. of streptomycin intramuscularly twice daily. Apparently well, he passed a large loose stool on the evening of the day after the operation and a loose greenish stool the next morning. At 5.45 p.m. that day he collapsed with severe diarrhoea, dyspnoea, and cyanosis, lapsing into semicoma. The pulse was rapid and the blood pressure unrecordable. Penicillin and streptomycin therapy was discontinued. A total of 1.5 g. of intramuscular streptomycin had been given. Examination of a direct smear of anal discharge showed Gram-positive cocci, later proved to be *Staphylococcus aureus*.

Despite massive intravenous therapy his general condition failed to improve. Erythromycin, 400 mg., was administered via an indwelling Ryle's tube at midnight and again at 6 a.m. three days after operation with 0.5 g. of chlortetracycline intravenously. Diarrhoea continued. The patient died at 10.45 a.m. on the third post-operative day.

At necropsy a normal stomach contained 300 ml. of bile-stained fluid. Loops of intestine were bound together by thin fibrinous adhesions. The jejunum and ileum were acutely inflamed with a very red mucosa, containing much mucus and soft yellow exudate. The colon contained mucus and similar yellow fluid. The anastomosis was perfect. The exudate showed large numbers of Gram-positive cocci and relatively few faecal organisms, although a culture of anal discharge taken a few moments before death had shown enterococci only. Culture gave a growth of coagulase-positive *Staph. aureus*, enterococci, and coliform bacilli insensitive to penicillin and streptomycin.

Case 3

A stout, well-preserved woman aged 82 had a perforated gastric ulcer oversewn. Premedication had included 500,000 units of aqueous penicillin and 1 g. of streptomycin.

During a satisfactory post-operative course she received 300,000 units of distaquaine and 0.5 g. of streptomycin twice daily. Her bowels moved normally on the morning of the third day. However, at 2 p.m. the same day persistent vomiting and severe diarrhoea developed. Later, yellowish mucoid fluid was frequently voided. Her general condition rapidly deteriorated. Penicillin and streptomycin were stopped. The streptomycin given totalled 3.5 g. Despite intravenous fluid and chlortetracycline she lapsed into coma and circulatory failure, dying at 2 a.m. on the fourth post-operative day.

Necropsy showed an oversewn healing gastric ulcer in the fundus of the stomach. The small intestine was injected and contained thin pale fluid. No ulceration was present. Culture of the fluid gave a moderate growth of staphylococci, coagulase-positive and insensitive to penicillin and streptomycin. Enterococci and coliform bacilli were also present.

Discussion

Sudden severe diarrhoea, collapse, vomiting, and the finding in the intestinal fluid of staphylococci resistant to the antibiotic used were the salient features of these cases. The sudden onset and severe cholera-like course are noteworthy.

Under oral erythromycin the intestinal fluid in Case 2 became free from staphylococci. Nevertheless these organisms were obtained from the mucosa and membrane at necropsy. Terplan *et al.* (1953) recorded the same state of affairs. It probably represents the first stage in the elimination of the staphylococci.

Penicillin active against Gram-positive organisms and streptomycin against Gram-negative organisms are, when given together, similar in action to, but less powerful than, the wide-spectrum antibiotics. This paper and the experiences of Fairlie and Kendall (1953) and Choremis *et al.* (1954) show that penicillin and streptomycin given together can give rise to antibiotic-resistant fatal staphylococcal enteritis.

The advent of antibiotic-resistant staphylococci makes the administration of antibiotics potentially hazardous. Their prophylactic post-operative "umbrella" use in abdominal surgery becomes inadvisable. McKittrick and Wheelock (1954) could find in their cases no evidence that routine antibiotic measures, in the absence of specific indication, lessened post-operative morbidity. Moreover, should infection ensue after such routine use, there is a very real danger that the causative organism will be resistant to the antibiotics used.

Neither of the two patients treated responded to the intravenous fluid given. Frequent vomiting militates against efficacious oral therapy even though the staphylococci may be presumed to be still sensitive to erythromycin. Early diagnosis and, better, prevention is important.

Diagnosis is made on the clinical picture and confirmed by the finding of Gram-positive cocci in a direct smear of the anal discharge. Intravenous fluid replacement must be commensurate with the intestinal loss of fluid. Isolation nursing of the patient to limit spread of the numerous antibiotic-resistant staphylococci is required.

If in special cases wide-spectrum antibiotics have been used pre-operatively, a specimen of the bowel contents taken at operation should be cultured. Should staphylococci be found, treatment with erythromycin will avoid overt superinfection (Dearing and Heilman, 1953).

Though the poorly absorbed sulphonamides have greatly reduced sepsis in large-bowel surgery, the search for more thorough sterilization continues. Neomycin alone, or fortified with phthalylsulphathiazole or bacitracin, may be such an antiseptic (Fog, 1953, 1954; Poth, 1953; Anlyan *et al.*, 1954). These, however, produce the most complete and prolonged bacterial vacuum so far known. The possible advent of new clinical syndromes consequent upon the disturbance of the normal intestinal flora should be remembered (Smith, 1952). Animal experiments suggest that too thorough bowel disinfection renders implantation of carcinoma at a suture line more likely (Vink, 1954).

The lesson to be learned from these cases is that, at present, pre-operative large-bowel antisepsis should be obtained by the use of the poorly absorbed sulphonamides alone and that the combination of penicillin and streptomycin can give rise to staphylococcal enteritis. The use of penicillin and sulphadimidine has not, so far as I know, given rise to staphylococcal enteritis.

Summary

Three further cases, all fatal, of antibiotic-induced post-operative staphylococcal enteritis are reported.

Established cases respond poorly to treatment.

At present, pre-operative large-bowel antisepsis should probably be confined to the use of the poorly absorbed sulphonamides alone. With scrupulous anastomotic suturing, free from tension, an uneventful recovery should follow.

Post-operative use of wide-spectrum antibiotics should normally be reserved solely for the treatment of established complications of some magnitude.

Staphylococcal enteritis is a heavy price to pay for prophylaxis against possible sepsis.

It is now quite evident that in an attempt to banish the risk of sepsis in abdominal surgery—an infection which the unmolested patient will overcome provided it is not excessive or continuing—we may subject the patient to infinitely more serious hazards by the precipitate administration of wide-spectrum antibiotics.

I wish to thank Dr. D. Evans and Dr. I. MacKenzie for the bacteriological work; Mr. J. R. Ratcliffe and Mr. G. Harrison for access to the cases; and Mr. H. Blacow Yates and Mr. F. O'Gorman for help and encouragement in writing this paper.

REPAIR OF INJURIES TO THE TENDONS OF THE HAND

BY

R. F. BOGDANOV, M.D.

Director of the Institute of Traumatology, Orthopaedics, and Restorative Surgery, Sverdlovsk; Corresponding Member of the Academy of Medical Sciences of the U.S.S.R.

In our country, Pirogov as early as the middle of the nineteenth century demonstrated experimentally the role of haemorrhage within the tendon sheath in the regeneration of damaged tendons. He was the first of many to contribute to the study of the circulation in relation to problems of regeneration and repair of tendon injuries.

During the last thirty-five years improvements in the surgery of tendon injuries have been made by Janelidse, Girgoloav, Ruffanov, Gorinovskaya, Nikilaev, Rosov, Priorov, Kotschergein, Bogdanov, Grigorieva, Weinstein, Nikiforova, and others. They have studied the methods of foreign authors, and particularly of Bunnel, Iselin, Allen, and Mason. With this as a basis there has been issued a guide to surgeons on the treatment of these injuries related to factors such as the site, type of injury, and occupation of the injured worker. A number of points remain in dispute, but we believe that certain general principles have been agreed. I will attempt to outline our policy as concisely as possible.

If it were possible to exclude mistakes at the time of primary surgery in all medical institutions it would certainly greatly decrease the number of difficult problems of tendon repair, which so often lead to unsatisfactory results. The first condition for success in the treatment of tendon injuries is the availability of qualified surgeons able to carry out the necessary technical procedures immediately, carefully, and gently, in a well-equipped operating theatre, following early admission to hospital. The organization of the Health Service in the Soviet Union has endeavoured to make such treatment widely available.

We have put particular emphasis on the organization of the surgical care of industrial injuries. Every industrial plant includes a health department with a surgery for traumatic cases, and hospital beds are available day and night. This organization primarily means that surgery can be carried out within two hours of the accident. The operating surgeon retains responsibility for the patient until recovery is complete.

This report is based on the results of operations on tendon injuries of the wrist and fingers in 375 patients (see Table I). Special attention is paid to industrial injuries as shown in Table II. It will be seen that only 28 of a total of 123 patients had isolated injuries of the tendons, the remaining 95 had accompanying extensive

skin defects, fractures, or nerve lesions. These complications must be taken into account in evaluation of our surgical technique.

Primary Suture

As a first-aid measure we insist on the immediate immobilization of the hand, with the fingers flexed into a fist for damage to the flexor tendons, and with the fingers extended in rupture of the extensors. This prevents retraction of muscles and torn tendon ends and facilitates primary surgery.

The role of surgery is then to transform the accidental wound into a surgical wound. Operating early with adequate assistance, we aim at accurate suturing of damaged nerves and tendons. This is followed by accurate skin apposition or grafting. Fractures are immobilized in the required position. Primary and accurate surgery during the first hours after injury can make a great contribution to the results obtained in these injuries. Primary suture of tendons restores the anatomical relations of the tissues; it removes a situation in which abnormal nerve impulses are engendered by the damage; it contributes to the re-establishment of normal physiological interrelations between the central nervous system and the local motor apparatus; and it predisposes to early recovery of function without rigidity or contracture.

Primary suture, if antibiotics are available, is in our opinion indicated for all tendon injuries when an experienced surgeon is available, except in the "no-man's-land" area. Outside this zone there are absolutely no contra-indications to primary suture even with fractures or skin defects, unless associated with severe disturbance of the circulation. The results of treatment depend not so much on the extent of the damage as its site.

We do not agree with those authors who state, "Repair in 'no-man's-land,' from the middle palmar crease to the middle finger crease, as a rule must be secondary." Primary suture within this zone is permissible, particularly in clean-cut incised wounds, if the hand has been at once correctly immobilized. We have rejected tendon sutures on the palmar surface with silk, and use capron. We permit the use of silk in the reconstruction of extensor tendons. Primary suture is not indicated: (1) If the surgeon is in any doubt about the efficiency of its use in the "no-man's-land" area. (2) In flexor tendon injuries in this region if the accident has occurred with the fingers flexed. In these cases, search for the retracted tendon ends necessitates a larger incision, with damage to the gliding mechanism. Suture is not desirable within the fibro-annular pulleys of the palm and phalanges. (3) In extensive injuries of palmar soft tissues or fractures of the distal part of the metacarpals or proximal phalanges with displacement.

Primary suture in isolated rupture of the profundus tendon over the middle phalanx distal to the bifurcation of sublimis may be carried out by direct suture.

In injuries of the long flexor to the thumb, the proximal end can usually be found between the two heads of origin of the short flexor. Where suture cannot be carried out here, free grafting will be necessary.

It is well known that the results of primary tendon suture vary with the mechanism of the injury. When the palm of the hand has been damaged by falling on a sharp cutting object with the fingers extended, the proximal end of the tendon, although displaced to the base of the palm, can be found and confidently sutured. In injuries to the palm with the fingers closed into a fist, as, for example, in grasping the blade of a knife, the distal end of the tendon retracts, primary suture is difficult, and its results are less satisfactory.

Most of these operations are carried out by us under local analgesia without a tourniquet, or under intraosseous analgesia with a broad pneumatic cuff. Careful use of this method can prevent the formation of a haematoma. Esmarch bandages are not used. Occasionally we operate under inhalational anaesthesia.

The technique of suture must be speedy, simple, and stable. To be stable the tendon must be crossed without damaging its circulation. The suture must be countersunk in the tendon so that only a minimal amount is left on the surface to interfere with gliding. We use a modification of the method described by Cuneo.

Primary tendon suture has given excellent and satisfactory results in 75% of flexor and 89% of extensor tendon injuries.

Delayed Suture

The second group comprises those in whom primary suture has not been carried out. These cases have been operated on 21 to 45 days after injury, when the inflammatory reaction has settled; occasionally later. In the majority we have succeeded in uniting the severed tendons by delayed suture, and only occasionally have we required to use grafts for injuries in the "no-man's-land" area or beneath the carpal ligament. If problems of skin cover do not interfere, the earlier we operate the easier is the operation found to be and the better its results. In our experience, with early surgery, the dense adhesions between the retracted ends of the tendons and the intermediate structures had not yet formed. Good mobility of the joints is one of the conditions which determine the success of surgery. Only on two occasions (on the 29th and 57th days) have we found extensive fibrous thickening with involvement of the tendon in deep scarring. We have excised these scars as is our practice in Dupuytren's contracture. We have then isolated and sutured the deep flexor proximal in the "no-man's-land" area, using a capron suture.

Where there has been delayed healing of a laceration of the palm or the fingers with extensive scarring we do not rush into reconstructive surgery. We use physiotherapy, including baths, to restore movement and circulation to the skin. Three days before operation we clean the operating field and keep the hand in a sterile bag. We have found it very necessary to remove damaged scarred skin in the palm, and to replace it by some form of plastic procedure, in order to obtain satisfactory results in tendon repair. It is well recognized that secondary repairs to flexor tendons in the zone of "no-man's-land" are very difficult, particularly where the pulleys are destroyed.

Our incisions run parallel to the palmar crease and are curved to the base of the hypothenar eminence. When both ends of the injured tendon or tendons have been located, the distal tendon with its scars may be removed from the sheath and from beneath the pulleys without damage to the annular ligament. We use special instruments designed by Rosov. The freed channel is filled by a free graft derived preferably from the long extensor of the third or fourth toe.

The paratenon is preserved, and is prevented from displacement by a stitch. The graft must exceed the length of the "no-man's-land" area. After extraction of the

FIG. 1.—Method of suture of distal end of flexor tendon graft.

graft it is sutured at the distal end to the bone of the distal phalanx. A wedge is cut in the distal tendon reaching to the bone. With the finest possible awl two holes are made which perforate the bone to the dorsum. The graft is then sutured to the bone by a stitch which is tied over a dorsal bolster of gauze. The sides of the wedge of the distal tendon are then sutured to the graft as described by Allen (Fig. 1). The stitch is withdrawn after three weeks.

The proximal graft is sutured side by side to the proximal end of the deep flexor tendon. Where both tendons have been injured we are convinced that only profundus should be sutured. In patients with multiple injuries to flexor tendons we operate by stages; firstly by repairing the tendons of two fingers only, and delaying reconstruction of the remaining tendons to a second stage. In cases of destroyed annular ligaments, Rosov, Dubrov, and Nikolaeva reconstruct them with free fascial flaps or by transplants from the extensor tendons of a toe. We have no personal experience of this method, and use a flap from the underlying lumbrical muscle.

In 25% of primary operations we have had good results with nearly full flexion and adequate extension. In 50%, flexion was adequate but not full. When the patient was not satisfied with the end-result because the tip of the finger did not reach the palm, we proposed a second operation—arthrodesis of the distal joint in 25 degrees of flexion. By

this means we improved the end-results in seven patients. The others refused the secondary operation and adjusted themselves to their work.

In the repair of tendons beneath the carpal ligament we usually use free grafts. If the median nerve is divided we suture it at the same time. In late cases with multiple damage to the tendons in this area we have sometimes been obliged to excise the carpal ligament in order to envelop the tendon suture with loose cellular tissue.

FIG. 2.—Pathology and treatment of injury to the extensor of the proximal interphalangeal joint.

the extensor aponeurosis over the proximal joint. The proximal aponeurosis is dissected out so as to define the lateral bundles. These are approximated with the finger in extension, with five or six fine sutures. The proximal stitches include not only the lateral bundles but also the middle bundle of the long extensor (Fig. 2).

Post-operative Treatment

After tendon repairs it is necessary to immobilize the hand in plaster for four weeks, to prevent retraction of the sutured tendon ends. Following repair of the flexor tendons, the plaster is applied to the back of the hand and forearm to stabilize the fingers in a position of flexion. In injuries of the extensor tendons the splint is applied to the palmar surface with the fingers extended.

The hand is elevated for three to four days after operation. Stitches are removed on the 9th or 10th day, and the patient is discharged from hospital. From the 21st day movement of the fingers is allowed. After six to eight weeks the patient returns to light work, progressing gently to full work after three months.

Aftercare includes physiotherapy and baths, started from the 15th day. The patient also receives corticotrophin, which we have found to help in preventing scar formation and in the absorption of scarring around the repaired tendons. The surgeon who has carried out the operation must keep his patient under personal observation, and should certainly see him at least twice a week. At the end of the third week the surgeon must direct active exercises, with gentle use, to ensure the best possible function.

Conclusion

In extensor tendon injuries, plastic repairs have given satisfactory results in 85% of the patients. Tendon repair on the palmar surface has given satisfactory results in 77%, including 65% in the area of "no-man's-land."

INCISION FOR GALL-BLADDER SURGERY

BY

D. C. CORRY, M.D., F.R.C.S.

Surgeon, the United Oxford Hospitals

The two incisions generally used for operating on the gall-bladder are the right upper paramedian and Kocher's incision. The paramedian incision is often chosen when the costal angle is narrow, and Kocher's when the costal angle is broad.

Kocher (1895) described his incision as an obliquely transverse incision 10 to 15 cm. long, made at a distance of 4 to 6 cm. from the costal margin. As generally carried out in this country it is 2 to 3 cm. from and parallel to the costal margin, care being taken at its lateral extremity to spare the ninth costal nerve. I was deterred from using Kocher's incision by seeing post-operative scar herniae after its employment, but for the past seven years have utilized with increasing frequency a modification which has the advantage of dividing the rectus sheath in the direction of the fibres of its main component—namely, the aponeurosis of the internal oblique. As a result, any straining after operation by tensing the external and internal oblique and transversalis abdominal muscles tends to approximate the fibres of the rectus sheath. It is essentially a muscle-splitting operation so far as the rectus sheath is concerned and so is easy to close, and the stitches do not subsequently cut out. Compared with any vertical incision the patient is far more comfortable after operation, breathing, bending, and moving easier. Normally, patients get out of bed the day after operation. I have never seen a scar hernia follow its use.

Technique

The incision (Fig. 1) is from the midline, one handbreadth—3½ in. (9 cm.)—above the umbilicus to the tip of the tenth right costal cartilage. In some fat patients there is a natural skin crease in this line which can be utilized. The skin,

FIG. 1.—The line of incision.

the subcutaneous tissue, the anterior rectus sheath, and the rectus muscle are divided in the line of the incision as far out as the outer border of the rectus abdominis (Fig. 2). The medial two-thirds of the posterior rectus sheath with the underlying peritoneum is cut in the same line, then the transversus abdominis is split laterally in the direction of its fibres.

When cutting the fibres of the rectus muscle, branches of the superior epigastric require ligation one-third and two-

thirds of the way across the muscle. More length is seldom required laterally unless it is desired for mobilizing the duodenum. It can be obtained by splitting the external and internal oblique and the transversalis muscles in the direction of their fibres. This incision over the gall-bladder gives an excellent exposure of the biliary passages and it is

FIG. 2.—The incision completed.

easy to explore the common bile duct and, in the average case, to pass the standard Desjardins forceps down this duct. For a barrel-chested patient with a high liver I have a more curved pair of Desjardins forceps available. Should more room be required medially the incision is extended through the linea alba into the left rectus sheath. As the incision lies between the eighth and ninth intercostal nerves, these nerves are in no danger of injury and do not have to be identified (Fig. 1). Should the lateral margin of the incision be made a little low the ninth intercostal nerve is seen lying on the posterior layer of the rectus sheath near its lateral margin. The direction of the ninth nerve at this point is that taken by the ninth rib in the axilla (Fig. 1).

Anatomical Points

Identification of Ninth and Tenth Costal Cartilages

The tenth costal cartilage can be felt by running the finger outwards along the smoothly curving lower costal margin till a definite step is felt, which is caused by the tenth costal cartilage. Fig. 1 shows the usual way the tenth cartilage turns up to form this step. In two cases the tenth rib was floating and did not articulate with the ninth, reminiscent of the three floating ribs of the anthropoids. The narrow spear-like tip of the ninth costal cartilage can be felt only by taking the ninth costal cartilage between the right finger and thumb, where it is lying along the postero-inferior border of the costal margin, and, by moving it, to feel with the other hand its sharp tip where it articulates with the broad eighth costal cartilage. This identification of the tip of the ninth is not a necessary step of the operation, but it is of interest in the diagnosis of gall-bladder tenderness, which is situated most commonly 1 in. (2.5 cm.) below the tip of the ninth costal cartilage on a line drawn from the tip of that cartilage to the umbilicus. It is the surface marking of the infundibulum (Hartmann's pouch), where, with the patient supine, stones tend to gravitate.

Direction of Fibres in Rectus Sheath

On exposing the anterior layer of the rectus sheath, fibres of the external oblique are seen running downwards and

FIG. 3.—Showing fusion of the external oblique/aponeurosis with the internal oblique.

the line of the incision. The external oblique aponeurosis becomes fused with the internal oblique about a quarter of the way from the lateral border of the rectus sheath (Fig. 3).

The posterior layer of the rectus sheath shows the stout fibres of the internal oblique running upwards and inwards along the line of the incision. The red muscular fibres of the transversus abdominis show through the outer third of the posterior layer of the sheath. These muscular fibres run transversely as a thin aponeurotic layer which becomes fused with the posterior rectus sheath at the junction of the outer and middle thirds of the sheath. The transversus aponeurotic fibres are by far the weaker component of the posterior rectus sheath.

Course of the Intercostal Nerves

The ninth intercostal nerve leaves the subcostal groove about the mid-axillary line and runs downwards and forwards, passing behind the tenth costal cartilage where the cartilage is turning up (Fig. 1). It lies on the transversus muscle and is below the line of the incision. The eighth intercostal nerve as it passes behind the ninth costal cartilage is directed upwards and medially and is above the line of the incision. In dividing the rectus muscle a fine twig connecting the eighth and ninth nerves can occasionally be seen. The line of incision runs between these nerves (Fig. 1).

Anatomical dissections by Davies, Gladstone, and Stibbe (1932) have shown that the rectus muscle does not receive a segmental supply from one intercostal nerve. As a result of communications in the thorax, and again between intercostal nerves when lying on the transversus abdominis muscle, any one segment of the rectus is supplied by at least three intercostal nerves. The division of any minor connecting branch in the rectus muscle does not affect the strength of the rectus muscle when the incision is healed.

I wish to thank Sir Wilfrid Le Gros Clark for drawing my attention to the work of Davies, Gladstone, and Stibbe and to the skeleton of the anthropoid, and to Miss M. C. McLarty for the drawings.

MULTIPLE TOXIC EFFECTS OF PHENYLBUTAZONE

REPORT OF A FATAL CASE

BY

THOMAS N. FRASER, M.D., F.R.C.P., F.R.F.P.S.

Physician, Rheumatism Unit, Killearn Hospital,
Stirlingshire

It is almost four years since Currie (1951) first drew attention to the therapeutic effect of phenylbutazone ("butazolidin"). Since then it has been employed extensively both in hospital and in general practice, and many reports on its use, mainly in the treatment of rheumatoid arthritis, have appeared in the medical press. There is general agreement that the drug has a marked analgesic action in rheumatoid arthritis in roughly one case in three, but it is doubtful whether it has any anti-inflammatory properties. As Hart (1953) pointed out, although occasionally a reduction of inflammatory swelling is seen, increase in range of movement and function tests, and decrease in stiffness, are essentially secondary to the relief of pain. Steinbrocker (1953) reported on the results he had obtained in a large series of patients on short- and long-term phenylbutazone treatment, and came to the conclusion that the drug was a powerful analgesic but that its antirheumatic effect, if any, was slight.

Since the introduction of phenylbutazone in the treatment of the rheumatic diseases numerous reports of its

toxic effects have been published, the incidence varying between 20 and 50%. While the majority of the side-effects are of a mild nature, serious complications have been encountered from time to time, and a not insignificant number of fatalities have been attributed to the use of this drug. Deaths due to agranulocytosis (*British Medical Journal*, 1952; *Lancet*, 1953; Newns, 1953; Etess and Jacobson, 1953; Steinberg *et al.*, 1953; Dilling, 1953; Wood, 1954), aplastic anaemia (Leonard, 1953), haematemesis (*British Medical Journal*, 1952), perforation of a peptic ulcer (Benstead, 1953), and to renal failure (Bruck *et al.*, 1954; Johnson and Larkin, 1954) have been recorded. The non-fatal complications are by now well known, and include sodium retention with oedema, various types of skin rashes, activation or perforation of a peptic ulcer, agranulocytosis, thrombocytopenia, nausea, vomiting and diarrhoea, jaundice, and bleeding manifestations with resultant anaemia—for example, haematemesis, melaena, and haematuria. Many patients have experienced two or more complications at the same time (Hart, 1953; Pemberton, 1954). The following case, which had a fatal termination, is of interest in that multiple toxic reactions, including a polyneuritis, made their appearance during the administration of phenylbutazone.

Case History

A single woman aged 41 was admitted to hospital on July 3, 1953, with a history of rheumatoid arthritis of seven years' duration, involving her hands, wrists, ankles, and feet. Six months before admission her doctor put her on phenylbutazone, when she was given 600 mg. a day for one week, 500 mg. a day for two days, and then 400 mg. for one day. The drug had to be discontinued at this point on account of a haematemesis of moderate severity. This was accompanied by ulceration of the mouth and lips. Recovery from the haemorrhage was rapid and the buccal ulcers healed. Six weeks later her joints became so painful that she persuaded her doctor, against his better judgment, to let her resume the phenylbutazone. She was put on 200 mg. daily, and this gave her considerable relief from pain. She was maintained on this dose for three months, when a rash appeared on her legs and the drug was stopped. After a few days the ulcers reappeared in her mouth and mild jaundice was noted by her doctor. Two weeks later she developed weakness of her arms and legs, and within a week she was unable to move her arms or legs. This was unaccompanied by pain.

On admission she was seen to be a thin and ill-looking woman with a sallow complexion, and lay limply in bed. She was afebrile, with a mild tachycardia. There was no evidence of jaundice. Multiple small punched-out ulcers were present on the ankles and feet, and a few superficial ulcers were seen on the lips and in the mouth. There was loss of all types of sensation in the arms below the elbows and in the legs below the knees. Weakness of the shoulder-girdle and hip muscles and complete loss of power below the elbows and knees were present. All deep reflexes in the arms and legs were absent; the plantar responses were flexor. There were chronic rheumatoid changes in the fingers, wrists, knees, ankles, and feet. The liver and spleen were not palpable. The heart and lungs were normal.

Laboratory investigations on admission resulted as follows: haemoglobin, 65%; red blood cells, 3,750,000; white blood cells, 11,800; blood film, normal; erythrocyte sedimentation rate (Westergren), 96 mm. in one hour; blood W.R., negative; blood urea, 30 mg. per 100 ml.; blood uric acid, 1.9 mg. per 100 ml.; plasma proteins, normal; thymol turbidity, 3 units; thymol flocculation, positive after 4 hours; alkaline phosphatase, 3.5 K.A. units per 100 ml.; van den Bergh, negative; icterus index, 4; urine: no sugar, albumin, bile, or urobilin; faecal occult blood, positive.

In spite of intensive medical measures, physiotherapy, and splintage, her condition slowly deteriorated and she became emaciated. Flexion contracture of the fingers and subluxation of the knees developed. She was unconscious for three days before she died on January 28, 1954, seven months from the date of admission.

Necropsy.—The body was that of an extremely emaciated woman with numerous pressure sores over the bony prominences. A moderate degree of rheumatoid arthritis of the fingers, wrists, knees, and ankles was noted. The heart appeared normal. The lungs showed evidence of a bilateral bronchopneumonia with abscess formation. Abdomen: a lesser-curvature posterior-wall chronic ulcer, 12 by 7 mm., with a small perforation and associated peritonitis, was found; the liver weighed 1,140 g. and was soft and pale; a few small gall-stones were present in the gall-bladder, which was small and had a thickened wall; the spleen was congested; the genito-urinary organs were normal. Endocrine glands: the pituitary, thyroid, and adrenals were normal. Apart from some general pallor and oedema, the brain was normal. Macroscopically, no gross abnormality was seen in the spinal cord or peripheral nerves.

Histological Examination.—There was evidence of a widespread polyneuritis with marked degeneration and vacuolation of the posterior columns of the cord. Both median nerves showed almost complete loss of myelin sheaths and very severe loss of axis cylinders. The ulnar nerves presented a similar but slightly less marked appearance. Many nerve bundles in the sciatic nerves looked shrunken, and the myelin sheaths stained irregularly, but the axis cylinders were well preserved. The liver showed a moderate degree of fatty infiltration around the portal tracts. There was no evidence of central necrosis. The spleen was normal. Some focal cellular infiltrate and tubular atrophy, with an occasional damaged glomerulus, were seen in the kidneys. A bronchopneumonia with abscess formation was present in both lungs.

Discussion

This case presents some interesting features. The patient received a total of only 5.6 g. of phenylbutazone prior to the haematemesis, which was of moderate severity. Careful questioning did not reveal any previous history of gastric disturbance. In addition to the haemorrhage, superficial ulceration of the mouth and lips was noted, a finding which may well have reflected the state of the gastric mucosa at that time. Multiple superficial gastric erosions were reported at necropsy by Dilling (1953) in a case of fatal agranulocytosis following phenylbutazone therapy.

It is obvious that treatment with phenylbutazone should have been permanently discontinued at this point, but six weeks later it was resumed at the patient's own request, and she was maintained on it for a further three months, when the second series of side-effects made their appearance.

It will be seen that this patient had six complications in all. Four of these—namely, ulceration of the mouth, rash, haematemesis, and perforation—could be directly attributed to the administration of phenylbutazone, as all are now accepted as toxic effects of the drug and have been reported on frequent occasions. Whether the jaundice and polyneuritis were associated with the use of the drug is difficult to establish, for as Currie *et al.* (1953) pointed out, not all symptoms occurring during drug therapy are necessarily due to the drug. While jaundice, mainly of the obstructive variety, has been reported from time to time (Bourne, 1953; Solomon, 1953), post-mortem examination in this case revealed several small calculi in the gall-bladder and only some fatty infiltration of the liver. The icterus, therefore, could have been due either to obstruction of the common bile duct by a gall-stone or to a mild toxic hepatitis, followed by regeneration of liver tissue.

Headache and vertigo have occasionally been encountered during phenylbutazone therapy, but neurological signs are apparently rare. Loxton *et al.* (1952) reported a case which developed a lesion of the central nervous system with

paralysis of the left leg and urinary incontinence and which they attributed to a haemorrhagic transverse myelitis. While the evidence incriminating phenylbutazone as the cause of the polyneuritis in the present case is purely circumstantial, no other aetiological factor could be demonstrated.

The immediate cause of death was presumably the acute peritonitis resulting from perforation of the gastric ulcer in an emaciated and moribund subject. Clearly, a fatal issue could, and should, have been avoided if the phenylbutazone therapy had been permanently discontinued by her doctor at the time of the haematemesis. It demonstrates once more how vital it is that medical men should not be influenced in their judgment by the entreaties of the patient.

It is generally accepted that phenylbutazone is rapidly absorbed when given by mouth. Pemberton (1954) regarded a blood concentration of 12–16 mg. per 100 ml. as the therapeutic range of the drug. On the other hand, Currie *et al.* (1953) found that an initial blood concentration of 8–11 mg. per 100 ml. was sufficient to suppress the symptoms, and that remission could be maintained by much lower concentrations—4.6 to 8 mg. per 100 ml. Bruck *et al.* (1954) obtained maximal suppression of symptoms in their series at any level between 5 and 10 mg. per 100 ml. Phenylbutazone is slowly eliminated from the body (Burns *et al.*, 1952), and appreciable levels remain in the blood for at least two weeks after the cessation of treatment (Pemberton, 1954). Toxic effects, therefore, can be expected after the drug has been withdrawn. Shields *et al.* (1953) reported a case in which perforation of a gastric ulcer occurred seventy-two hours after discontinuation of phenylbutazone therapy, and Wood (1954) a case in which a rash appeared six days after the drug was stopped.

Some observers (Bruck *et al.*, 1954) have found a striking correlation between the frequency of toxic reactions and the blood phenylbutazone level, while others (Leonard, 1953; Nassim and Pilkington, 1953; Pemberton, 1954) have failed to confirm this observation, and feel that the administration of small doses of phenylbutazone does not eliminate the possibility of the occurrence of toxic side-effects. In the case reported here a moderately severe haematemesis with ulceration of the mouth and lips developed after a total dosage of only 5.6 g., the maximum dose being 600 mg. a day. This raises the question whether the toxic effects of phenylbutazone are due entirely to overdosage or whether an idiosyncrasy to the drug may be responsible in certain cases. Support for the latter view has been produced by O'Brien and Storey (1954), who recorded a case in which they attributed the cause of death during phenylbutazone therapy to a hypersensitivity reaction, which was manifest histologically by three types of lesion: polyarteritis nodosa, hypersensitivity angitis, and granulomatous lesions. A severe case of sensitivity to phenylbutazone with the features of Stevens-Johnson syndrome and granulocytopenia was described by Steel and Moffatt (1954). It has also been suggested that agranulocytosis may be due to an idiosyncrasy to the drug (Stifel and Burnheimer, 1953), and that the drop in the white-cell count is sudden, so that daily counts, which give a false sense of security, are of doubtful value in anticipating this complication.

If toxic symptoms develop during phenylbutazone therapy the drug is generally withdrawn either temporarily or permanently, according to the nature and severity of the reaction. Many observers advocate the resumption of the drug, usually on a smaller dosage, once all signs of the reaction have disappeared, except in cases with the more serious complications. In this connexion, Fishman and Reynolds (1953) issued a warning, stating that it was unwise to resume treatment with phenylbutazone, however mild the toxic effects. They reported the case of a woman who received phenylbutazone for a whiplash injury of the neck following a car accident. A mild rash appeared after she had taken sixteen 200-mg. tablets, and was of the morbilliform type. This began to subside fairly quickly with treat-

ment and omission of the drug, and had almost disappeared when, for no obvious reason, it suddenly flared up again and developed into an exfoliative dermatitis which nearly proved fatal.

My experience with the present case, added to an overall incidence of 26% of toxic reactions, including four patients with severe haematemesis, forces me to the conclusion that phenylbutazone is a dangerous drug and that the risks attached to its use in rheumatoid arthritis are not outweighed by its advantages. As it is still widely employed in general practice, where for obvious reasons patients cannot be kept under the strictest supervision, I feel that the publication of reports on its toxic effects may act as a deterrent to its use in the treatment of rheumatoid arthritis. In its place one would recommend aspirin, given in maximum tolerated doses as described in the recent Medical Research Council and Nuffield Foundation Report (1954).

Phenylbutazone, however, would appear to be an effective therapeutic agent in the acute stages of gout (Huffman *et al.*, 1954) on which it has a marked uricosuric effect. The majority of acute attacks of gout are brought under control within 8–12 hours, and the drug need be given only for a matter of days, thus greatly reducing the danger of side-effects.

Summary

The literature on the toxic effects of phenylbutazone therapy in rheumatoid arthritis is briefly reviewed.

A fatal case is reported in which six complications developed during the administration of the drug—namely, ulceration of the lips and mouth, a rash, haematemesis, perforation of a gastric ulcer, jaundice, and a polyneuritis—and their causal relationship to the use of the drug is discussed.

The possible factors in the production of side-effects are mentioned.

It is felt that phenylbutazone is a dangerous drug and should not be employed in the treatment of rheumatoid arthritis, and that aspirin given in maximum tolerated doses is as effective and much less toxic.

My thanks are due to Professor E. J. Wayne for helpful criticism, and to Professor D. F. Cappell and Dr. M. Leslie for post-mortem, histological, and laboratory reports.

A CASE OF STEVENS-JOHNSON SYNDROME WITH EXTENSIVE SURGICAL EMPHYSEMA

BY

HUMPHREY J. A. HAHN, M.B., B.S.

Late Registrar, Fever Unit, Grove Hospital, London, S.W.17

The condition known as Stevens-Johnson syndrome, a skin eruption resembling erythema multiforme, with lesions of the mouth, conjunctivae, genitalia, and anus, was described by Stevens and Johnson in 1922. A similar condition had been recorded in the last century, but does not appear to have been thought worthy of special notice. The cause of the disease is unknown. It is suggested that the eruption may be due to hypersensitivity or allergy, because some cases give a history of recent upper respiratory infection or of the administration of sulphonamides. A virus has been suggested, but at present there is no proof of this. The condition usually runs a benign course, with full recovery in ten days, but respiratory complications may occur (Liddle, 1951).

The following case of Stevens-Johnson syndrome is reported because of its severity and because of the unusual complication of surgical emphysema.

Case History

A boy aged 9 years 11 months was admitted to hospital on May 1, 1954, with the following history. Five days previously he had complained of headache, and was listless. His throat and conjunctivae were inflamed, and his temperature was 102° F. (38.9° C.). He was started on a course of "tresamide" (each 0.5-g. tablet containing sulphamerazine 0.1 g., sulphadiazine 0.2 g., sulphacetamide, 0.2 g.), which was replaced by chloramphenicol on the fourth day of the illness because of the appearance of a morbilliform rash on the chest. On the next day the rash spread all over the face, chest, and limbs, and many of the lesions became vesicular. He had severe toxæmia, headache, and nausea, and his temperature rose to 105° F. (40.6° C.).

He was admitted to an isolation hospital as a suspected case of smallpox, and thereafter transferred to the Grove Hospital on the sixth day of the illness.

On admission he was seen to be a well-built boy, with no history of previous illness. He was semicomatose and profoundly toxæmic. His temperature was 99° F. (37.2° C.), pulse 108, and respirations 20. There was the dusky-red rash of erythema multiforme on the face, neck, trunk, and limbs. In places the rash was confluent and there were many large vesicles containing yellow fluid. Some vesicles had burst, particularly round the eyes, ears, and neck, and the underlying dermis was fiery red. The lips were purplish, cracked, and bleeding. The buccal mucosa was overlaid with collapsed vesicles, and gingivitis and ulceration of the tongue were present. The conjunctivae were deeply injected and oedematous. He had photophobia, but no corneal lesions were seen. There was some ulceration of the glans penis and dysuria, probably due to lesions within the meatus. There was no urethral discharge. Gross surgical emphysema was present on the chest, stretching from the neck to the lower abdomen. Respiration was a little laboured and there was a suggestion of cyanosis. Anteriorly, breath and heart sounds were difficult to hear, but auscultation of the back of the chest revealed moist crepitations in all areas. The spleen and liver could not be felt. A diagnosis of Stevens-Johnson syndrome was made.

The patient was placed in an oxygen tent and parenteral penicillin (250,000 units six-hourly) and streptomycin (0.5 g. six-hourly) were given. On the day after admission the general condition was unchanged and the surgical emphysema had spread downwards to the groins and into the upper parts

of the thighs. In the region of the lower ribs large pockets of air were palpable under the skin.

On the fifth day after admission exudation into the vesicles was maximal, with dehydration and circulatory collapse. The temperature rose to 104° F. (40° C.), and the pulse was frequent and weak. Intravenous plasma was given (3 pints - 1.7 litres) as it was thought that protein loss in the exudate was high. The plasma was followed by glucose-saline. Intravenous therapy was continued for two days, after which the patient's condition began to improve. On the sixth day, when the mouth lesions were clearing, oral chlortetracycline was given (250 mg.) six-hourly, in place of the penicillin and streptomycin. By the tenth day the rash had begun to fade and the raw areas were drying. There was heavy desquamation of the hands and feet. By this time the conjunctivae were nearly normal, and there were no corneal lesions.

The chest was slow in clearing. Three weeks after admission the patient was still raising much thick sputum, although by then the pyrexia had subsided. From the third week onwards recovery was uninterrupted. The patient was discharged after five weeks, the only sequelae being some staining from the rash and loosening of all finger- and toenails.

Chest X-ray Examination.—Films were taken on the third, seventh, and twelfth days after admission. In the first film pronounced surgical emphysema was seen in the soft tissues of the neck and thoracic wall, but the lungs were clear. On each side of the superior mediastinum thin vertical lines of opacity were visible. These lines appeared to represent lateral displacement of the mediastinal pleura, suggesting the presence of mediastinal emphysema. The second film showed patchy shadowing of the lung fields, and the mediastinal appearances were the same. The final film showed some left basal collapse, the surgical emphysema was less marked, and the mediastinal pleura was no longer displaced.

Comment

This case represents a severe form of the Stevens-Johnson syndrome, in which skin, mucous membranes, and respiratory systems were all heavily affected. In addition there was severe toxæmia. The chief point of interest was the surgical emphysema which occurred early in the disease and which persisted for nearly three weeks. The likely explanation for the surgical emphysema seems to be as follows. In respiratory infections, such as pertussis, influenza, or measles, and in bronchial asthma, valvular obstruction of terminal bronchioles may be produced by mucous plugs or by inflammatory oedema of the lining mucosa. Alveolar air trapped behind the obstruction may be forced into the interstitial spaces of the lung by expiratory pressure. The air may then pass along the vascular sheaths (Aisner and Franco, 1949), to reach the hilum and thence the mediastinum. Air may then escape from the mediastinum into the tissues of the neck.

Similar cases of mediastinal emphysema have been described in association with the muscular straining of parturition (MacRae, 1949) and the lifting of heavy weights. Here the expiratory muscles are forcibly contracted with the glottis closed, causing rupture of alveoli.

In the present case it seems probable that the obstruction was caused by thick mucus or by the swelling of the mucosal lining of the small air passages.

The area of collapse seen in the third x-ray film may be significant. Possibly it marks the site at which a number of bronchioles became obstructed, causing the air in the alveoli distal to the obstruction to be forced into the vascular sheaths of the lung.

My thanks are due to Dr. J. S. Anderson, medical director of the Fever Unit, Grove Hospital, and to Dr. J. C. McEntee for permission to publish this case.

PARAPLEGIA FOLLOWING THE USE OF "EFOCAINE"

BY

MAURICE J. PARSONAGE, M.B., B.Sc.
M.R.C.P., D.C.H.

Assistant Physician to the Department of Neurology,
General Infirmary, Leeds

DERYCK TAVERNER, M.D., M.R.C.P.

Senior Lecturer in Medicine, University of Leeds

AND

G. H. WOOLER, M.D., F.R.C.S.

Assistant Surgeon to the Department of Thoracic Surgery,
General Infirmary, Leeds

"Efocaine" is a long-acting local analgesic consisting of a solution of 1% procaine base, 0.25% procaine hydrochloride, and 5% butyl-*p*-aminobenzoate in a solvent composed of 2% polyethylene glycol-300, 78% propylene glycol, and water. It also contains 0.1% sodium metabisulphite and phenylmercuric borate (1:25,000) as preservative. When diluted with body fluids the aqueous insoluble analgesic base is deposited in a micro-crystalline form. The slow absorption of this deposit is believed to be responsible for the long-acting analgesic properties of efocaine, but it is evident that such a compound might cause serious ill effects if deposited in delicate tissue.

Three examples of such complications have been reported from America by Shapiro and Norman (1953); in one patient intercostal nerve block in the thoracic region was followed by "transverse myelitis" causing permanent paraplegia. Three further examples have been reported by Brittingham *et al.* (1954); in all three, paravertebral block of several intercostal nerves with efocaine was followed by paraplegia. Two of these patients improved to some extent, but the third was permanently paralysed. Angerer *et al.* (1953) described another striking case in which paraplegia developed within a few minutes of the injection of efocaine into an intercostal nerve. This patient died, and the necropsy findings suggested that the spinal cord lesions were secondary to thrombophlebitis of an intercostal vein.

The present report deals with a patient in whom evidence of severe spinal cord damage occurred after the injection of efocaine into intercostal nerves for the prevention of post-operative pain after the reduction of a hiatal hernia.

Case Report

A married woman aged 50, who had complained of indigestion for many years, was found to have a sliding hernia of the stomach through the oesophageal hiatus of the diaphragm. In spite of medical treatment her condition deteriorated until she could take only fluids by mouth. Oesophagoscopy showed superficial ulceration of the lower oesophagus adjacent to the herniated gastric mucosa.

On January 1, 1953, left lateral thoracotomy was performed under general anaesthesia with thiopentone, D-tubocurarine, gas and oxygen. The patient lay in the right lateral position and the left seventh rib was resected. A local analgesic consisting of 1/2,000 amethocaine hydrochloride and 0.25% procaine was injected into the third, fourth, fifth, sixth, seventh, eighth, and ninth intercostal nerves, into the mediastinal tissues, and into the splanchnic nerves. The hernia was reduced and the diaphragm repaired without difficulty. Before closing the chest 1 ml. of efocaine was injected directly into each of the sixth, seventh, eighth, and

ninth intercostal nerves at the angles of the ribs, where the nerves were clearly visible under the parietal pleura.

After returning to the ward the patient complained of numbness and paralysis of the legs. On January 2 she was found to have a flaccid paralysis of the lower trunk and leg muscles with complete sensory loss from the seventh dorsal dermatome downwards. Retention of urine and incontinence of faeces were present. On January 3 the C.S.F. contained 13 polymorphonuclear leucocytes per ml. and 950 mg. of protein per 100 ml., but there was no evidence of block on jugular compression. During the next three weeks her neurological condition did not change, but the C.S.F. returned slowly towards normal. On January 9 the C.S.F. protein value was 788 mg. per 100 ml. and on January 15 it had fallen to 435 mg.

The glucose and chloride content of the C.S.F. remained normal throughout. The C.S.F. Wassermann reaction was negative.

The thoracotomy wound healed normally and the digestive symptoms disappeared. A post-operative barium swallow showed complete reduction of the hernia and a normally functioning cardia. On January 24 the patient was transferred to a neurological unit for long-term rehabilitation.

On admission to the neurological unit some three weeks after operation the patient was found to have complete loss of spinal cord function from the seventh dorsal segment downwards. As she had complained of shoulder and trunk pains prior to operation the possibility of coincidental spinal cord compression was considered. A lumbar puncture on February 3 revealed the spinal fluid to be under a pressure of 110 mm. of water, with a rapid rise and fall of pressure on bilateral jugular compression. The fluid contained 3 cells (2 mononuclear and 1 polymorphonuclear), 100 mg. of protein per 100 ml., and an increased amount of globulin (Nonne-Apelt and Pandy). Radiographs of the spine showed no abnormalities apart from a minimal degree of osteophytosis in the mid-dorsal region, and a myelographic examination was within normal limits.

The usual measures for the long-term treatment of a spinal paraplegic subject were instituted. During the succeeding nine months there was never at any time evidence of returning spinal cord function. There remained complete absence of sphincter control, necessitating the regular administration of enemata and the maintenance of an indwelling vesical catheter. At the time of admission a small sacral bedsore involving skin and subcutaneous tissue was already present. This took many months to heal, and, despite the greatest possible care, it was impossible to prevent the development of similar lesions over the femoral trochanters. These later-developing lesions proved most resistant to treatment, so that at the end of the nine months' observation period they were still incompletely healed.

The patient was much troubled by persisting sensations of burning and "tightening" in her legs and lower abdomen, in addition to hallucinations of movements of her toes. These symptoms varied considerably in intensity from time to time and proved difficult to analyse, since they appeared to be dependent upon factors of both physical and psychogenic origin. Their response to the simpler analgesics was also variable, but at no time did they seem to become intolerable to the patient. On October 7 the spinal fluid was found to be normal in all respects, but in view of the extensive motor paralysis it was not possible to rehabilitate the patient beyond the state of a wheelchair existence, despite the application of appropriate leg splints. A final neurological examination confirmed that there was no objective evidence of spinal motor, sensory, or reflex function from the seventh dorsal segment downwards, a moderate degree of wasting of the legs having occurred by this time.

Discussion

This case emphasizes the possible catastrophic effects of the injection of a long-acting analgesic such as efocaine. It is conceivable that the drug passed along the perineural

sheath of one of the intercostal nerves, but the very high C.S.F. protein figures and the complete lack of recovery of reflex function below the level of the lesion suggest that extensive necrosis of the spinal cord occurred. Such widespread damage cannot reasonably be attributed to the small amount of efocaine which could have entered the spinal cord via the perineural sheath.

The clinical picture and C.S.F. changes can be explained on the basis of necrosis through interference with the blood supply of the spinal cord. The injection of efocaine close to an intercostal vein might have produced thrombosis which spread into the spinal cord and caused intramedullary thrombosis with necrosis. This view is supported by the necropsy findings in the patient reported by Angerer *et al.* (1953). Forty-four hours after the injection of efocaine they found that the intercostal vein immediately beneath the needle puncture was acutely inflamed and filled with recent thrombus. The spinal cord itself showed extensive necrosis, with evidence of acute inflammation.

The mode of action of efocaine has been reinvestigated by Mannheimer *et al.* (1954), and they have shown that the substance produces necrosis of both nerve and muscle of similar severity to that caused by the injection of alcohol and phenol. These findings, together with the published reports of gross neurological damage, lead to the conclusion that the clinical use of efocaine is no longer justifiable.

Medical Memoranda

Long Survival in Renal Carcinoma

There are many gaps in our knowledge of the natural life history of malignant tumours, and renal cancer seems to be particularly unpredictable. In the patient we are here reporting, at least a quarter of a century elapsed before the disease caused death, and treatment was refused for a decade after the tumour was clinically apparent.

CASE REPORT

In 1930 a Jewish business man, aged 31, began to experience pain in the left flank and haematuria. The pain was episodic until 1934, when its severity so increased that he sought admission to hospital. A mass was then discovered in relation to the left kidney, of such a size that it caused obvious deformity of the stomach on radiological examination.

Surgical treatment was strongly urged, but the patient stubbornly refused to submit to operation until 1943. The operation disclosed a rounded tumour which replaced the lower pole of the kidney and was "much larger than the renal tissue proper." There was no involvement of the renal vein, or any evidence of metastases. Nephrectomy was carried out.

Pathological examination of the tumour by the late Colonel Harvey showed the tumour to be a glandular carcinoma (hypernephroma) of clear cell type. Its structure was unusually glandular, and of the small alveolar and tubular type rather than the larger and more cellular masses more common in this tumour. There was considerable polymorphism of the cell nuclei, suggestive of degenerative forms. Though mitotic activity was not recognized, the tumour had spread into the fibrous tissue separating the growth from the kidney. In some areas haemorrhage and necrosis were marked.

The patient remained relatively well until 1949, when he began to complain of vague abdominal discomfort. Sundry investigations were negative; but in 1952, when he came under our joint care, there was a mass in the left flank and some enlargement of the liver. Barium enema revealed a filling defect suggestive of extrinsic pressure in the descending colon, and a radiograph of the chest showed a rounded opacity in the right mid-zone. As much for diagnostic as therapeutic reasons, he was advised to undergo laparotomy.

At operation extensive malignant disease was found throughout the abdominal cavity, including a large fixed mass involving the descending colon and the adjacent part of the posterior abdominal wall. Numerous secondary growths were present in the liver, including a massive growth in the left lobe. It was found practicable to remove the pericolic tissue and so relieve the obvious obstruction.

Histological examination showed the tissue to be metastatic hypernephroma. There was a remarkably good immediate recovery, and he was able to return to the business he had conducted so successfully throughout the years; thereafter his condition deteriorated; but in spite of the extensive metastases he survived for another two years, and died in September, 1954.

COMMENT

It is notoriously difficult to forecast the expectation of life in patients with renal tumours. Herbut (1952) has stated that symptoms and signs may be prolonged up to 35 years; and Griffiths and Thackray (1949) reported a 10-year survival rate of 21% after nephrectomy. The "best" American figures—those of Priestley (1939) at the Mayo Clinic—record a 10-year survival in 27.3% of 395 cases. Nevertheless, survival for 25 years despite the well-substantiated existence of renal carcinoma, as in the present case, seems to us most exceptional. Possibly the phenomenon was thrown into sharper relief by a number of contemporary cases in which the course was very rapid.

The corollary is obvious—that great caution must be exercised in venturing a prognosis in renal tumours, both with and without operation, and that even greater caution is needed when claims are made for the efficacy of treatment.

We are indebted to Dr. Alister Matheson for letting us have access to his careful records regarding this patient.

Case of Bilateral Calcification of the Breasts

The deposition of calcium in the soft tissues of aged subjects is not uncommon, particularly in those parts where fibrous tissue normally predominates. In the breast, fibrous tissue is laid down in varying amounts after the menopause; only very rarely, however, does it go on to calcification so extensive as to be detectable both clinically and radiologically. The following is a case discovered accidentally shortly before the patient's death.

CASE RECORD

A woman aged 85 was admitted to hospital with a three-weeks history of pain in the left groin. Her private practitioner suspected the presence of a fatigue fracture of the neck of the left femur, no history of trauma being elicited. This was confirmed radiologically. Examination of the

breasts to exclude a primary malignant tumour revealed hard craggy mobile masses in the lower and outer quadrants of both breasts. The skin overlying them was normal, and no glands were palpable in the axillae or the supraclavicular fossae. Despite the remarkable hardness of the tumours, they were thought to be the result of fibro-adenosis. A routine chest x-ray examination revealed no intrathoracic abnormality, but the lower and outer quadrants of both breasts were found to be involved by extensive calcium deposits.

The patient underwent pinning of her femur, but succumbed to a hypostatic pneumonia ten days later. Specimens of her breast tissue were obtained at necropsy. The sections showed that the breasts had been practically replaced by fibrous tissue; large calcium deposits were irregularly scattered throughout the portions clinically involved.

COMMENT

It is unlikely that the breasts had previously been affected by fibro-adenosis; if they had, no remnant of such a condition was evident on microscopy. Such symmetry as was displayed here is, in any case, unusual. This symmetry may, however, be the clue to the aetiology of this condition. The pendulous unsupported breasts weigh heavily on the fibrous tissue, as they rotate downwards and outwards in the normal subject. Prolonged stresses and strains occurring in an abnormally fibrous breast are likely to exert their maximum effect on the lower and outer quadrant. Elsewhere in the body, fibrous tissue subjected to chronic stress not infrequently undergoes calcification; and it may be that a similar mechanism is responsible for the interesting distribution of calcium deposits, of which the above is an example.

My thanks are due to Mr. E. Chitty for permission to publish.

Surgical Registrar, St. Stephen's Hospital, London, S.W.10.

Varicella with Neurological Complications in an Adult

Although chicken-pox is so common, involvement of the nervous system is extremely rare. In a study of 2,534 patients with varicella, Bullowa and Wishik (1935) found five cases of encephalitis and three cases of meningitis. Of the 108 cases with neurological complications described in the literature, in only eight was the patient over the age of 20 years, and about 90% were in the first decade of life.

CASE REPORT

An unmarried cashier aged 21 was admitted to hospital in September, 1952, with a severe attack of varicella, the rash of which had appeared almost three weeks previously. About a week after the onset of the illness she began to vomit once or twice a day, and continued to do so for two weeks. Twelve days after she had first noticed the rash she found that she was seeing double and that she had to close one eye in order to see clearly. Her past history was irrelevant. She had been vaccinated in infancy.

On admission she did not look unduly ill. She was co-operative and mentally clear. Her temperature was 101° F. (38.3° C.). She had a profuse rash on the trunk and limbs and to a less degree on the face. The lesions had a typical centripetal distribution and were mainly in the scab stage, but there were some pustules. There had been obvious haemorrhages into the more recent lesions.

Examination of her nervous system revealed no neck or back stiffness. Her pupils were equal and regular and reacted to light and on accommodation, but she was unable to abduct her right eye beyond the central position, and on looking to the right she had diplopia, the false image being projected to the right of, and level with, the

true image. All other movements of the right eye and all movements of the left eye were normal; other cranial nerves and the disks and retinae were normal; tendon reflexes in the upper limbs were present and equal on the two sides; abdominal reflexes were present. The knee- and ankle-jerks were absent in both legs; plantar reflexes were flexor. Sensation to light touch, pain, heat and cold, vibration, and posture was normal. A coarse tremor of the outstretched hands, more marked on the right than on the left, was noticeable, but no intention tremor was present and there was normal co-ordination of movements in all limbs; no muscle weakness or wasting was found. There were no abnormal physical signs in any other system.

Investigations.—A full blood count was normal. The Wassermann reaction and Paul-Bunnell and Widal tests were negative. Blood culture was sterile. There were no pathogenic organisms in nose and throat, urine, or faeces. The C.S.F. on admission contained 110 mg. of protein per 100 ml.; leucocyte count, chlorides, and sugar were normal. The C.S.F. showed practically no change during the next five weeks, and even on discharge the protein was still 110 mg. per 100 ml.

Crystalline penicillin, 500,000 units six-hourly, was given, but she continued to have a swinging temperature, and on the fifth day of treatment the penicillin was discontinued and chloramphenicol, 500 mg. six-hourly, was given for seven days. Though the temperature subsided two days later, the impression was formed at the time that the improvement was coincidental and not in fact due to the treatment.

Towards the end of the second week in hospital it just became possible to elicit the knee- and ankle-jerks on reinforcement, and by the fifth week the reflexes were considered to be within normal limits; at about the same time the paresis of the right eye was beginning to show some improvement. Despite the improvement she was having mild attacks of depression with bouts of crying because she felt that her friends would laugh at her as she had a squint. She was discharged home on November 8.

When seen again two months later she complained of feeling nervous but was no longer depressed. She had occasional double vision and the right eye still showed some weakness of abduction; all other cranial nerves were normal and her tendon reflexes were present and equal. When last seen in October, 1953, she was considerably improved, had lost her nervousness, and had gained over 14 lb. (6.4 kg.) in weight. She had no diplopia and all movements of both eyes were full.

COMMENT

That nervous manifestations do not occur more often is surprising when it is considered that the causal organism of varicella is closely allied to, if not identical with, that of the neurotropic virus of herpes zoster. In the great majority of cases nervous complications occur between four and ten days after the appearance of the rash.

The C.S.F. findings have been recorded in only about 50% of published cases; the protein content was normal or slightly increased in 75%, but in the remainder there was a considerable increase; the leucocyte count was within the normal range in most cases.

The prognosis is good; about 90% of the patients recover. Residual defects are unusual, but are most common when ocular signs are the prominent or only manifestation of nervous system involvement.

I am indebted to Dr. Ernest Evans for his valuable criticism.

Reviews

PTERIDINES

Ciba Foundation Symposium on Chemistry and Biology of Pteridines. Editors for the Ciba Foundation: G. E. W. Wolstenholme, O.B.E., M.A., M.B., B.Ch., and Margaret P. Cameron, M.A., A.B.L.S. (Pp. 425+xiv. 42s.) London: J. and A. Churchill, Ltd. 1954.

When the late Sir Frederick Gowland Hopkins took up the study of butterfly pigments at the beginning of his career he believed that these substances might have metabolic significance. When he died in 1947 he had lived to see a tale unfolding which, although it still has much to reveal, has already borne witness to his prescience. Hopkins himself thought at first that the coloured substances he had extracted from butterflies were uric acid derivatives, and, since they appeared to be present in material voided from the rectum of lepidoptera, he inferred that "a normal excretory product subserves the purposes of ornament." It was not until 1940 that the difficulties of analysis and synthesis of these pigments were finally overcome, and one of the commonest, leucopterin, was shown to be not a purine but a pteridine derivative, pteridines being chemically related to the nucleus of riboflavin. Subsequently the structure and synthesis of many related insect pigments and other substances have been elucidated and some shown to have great metabolic importance.

In 1944 the name "folic acid" (Latin *folium*, leaf) was coined to describe a growth factor from plant sources for *Streptococcus faecalis*, which later was found to be pteroylglutamic acid, a substance formed by the union of a pteridine with *p*-aminobenzoic acid and glutamic acid. Before this, in 1940, Woods and Fildes had recognized that *p*-aminobenzoic acid must be of importance in cellular metabolism because of its ability to overcome the inhibition of bacterial growth which can be brought about by sulphonamide drugs. Since pteroylglutamic acid was first isolated many related substances have been obtained from natural sources. Some have more than one glutamic acid residue in the molecule, and a number have been recognized as growth factors for micro-organisms of various strains. Rhizopterins (from *Rhizopus nigricans*) has a most interesting chemical constitution—namely, N_{10} -formyl-pterioic acid, pterioic acid being the substance obtained by the removal of the glutamic acid residue from pteroylglutamic acid. The fact that rhizopterins possessed one carbon atom in a reactive side-chain—a formic acid residue—was of particular interest.

The organism *Leuconostoc citrovorum* will grow on a medium containing liver extract, but in 1948 research showed that the liver extract could be replaced by a single substance folic acid ("leucovorin" or "citrovorum factor"). Folic acid is another formyl derivative, being N_{5} -formyl-tetrahydropteroylglutamic acid. In the processes of metabolism *p*-aminobenzoic acid is almost certainly converted into a substance closely related to folic acid, this postulated substance, coenzyme F, being concerned in processes of biosynthesis in which one-carbon-atom units are utilized. Such a coenzyme or coenzymes may be involved in the synthesis of methionine, serine, histidine, and possibly other amino-acids, as well as in the formation of purines and thymine. In such instances a single carbon atom is introduced into the molecule under the aegis of the coenzyme, this atom almost certainly originating in a formic acid residue of the type found in folic acid. Although these processes have mostly been worked out in micro-organisms, there is every likelihood that they also apply in the main to higher animals. There is now good evidence that sulphonamides inhibit bacterial growth by preventing competitively the utilization of *p*-aminobenzoic acid for the production of folic acid or related substances, which the bacteria themselves need.

Pteroylglutamic acid is effective in the treatment of various types of experimental anaemia, and is of value as an addition to vitamin B₁₂ (cyanocobalamin) in the treatment of

pernicious anaemia in man. Here the biosynthesis of nucleic acids, dependent as it is on that of purines and thymine, may rest on the presence of co-factors closely related to folic acid.

Antagonists to pteroylglutamic acid have been synthesized in the laboratory, of which aminopterin (4-aminopteroylglutamic acid) is the best-known. This substance can induce death with anaemia and leucopenia in experimental animals, and has been used in the treatment of acute leukaemia in children. Although it does not cure leukaemia, it may bring about a remission and can therefore be of aid in the treatment of this disease. Aminopterin inhibits mitosis in mammalian cells, and this suggests the possibility that folic acid derivatives may be of wide-spread significance in cellular reproduction, a process in which the synthesis of nucleic acids is of course of prime importance. Xanthopterin, a pteridine derivative simpler than pteroylglutamic acid, is a yellow colouring matter found in butterfly wings and in the yellow bands of wasps. Its administration to mammals is followed by enlargement of the kidneys to many times their normal size. Xanthopterin apparently directly stimulates mitosis and cell division in the epithelium of the renal tubules.

It is clear that a colloquium on the chemistry and biology of pteridines is dealing with matters of wide and deep significance. The volume under review gives the proceedings of a small international conference on recent progress in the research of pteridines, held under the auspices of the Ciba Foundation. The symposium was divided into two parts, the first on chemistry under the chairmanship of Professor A. Albert, and the second on biological aspects under that of Dr. W. Jacobson. Some of the titles of the sections will illustrate the scope of the discussions. "Recent development in pteridine synthesis," "The pteridines of *Drosophila melanogaster*," "Sulphonamide derivatives of pteridines," "Metabolic relations between *p*-aminobenzoic acid and folic acid in micro-organisms," "The function of folic acid in the biosynthesis of purine and pyrimidine derivatives," "The effects of folic acid analogues on the growth and cell division of micro-organisms," "The mode of action of folic acid antagonists and the function of the *Leuconostoc citrovorum* factor," "Some aspects of disordered folic acid metabolism in man," "Occurrence of hepatic fibrosis in children with acute leukaemia treated with folic acid antagonists." The book is well edited and the accounts of the discussions after each of the papers are very readable. The width of the discussions which occur when biologists and chemists meet together with a common interest is well illustrated by a colloquium which ranges from insect pigments to diseases of man. Biochemistry knows no boundaries of species and type, and, although one would not have expected *a priori* that the study of insect pigments would be of benefit in human medicine, such is the simple but stirring truth.

F. G. YOUNG.

RENAL FUNCTION

Reflections on Renal Function. By James R. Robinson, M.D., Ph.D.(Cantab.). (Pp. 163; 17s. 6d.) Oxford: Blackwell Scientific Publications, 1954.

This small book is based on lectures given to Cambridge students reading for an honours degree in physiology, and we are glad that the author has been willing to share his reflections with a larger public. The result is eminently suitable for a variety of readers, for, although Dr. Robinson makes no concessions to popularity, he requires really nothing of his reader beyond a reasonable intelligence and a willingness to be interested, and indeed entertained, by his clear account of a fascinating subject, written as it is in most attractive English. It is not long enough to tire him, nor so short as to be a mere synopsis. The more advanced reader will find here a point of view as well as an exposition, together with enough references to make a useful, if not comprehensive, bibliography.

A brief quotation from the introduction will give a better impression of the style and scope of this work than a summary of its contents. "The kidneys may be regarded as organs which help to stabilize the internal environment of

the body and to keep it chemically distinct from its surroundings. The elimination of waste products is but one aspect of this much larger task. . . . The two main questions to be considered are, first, how the kidneys do what they do, and, secondly, how they know what to do, or more properly, how they are directed to do it. This second question is concerned with the kidney as one part of the body in relation to other parts, and is for that reason more complex. The simpler question of the mechanism of the kidney itself will be taken up first."

ROBERT PLATT.

RESPIRATORY TRACT IN INFLUENZA

The Histopathology of the Respiratory Tract in Human Influenza. By J. F. Ph. Hers, M.D. (Pp. 77; illustrated. 17.50 Dutch florins.) Leyden: H. E. Stenfort Kroese, N.V. 1955.

This monograph provides much-needed evidence concerning histological changes in the trachea, bronchi, and lungs in human influenza. It is the most detailed account yet to appear of correlated bacteriological and histological studies designed to elucidate the precise role played by the influenza virus in the various forms of fatal influenzal bronchitis and pneumonia. The author marshals evidence from patients who died from infection by bacteria such as *Haemophilus influenzae* and the pneumococcus but in whom influenza virus infection could not be demonstrated. The changes in other patients with combined virus and bacterial infection are then compared and are used to attempt an interpretation of the relative role of virus and bacteria in the production of the well-known necrotizing epithelial lesions of influenza-virus-staphylococcal pneumonia. The argument that the virus and not the bacterium is responsible for necrosis of the ciliated epithelium of the trachea and bronchi, which has formerly been advanced purely on the basis of animal work, is thus reinforced by human evidence. Although the number of patients thus studied is small, the studies are elaborate and the results convincing.

The book is easy to read and beautifully illustrated. It also contains some interesting comments on the lungs in measles and chicken-pox and a few histological preparations from material collected in the 1918 epidemic and preserved in Leyden ever since.

C. H. STUART-HARRIS.

REGIONAL ALLERGY OF NORTH AMERICA

Regional Allergy of the United States, Canada, Mexico, and Cuba. A Symposium of Thirty-nine Contributors. Edited by Max Samter, M.D., and Oren C. Durham. (Pp. 395+xvii; illustrated. 61s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1955.

As is stated in the preface to this book, "the shifting industrial pattern of the country has made camp followers out of large sections of the population," and thus allergists throughout the North American Continent are frequently asked by their patients what effects a transfer to a different region will have on their symptoms and what regions are the most free from the particular allergens to which the individual patient may be sensitive.

This volume, which is the joint effort of some thirty-nine contributors in different regions of the continent, answers these questions very fully. The pollen and mould season and counts in the different regions throughout the year are given in detail and the major allergenic factors present in each region described. A special appendix lists the Ragweed Pollen Indices for the chief districts throughout North America, and should be particularly useful.

This book will prove invaluable to all allergists in the Americas, and to allergists in this country whose patients are considering immigration or are making visits abroad. The amount of geographical and climatic information given about each region makes the book surprisingly readable and will be of interest to many readers other than allergists. The printing and production are of the excellence expected of this publisher.

C. J. C. BRITTON.

SURGERY OF PULMONARY TUBERCULOSIS

The Surgery of Pulmonary Tuberculosis. By James H. Forsee, A.B., B.S., M.D., F.A.C.S., F.A.C.P. (Pp. 208; illustrated. 48s.) London: Henry Kimpton. 1954.

An up-to-date monograph on the value of surgery in pulmonary tuberculosis is particularly welcome, since the treatment of the disease has undergone radical changes in the past few years. The introduction of chemotherapy and pulmonary excision are the two most striking advances and have caused a therapeutic revolution. The author is an enthusiastic supporter of both these principles, and is optimistic enough to feel that an accurate forecast can be made of the time required for treatment.

The book is divided into sections, starting with the patient and his disease and the general application of surgery to pulmonary tuberculosis. The individual operations and their techniques are then described, and finally an analysis is made of the surgical treatment. This last section is worked out in detail, and supports the author's contention that excision of an arrested or controlled disease focus is a safe and satisfactory procedure. The figures given for thoracoplasty between the years 1947 and 1952 show a 74% good result in over 300 patients, as opposed to a 91% good result in 400 cases of pulmonary excision over the same period.

It is unlikely that precise indications for the selection of patients suitable for surgery will be widely agreed upon, but Colonel Forsee has defined his own attitude quite clearly and has based his opinions on an extensive experience.

GYNAECOLOGY FOR STUDENTS AND G.P.s

Gynécologie. By Nicolas C. Louros. Translated from the Greek by Dr. Télémaque Nicoglou. (Pp. 404; illustrated. 5,500 fr.) Paris: Expansion Scientifique Française. 1955.

This is a French translation of a textbook on gynaecology for students and general practitioners written by Professor Louros of the University of Athens. Professor Louros is well known in this country, especially for his writing on obstetrics, so it is all the more interesting to learn his views on gynaecology. And it is amazing to see how many he is able to express within the compass of this comparatively small and copiously illustrated book. For its subject-matter is all-embracing; it includes sections on endocrinology and operative gynaecology, and recalls shades of the past by adding breast surgery (including plastic operations) to gynaecology.

It is inevitable that some subjects receive little more than a mention to whet the appetite, but, by and large, the accounts of pathology and treatment tally closely with those obtaining in this country. The illustrations invite particular attention; many are reproductions from the German and American literature, but some of the best are simple line-and-wash drawings by the author himself. The half-tone illustrations relieved by a single colour are often more effective than those in full colour, but the production as a whole has a finish which makes it attractive.

T. N. A. JEFFCOATE.

MODERN CYTOLOGY

General Cytology. By E. D. P. De Robertis, M.D., W. W. Nowinski, Ph.D., and Francisco A. Saez, Ph.D. Second edition. (Pp. 456+xiv; illustrated. 40s.) Philadelphia and London: W. B. Saunders Company. 1954.

The first edition of this book was published in Argentina in 1946. This, the second edition, is a greatly expanded version of the first and can justifiably claim to be a reliable and readable general account of modern cytology written for those who, having a basic knowledge of genetics and the physical sciences, would like to learn some of the potentialities of this rapidly expanding science and the methods whereby the submicroscopic organization and ultimate metabolism of the cell are investigated and correlated with its manifold functions.

The illustrations are of good quality and carefully selected, there are many clear diagrams, references are plentiful, and the volume is neither heavy nor cumbersome.

G. HADFIELD.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MAY 28 1955

ANAEMIA AND PROTEIN MALNUTRITION

Anaemia is a major medical problem among the natives of tropical countries and several factors contribute to it. Malaria, *Ancylostoma duodenale*, and many other parasitic and infectious agents may lead to anaemia, but malnutrition is probably the most important single factor. The dietary ingredients necessary for normal haemopoiesis are many and diverse, including iron, trace metals, vitamin B₁₂, folic acid, vitamin C, and sufficient protein of high biological value. Whereas anaemia in Britain, when due to a deficiency of any of these factors, is usually attributable to a lack of absorption of iron or B₁₂, in the Tropics insufficient dietary protein seems to be the principal cause, and Professor A. W. Woodruff shows this to be so in his Goulstonian Lectures for 1954, published in our opening pages this week.

Woodruff has now been able to study 45 Nigerian women suffering from anaemia associated with pregnancy, his report¹ on the first 25 cases in this series having been published in this *Journal* in 1951. This anaemia was normocytic in about half the cases, macrocytic and microcytic respectively in about one-quarter. Reticulocytes averaged about 4%, indicating a fair degree of marrow activity, which was confirmed by marrow studies. With two exceptions the picture was macronormoblastic. The exceptions, in which megaloblasts were found, were among the minority of cases which showed a histamine-fast achlorhydria. Despite the considerable variation in mean corpuscular volume, the red cells throughout this group of patients were characterized by their unusual thinness, which is best expressed as the ratio of the mean cell diameter to the mean corpuscular average thickness. The increased variation of red cell diameter in each individual as revealed by a Price-Jones curve was a further characteristic of importance. The significance of these various minutiae of red cell shape and size lies

in their remarkable similarity to those established by G. Larsen² as characterizing the anaemia associated with hepatic disease; this concordance is enhanced by the fact that the liver and spleen are enlarged in two-thirds of these Nigerian cases. Further evidence of hepatic damage was obtained by biopsy, which showed fatty infiltration or excessive fibrosis in all the 42 subjects so studied, findings usually associated with deficiency of dietary protein. The low level of the serum albumin and the high level of serum globulin, especially its γ fraction, seen in most of these cases is a further feature usually found in subjects with chronic liver disease. Haematology, blood protein levels, and hepatic biopsy therefore all agree in associating the anaemia with hepatic injury of the kind that is found both clinically and experimentally in conjunction with dietary deficiency of lipotropic factors—which, in terms of practical dietetics, implies a deficiency of protein.

Owing to the curious custom in tropical Africa by which the relatives are responsible for the feeding of hospital patients a fairly accurate estimate of their everyday diet could be obtained. This revealed that, although the caloric intake was perhaps adequate for subjects confined to bed, the protein level of 36 g. per day was less than half that recommended for pregnant women in the League of Nations 1936 report on the physiological basis of nutrition.³ At this level there can be no doubt that the patients were indeed suffering from protein insufficiency. The complete failure of the anaemia to respond to folic acid, B₁₂, or iron, and the gradual but unequivocal response to a daily supplement of 56–113 g. of casein, show moreover that it is to this insufficiency that the anaemia must be attributed. Further evidence pointing to protein deficiency as mainly responsible for the anaemia is obtained from a study of the similar condition prevalent in the same community among young children and non-pregnant adults. The details of 9 young children and 21 older children and adults that Woodruff has collected can leave little doubt that the anaemia of pregnancy which he studied is but a special example of the general anaemia common among people subsisting on a diet poor in protein.

Since, according to the figures given by Tristram,⁴ nine of the ten essential amino-acids make up 61% of the haemoglobin molecule, it is not surprising that an adequate intake of protein of good quality is essential for the maintenance of a normal haemoglobin level. Diets deficient in one or more of the essential amino-acids soon cause anaemia in experimental animals. This has been shown in rats when supplied with a diet deficient only in lysine⁵ or methionine.⁶ Moreover, with methionine deficiency the marrow

¹ *British Medical Journal*, 1951, 2, 1415.² Larsen, G., *Acta med. scand.*, 1948, 132, suppl. 220.³ *The Problem of Nutrition*, 1936, 2, League of Nations, Geneva.⁴ Tristram, G. R., *Advanc. in Protein Chem.*, 1949, 5, 84.⁵ Gillespie, M., et al., *Biochem. J.*, 1945, 39, 203.⁶ Glynn, L. E., et al., *Brit. J. exp. Path.*, 1945, 26, 326.⁷ Wills, L., *Indian J. med. Res.*, 1933–4, 21, 669.⁸ Robschtein-Robbins, F. S., and Whipple, G. H., *J. exp. Med.*, 1949, 88, 339 and 359.⁹ ——— *ibid.*, 1951, 94, 223.¹⁰ *British Medical Journal*, 1955, 1, 1245.

picture was typically macronormoblastic and indistinguishable from that described by L. Wills.⁷ Woodruff, and others in their cases of anaemia in the Tropics. Further, since haemoglobin contains so high a proportion of amino-acids which the body is incapable of synthesizing, the nature of the dietary protein is at least as important as its mere quantity. Whipple and his colleagues^{8,9} have made a special study of this problem, using for the purpose dogs depleted of both protein and haemoglobin by repeated bleeding. They have found that the processes by which haemoglobin and plasma protein are restored do not run parallel: beef protein, for example, favours formation of haemoglobin, while egg protein favours formation of the plasma proteins. In view of Woodruff's encouraging therapeutic results with casein it is of interest that Whipple has found that this is a "superior protein as promoting new haemoglobin and plasma protein output," comparing favourably with liver and beef under experimental conditions. Vegetable protein, such as peanut meal and wheat gluten, was far less satisfactory, partly because it was unpalatable to the experimental animal. This in itself may be a reflection of its inadequacy, since it has been shown,⁶ for example, that small supplements of methionine greatly improve the impaired appetites of rats on diets deficient in this amino-acid.

Anaemia in pregnant women is by no means confined to the Tropics, though in Europe and the U.S.A. it is rarely attributable to deficiency of dietary protein; the great majority of cases are of the iron-deficient type. The rarer macrocytic variety is usually megaloblastic, and, although resistant to B₁₂, it responds readily to folic acid, as Professor L. J. Witts and his colleagues¹⁰ reported in last week's *Journal*. The speed with which these cases respond is in marked contrast to the very slow reaction of the protein-deficient group. As Woodruff rightly points out, the protein deficiency of his tropical patients may amount to hundreds of grammes, and, though haemoglobin synthesis ranks high among the priorities, much of this deficit must be made good before the haemoglobin response becomes adequate.

STERILIZING THE GUT

In recent years, and especially since 1952, there have been increasingly frequent reports of sudden and severe, often fatal, enterocolitis after surgical operations. The main facts seem to be clear. The increase in this syndrome has followed the widespread use of powerful antibacterial drugs; the surgical operations which it follows are abdominal operations in which pre-operative antibacterial treatment has been used; in most cases almost complete sterilization of the

faeces has been achieved before and just after operation; in many cases staphylococci are the only or the predominant organisms subsequently isolated; and these staphylococci are found to be resistant to the drug which has been used in pre-operative medication. The disastrous nature of this syndrome has been emphasized in this and other journals more than once,^{1,2,3} but a paper by Mr. B. J. Fowler (page 1313) describing three fatal cases once again draws attention to this serious sequel of modern surgical pre-operative technique.

The first of Fowler's cases, a woman of 68, after a course of penicillin and streptomycin which failed to control local sepsis, at first showed rapid improvement when given chloramphenicol. Yet three days later she vomited, had severe diarrhoea, and died ten days after operation. The second patient, a man of 35, had received succinylsulphathiazole and streptomycin, went into a state of collapse after developing diarrhoea, continued to deteriorate on treatment with erythromycin and chlortetracycline (aureomycin), and died on the third post-operative day. The third patient, a woman of 82, had had penicillin and streptomycin, developed vomiting and diarrhoea, and died on the fourth day after operation. From the intestinal contents of all three patients coagulase positive staphylococci resistant to penicillin and streptomycin were isolated after death.

There can be little serious doubt that in Fowler's cases, as in so many others previously described, the disastrous outcome was the result of the antibiotic "umbrella" used to cover the operation. Although oxytetracycline (terramycin) has often been singled out as a conspicuous cause of post-operative enterocolitis, this syndrome is no respecter of antibiotics, and Fowler's cases show that the combination of penicillin and streptomycin can be just as dangerous. Some surgeons now feel that the fashion of gut sterilization has gone too far and would agree with Fowler's plea for the use of the poorly absorbed sulphonamides. The recent great fall in the incidence of peritonitis after abdominal operations seems to have been in large part due to the sulphonamides, and the more complete sterilization of the gut achieved by the antibiotics has been of doubtful value to the surgeon, who has to weigh one risk against another. If the danger of peritonitis after abdominal operations can be shown to have become very small as a result of using poorly absorbed sulphonamides, there would seem to be little point in striving to eliminate that risk completely if the process of eliminating it results, as so often seems to happen,

¹ *British Medical Journal*, 1953, 1, 1382.

² *Lancet*, 1953, 2, 1245.

³ *British Medical Journal*, 1954, 2, 221.

⁴ *Ibid.*, 1955, 1, 973.

in greatly increased risk of fatal enteritis. One of the first things that needs to be done is to obtain an accurate appraisal of the facts and from that an accurate estimate of the risks involved.

There are several other questions arising out of this post-operative syndrome which urgently demand an answer. One of the most important of these is the question of dosage. Mennie⁴ has sensibly pointed out that the doses of the drugs used are often far greater than the dose claimed by the manufacturers to be effective and indicated by preliminary pharmacological tests. One of the great difficulties with new drugs is to determine the smallest dose which will be clinically effective in man, and to determine it quickly before excessive dosage throws a drug into undeserved ill-repute. Then there is the epidemiological aspect of this syndrome. It mainly occurs in institutions, since it is there that nearly all operations take place. It also naturally tends to occur in certain wards, particularly where there is one surgeon who specializes in certain abdominal operations. The part played by the staphylococcus in the syndrome, however, is still mysterious. The staphylococcus is not always the cause, and bacteriological investigations are often not done or are done too late. There is a strong inference, however, that where the staphylococcus fills the "bacteriological vacuum" produced by over-efficient sterilization of the gut the strain which multiplies in the gut is one which is already present in the environment and which was already drug-resistant when it reached the victim's alimentary tract. The use of a particular drug, in fact, has merely given the drug-resistant organism the chance for which it was waiting. If so, then careful epidemiological studies of staphylococcal types in surgical wards would be of great interest.

Finally, what can be done in the treatment and prevention of this condition? Some lives have been saved by the prompt administration of erythromycin, often the only drug to which these staphylococci will respond. But in many cases both specific and general methods of treatment are bound to fail, since the condition is an acute and fulminating one. It is conceivable that vitamin deficiency may play a part in the development of the condition, and it has been suggested that the liberal use of vitamins may help to prevent it. But convincing evidence of this is lacking, and for the present it seems wiser to rely on some of the methods of prevention that have already been discussed—smaller dosage of antibiotics or, perhaps better still, none at all, with a return to the use of poorly absorbed sulphonamides, and at the same time energetic measures to eliminate staphylococcal infection from surgical wards.

AN EPIDEMIOLOGICAL CENTENARY

The Section of Epidemiology of the Royal Society of Medicine marked the centenary of the publication of the 1855 edition of John Snow's work on cholera by holding a meeting at the London School of Hygiene, where the public health students had prepared an exhibition containing many interesting relics—an outstanding exhibit being a portrait in oils, not exhibited before, lent by a member of the Snow family. Professor J. M. Mackintosh was unfortunately unable to be present because of illness, but in a paper read for him he sketched the social background to Snow's work and told how the opposition of the water companies of the time delayed the universal recognition of his conclusions.

The president of the Section, Professor Bradford Hill, in his appreciation of Snow, pointed out that his reputation rested not upon the removal of the handle of the Broad Street pump—an event that could have had little effect on an already waning epidemic—but upon his theory of the mode of spread of cholera, built up by reasoning based upon innumerable careful observations. Snow did not merely demonstrate the part played by infected water in the dissemination of cholera: by studying the way in which the disease spread from person to person he was able to infer—thirty years before the discovery of the cholera vibrio—that it was caused by "some material which passes from the sick to the healthy and which has the property of increasing and multiplying in the systems of the persons it attacks": that this material derives from the faeces and vomit of patients and is introduced into the alimentary tract by swallowing; and that "the morbid matter of cholera, having the property of reproducing its own kind, must necessarily have some sort of structure, most likely that of a cell." From this basis he proceeded to show the part that was played by sewage-infected water in furthering the spread of the disease.

Many present-day workers see Snow as one of the founders of modern epidemiology. W. H. Frost wrote in the introduction to the American reprint of Snow's work, "Epidemiology . . . is something more than the total of its established facts. It includes their orderly arrangement into chains of inference which extend more or less beyond the bounds of direct observation." Much of the evidence produced in epidemiological studies is circumstantial in character, but such evidence can often be quite convincing, particularly when the epidemiologist makes use of the modern statistical techniques which are the outstanding contribution of the twentieth century to his subject. To-day the epidemiologist sees his greatest challenge in the aetiology of the common killing diseases of middle and later life. In his task he is finding that the old method of arrangement of facts into chains of inference to formulate a hypothesis, followed by the use of other data to test the hypothesis, is still a rewarding method of investigation. Although his analytical techniques have a refinement that was impossible a century ago, his method of working is in the direct descent from John Snow.

CLINICAL THERMOMETERS

About 3½ million clinical thermometers are sold in Britain annually, and it would be surprising if an occasional one out of so many instruments did not fall below its purchaser's expectations. But how many do not show the accuracy required of them is problematical. Since they are commonly read to the nearest 0.2° F., their materials and manufacturer must conform to strict standards, and the intricacies of glass-blowing are such that these standards are not easily attained. No doubt the manufacturers are constantly checking samples of their products, but a recent American investigation suggests that some independent checking might be worth while in Britain. E. G. Dimond and M. H. Andrews¹ tested 465 thermometers—all in use at a large general hospital—against a standard thermometer of known accuracy. Of these 465 clinical instruments, 34 (7%) were exactly in accord with the standard, 7% showed variation of 1° F. or more from the standard, and about 78% varied by less than 0.5° F. The greatest error was 3.3° F. from the standard. Clearly the unreliability of a small proportion of these thermometers could lead to difficulties in, for example, the investigation of a case of supposed continued low-grade fever in a child or the notification of a case of puerperal pyrexia. In Britain the National Physical Laboratory tests some clinical thermometers, and marks with its monogram those that pass the test. Some thermometers, too, are manufactured in accordance with the limits of tolerance set by the British Standards Institution, a letter from whose technical director appears at page 1339, and some of these are included among the instruments tested by the N.P.L. The British Standard permits a maximum error of $\pm 0.2^\circ$ F. at and below 106° F. The N.P.L. and B.S.I. thermometers cost slightly more, and comprise only a minority of those in use. Whether the cheaper types are sufficiently accurate for clinical practice is something that might well be investigated.

TENDON REPAIR

At the end of the first world war Sterling Bunnell² laid down the principles governing successful tendon surgery, but it required the second world war to produce a rapid acceleration in their application and the growth of surgical teams primarily interested in hand surgery. The fundamental principles governing tendon repair are two³: first, all tendon repair demands vascularization from adhesions to neighbouring tissues, since the tendon has no blood supply of its own; and, secondly, any adhesions in the digital tendon sheath will affect the function of the tendon adversely. It has taken forty years of work to strike a practical balance between these mutually antagonistic factors.

Before the importance of early treatment to the injured hand was appreciated, experience had to be gained from the results of treating late hand injuries. It was found that if a tendon was to function there must be no adhesions to it; but local repairs in the tendon

sheath almost inevitably produced local adhesion. The procedure of grafting was then devised, in which the tendon graft was sutured at the base of the terminal phalanx, where its gliding movement was small and adhesions necessary for its attachment were minimal, and suture of the proximal portion was done in the palm outside the tendon sheath. Careful attention to the digital sheath and its pulleys is essential to avoid adhesions, and difficulties are encountered where the sheath is occupied by two tendons, the so-called "no-man's-land" between the distal palmar crease and the proximal interphalangeal crease. Here the pressure on the graft resulted in adhesions to the sheath or to its fellow tendon, either or both usually leaving the finger with flexor sublimis function only. It was soon recognized that an actively functioning flexor profundus alone was all that was required, and the sublimis tendons were sacrificed by removal. On this basis very satisfactory delayed repair was possible.

To avoid the necessity for this complicated technique and the time wasted by the patient, attention was naturally turned to the acute injury, and some measure of general agreement has been arrived at in treatment. Again there are two main factors to consider. First, the type of wound has an important bearing on treatment. Two types may be distinguished: the incised wound—often surgical in its tidiness but most unsurgical in its disregard for anatomy—in which primary repair is possible; and the crushing injury in which fractures, bursting of the tendon sheath, and loss of skin may occur and are inevitably followed by adhesions and which demands delayed repair. Secondly, there is the level of the wound to be considered. If it is in the wrist, then primary suture is aimed at, since secondary repair is very difficult here. Once again the sublimis tendons can be sacrificed if necessary. In the palm primary suture is usually satisfactory. In the tendon sheath distal to the proximal finger crease the profundus can be sutured with every chance of success if the wound is a clean incised one. In "no-man's-land," because of the difficulties encountered, it has been the habit of many surgeons⁴ to leave the wound and do a delayed graft. The terrors of this area may be more imaginary than real, for Allen and his colleagues in Chicago are now excising the sublimis and carrying out primary repair in this area when the wound is clean. It is interesting to note that Professor R. F. Bogdanov, of Sverdlovsk in the U.S.S.R., writing in this issue on the subject (p. 1315), is also quite definite that repair in this area need not be secondary. Extensor tendons, being surrounded by mesotendon and paratendon, offer no difficulty in repair, and the same proportion of successful results as is claimed by Professor Bogdanov for primary suture would be expected in English-speaking countries. Comparison of figures is, however, difficult, since Professor Bogdanov's statistics are based on a regional classification, and the end-results are much more strongly influenced by the character of the wound than its position. It is obvious from his report that surgeons in Russia are prepared to exercise

the patience and scrupulous attention which the precision surgery of the hand demands, and are developing that special experience of their craft which is essential for success and which justifies the segregation of hand injuries in special clinics.

ROYAL SOCIETY CONVERSAZIONE

In spite of the enormous grants nowadays poured by the Treasury and industry into scientific research, at least some scientists seem to be free still to carry out investigations that have no immediate bearing on man's affairs. They were fairly well represented once again at the Royal Society's Conversazione held on May 19, when exhibits intended to illustrate some of the more important lines of research were displayed at the Society's rooms off Piccadilly. The songs of birds and the music of the spheres (detected by radio-telescope), the hearing of whales and the spinning of spider's webs, were the subject of exhibits that did not seem to portend the immediate exploitation of man's environment. But not quite the same could be said of the animated diagram showing how a chain reaction works in a nuclear reactor.

Of special interest to medical men was an exhibit by Drs. Jean Hanson and H. E. Huxley (of London and Cambridge respectively) showing how striped muscle contracts. Two different types of protein filament lie alongside each other, partly overlapping. Contraction occurs when the filaments of one type slide along those of the other type, so that the two arrays come to overlap almost completely. Supply of adenosine triphosphate causes this movement, and it was demonstrated under the microscope. Cinematography was the basis of two exhibits. Drs. G. M. Ardran and F. H. Kemp (Nuffield Institute of Medical Research, Oxford) illustrated the swallowing mechanism by means of short x-ray cine films taken of subjects swallowing radio-opaque fluids. This technique has shown, among other things, that the soft palate closes down on to the back of the tongue to help form a bolus in the mouth just before swallowing, and that this is its main role rather than shutting off the nasal from the pharyngeal cavity. Apparently it is true too that some people, though very few, really can pour a glass of beer straight down their throats without any appreciable swallowing movements with the mouth. The use of high-speed cinematography in analysing fast movements in living creatures was demonstrated by Dr. D. A. McDonald (St. Bartholomew's Hospital). His film, taken at 1,000-2,000 frames per second, showed a cat righting itself in falling (successfully but not quite so expertly when blindfolded), the flow of blood through arteries in experimental animals, and human responses to a blow to the face—all with an infinitely lethargic motion that would have appealed to Marvell's coy mistress.

Human respiration came in for a surprising amount of attention. Drs. A. J. Buller and A. C. Dornhorst (St. Thomas's Hospital) translated into electrical wave patterns the sounds passing through the chest wall, thus providing a visual analysis of such time-honoured

clinical signs as aegophany, amphoric breathing, and dullness. Dr. B. M. Wright (Pneumoconiosis Research Unit, Cardiff) showed a small meter for measuring the amount of air breathed by a man at work. The mechanism consists mostly of wrist-watch wheels, and the air drawn through it when it is fitted into a mask turns a dial to record the volume. It was originally developed to estimate the dust inhaled by miners. Mr. H. S. Wolff (National Institute for Medical Research) was also occupied with a flow-meter, though of a different kind. It measures the volume of air a person expires while working, and also takes a sample for subsequent analysis. The oxygen consumed in a variety of jobs—some of them strenuously athletic—can be measured with it; and it can be worn for many hours, allowing the wearer to drink and to smoke. For light relief the visitor could contemplate a curious optical illusion staged by Dr. R. A. Weale (Institute of Ophthalmology, London).

No demonstration of current research would be complete without those sub-atomic particles of biology, the viruses. Dr. Elinor McCloy (London School of Hygiene and Tropical Medicine) showed how prophage—a kind of derivative or incomplete phage—is thought to become attached to specific sites on the genetic apparatus of bacteria, thereby blocking the destructive effects of phage in those bacteria. Drs. R. E. F. Matthews and J. D. Smith (Cambridge) illustrated the chemotherapy of plant viruses with some synthesized compounds similar to, but not identical with, the natural bases of the virus nucleic acids. The virus particles incorporate these synthesized competitors, and their powers of infection are thereby inhibited. With any luck this work may ultimately be of great importance not only in the treatment of human virus diseases but in furthering our understanding of what distinguishes living organism from dead matter.

TOXIC EFFECTS OF COBALT

The benefit conferred by cobaltous chloride in the treatment of certain anaemias of childhood and in the anaemias associated with chronic infection, renal disease, and carcinomatosis has been discussed recently in these columns.¹ Side-effects appear to be uncommon and occur usually with doses in excess of 100 mg. daily. Anorexia, nausea, and vomiting can largely be prevented by administering enteric-coated tablets. Tinnitus, deafness, flushing of the face and extremities, and paraesthesiae have been reported.² Large doses in animals cause renal damage, but this hazard has not yet been encountered in man, even in patients with severe renal disease. Recently, however, Kriss and his colleagues³ have reported a serious and unexpected toxic action on the thyroid; they found hypothyroidism with hyperplasia of the thyroid in five of their patients. Goitres developed during treatment, and tests of thyroid function, including radioactive iodine, showed reduction of normal activity. This goitrogenic action has since been confirmed in

¹ *British Medical Journal*, 1954, 2, 1038.

Britain.⁴ Recovery follows withdrawal of the drug, and it would be interesting to know whether thyroid function is invariably depressed in patients receiving cobalt.

Why cobalt should cause polycythaemia remains a mystery, though animal experiments suggest that the metal inhibits enzyme systems containing sulphhydryl groups. Kriss *et al.* believe—and there is some support from Kirkwood's experiments⁵—that it has a similar inhibitory action on the tyrosine iodine system in the thyroid. It seems likely that the drug is a poison rather than an essential element in erythropoiesis, and this should be borne in mind when treating patients. While it is reasonable to treat cases of chronic renal disease and of carcinomatosis with cobalt, administration of the drug to children should await further knowledge of its side-effects. Many would agree that its inclusion in proprietary preparations for the treatment of anaemia is unjustified. Though caution is necessary in therapy, the demonstration that cobalt is a goitrogenic agent may help to unravel the biochemistry of thyroid function.

CINERADIOGRAPHY

Cineradiography, the formation of x-ray pictures at the rate of 16 per second or faster, has nearly always been carried out by the indirect method of photographing a fluorescent screen image. Speeds of up to 100 frames per second have been possible. However, the work has often been limited by overheating of the x-ray tube, poor definition, and the high dose of radiation necessary. The combination of fast film (35 mm.) and fluorescent screens together with wide aperture lenses (f 1.0 to f 0.71), camera shutters preferably closed for only one-quarter of the cycle, and pulsed x-ray units leaves little room for improvement along these lines. The dose rate depends on the type of examination being performed, but an antero-posterior view of the heart requires a skin dose of the order of 0.1–0.3r per picture.

Recently several methods have been devised by which a considerably brighter image of the fluorescent picture may be obtained.^{1,2,3} The method developed by Colman¹ consists of an electron lens which uses a fluorescent screen as object and produces a luminous image reduced in size but greatly increased in brightness. The Westinghouse-Marconi¹ and Philips⁴ image intensifiers are of this type. Cinematography of the reduced, intensified image can be performed if a suitable optical system is available. With an apparatus of this type the skin dose of radiation for an antero-posterior view of the heart is about 0.2–0.5r per 100 frames, and 1.2r per 100 frames for an abdomen. The definition at maximum intensification is limited by statistical fluctuation of the x-ray quanta, as predicted by Sturm and Morgan,⁵ demonstrated by Ardran and Wyatt,^{6,7} and described by Tol and Oosterkamp.⁸ A compromise may have to be made

between definition and amplification of brightness. Thus within limits the definition will depend on the dose of radiation used. The definition approaches that of conventional intensifying screen radiography as the dose of radiation approaches that used in screen radiography. The best possible definition is not always required when moving pictures are viewed by projection, and thus the radiation dose may be kept low. The definition obtained in cineradiography by means of the image intensifier may, with only 2–5% of the radiation dose, be as good as or better than the definition obtained with orthodox cine fluorography. At present the small field which can be examined (approximately 5 in. (12.5 cm.) in diameter) limits the usefulness of the apparatus, but it may be employed for studying the act of swallowing, selective angiocardiology, and movements of the duodenal cap. Image intensifiers covering larger fields are being developed.

In the future almost all cineradiography and much rapid serial work may well be carried out with image intensifiers, when these are available in a size which covers the part under examination. Now that the limit imposed by overheating the x-ray tube has been removed it must be remembered that, although the dose per picture can be exceedingly low, the total dose can rise to a dangerous amount if the cineradiographic examination is continued for a long period. Great care will still be necessary to avoid an excessive dose to the gonads when the abdomen and pelvis are examined by cineradiography.

"SURGERY, GYNECOLOGY AND OBSTETRICS"

Surgery, Gynecology and Obstetrics comes high on the list of famous and successful medical journals. For fifty years now leading surgeons have contributed to it, and their colleagues all over the world have turned to it as a source of authoritative information. The high and, indeed, luxurious standard of presentation reflects the pride of the editors, publishers, and printers in their journal, which in this its golden jubilee year has temporarily dispensed with its familiar cover and appears handsomely dressed in blue and gold. In the first number of the year Dr. Loyal Davis, the present editor, describes how the journal came into being in 1905. It was so successful financially that it could pay for the meeting of the Clinical Congress of Surgeons in London in 1913. Following that meeting the American College of Surgeons was founded, and since 1935 the College has owned the journal, the earnings of which are used to further the educational purposes of the College. In an editorial also appearing in the first number for 1955 Dr. Sumner L. Koch, an associate editor of the journal, looks beyond the remarkable surgical advances of the last few decades. If, as in his view is entirely conceivable, the centre of activity of surgeons moves during the next half-century from the operating-room to the laboratories of physics and chemistry, *Surgery, Gynecology and Obstetrics* will be there to guide them, as it has in the past, through the intricacies of new and strange techniques.

EMERGENCIES IN GENERAL PRACTICE POST-PARTUM MATERNAL COLLAPSE

BY

JOSEPHINE BARNES, D.M., F.R.C.S., F.R.C.O.G., M.R.C.P.

Assistant Obstetrician and Gynaecologist, Charing Cross Hospital and Elizabeth Garrett Anderson Hospital

For the purpose of this article it is proposed to limit discussion to those cases in which sudden collapse of the mother occurs within a few minutes or hours after delivery. Such a condition may arise at any time during pregnancy or during the puerperium, but the varieties most commonly encountered in practice occur mainly during the immediate post-partum period.

A full discussion of these conditions would involve a survey of all the general medical and surgical conditions, to say nothing of those of obstetrical origin, which can lead to sudden collapse or shock. Broadly, they can be divided into conditions directly due to pregnancy and childbirth—that is, to obstetrical conditions—and those due to general medical or surgical diseases which are acutely exacerbated by the process of labour.

Obstetrical Causes

The causes arising directly out of pregnancy and labour which may lead to post-partum collapse may be defined as follows.

Haemorrhage.—This must be regarded as the commonest and most important cause of post-partum collapse. Bleeding may come from the birth canal and be visible externally; the main causes are retained placenta, uterine inertia, and bleeding from lacerations of the genital tract. Internal haemorrhage may occur, the most frequent cause being rupture of the uterus; internal bleeding may also occur from rupture of a vessel in the broad ligament or tearing of the vaginal vault. Antepartum haemorrhage, whether of the accidental variety or due to placenta praevia, is apt to be followed by post-partum haemorrhage.

Trauma.—Surgical shock may result from a difficult delivery or may follow precipitate labour. Many obstetric operations, and especially difficult forceps delivery and craniotomy, may lead to maternal shock; the cause appears to be linked with the effect of traction on the broad ligaments. A similar effect is seen when shock follows an attempt to deliver the placenta by Credé's method. The dangers of forcible manipulation of the uterus cannot be overemphasized, and indeed Credé's method has now been entirely abandoned by many obstetricians, who feel that they prefer manual removal of the placenta as the safer procedure.

Acute Inversion of the Uterus.—This may result from trauma, but in many recorded instances the uterus has become inverted in the absence of any interference. Acute inversion may be complete, the uterine fundus protruding from the vulva and lying between the mother's thighs, or it may be partial so that the fundus is not visible. In either instance the mother collapses in a state of profound shock which is probably caused by traction on the broad ligaments.

Embolism.—Pulmonary embolism may occur from previous venous thrombosis in cases in which thrombophlebitis or phlebothrombosis has occurred during the latter part of pregnancy; in general, however, pulmonary embolism from this cause is commonest between the tenth and fourteenth days of the puerperium. In cases of cardiac disease thrombi in the heart itself may be displaced during labour. Amniotic fluid embolism is a somewhat obscure condition, but the presence of amniotic fluid in the mother's lungs has been demonstrated in cases of unexplained sudden death during

or shortly after labour. Air embolism is recognized as an occasional happening in labour. It may occur at forceps delivery, during manual removal of the placenta, or during packing of the uterus. It is possible that a low-lying placenta may predispose to its occurrence.

Drugs.—Pituitary shock is well recognized as a cause of collapse in the recently delivered woman and is believed to be due to spasm of the coronary vessels. Two important points must be made in this connexion. The danger of shock results chiefly from repeated administration of posterior pituitary extracts for arrest of post-partum haemorrhage. For this reason many prefer not to use them but to rely on ergometrine, which does not carry this risk and is equally effective. Posterior pituitary extract is much more dangerous than injectio oxytocini (B.P.), as the latter contains mainly the oxytocic factor. Nevertheless, as no pure preparation of oxytocin exists as yet, all known preparations of oxytocin containing a small proportion of vasopressin, shock may follow the use of the oxytocic factor. Thus if pituitary extract is given in the post-partum period, oxytocin should be used, but only one injection should be given; it should be used intravenously only with the greatest caution and in a dose not exceeding two units, if indeed it is used at all. Sudden collapse may follow the administration of anaesthetics during labour; the recently delivered woman appears to be particularly susceptible to this. Recent reports of maternal deaths due to inhalation of vomit have received considerable notice, and it must always be remembered that the stomach empties slowly during labour. Chloroform is especially dangerous in causing collapse.

Toxaemia of Late Pregnancy.—An eclamptic convulsion may occur in the recently delivered mother, and in severe toxæmia cerebral haemorrhage may cause collapse with coma.

Nervous Influences.—There are many who believe that post-partum collapse rarely if ever occurs without a cause such as one of those already described. Occasional cases are, however, encountered where the mother goes into profound shock after a normal delivery and no apparent cause is found. Collapse may sometimes follow a psychological shock at the time of delivery. Such an occurrence is described in the First Book of Samuel, Chapter 4, where the death of Eli and the birth of Ichabod are described: "And his daughter in law, Phinehas' wife, was with child, near to be delivered: and when she heard the tidings that the ark of God was taken, and that her father in law and her husband were dead, she bowed herself and travailed; for her pains came upon her. And about the time of her death the women that stood by her said unto her, Fear not; for thou hast born a son. But she answered not, neither did she regard it."

In practice, post-partum collapse in the absence of shock or haemorrhage is very uncommon, and it should be a rule always to exclude all possible physical causes before ascribing it to nervous influences.

Non-Obstetrical Causes

In the majority of cases where the mother collapses suddenly after childbirth an obstetrical cause is responsible. Nevertheless there is a variety of non-obstetrical causes for such a catastrophe. The main group consists of cases of heart disease, especially mitral stenosis. The woman who is in incipient heart failure before the onset of labour may

⁸ *Nature, Lond.*, 1954, 174, 397.

collapse suddenly when the uterus empties. Here an overloading of the maternal circulation results from the sudden release of blood from the pelvic organs, and this may even be fatal. Other less common cardiovascular diseases include myocarditis, pericarditis, and pericardial effusion.

Rupture of a vital organ may occur, as, for example, the heart, spleen, pancreas, aorta, mesenteric vessels, bowel, or gall-bladder. Internal haemorrhage may occur from the lungs, stomach, or splenic veins. Cerebral haemorrhage sometimes occurs even in the absence of severe toxæmia. Uraemia may become manifest for the first time in the immediate post-partum period. Profound anaemia in pregnancy may become evident for the first time after delivery, especially if there has been loss of blood during labour.

Diagnosis

The practitioner who is called to a case where the mother has collapsed suddenly after delivery is faced with a grave situation demanding immediate action. There will be time only for a rapid survey of the situation, but this is well rewarded, as correct diagnosis is essential before treatment is begun.

A brief history is taken; this will include the history of past illnesses, with special reference to conditions such as heart disease and anaemia. The history of past pregnancies is important. Operations such as caesarean section, hysterotomy, and myomectomy may have left a potentially dangerous uterine scar. The history of the present pregnancy will include the presence of any abnormalities and the amount of antenatal care received. Important events include toxæmia, anaemia, breathlessness, varicose veins, or antepartum haemorrhage. The history of the labour is next taken, including the length of each stage, and of the actual delivery, whether normal, difficult, or precipitate. A note is made of all drugs, including anaesthetics, given during labour and of any untoward symptoms such as vomiting or pain in the chest or abdomen. The history of the third stage is very important and should include an account of all attempts, whether successful or not, to deliver the placenta. If the placenta is available it should be examined to ensure that it is complete.

A general examination of the mother follows. The skin and mucous membranes are inspected for pallor and sweating. The rate and volume of the pulse are noted and the blood pressure is recorded. A note is made of obvious symptoms such as dyspnoea, restlessness, or pain in the chest or abdomen. The heart and lungs are next examined; a churning sound in the heart is characteristic of air embolism. The lungs may show evidence of pulmonary oedema.

Examination of the abdomen follows; the uterine fundus is felt to see if it is firmly contracted and palpable per abdomen. Tenderness or rigidity may be felt in the abdominal wall or over the uterus itself. Free fluid may be detectable if there is intraperitoneal haemorrhage. The vulva is next inspected to see if blood is still being lost. A pelvic examination should follow but may be deferred if the placenta is still retained. Pelvic examination after removal or expulsion of the placenta may reveal a laceration of the cervix or vagina or an incomplete inversion of the uterus.

The clinical signs of shock and haemorrhage are very similar. The patient is pale, sweating, restless, and anxious, the pulse is soft, and its rate rapid, often up to 150 a minute. The blood pressure falls, the systolic pressure falling more in proportion than the diastolic.

Prevention

Prevention of post-partum collapse begins in the antenatal period, when abnormalities such as toxæmia, anaemia, heart disease, and thrombophlebitis may be detected and treated. Disproportion, even in multiparae, must be excluded and potentially dangerous conditions such as multiple pregnancy and malpresentation diagnosed. The choosing of cases for home delivery is important: all cases with a previous history of grave disease and cases of multiple pregnancy, of mal-

presentation and of suspected disproportion are safest in hospital, where there are facilities for any emergency treatment that may become necessary.

During labour the emphasis must above all be on avoiding trauma and haemorrhage. Caesarean section has become so safe that it is to be preferred to difficult delivery, and it is now used without hesitation in many conditions. Few would condone the old "difficult forceps" delivery with excessive traction on the maternal soft parts and foetal skull; forceps should rarely if ever be applied before full dilatation of the cervix. The danger of Credé's manoeuvre for expulsion of the placenta cannot be overemphasized, and it is doubtless still responsible for much unnecessary obstetric shock. In fact its use should no longer be taught to medical students or pupil midwives except to stress its dangers. Care must be exercised in the use of all drugs during labour, two of the most dangerous being chloroform and posterior pituitary extract. Perineal sutures should be inserted under local analgesia.

A massive post-partum haemorrhage will demand immediate treatment. The slow, steady trickle is almost more dangerous in that it may go on unnoticed until the mother is in a grave condition. The amount of blood lost after delivery should be most carefully watched and action taken when the total reaches 20 oz. (568 ml.), if not before.

Treatment

The treatment adopted in the individual case of post-partum collapse will depend on the cause; in most cases haemorrhage or shock will be responsible, and their treatment is dealt with in some detail.

The treatment of post-partum haemorrhage may be outlined as follows. If the placenta has not been delivered the uterine fundus must be gently grasped and rubbed up until it contracts: ergometrine, 0.25 to 0.5 mg., is then given intravenously. A strong contraction will occur in about half a minute and an attempt may then be made to deliver the placenta by gentle fundal pressure. Excessive force must be avoided, as this will only increase existing shock. If the attempt fails preparations should be made for manual removal, and meanwhile haemorrhage will have been checked. It has been shown that shock tends to increase for as long as the placenta is retained. Anaesthesia for manual removal will depend on the circumstances; the ideal anaesthetic for this purpose is a small dose of thiopentone, provided the necessary equipment, which must include oxygen, is available. In an emergency, manual removal can be gently performed without anaesthesia, or with analgesia with gas and air or trichlorethylene ("trilene").

If bleeding occurs after complete expulsion of the placenta, ergometrine should immediately be given intravenously; intramuscular injection is apt to be less effective in the shocked patient. The uterus will contract and bimanual compression should be carried out until bleeding is arrested. This is best done by the external method; the uterus is lifted well up into the abdomen and held firmly between the two hands. The patient's legs should be straightened and the foot of the bed raised. If bleeding continues and the uterus is empty and well contracted, the blood may be coming from a laceration of the genital tract, and arrangements should be made to suture this as soon as possible. In domiciliary practice it may be necessary to pack the vagina firmly with gauze until such arrangements can be made.

All cases of serious haemorrhage require blood transfusion, and it is here that in domiciliary practice the obstetric flying-squad service has proved most valuable. Restorative measures must be carried out while awaiting the arrival of blood. The foot of the bed is raised and moderate but not excessive warmth applied to the patient's body. Morphine, $\frac{1}{2}$ gr. (16 mg.), is given if she is restless and anxious. Blood should be taken for cross-matching and intravenous therapy begun without delay. There is no substitute for blood in a case of haemorrhage, but it may be some time before transfusion can be given. In the interval, glucose saline, or,

better still, one of the plasma substitutes, may be given by intravenous drip. Every practitioner who conducts midwifery cases should include in his equipment a giving set and one or more bottles of plasma substitute.

Three satisfactory plasma substitutes are at present available: polyvidone ("plasmosan" consists of a 3.5% aqueous solution of polyvidone with electrolytes in the same proportion as in plasma), dextran, and improved preparations of gum acacia. Blood must be taken for cross-matching before administering plasma substitutes, as their effect on the red corpuscles may make subsequent matching of blood difficult.

Plasma substitutes are advantageous in the treatment of post-partum collapse in that they have a pressor effect, so that within a short time of commencing administration there is often a dramatic improvement, the blood pressure rising and the pulse rate falling. In cases in which the blood pressure remains persistently low a small dose, say 10 mg., of methylamphetamine hydrochloride may be added to the drip, but this drug should be used with caution and in the minimal dose.

As a general principle, where there has been haemorrhage the amount of blood lost should be replaced by transfusion, but care must be taken not to overload the circulation, and the actual amount given will depend on the response to treatment.

When no improvement follows the arrest of external haemorrhage and adequate restorative treatment, including blood transfusion, internal haemorrhage must be suspected and the situation is grave. Immediate laparotomy is likely to offer the only chance of saving the patient's life, and arrangements for this, including removal to hospital if necessary, must be undertaken without delay.

Cases are now being described of post-partum haemorrhage due to afibrinogenæmia; they usually follow accidental antepartum haemorrhage. Steady and continuous loss of blood occurs after delivery, and if the blood is examined in a test-tube it is found that normal clotting is not occurring. The treatment of such cases is to give fibrinogen, but supplies of this substance are not as yet easily available. Bottled blood is useless as it contains little fibrinogen, but fresh blood or reconstituted dried plasma may be given if fibrinogen is not obtainable.

Oxygen is invaluable in all cases of shock and collapse, and should be given in high concentration, preferably with a special oxygen mask.

In treating shock in the absence of haemorrhage the same general principles apply, except that blood should not be given; general restorative measures should include moderate warmth, morphine for restlessness, oxygen, and intravenous infusion of a plasma substitute, with a small dose of methylamphetamine hydrochloride when the blood pressure remains low.

Acute inversion of the uterus may be responsible for unexplained shock; incomplete inversion may not be diagnosed without vaginal examination. The patient is likely to show profound shock, and, in addition, there may be haemorrhage. Restorative treatment should be begun at once. Replacement of the uterus may be undertaken by O'Sullivan's method. If the placenta is still attached to the uterus it is gently peeled off; the uterine fundus is replaced by giving a hot douche under pressure, while occluding the vaginal orifice with the forearm. This simple method has proved its value in many recorded cases.

In cases of embolism little can be done except to give oxygen; intravenous therapy is best avoided owing to the risk of overloading the already embarrassed heart. In the cases of collapse due to the rarer conditions treatment must be applied according to the cause, and accurate diagnosis becomes of the utmost importance.

Conclusion

Post-partum collapse is most frequently the result of haemorrhage or shock, and these still rank high among causes of maternal mortality. Their prevention and prompt

treatment can save many lives. The contributions made by the National Blood Transfusion Service and the obstetric flying squads have done much to reduce maternal mortality to its present low level.

Next article on Emergencies in General Practice.—
"Acute Hepatic Failure," by Dr. Sheila Sherlock.

Refresher Course Book.—Copies of the second volume of collected articles from the Refresher Course for General Practitioners are still available at 25s. (postage 1s.) each. The first volume is now sold out.

Clinical Pathology Book.—"Clinical Pathology in General Practice," a collection of 39 articles on clinical pathology that appeared in the Journal as part of the Refresher Course for General Practitioners, is now available, price 21s. (postage 9d.).

Both these volumes are obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller.

JUBILEE OF SHEFFIELD UNIVERSITY

The University of Sheffield, with its 2,000 full-time students and 300 full-time staff, is engaged in a session-long celebration of its jubilee. The celebrations began last October with a visit by the Queen, were continued during the month of April in a series of "open days," when the public visited the departments, including the 13 departments of medicine, and they reach their climax on May 31 with a cathedral service and a little later with an honorary degree congregation. It was on May 31, 1905, that the royal charter was brought to the city, escorted from the station, we are told, by a procession of thirty carriages decorated with college colours.

The School of Medicine

Sheffield University grew out of three institutions, the oldest of which was the Medical School, founded in 1828. This was known earlier as the Medical Institution, but by 1868 it had become the Sheffield School of Medicine, having passed through many vicissitudes and perils, but gradually altering its character from an old school of anatomy concerned with apprentice assistants to that proper to a medical faculty. The greatest of its builders was Arthur John Hall (1866-1951), who joined the staff in 1889 and became eventually a legendary figure in the university. Another name which appears in the early records is Christopher Addison, who was professor of anatomy at Sheffield from 1897 to 1901. In the year that Addison came to Sheffield, University College (1897-1905) was founded, the Medical School joining with two institutions for arts and science and technology. The movement for higher education in Sheffield had been started by a group of great industrialists—Mark Firth, the Master Cutler, after whom the present Firth Hall is named, Henry Stephenson, and Frederick Thomas Mappin, all of whom belonged to the mid-Victorian era and established Firth College as an embryo university in which research in relation to local industries was specially developed. The Medical School came into the set-up not as a poor relation, as had been feared at one time, but as an equal partner, though it is true that, left on its own, the Medical School could hardly have developed into a university.

In 1905 King Edward VII opened the new university buildings on Western Bank, which meant for the medical departments far more satisfactory accommodation than they had had hitherto in their cramped quarters in the centre of the city. The first decade of this century saw the rise of a number of new universities. Leeds had been incorporated the previous year, Liverpool the year before that. The steel metropolis was in no way behind in the acclaim with which the creation of its university was greeted. At its

first conferment of degrees the awards, honorary and other, were so numerous as to move a local rhymester:

"Oh, why this face of woe?" I asked a wight,
With whom I talked awhile on yesternight—
Said he, "I am the only man in town
Who hasn't got a Doctor's hood and gown."

Sheffield and the B.M.A.

It was shortly after the establishment of the university that the British Medical Association held its annual meeting in Sheffield, when fifteen further honorary degrees were conferred on distinguished medical men, among them the president of the Association, Simeon Snell. There had been two previous annual meetings in Sheffield, one in 1876, when the president was Martin de Bartolomé, for many years president of the Medical School and leader of the profession in Sheffield, and the other in 1846, when the president was Dr. F. C. Favell, one of the eleven proprietors of the then Sheffield Medical Institution. Many famous names in medicine have been associated with the more recent history of the university—J. B. Leathes, professor of physiology, 1919-33; Edward Mellanby, professor of pharmacology 1920-34, whose appointment was the first to be made more for research than for teaching; and Howard Florey, professor of pathology 1931-5, who was later to make his name for his work on penicillin. In 1946 came the appointment of the first full-time professor of medicine, the present holder of the chair, Dr. C. H. Stuart-Harris.

The jubilee of the university is commemorated in a handsome and massive volume, *The Story of a Modern University*,¹ very closely documented, excellently illustrated, and altogether worthy of the occasion. It is the work of Dr. Arthur W. Chapman, the registrar of the university since 1944. It prints as a foreword a noble passage spoken by John Masefield at the inauguration of the late Earl of Harewood as Chancellor of the University nine years ago:

"In these days of broken frontiers and collapsing values, when the dams are down and the floods are making misery . . . wherever a University stands, it stands and shines; wherever it exists, the free minds of men, urged on to full and fair inquiry, may still bring wisdom into human affairs."

Reports of Societies

PSYCHOLOGICAL FACTORS IN EDUCATIONAL DISABILITY

The Section of Psychiatry of the Royal Society of Medicine discussed "Psychological Factors in Educational Disability" at its annual general meeting on May 10, with Dr. W. MAYER-GROSS, president of the Section, in the chair.

Dr. D. RUSSELL DAVIS and Dr. NORMA KENT (Cambridge) described a study of intellectual development in schoolchildren with special reference to family background. They restricted themselves to those aspects of intellectual development that are measured by conventional intelligence tests. Their aim was to see in what way the home environment affects intelligence. Do the degree and character of a child's intelligence at a given age depend on his upbringing? They agreed that intelligence is due partly, but only partly, to genetical factors.

Home Influences

Ideally, they said, the effects of environment were best studied by comparing the abilities of pairs of identical twins where one of each pair had been brought up in a different family from the other—only such twins were rare. Another way was to study the intelligence of children transferred at different ages from their natural parents to foster-parents, and to see how far the children's I.Q.s correlated with those of the natural and adoptive parents. These correlations varied in degree according to the age of the children at

¹ Oxford University Press, 50s. net.

adoption; when they were adopted at a few months old their intelligence later on was much closer to that of their foster-parents than of their natural parents. In assessing a child's upbringing, the factors most easily measured were probably not the most important. Notably in Iowa, attempts had been made to assess the "stimulation value" of the home, taking into account such things as the availability of toys, the participation of parents in play, the provision of space for play, and the quality of the talk and books in the home. Assessments made in this way correlated relatively highly with the intelligence of the children.

The rate of intellectual development was set not at birth but only gradually during the first few years of life. This was shown by the results of studies of children fostered at different ages and by studies on the "constancy" of I.Q.s. Thus correlations between tests and retests showed that I.Q.s were relatively constant during school years but were much less so at younger ages. Taking the correlation coefficients for test and retest after two years as measures of constancy, constancy was found to show a substantial increase between 2 and 6 years old. It was therefore in the children's circumstances during those years and earlier that one should look for the factors which affect the children's intelligence subsequently. Levy had shown that over-protected children were relatively good at reading and bad at arithmetic. Only children, and children first and last in order of birth, seemed to do well intellectually. Striking differences in the intelligence of the sibs in one family were common, and these might be attributed partly to difference in the ways in which the sibs had been brought up.

Discipline and Intelligence

Recent investigations in Cambridge had shown that there were consistent variations in the intelligence of school-children according to the kind of discipline adopted by the parents. At lengthy interviews with the mothers, the kind of parental training was assessed, note being taken of the frequency, consistency, and generosity of rewards, etc., so that the child's upbringing was assessed as predominantly "normal," "demanding," "over-anxious," or "unconcerned"; a demanding parent, for instance was one who set high standards, was inflexible in applying them, and gave poor rewards. One hundred and eighteen 8-year-old primary-school children had been given the Binet Scale (Form M), the W.I.S.C. "performance" subtests, and the Schonell graded word vocabulary test to measure reading age. Those who had demanding parents had a significantly higher mean I.Q. on the Binet than those from "normal" homes (124 compared with 110); their reading age was rather higher, but not significantly so. Of the 12 children with high I.Q.s (over 140) in the sample of 118, no fewer than 9 came from demanding homes. Children from "over-anxious" homes did significantly less well than the "normal" on the "performance" subtests (mean I.Q. 101 compared with 110), but did not differ significantly on the Binet Scale and reading test. Children with "unconcerned" parents showed a Binet I.Q. lower than that of the normal (97 compared with 110) and were particularly backward in reading—a pattern of test results shown by juvenile offenders. The conclusion was that the discipline in the home exerts a powerful influence on intellectual development, and that these findings have a bearing on the aetiology of mental defect.

Anxiety: Spur or Curb?

Mr. R. LYNN (Cambridge) spoke on "Emotional Factors in Reading Attainment" and concentrated on the effect of anxiety. There were two schools of thought: those like Schonell and Kanner who thought that when children were anxious for success their anxiety inhibited their efforts, and those who with Burt and Klein believed anxiety was a spur to effort and that the growth of reading skill was a form of defence against emotional upset. Mr. Lynn's survey was of 42 boys and 38 girls aged 7½ to 11 selected by their headmaster as good, poor, or average readers. Their reading age was assessed with Schonell's graded word vocabulary test,

and their tendency to anxiety by four informal interviews totalling three hours with the psychologist. At the interview they were asked informally six questions concerning personal anxieties, based on the Freudian view that the fear of loss of the mother was a source of anxiety, and six questions concerning impersonal anxieties. The questions in the first group included: "Have you ever been frightened your mother might die?", "Does scolding upset you?", "Are you easily hurt?", "Do you dislike being alone?" Those in the second group included questions about fear of thunder, of animals, of the dark, and tendency to nightmares. The results showed positive correlations between the reading age and affirmative replies to anxiety ($r = 0.33$ for personal group, $r = 0.24$ for impersonal group). The most striking individual case was a girl of 10½ with a reading age of 16½ and Binet I.Q. 146 who replied "yes" to four out of the first six questions and three out of the second six. She was discovered to come from a broken home with a timid, over-anxious mother. This supported the idea that anxiety favoured good school work, or perhaps it was that a central nervous system good at learning to read was also good at feeling anxiety.

Mr. Lynn went on to discuss anxiety as a socializing force, and to suggest that it might sometimes need redirecting rather than eliminating altogether, and this point was taken up in subsequent discussion when speakers suggested that neurotic anxiety was different from Lynn's questionnaire measure, and that the quantity of anxiety was important. A little might be good, a lot was bad. Other discussion turned on the relative value of questionnaire and interview, on the reliability of intelligence tests, on the exponential growth curve, which implied that a two-years span at three years old was not the same thing as two years at seven. Dr. DAVIS made it clear that in his results there was no correlation between parental I.Q. and the class of discipline in the home.

Constitutional Factors

Finally, Mr. GEORGE ETLINGER read a paper by himself and Mr. C. V. JACKSON (Institute of Neurology, London) on "Organic Factors in Developmental Dyslexia."

Difficulty in reading was commonly associated with certain factors which included anomalies of lateral preference, anomalies in the visual perception of apparent movement, minor E.E.G. abnormalities, anomalies of maturation of spatial and temporal perception, as well as indications of a specific genetical background. They had excluded from a group of 24 dyslexics referred to the National Hospital for Nervous Diseases at Queen Square 16 on account of the presence of frank neurological disorders or marked emotional or psychoneurotic features (which could be construed as primary to the dyslexia) or on account of insufficiently pronounced dyslexia. The remainder seemed to show marked reading disability without neurological signs and in association with better than average general intelligence. Half of these cases were, however, also retarded on visuo-constructive tests. Of special interest was the finding that only four cases were fully right-handed, and consistent unilateral hand, foot, and eye preferences were present in only one-third of this admittedly small group of cases. Moreover, some sinistral ancestry was reported in five out of the six cases in which relevant data were available, and a family history of dyslexia was established in one case. The results on the Jasper-Raney test of lateral dominance accorded with the view put forward by McFie that in many dyslexics normal dominance had not become fully established in either cerebral hemisphere. The present study, though insufficient in numbers for sure conclusions, emphasized the constitutional origin of specific dyslexia, which was best regarded as a selective failure of learning, directly due to defective maturation of those cerebral mechanisms underlying language and its development.

In the subsequent discussion it was suggested that many if not all of the cases of specific reading disability that were not secondary to mental defect could be regarded in this

light (according to Dr. MAYER-GROSS 24% of Army recruits are backward in reading). Nor did such cases show any speech disorder or motor clumsiness, even of a minor kind. The speakers had no suggestion for their treatment.

Nova et Vetera

DAVID BRUCE (1855-1931)

Sir David Bruce, who was born in Melbourne of Scottish parents on May 29, 1855, received his medical education at Edinburgh. After qualification in 1881 and two years in general practice he joined the Army Medical Service. While on duty in Malta he investigated many cases of the obscure continued fever then prevalent on the island, and in 1886 he isolated from the spleen in fatal cases an organism, *Micrococcus melitensis*, which he proved was the cause of Malta fever.¹ It was later renamed *Brucella melitensis*.

Bruce left Malta in 1888, and after a teaching appointment at Netley he was posted to South Africa in 1894. Here his attention was directed to nagana, a disease causing many fatalities among horses and cattle. Within two months he was able to report² the discovery of an organism (later named *Trypanosoma brucei*) in the blood of infected animals. During the next two years Bruce and his wife elucidated the main facts as they are now known about trypanosomiasis and its transmitter, the tsetse fly. The Bruces were among those besieged in Ladysmith during the South African war, and served respectively as operating surgeon and theatre sister.

It was J. Everett Dutton³ who in 1901 first recognized trypanosomes (*T. gambiense*) in the blood of humans suffering from sleeping sickness. In 1903 Bruce went to Uganda to supervise and control the Royal Society's Sleeping Sickness Commission. With D. N. Nabarro he showed that the tsetse fly was the vector.⁴ Castellani, a member of the commission, had found trypanosomes in the cerebrospinal fluid in five cases of sleeping sickness a year previously⁵ and had informed Bruce of the fact. Trypanosomiasis due to *T. brucei* did not affect man, but Bruce recognized the implications of Castellani's findings. He set up fly-feeding experiments, and by August, 1903, he had proved that sleeping sickness was caused by a trypanosome, that the vector was the tsetse fly, and that the disease could be transmitted by the bite of this insect.

Later work by Bruce included the demonstration of the source of infection of Malta fever in goat's milk, and research on the aetiology and control of trench fever and tetanus. He was knighted in 1908. A bibliography of his publications, together with appreciations of the man and his work, appears in the current *Journal of the R.A.M.C.* (April, 1955).

Bruce married in 1883 Mary Steele, a daughter of a general practitioner, and she assisted him in all his scientific work, both at home and abroad. He died in London on November 27, 1931, four days after Lady Bruce.

Sir Rickard Christophers has concluded a biography⁶ of Bruce with the following discerning sketch of his character: "Bruce was a man of strong physique and forceful mind. . . . His approach to the problems which he undertook to solve was extraordinarily simple, logical, vigorous, and direct, and this was backed by a remarkable, seemingly intuitive, perception of the essential point for attack. In his personal relations, whilst he is said to have been somewhat reserved and self-contained, all agree as to his loyalty and integrity of mind and purpose."

BRITISH ASSOCIATION OF PHYSICAL
MEDICINE

ANNUAL MEETING IN LONDON

The annual meeting of the British Association of Physical Medicine was held at St. Thomas's Hospital, London, on April 22 and 23.

The first subject discussed was "The Use of Hydrocortisone by Local Injection," and Dr. J. H. CYRIAX drew attention to the great importance of accurate anatomical localization of soft-tissue lesions for the effective use of hydrocortisone. Dr. P. HUME KENDALL described results obtained at Guy's Hospital. In selected cases of rheumatoid arthritis it had been confirmed that the chief value of the hormone appeared to have been the production of a remission sufficient to permit the commencement of more active physiotherapy than would previously have been possible. In osteoarthritis hydrocortisone had been of use only in the early case or where symptoms had been aggravated by recent injury. In acute rotator cuff lesions of the shoulder results had been good, but the effect on the "frozen shoulder" was usually disappointing. Various soft-tissue lesions such as tennis and golfer's elbow, plantar fasciitis, de Quervain's syndrome, and tenosynovitis had responded well. In acute traumatic articular effusions uncomplicated by serious bone or ligamentous injury the results were often dramatic, even in the presence of haemarthrosis, where hyaluronidase was combined with hydrocortisone after aspiration.

The Department of Physical Medicine

Opening a discussion on "The Department of Physical Medicine," Dr. W. S. TEGNER reviewed the evolution of the modern physical medicine department of a large hospital. Physical medicine had been and was still undergoing changes, and that necessitated fluidity in the make-up and organization of departments. Space and ease of access were important, and many architects still thought in terms of a rigid design incapable of adaptation. As regards staff, doctors, physiotherapists, technicians, and often nurses worked together, and there might be difficulties in integrating their various activities to secure efficiency. This also raised the question of the relationship of the physiotherapy school with the physical medicine department, and Dr. Tegner deplored attempts to use students as a form of cheap labour, particularly where this practice had prompted the opening of a school of physiotherapy. Beds and doctors in adequate numbers were required by physical medicine departments, since attendances and waiting-lists continued to grow all over the country.

Dr. W. A. FELL drew attention to the problems peculiar to physical medicine departments outside London and the bigger provincial centres, since over 25% of the patients might come from many miles away and have to spend a whole day away from home or work for the purpose of receiving one treatment. Some of those with even minor complaints found it impossible to travel the mile or so from home to the nearest point at which public transport was available. The only alternative in these cases was to use expensive hospital transport. At present it was necessary to treat patients in the central department, because only there could be found the requisite medical and technical staff and equipment. There was thus an overwhelming case for the provision of properly constituted peripheral clinics.

Disadvantages of the "Closed" Department

Dr. A. T. RICHARDSON said that the maintenance of closed physical medicine departments was indefensible for any reason, since it wasted the time of patients, doctors throughout the hospital, and physiotherapists, and prevented the general practitioner from having direct access to the physical medicine specialist. It might be argued that the closed system permitted a filtering of patients referred to physical medicine specialists, but surely they were the very people best fitted to reject cases for which there were no indications for treatment in the department. A great deal of time could be saved by a sound system of decentraliza-

tion whereby a patient could go to the department with a written prescription—e.g., from the dermatologist for ultra-violet-light therapy, from the chest department for breathing exercises, or from the orthopaedic surgeon for post-operative exercises. To achieve real efficiency, however, the physical medicine specialist and the physiotherapy services must be used intelligently, and this in turn depended on the better training of students in this field of medicine.

Dr. Richardson included within the scope of physical medicine the diagnosis and treatment of the medical disorders of the locomotor system, the treatment of these and other disorders by physiotherapy, and medical rehabilitation. It was now considered that the M.R.C.P. or its equivalent was essential for the attainment of consultant status in physical medicine, in addition to considerable experience in the specialty and the possession of the Diploma in Physical Medicine. There were now a sufficient number of fully qualified registrars to ensure that future appointments to consultant grade would fulfil these criteria.

Dr. F. S. COCKSEY expressed his concern at the shortage of physiotherapists. Unless a lowering of the standards of training for physiotherapists was to be accepted (a suggestion firmly rejected by many later speakers) there would have to be a continual economy in the prescription of treatment. He made a plea for a firm integration of the medicine practised in the physical medicine department with other hospital services and in close association with the local authority services and general practitioners.

In the ensuing discussion a number of speakers mentioned the apparent ignorance of many members of the medical profession and of lay committees of the proper function of the qualified physical medicine specialist and his department.

Correspondence

Diversities of Sex

SIR,—Dr. C. N. ARMSTRONG (*Journal*, May 14, p. 1173) has made a most graceful contribution to an important and difficult subject. He has given a simple practical classification of the diversities of sex, which in the past have been enshrouded in ambiguity. Few previous classifications have helped to simplify; most, owing to their complexity, have increased confusion.

I agree that there is no precise definition in law or medicine of what really constitutes male or female sex. Social laws demand it, but law and medicine, being exact and enlightened sciences, recognize the fact that there is often no clear-cut definition between the male and female. Sex perhaps, like most other things, is merely a question of relativity. Dr. Armstrong wisely emphasizes the difference between the genetic and the gonadal sex of the individual. Fortunately, in most people these correspond and there is no problem, but serious difficulties may arise when there is divergence between the genetic and gonadal sex and if there is added to this an imbalance of hormones. The subject then becomes extremely complex and a clear-cut definition of the sex is impossible. I believe, also, that the process of sexing by chromosomes is at present inexact and unreliable. This may be due to human errors and lack of experience in a new field. At present, I have under my care a patient whom I believe to be what Dr. Armstrong would describe as "a female pseudohermaphrodite." One authority on chromosomes called her a girl and another a boy. She is a girl, and has always been brought up as one, and will, I hope, always remain one.

It is of very great practical importance to make the right sex diagnosis in small babies soon after they are born, if possible, because they will soon have to be christened and a correct diagnosis will make life easier and more happy for them. However, if a patient of doubtful sex comes for treatment and advice in adult life, it is usually unwise to change the sex in which they have been reared and in which they usually wish to remain. I thoroughly

agree, however, that if the sex is obvious and the patient wishes to "change," being a transvestist and psychologically bizarre, it is most improper to accede to this. Moreover, the gonads should not be removed from any patient of doubtful sex in order to satisfy the patient, the surgeon, or the barrister. It may cause irreparable misery, and I expect Dr. Armstrong recognized this mistake in his Case 1, although he does not mention it. Everyone interested in this subject will remember Harold Chapple's¹ classical description of the really beautiful girl, with ardent amorous instincts and activities, who lost all her womanly beauty and charm, and then her happiness, when, against his sound advice, her testes were removed.—I am, etc.,

Leeds, 1.

MICHAEL C. OLDFIELD.

"Half-minute" Thermometers

SIR,—In your issue of May 7 (p. 1158) Dr. Peter Gilbert drew attention to the unreliability of the conventional "half-minute" indication on clinical thermometers, and he asked whether it would not be possible for every thermometer to be supplied with a "certificate of time" as well as of accuracy.

Apart from the fact that the provision of such an additional certificate would involve extra cost for the manufacturer, it still would not overcome the difficulty that the time required for a particular thermometer to indicate the true temperature of a patient depends on a variety of factors outside the manufacturer's control. We are advised by medical authorities that the most important of these are: the initial temperature of the thermometer, the manner in which it is placed (and retained) in position, and the physical condition of the patient. Even to indicate a minimum time, such as three or five minutes, might well be misleading in some circumstances of use. It is expressly for these reasons that a time indication is not given on a British Standard clinical thermometer. Thermometers made in accordance with the provisions of British Standard 691 (which was revised last year) are classified as "quick," "medium," or "stubby," and each must be accompanied by an explanatory note drawing attention to the considerations mentioned above.

Although British Standard clinical thermometers are coming into increasingly wide use by the medical profession and hospital authorities, it is known that the advantages they provide for a very slight additional cost are still not appreciated by many people, and for that reason this Institution is shortly undertaking an information campaign to encourage the wider use of British Standard thermometers. The interest and help in this direction of professional people would be as welcome as it would obviously be valuable.—I am, etc.,

London, W.1.

Technical Director,
British Standards Institution.

Niddah and Sterility

SIR,—Sir Ernest Kennaway (*Journal*, May 7, p. 1107) suggests that there is some doubt as to how often the law of Niddah (post-menstrual abstinence from coitus) is observed to-day among Jewish patients. I would suggest that it is far more frequently observed than many people imagine and that in this infertility clinic it is a most important cause of sterility.

Where a woman has a short menstrual cycle, for example 23 days, she will ovulate about the ninth day. If, as often happens, she menstruates for eight days and then observes seven days' abstinence, the first coitus will not be until the 15th day—that is, when the ovum is presumably dead. Every year I meet with a number of cases of this type, which quite often have been subjected to considerable useless treatment for what is a very simple condition, once the knowledge of Niddah is kept in mind. The administration of oestrogen or sometimes testosterone at the onset of the period will postpone ovulation and enable such patients to have intercourse when the ovum is still alive. The fact

that Niddah is such an important factor in my clinic suggests that it is observed by many other orthodox Jewish patients, and therefore may well be an important factor in cervical cancer, as Sir Ernest suggests. Certainly all those dealing with orthodox Jewish patients who are infertile should inquire about its observance.—I am, etc.,

Manchester, 8.

BERNARD SANDLER.

Professional Secrecy

SIR,—My attention has been drawn to a communication, H.M.(55)46, from the Ministry of Health, dated May 10, 1955, addressed to regional hospital boards and hospital management committees concerning "Carnal Knowledge of Mental Defectives" (see *Journal*, page 1350). This memorandum describes the new procedure to be adopted when a certified mental defective is found to be pregnant, or there is reason to think that sexual intercourse has taken place. A previous memorandum on this subject advised that a report should be submitted to the Board of Control but that the local police should not be informed. The new memorandum repeats the advice of reporting the facts to the Board of Control, but reverses the advice on communication with the police. It states that "the Ministry is of opinion that it is desirable that in future such cases should be reported to the police not necessarily with a view to prosecution but to enable the police, in consultation with the medical superintendent, to decide what is the best course to take in all the circumstances." It concludes that medical superintendents should send reports to the local chief constable even where the offence has been committed in another police area.

The current policy of the Association concerning professional secrecy is expressed in the following terms: "It is a practitioner's obligation to observe strictly the rule of professional secrecy by refraining from disclosing voluntarily without the consent of the patient (save with statutory sanction) to any third party information which he has learnt in his professional relationship with the patient."

Unfortunately the advice now tendered by the Ministry of Health has apparently been prepared and issued without any prior consultation with the British Medical Association or any of the defence bodies who are materially interested in this matter for the protection of their members. Furthermore, reasons have not been advanced to justify the change of advice and the abrogation of the rule of professional secrecy in the case of mental defectives.

There may well be occasions when it would be fitting and proper for the police to intervene by the institution of legal proceedings against a suspected offender, and there may also be sound reasons in law for issuing the advice described above. The writer feels, however, that, before a change of this order is sponsored by official Governmental departments relating to an important ethical tenet, the least that the Association could expect would be a communication from the parties who propose an alteration, setting out their reasons and any legal sanction that might be invoked for their support. I hope that opportunity will be afforded in the near future for representatives of the Association and of the Ministry to meet to discuss the situation created by the issue of the memorandum.—I am, etc.,

London, W.C.1.

ROBERT FORBES,
Chairman, Central Ethical Committee

Reserpine in Treatment of Chronic Psychotics

SIR,—I was interested to read the paper by Dr. E. S. Foote entitled "Reserpine in Treatment of Chronic Psychotics" (*Journal*, May 14, p. 1192). Chronic psychotics have been under treatment here on similar doses of reserpine for the past five months, but preliminary results in a controlled series have been rather disappointing so far. The practice has been to leave the patients' routine unaltered, apart, of course, from the administration of the tablets and the daily blood-pressure readings, and this may possibly be a reason why our results have been less promising than Dr. Foote's.

With regard to side effects, I think it is worth reporting at this stage the case of a female patient who complained of feeling "faint and dizzy" on two occasions when climbing the ward stairs during the first three days of treatment

with reserpine (1½ mg. three times a day). She stated that she had never felt like it before, and, in spite of continuing with the same dose, has had no similar symptoms since. Her daily blood-pressure readings showed no significant alteration from her pre-treatment readings, but one cannot help feeling that these two incidents were the result of a temporary fairly profound fall in blood pressure associated with moderately large initial doses of reserpine. I therefore agree with Dr. Foote that the initial dose should not be more than 0.5 mg. three times a day, and this dose is now given here as a routine for the first four days of treatment. I was interested to read of Dr. Foote's report of oedema occurring in patients with no apparent organic cause, as I have also had one similar case and wondered if it might be the result of reserpine therapy.—I am, etc.,

Epsom.

D. L. M. McNEILL.

Agricultural Pesticides

SIR,—May I be permitted space to comment upon the remarks made by Mr. A. F. McK. Jackson (*Journal*, May 7, p. 1157) relating to aldrin and dieldrin? Shell Chemicals Limited has not issued any literature containing a statement to the effect that dieldrin has eight times the oral toxicity of D.D.T. to mammals, nor, to the best of my knowledge, is there any other authority to that effect. What they have said, however, is that these compounds have an insecticidal efficiency of some eight times that of D.D.T. against many insect species. Aldrin and dieldrin, in common with all other chlorinated hydrocarbon insecticides, can be absorbed through the intact skin, but there is no question of such absorption taking place through the soles of normal footwear in ordinary everyday use, as is suggested by your correspondent. No special measures, other than those recommended for handling insecticidal chemicals such as D.D.T., are required for the processing, mixing, or application of aldrin- and dieldrin-based products.

Since their introduction over five years ago no serious cases of intoxication by aldrin or dieldrin have occurred during manufacture, formulation, or application of tens of millions of pounds of the technical materials, despite the fact that in a number of cases normal precautions were flagrantly disregarded. This record is particularly notable in view of the fact that large quantities of these insecticides have been handled by totally unskilled labour in many of the under-developed areas of the world. In a few instances there have been suicide attempts using aldrin and dieldrin, but in spite of the fact that gross overdoses—in one case amounting to 25.6 mg. of aldrin per kg. of body weight—were taken orally, no case proved fatal and the patients recovered without sequelae.

The last thing I wish to suggest is that materials of this nature can be handled without taking due and proper precautions, but, provided such precautions are taken, I see no reason, on the evidence available, to be alarmist in regard to the handling of these two compounds. It may be of interest that in Venezuela, for example, over 300,000 human dwellings have already been sprayed with dieldrin for the control of the vectors of South American sleeping-sickness and malaria. This programme with dieldrin is continuing under the direction of the Malaria Division of the Ministry of Health and Social Welfare.—I am, etc.,

London, E.C.3

RUPERT SCOTT,
Chief Medical Officer,
The Shell Petroleum Company Ltd.

Idiopathic Pulmonary Haemosiderosis

SIR,—I was interested to read the article by Captain N. A. J. Hamer (*Journal*, April 23, p. 1008) particularly because another example of this condition has recently come to my notice.

A man, now aged 28, had a perforated duodenal ulcer closed at an emergency operation in 1952, and subsequently he has never had more than minimal dyspeptic symptoms; in particular he denies a haematemesis or melaena at any time. In October, 1953, he had pneumonia in Hong Kong and was away from work for five weeks; no details of this illness are available, although it is

known that a chest film in January, 1954, was reported clear, but subsequently he noticed occasional blood in his sputum which he ignored because he felt in normal health. He was admitted to hospital on April 2, 1955, complaining of lassitude and a cough of three weeks' duration, which was productive of small amounts of blood-stained sputum. There had been no frank haemoptyses, but occasionally the sputum contained clots of blood: his appetite had been poor for several days, but his weight was steady.

On Examination.—A well-covered but remarkably pale man. T. 97.8° F. (36.55° C.); P. 118, regular; B.P. 150/70; heart normal. Abdomen: healed epigastric scar; no mass felt and no tenderness elicited. Chest: signs suggesting early consolidation at the left base.

R.B.C., 1.8 million per c.mm.; Hb, 36% (5.32 g.); colour index, 1.00; W.B.C., 11,900 (polymorphs 82%, lymphocytes 14%, monocytes 3%, basophils 1%, reticulocytes 4.2%); packed cell volume 15%. Blood group O; rhesus anti-D positive. Stool negative for occult blood (benzidine test). Direct van den Bergh negative. Serum bilirubin 0.7 mg.%.

A chest film on the day of admission revealed no definite abnormality, but a diagnosis of idiopathic pulmonary haemosiderosis was considered possible, and arrangements made for daily x-rays of the chest. On April 3 (the day following admission) there were multiple small, soft, round opacities scattered throughout both upper and middle lobes, with accentuation of the hilar shadows, but on April 4 the shadows were both smaller and harder in appearance, and on April 5 they had disappeared. On April 6 the medial parts of the left upper and middle zones and the right middle zone were granular in appearance; these appearances were unchanged on April 7, but they had become less marked on April 8, and the chest was radiologically normal on April 16.

Within 24 hours of admission the patient was running a temperature of 101° F. (38.3° C.), and in view of the persistent signs at the left base he was given a course of parenteral penicillin: moreover, his general condition was sufficiently poor for him to be given two pints (1.1 litres) of cross-matched blood on April 3. Following the transfusion his condition improved rapidly, and on April 6 a blood count showed: R.B.C. 3.02 million per c.mm., Hb, 52% (7.69 g.), reticulocytes 5.4%, M.C.H. 25.5 micromicrograms, M.C.H.C. 29.5%, M.C.V. 86 cubic microns. He was given tab. ferri. sulph. co., and on April 19 there were 3.69 million R.B.C. per c.mm., with Hb 73% (10.79 g.), and colour index 0.98. While in hospital he has continued to have small haemoptyses, but repeated examinations have failed to reveal tubercle bacilli or haemosiderin-containing macrophages in the sputum; neither have these cells been found in the gastric residue. There was no increase in the red cell fragility, and the platelets appeared normal in the blood examined.

This patient's illness is characteristic of the acute phase of early idiopathic pulmonary haemosiderosis, with the small haemoptyses, profound anaemia, and transient shadows in the chest films. It is not clear why haemosiderin-laden macrophages were not found in the sputum or gastric residue, but such a finding is not reported in every case in the literature. The course of the illness resembles that of a man aged 20 where the radiological opacities cleared rapidly after the first episode of haemoptyses with anaemia, but following a further attack there was "fixed" shadowing at the right base, the time interval between the first illness and the latter finding being practically three years. So far as the prognosis is concerned I would disagree with Captain Hamer's statement that the outlook is generally good in young adults when compared with children, in view of Walton and Williams's report² on the post-mortem findings in a youth of 19 with three years' symptoms.

I wish to thank both the medical officer-in-charge, R.N. Hospital, Plymouth, for access to the records and the Medical Director General of the Navy for permission to publish this letter. Surgeon-Commander P. H. K. Gray interpreted the chest films.—I am, etc.,

London.

A New Barbiturate Antagonist

SIR,—We have recently treated four cases of barbiturate poisoning with the new barbiturate antagonist β methyl β ethyl glutarimide (N.P.13, "megimide"). The patients had taken between 36 and 90 gr. (2.4 and 6 g.) of barbiturate

several hours before admission. They did not respond to pain and all reflexes were absent on admission. Routine stomach washout was performed. With the first three patients, who had all taken approximately 36 gr. (2.4 g.) of barbiturate, 100 mg., 200 mg., and 250 mg. of N.P.13 respectively were given intravenously over the course of about one hour. At the end of this time the patients were groaning, making spontaneous movements of the limbs, and would respond to simple commands. After this they were easily rousable and their further course was uneventful. The fourth patient, a lady of 41 years, had taken 90 gr. (6 g.) of a barbiturate mixture, "tuinal," three hours before admission. A glucose drip was set up and 100 mg. of N.P.13 given into the drip every five minutes to a total of 600 mg. After ten minutes the corneal reflexes returned, and half an hour after the beginning of treatment the patient was talking and attempting to raise herself from the bed. Subsequently she was easily rousable, and two hours later was awake and would take food. Further progress was uneventful.

In these cases there was a significant rise in the level of consciousness during treatment with N.P.13, and in each case the improvement was maintained. In the first three cases only small quantities of the drug were available for treatment, and it is suggested that, as in the fourth case, larger amounts of N.P.13 should be used. No toxic or side-effects were noted with the amount of drug used. It is felt that N.P.13 offers considerable advantages over existing methods of treatment of barbiturate poisoning and merits further trial. We would like to thank Professor R. E. Tunbridge, Professor S. J. Hartfall, and Dr. O. H. J. Maxwell Telling, under whose care these patients were treated, and Nicholas Products Laboratories, Ltd., for supplies of N.P.13.—We are, etc.,

J. P. BINGLE.

J. G. WHITWAM.

Leeds, 1.

Chronic Appendicitis

SIR,—I was most interested to read the article "Right Iliac Fossa Pain" (*Journal*, March 26, p. 752) and your leading article on "Chronic Appendicitis" (p. 776).

In 1953 in Capetown I investigated 200 consecutive cases of appendicitis, of which 93 were designated, clinically, chronic appendicitis.¹ These latter cases were admitted only after all investigations for other possible causes of their right iliac fossa pain had proved negative. The histological investigation, consisting of examination of serial sections, was undertaken by the pathology department of the University of Capetown. In this "chronic appendix" group only 19.4% (18 cases) showed appendicular histological abnormalities; 12.9% (12 cases) presented other intra-abdominal pathology. In the remaining 67.7% (63 cases) no pathological evidence could be found to account for the patients' pain. A follow-up questionnaire was sent to these 63 cases, but the response was too poor to allow of critical analysis.

These findings bear out the contention that the clinical and pathological correlation of chronic appendicitis is still far from satisfactory.—I am, etc.,

London, W.12.

Aftermath of Hysterectomy

SIR,—I was writing of the new biochemical pathology of atherosclerosis and "the coronary woman"; Miss Louisa Martindale (*Journal*, May 7, p. 1155) is raking in the old sweet garden of memory and surmise. I would challenge any private or public clinic to produce even a ten-year attested follow-up in regard to blood pressures and the physical *cum* psychosomatic symptoms of patients treated by ovarian ablation, radium, or deep x-ray therapy for non-malignant conditions of the pelvis. Indeed, I would fling the gauntlet further and ask why it is that women

suffer from acute lumbago (not disk disease) ten times less frequently than men do. It cannot be clothes or lack of exposure. Can it be an oestrogen *cum* adrenal protective mechanism? Tentative therapy of the male sufferer suggests that this is so.—I am, etc.,

London, W.1.

V. B. GREEN-ARMYTAGE.

Undergraduate Education in Preventive Health

SIR,—At the recent Royal Sanitary Institute Congress at Bournemouth (*Journal*, May 7, p. 1147) Professor R. H. Parry called attention to the need for closer integration of undergraduate medical training with the public health department. He also stated his belief that in time the general practitioner would be able to take over medical responsibilities at the health clinics. With this latter suggestion I am in full accord; but I submit that it cannot satisfactorily take place until Professor Parry's first proposal has been implemented and there has been a reorientation of undergraduate paediatric training. The work of the "baby" clinic is essentially preventive in outlook and deals with healthy babies. Undergraduate paediatric training, on the other hand, despite improvement in recent years, is largely concerned with disease. Anatomy and, what is more important, physiology, as taught to the medical student, are that of the adult. A course in paediatrics should begin with the study, largely on a practical basis, of the development of the child in its first two years and with the management of the healthy child in those years. Only when this has been achieved should the student go on to the study of departure from the normal. Here lies the way to that closer integration for which Professor Parry has asked.

It is useless to ask for earlier diagnosis of such conditions as cerebral palsy and congenital deafness when the newly qualified doctor is unacquainted with the normal development of locomotion and speech of the infant. Miss E. Whetnall (*Journal*, January 22, p. 227) has suggested the post-natal clinic as the ideal place for increasing the mother's awareness of the possibility and implications of partial deafness. All too often, however, the mother has to badger the doctor into such an awareness.

The syllabus and examination for the Diploma in Child Health lay much stress on the work of the school health service. The school medical officer should deliver a short series of undergraduate lectures and demonstrations on the handicaps of childhood and the application to them of the Education Act, 1944. The general practitioner may never see an example of the lipoidoses (I have not seen one in 11 years of clinical medicine). What he will have to deal with are the rheumatic child and the asthmatic child, not in isolation, but in relation to the world in which the child lives. These suggestions are, I submit, concrete examples of the application of such terms as preventive and social medicine to paediatrics.—I am, etc.,

London, N.12.

A. YARROW.

The Changing Face of Medicine

SIR,—Dr. Clifford Kennedy's article on "The Changing Face of Medicine" (*Journal*, April 30, p. 1045) was full of interest. I only want to refer to his courageous suggestion that merit awards for consultants should be done away with, and the money spent otherwise. I would suggest that the money be spent on a large increase in domiciliary consultations. Consultants and specialists are not synonymous terms, but specialists should be consultants. In the good old days a consultant was a wise doctor whom his colleagues liked to consult. The meritorious consultant got his reward in an increasing number of consultation fees. The same could easily be possible again if the administration permitted.

There would be many advantages. The waiting-lists for first visits to out-patients (though not necessarily for investigations) would be reduced. The consultant and specialist would be brought outside the hospital's four walls. The general practitioner would be brought into much closer contact with the leaders of the profession. It should be

remembered that every consultation provides the occasion for a miniature postgraduate course—which the hospital letter does not. If done on a large scale it would be necessary also to provide a small fee for the general practitioner, who has to find an hour of unpaid time at present. I would like to put this idea forward as a subject for discussion by the College of General Practitioners, and the Consultants and Specialists Committee.—I am, etc.,

Crowthorne, Berks.

H. D. FORBES FRASER.

SIR.—This is not an attempt to discredit the National Health Service. On the contrary I would like to concede that the N.H.S. has proved a boon and a blessing to the public; but it would be too optimistic to expect that such a revolutionary measure would not reveal in practice imperfections and even faults. With good will and determination these could all be smoothed out.

From the young doctor's point of view the most pressing problem is the finding of suitable employment. Under present conditions unemployment is likely to increase as time goes on, unless a remedy is found. Paradoxically, the position is largely due to the fact that junior hospital posts have been greatly multiplied since the advent of the N.H.S. This has encouraged greater numbers of students to take up medicine than is necessary for the smooth maintenance of the service. After the completion of a year's hospital service there are not sufficient posts available to absorb all the young doctors looking for suitable and remunerative employment. The number of well-qualified registrars appears to be in excess of the number required to fill vacancies for specialists or consultants, and general practice is apparently not able to absorb all the young aspirants to general practice. We have on the one hand, therefore, the apprehensive or disappointed registrar, and on the other the young graduate with inadequate experience for general practice swelling the ranks of the unemployed. The remedy can, I believe, be found in a realistic redistribution of hospital beds, and reduction of the lists in the larger practices. The specialized hospitals are too big, and the G.P. hospitals too small and too few. General practice could also absorb more general practitioners, as there are still too many large practices employing assistants, where more principals are needed. The employment of an assistant in a large practice may be good business, but I refuse to believe that it is conducive to good medicine. Extension of the G.P. hospital to, say, 100 to 200 beds, where these could be fully utilized, would absorb many young graduates and afford the right kind of postgraduate training for the aspirant to general practice, and would save the more specialized hospital from being cluttered up with patients requiring no specialized investigation or treatment. The patient would also gain by remaining, while in hospital, under the care of the home doctor. The G.P.'s status would be enhanced. He would be able to take a practical share in the main divisions of medical work, medicine, surgery, anaesthetics, and midwifery, while co-operating with the consultant or specialist where necessary. With ready access to the regional laboratory he could conduct most of his own investigations.

I consider I have been very fortunate in always having been on the staff of local hospitals, general and maternity, and child welfare clinics. With the facilities provided by the regional laboratories I do the major part of the medical investigations of my practice, have conducted something like 4,000 maternity cases with only two maternal deaths, have given thousands of general anaesthetics, including spinal, and from time to time have been doing straightforward surgery without a single mishap. I have therefore been fortunate enough to be able to avoid becoming a sign-board. While not earning the remuneration of the doctor with the big list, I have experienced a full and satisfactory professional life.

Under present conditions the G.P. has not the facilities to give the best of which he is capable. The specialist's time to a considerable extent is wasted with cases which

could be looked after by the family doctor. Under the conditions I have visualized there would be a better all-round use of medical personnel and of hospital beds, and I believe a reduction in hospital expenditure, while the training provided for the young aspirant, whether for G.P. or specialist post, would be more in keeping with his or her respective needs and requirements.—I am, etc.,

Fraserburgh.

J. MACLEOD.

Opportunities for Medical Practice

SIR.—Sir Stanley Davidson's article (*Journal*, May 14, p. 1171) makes clear the urgent need for a change in the official attitude to medical education and to medical practice. It is obvious that medical practice, in the sense that this is now understood, cannot continue to absorb the numbers of practitioners now becoming qualified. From now on, either the number of doctors must be kept constant, or the remuneration *per capita* must fall, or the State health services must pay out more and more. Is there, in fact, any over-doctoring in the absolute sense? A more liberal supply of doctors, if this implies increased medical care and the disappearance of the "overworked practitioner," might be a very good thing indeed. And surely medical practice is but one aspect of the aim of medical education. The modern world needs medical men in many fields—in commerce, law, scientific research, and even politics. My guess is that demand for medical graduates in these fields will increase steadily. The men working outside medical practice are not a loss to the profession. They are vital to it, fully utilizing a general medical education, and continuing throughout their careers to maintain contact with practising doctors.

It would be dangerous in the extreme to tamper with the autonomy of universities in the admission of students for medical training, on the basis of the alleged over-doctoring of the population. A plea may be made, however, for cutting out some of the detail in the present medical course, which is designed to suit the traditional needs of general practitioners, some of which needs hardly exist any longer. General practice has rapidly become a specialty where, in the future, standards should be established and guarded by the College of General Practitioners. The undergraduates' course could therefore be redesigned with an eye to producing a new type of medical graduate much better fitted to choose between practice and the ancillary branches of medicine. The course could be shortened from the present six years to five years, or even less, and made more intensive in its purely scientific and clinical aspects. Undergraduate "specials," which are cram courses designed to suit the needs of a general practitioner of 30 or more years ago, could be covered more generally in medical or surgical teaching. The present state of affairs is uneconomic and threatens to become more so. If things continue as they are a medical man will have spent one-half his life as a liability on his parents or on the State, only to find that in the second half he is barely able to meet his economic responsibilities.—I am, etc.,

Stourbridge.

O. C. FORBES.

Cancer of the Upper Alimentary Tract

SIR.—Dr. L. D. Sanghvi and his colleagues (*Journal*, May 7, p. 1111) point out that intra-oral carcinoma accounts for 35.9% of all cancer cases in Bombay, whereas only 6.7% of cancers treated in London hospitals were situated in the oropharynx. These striking figures indicate that interest must presumably focus on some outstanding difference between the habits of Indians and Europeans.

Smoking and chewing tobacco (the practices investigated in the article by Dr. Sanghvi *et al.*) have, after all, got their western equivalents. No European, however, constantly subjects his oral cavity to the intense (but delicious) irritation of a curry, while most Indians do so twice daily. As one who has experienced the prolonged intra-oral burning which invariably follows an Indian curry, I am surprised to find that

the writers did not ask their patients for data concerning the spices in their diet. Surely this factor cannot be omitted when investigating the aetiology of carcinomas of the mouth and pharynx in Indians.—I am, etc.,

London, E.1.

F. E. LOEFFLER.

Giant Cells in Measles

SIR.—I read with interest the annotation on "Giant Cells in Measles" (*Journal*, April 30, p. 1078). Three years ago I performed a necropsy on a child dying of measles who had been treated with antibiotics and showed apparently pure measles pneumonia. I do not remember seeing giant cells within the bronchi, but these were very frequent within the alveoli and showed degenerative appearances. They appeared to be formed by desquamation and fusion of alveolar epithelium. Small rounded acidophil intracytoplasmic inclusion bodies were very frequent within them and also within single epithelial cells. No giant cells could be found in the pulmonary lymph nodes, however. It would certainly seem very reasonable that these cells, quite possibly containing inclusions, should be found in the sputum.—I am, etc.,

Southampton.

R. A. GOODBODY.

Chicken-pox Quarantine

SIR.—Dr. J. J. Linehan's scepticism as to the protective value of chicken-pox against zoster (*Journal*, May 7, p. 1156) will no doubt endure until it is possible to grow the relevant virus and then submit suitable volunteers to challenge with it. Otherwise the available evidence must be based on histories that are rarely verifiable and on one's own personal experience. On this point, for some years past I have made it a practice to question—and examine—all cases of zoster for evidence of previous chicken-pox. So far I cannot recall one that convinced me. This may of course be no more than coincidence, though I wonder. In any event, Dr. Linehan will, I am sure, agree with me that to rely on histories in infectious work is to court, and not infrequently to experience, disaster.

Common ground at present is that the one disease may give rise to the other, and that, so far as virology can ascertain to-day, the two viruses appear to be identical. The hypothesis that "herpes zoster is a response of an immune person to an overwhelming dose of varicella-zoster virus" is surely dismissed by those cases of zoster (I have seen two recently) who proceed to develop a generalized chicken-pox eruption. Here it seems that a hitherto localized infection suddenly spills over into the blood. Incidentally, I have never known the converse to occur. It might be argued with more cogency that a localized infection like zoster will not give rise to such a stable immunity as when the virus has challenged the whole body as in chicken-pox. Perhaps I may here be allowed to cite a personal experience. Having enjoyed a mild attack of shingles at school, I have subsequently been exposed to chicken-pox on literally thousands of occasions, but I have never developed the disease. Clearly, in some cases at least, zoster can protect against chicken-pox as well.—I am, etc.,

Isleworth.

G. E. BREEN.

Salk Vaccine

SIR.—Dr. J. G. Humble (*Journal*, May 7, p. 1154) asks if rhesus sensitization is a possibility after inoculation with anti-poliomyelitis vaccine. At the suggestion of Professor Stuart Harris, samples of the vaccine prepared in this country have been studied at this centre. A number of *in vitro* inhibition tests against rhesus anti-sera (anti-D, anti-C, anti-E, and anti-c) have been carried out, but so far I have not found that the material contains any substance capable of inhibiting either immune rhesus antibodies or the normal isoagglutinins. As yet there has been no opportunity of estimating whether the vaccine is more powerful *in vivo*.—I am, etc.,

Sheffield, 10.

J. S. CAMPBELL.

Ban on Heroin

SIR.—Mr. D. K. Mulvany's letter on the subject of the ban on heroin (*Journal*, May 14, p. 1221) contains the extraordinary suggestion that a consultant should have to add his signature to the general practitioner's prescription so that "the procurement of heroin could be tightened up." Apart from the difficulty of obtaining his signature for each prescription in the case of a patient dying at home, has Mr. Mulvany considered the implications of his suggestion? One of these appears to be that general practitioners' lax prescribing of heroin is a source of danger. The other is that consultants are more responsible than general practitioners in prescribing dangerous drugs.—I am, etc.,

Farnham Common.

DAVID MILWARD.

SIR.—I cannot believe that the individuals who have been responsible for the decision to ban heroin fully appreciate its indispensable role in the relief of suffering and pain associated with incurable malignant disease. It is also irritating to have handed out to us the misinformed statement, which surely does not find support in the experience of unbiased medical men, that we already have efficient substitutes for heroin. What a boost this is for the drug houses, but what a piece of presumptuous poppycock. With growing numbers of incurable cancer patients coming under our care, the ban can only be regarded as an iniquitous action which we can scarcely condone.

Apart from the few troubled voices of those crying in the wilderness, I am not aware of an organized protest from any of the official bodies within the profession. Is there any reason why we cannot have a nation-wide ballot—conducted, for example, by the B.M.A., the Royal Colleges, or the College of General Practitioners—in order to determine the consensus of medical opinion in the matter? The results could form the basis of a concerted protest by the profession to the Government against removal from our pharmacopoeia of this valuable and irreplaceable drug. The banning of heroin, in its practical consequences and in the manner in which it has been decreed, poses an issue of considerable moment to all who practise the healing art.—I am, etc.,

Perth.

R. G. SIMPSON.

SIR.—May I be allowed to add my protest in support of Dr. A. H. Douthwaite (*Journal*, April 9, p. 907), Dr. R. Hale-White (*Journal*, April 30, p. 1092), and others on the ban on heroin? As an anaesthetist I seldom have recourse to this drug, but there are occasions when it is the only effective remedy. Cannot the B.M.A. take a really strong and conclusive line on this question?—I am, etc.,

Hove.

J. H. CRAWFORD.

Food-poisoning

SIR.—May I draw attention to a small error in Dr. Christopher Hardwick's interesting article (*Journal*, May 14, p. 1205)? Unless corrected this may give rise to some confusion. It is quite correct to say that *Amanita phalloides* may be eaten in mistake for the field mushroom. Indeed, this fungus is said to be responsible for 90% of the deaths due to mushroom poisoning. However, the English name for this variety is not "fly agaric," as Dr. Hardwick states, but "death cap."

The fly agaric is the *Amanita muscaria* and contains muscarufin as well as muscarine, and this presumably accounts for its distinctive colour. It is the decorative fungus which may be seen ornamenting the pages of many fairy-tale books or the back-cloth of the pantomime. Its former use as a fly killer has determined its name in many languages besides Latin and English. The Russian "mukhomor" means "fly-death." The fly agaric has a scarlet cap with white spots and because of this brilliant colouring is very unlikely to be eaten in mistake for some other variety.

The death cap on the other hand is white, almost entirely lacking in pigment. It may grow on grassland verging woods. It can be distinguished from the field mushroom (*Psalliota campestris*) by the colour of the gills, which are white, not pink, brown, or black, and by the volva, which is a distinct cup at the base of the stem presenting (hence the botanical name) a phallic appearance in the young specimen.—I am, etc.,

London, S.W.17.

BRIAN H. KIRMAN.

Difficulties of Child Adoption

SIR.—Our attention has been drawn to Dr. P. M. Fea's letter (*Journal*, April 30, p. 1096). I am afraid the fact is that there simply are not any girls of about 5 available for adoption by anybody. Girls are far more in demand than boys, and every society has a long waiting-list of adopters waiting for girl babies. This is aggravated by the fact that girls are also more readily received by grandmothers, and even by employers, than boys, so that not only are more girls than boys asked for, but fewer girls than boys are offered for adoption. Only about 1% of the "inmates of homes" are available for adoption, and it is safe to say that none of those available is a girl of 5—girls have all been adopted long before reaching that age. Once a child reaches school age unadopted, the chances of its being offered for adoption are much less than before, since a mother who has managed to keep her child with her up to that age finds her task much easier once the child goes to school. And a girl of 5 who is orphaned usually has relatives who are able and willing to take her on. Every adoption society is overwhelmed by requests for toddler girls, which it would be happy to satisfy if the children were available—we should not be concerning ourselves with adoption at all if we preferred to leave children languishing in homes. But the number of people wanting to adopt children as a whole is about 10 times the number of children offered for adoption, and in the case of girls probably 20 times. For girls of 5 it must be hundreds to one.—I am, etc.,

London, N.W.11.

M. E. EDWARDS,

Chairman, Standing Conference of
Societies Registered for Adoption.

British Society of Dental Hypnotists

SIR.—At the annual general meeting of the British Society of Dental Hypnotists it was decided unanimously to change the name of the Society to the Dental and Medical Society for the Study of Hypnosis. This was done at the request of the increasing number of medical practitioners who have joined the Society and taken theoretical and practical study courses in the use of hypnosis. They felt that it would be a wise thing if the Society were expanded into dental and medical sections, with separate committees and a joint committee to dictate general policy. Some of our future meetings will be of a general nature and others of more specialized type to suit each profession. The courses of instruction will continue but will become, in their later stages, more specialized in character, and the students will separate for this purpose. The Society now numbers nearly 200 members, of whom over 150 have attended the courses of instruction we have held on the theory and practice of hypnosis, its uses, limitations, and dangers.

The Society, since its inception, has laid special emphasis on the needs of the general practitioner both of medicine and dentistry, and in view of the recent B.M.A. report supporting further teaching and investigation in hypnosis we should welcome further members of both professions who are interested. At our annual general meeting held on May 3 the following resolution was passed unanimously: "This Society feels strongly that the use of hypnosis should be confined to the members of the medical and dental professions."—I am, etc.,

London, W.1.

E. E. WOOCKEY,
Chairman.

Obituary

W. M. ROBSON, M.D., F.R.C.P.

Dr. W. M. Robson, consulting physician to Northampton General Hospital and to the Oxford Regional Hospital Board, died at his home at Northampton on May 10. He was 77 years of age.

William Morton Robson was born in 1877, the son of John S. Robson, J.P., of Butterknowle, Co. Durham, and was educated at St. James's School, Bishop Auckland, and at the Forest School, Walthamstow. He entered Guy's Hospital as a medical student in 1895 and qualified M.R.C.S., L.R.C.P. in 1901, taking the London M.B. in the same year. After holding several hospital appointments at Guy's and other London hospitals, he went to Northampton in 1903 as junior medical officer at St. Andrew's Hospital, an appointment which gave him time to work for higher qualifications. He proceeded to the M.D. in 1903, winning a gold medal, and obtained the M.R.C.P. two years later, when he was elected to the honorary staff of Northampton General Hospital as assistant physician with charge of the electrical department. This was the forerunner of the present x-ray department. In due course Robson became radiologist as well as physician, and it was in no small part due to his influence that an anonymous benefactor subsequently gave much of the present equipment of the x-ray department to the hospital. Robson's skill as a clinician helped him greatly in his radiological duties, and for many years he was in charge of the diagnostic and radiotherapeutic work. His diagnostic reports, notable for their brevity, were always written by his own hand; in x-ray therapy he followed closely the technique of Coutard, and, though his dosage by modern standards was often low, his results were remarkably good and he seldom distressed patients by his treatment. His interest also extended to venereology, and he established the venereal diseases clinic, which remained under his direction until his final retirement in 1950. During the first world war he served with the rank of major in the R.A.M.C., and was attached to Berry Wood Mental Hospital, which had been taken over for the reception of Service casualties.

Robson was elected F.R.C.P. in 1920, and for thirty years as senior physician was a central figure in the life of the Northampton General Hospital. Always quietly courteous and thoughtful, his judgment was extremely sound and his opinion carried weight not only in clinical matters but also in the board of management on which he served many years. He was honorary secretary of the old Northamptonshire Division of the British Medical Association from 1922 to 1927; chairman of the Division in 1930-1; and honorary secretary of the Northamptonshire Branch in 1935. He wrote little, but, despite many hospital commitments and a considerable private consulting practice, he found time for relaxation in sport and the entertainment of his friends. He was an excellent shot and in later years a keen and expert fisherman. A genial host—and a connoisseur of port—he was a master of the bridge table. He leaves a widow and one daughter.—R. O. L.

W. F. ANNAND, M.D.

The medical profession in Coventry heard with deep regret of the death on May 6 at the age of 75 of Dr. W. F. Annand, consulting physician to the Coventry and Warwickshire Hospital.

William Fraser Annand was born at Peterhead, Aberdeenshire, on September 20, 1879, and went to school at South Shields, where his father, R. C. Annand, J.P., was an engineer and an inventor of printing machines. He began his medical studies at Durham University and went on to University College Hospital, London, where he had a distinguished student career, gaining gold medals in medicine, surgery, and pathology. He graduated M.B., B.S. at London University in 1903 and proceeded to the M.D. two years later. After holding house appointments at University College Hospital, the East London Hospital for Children, and at Queen Charlotte's Hospital he went into general practice at Stafford, where he was appointed honorary physician to the Staffordshire General Infirmary.

In 1909 Annand moved to Coventry, and three years later began his long association with the Coventry and Warwickshire Hospital as honorary anaesthetist. In 1919 he became honorary physician to the hospital, taking a very keen interest in its development and serving on the board of governors. For a long period he was chairman of the medical advisory committee. On his retirement in 1939 the board of governors appointed him honorary consulting physician to the hospital. He was chairman of the Coventry Division of the British Medical Association in 1925-6.

The death of Dr. Annand's wife in 1939 was a great blow to him, for her gaiety and zest of life were a constant joy to him after hours of heavy responsibility. During the second world war he returned to active duties at the Coventry and Warwickshire Hospital, and in 1941 he received Royal commendation for his work during the air raids. He finally retired in 1946, but four months later, while on holiday, he had a severe heart attack and since then had had to lead the life of an invalid. His recreations were golf and bridge, and fortunately he was able to continue to play bridge up to a week or two before his death. He is survived by a son and a daughter, who is matron of the National Temperance Hospital, London, and to them and to all his relatives we extend our deepest sympathy. In the passing of William Fraser Annand, Coventry has lost a great physician and his colleagues a loyal and trusted friend.—W. P. E.

T. W. J. JOHNSON, M.D., F.R.C.P., F.R.A.C.P.

Dr. T. W. J. Johnson, consulting physician to the Auckland Hospital, New Zealand, died at his home at Auckland on October 16, 1954, after a short illness.

Born at Auckland in 1885, Thomas William James Johnson was educated at Thames High School and at Auckland Grammar School, where he won a junior scholarship to Otago University. At the university he more than maintained his early promise and gained many prizes, including the first award of the medical travelling scholarship. He graduated M.B., Ch.B. at the University of New Zealand in 1909, and then held posts at Dunedin Hospital before coming to London, where he worked at the Middlesex Hospital and the Maida Vale Hospital for Nervous Diseases. After obtaining the London Conjoint diploma in 1911 and the M.R.C.P. in the same year, he returned to New Zealand, where he proceeded to the M.D. in 1912 with a thesis on the apex beat. For the next 10 years he was in practice at Napier, being elected to the honorary staff of the local hospital.

In 1921 Johnson again came to London for postgraduate studies, after which he settled at Auckland, where

in due course he was appointed senior honorary physician to the Auckland Hospital, a post he continued to hold until his retirement in 1951. He was elected a Fellow of the Royal College of Physicians of London in 1932. Six years later he became a Foundation Fellow, a Censor, and a member of the Dominion Committee of the Royal Australasian College of Physicians, and in 1942 he was elected a vice-president of the College. He was an examiner in medicine for the University of New Zealand, consulting physician to the Royal New Zealand Navy and to the Fiji Government in New Zealand, and had served on the Medical Council of New Zealand. He also did good work as the chairman of the Miners' Pension Appeal Board and of the Dominion Tuberculosis Committee, and he helped to establish the Auckland Clinical Society and to found the medical library at the Auckland Hospital. When he retired in 1951 he was appointed consulting physician to the Auckland Hospital and became a member of its committee on appointments. From 1936 to 1938 he was chairman of the Auckland Division of the British Medical Association. Johnson was an excellent teacher. He expressed himself clearly and in simple language and gave every possible assistance to his students. To the newly qualified he was a never-failing source of encouragement. He helped them in their work when the need arose, and his advice, eagerly sought, was of great value to them in their careers. An all-round sportsman, he played hockey for his university, and in later life became an expert angler and a competent golfer. A man of many hobbies, he was particularly interested in the history, folk-lore, and language of the Maori people, and was well versed in the natural history of New Zealand. He is survived by a widow and two sons, both members of the medical profession.

OTTO ROSENHEIM, Ph.D., F.R.S.

Dr. Otto Rosenheim, who made notable contributions to biochemistry and physiology, died in London on May 7 at the age of 84.

Otto Rosenheim was born and educated in Germany. At the University of Würzburg, where he took his Ph.D. degree, he worked under Emil Fischer, and later he continued his studies at the Universities of Bonn and Geneva. In 1895 he came to England, where he secured an appointment at the University of Manchester. Six years later he moved to London, having obtained a research studentship in pharmacological chemistry at King's College. In 1904 he was appointed lecturer at King's College and, later, assistant professor of physiology. He also held a readership in biochemistry in the University of London until 1920. Having given up his official appointments, Rosenheim became a voluntary worker at the National Institute for Medical Research at Hampstead, where his research into the chemistry of sterols with Dr. Harold King led to some notable advances. Rosenheim was elected a Fellow of the Royal Society in 1917 for his work on brain chemistry. He married Miss Mary Christine Tebb, whom he met when she was on the staff of King's College, and with whom he collaborated in research work. She died in 1953.

We are indebted to Dr. HAROLD KING for the following appreciation:

It is difficult in a few words to do justice to the work of a born investigator like Otto Rosenheim. He chose for his field of operations physiological chemistry, and at King's College, London, between the years 1901 and 1920

contributed fundamental observations to this subject. With Tunnicliffe he was concerned with the toxicity of beer containing selenium which arose from the sulphuric acid used in preparing the sugars for fermentation; and in another inquiry he showed that formaldehyde—1:5,000 in milk and 1:9,000 in food—had no effect on healthy children. With Locke, Rosenheim took part in a classical investigation: they devised a new perfusion method for the mammalian heart, using dextrose in oxygenated Ringer solution, and followed the sugar metabolism. An outstanding piece of research work then followed in which Rosenheim was assisted by Mary Christine Tebb, who later became his wife. They took up the chemistry of brain, and incidentally laid low the myth of protagon as a single entity, but, more important, they devised methods for the separation of the constituents of the brain—phrenosin, kersin, and sphingomyelin—leading to the elucidation of the structure of the two former substances. At King's College, too, Rosenheim demonstrated that, contrary to Dixon and Taylor's findings, an extract of placenta had no pressor effect if there was no putrefaction.

After five years of retirement, Rosenheim joined the National Institute of Medical Research at Hampstead as a voluntary worker and revelled in the facilities provided. With Dudley he cleared up the distribution of two mammalian bases of unknown function, spermine and spermidine, and elucidated their structures. A fruitful co-operation with Webster resulted in the proof that the substance which on irradiation cured rickets in rats, the so-called provitamin-D, was ergosterol. Much has flowed therefrom. In association with Drummond he delved in the vitamin-A field and found that arsenic trichloride gave with cod-liver oil a blue colour proportional in intensity to the vitamin-A content. Other fish and bird oils were examined, some of which are now in daily use in medicine. The writer was fortunate in a collaborative effort with Rosenheim whereby revolutionary formulae were proposed for the sterols and bile acids in 1932. These have received universal acceptance and have led to remarkable advances in the knowledge of certain heart poisons, sex hormones, and principles of the adrenals.

The death of Dr. J. MAC K. JOHNSTONE occurred at his home at Leven, Fife, on April 17. James MacKersie Johnstone was born at Muirkirk, Ayrshire, on August 20, 1881, but most of his early life was spent in Lanarkshire. He received his medical education at Edinburgh University, where he graduated M.B., Ch.B. in 1902. After a few months as a locumtenent he went as assistant to Dr. W. Young, of West Calder, Midlothian, and then took up practice in 1905 in the Lanarkshire village of Tarbrax. After service in the first world war he returned to his practice, but in 1919 he moved to Leven, where he continued to practise until his death. Dr. Johnstone was a keen member of the British Medical Association, and from 1924 to 1947 he carried out the duties of honorary secretary of the Fife Branch, as well as those of honorary secretary of the Fife panel committee. In 1947 his colleagues showed their appreciation of his devoted services by making a presentation at a dinner given in his honour, and later they elected him president of the Fife Branch for 1948-9. He also served the profession on the Scottish Committee of the B.M.A. for many years, was vice-chairman of the Fife executive council, and a member of the East Fife hospitals management board. Although he had not enjoyed the best of health for some time, his sudden death came as a great shock to his colleagues. Our sympathy goes out to his widow, daughter, and two sons.—A. M. G.

Mr. A. H. B. HEESOM, dental surgeon to the East Surrey and Redhill County Hospitals, died at his home at Reigate on April 19 at the age of 54. Alan Hedley Beecroft Heesom was born at Redhill on September 29, 1900, and was educated at Marlborough and at Guy's Hospital, qualifying L.D.S. in 1926 and taking the Conjoint diploma of M.R.C.S., L.R.C.P. in the following year. After holding the appoint-

ment of dental house-surgeon at Guy's Hospital he joined his father, Mr. E. E. D. Heesom, in 1929, succeeding to the practice two years later, when his father retired. He was honorary dental surgeon to the East Surrey Hospital from 1934 until the inception of the National Health Service in 1948, when he was appointed senior hospital dental officer to the Redhill Group of Hospitals. He was extremely popular with all his patients and his professional colleagues, both medical and dental, as was shown by the very large attendance at his funeral service, the congregation being representative of all walks of life in the borough. He is survived by his widow and a son and a daughter.

The death occurred at Bolton on April 22 of Dr. JAMES SCOTT, honorary consultant gynaecologist to the Bolton Royal Infirmary. He was 73 years of age. James Scott was born on February 26, 1882, and received his medical training at Edinburgh University, where he graduated M.B., Ch.B. in 1907. He went to the Bolton Royal Infirmary as a house-surgeon in the same year, and remained for three years. During this time his ability and keenness were fully appreciated, with the result that he went as assistant to one of the staff who was also in general practice. In 1911 he was appointed to the staff of the Bolton Royal Infirmary as honorary assistant surgeon, and in 1913 he obtained his own general practice at Bolton. With the outbreak of the first world war in 1914 he joined the R.A.M.C., retiring with the rank of captain, and during his service he was awarded the Military Cross. He returned to the staff of the Bolton Royal Infirmary in 1920, and from then on his main interest was in gynaecology. In 1929 he was appointed honorary gynaecologist to the Royal Infirmary, where he founded the department. He remained in this position until 1948, when he retired from the active staff and was appointed honorary consultant gynaecologist. Dr. Scott was hard-working, conscientious, and took scrupulous care in all he did. He was a very capable surgeon, and was always insistent that everything in the operating theatre should be exactly as he wished it, but he was completely disinterested in the clock. He was never happier in the theatre than when doing a colporrhaphy, which provided him with plenty of opportunity to show his care and neatness. He continued in general practice until 1954, when he was forced by ill health to retire, and later in the year he returned to his beloved Scotland, living at Selkirk.—T. N. H.

Dr. LLEWELYN WYNNE DAVIES, who was formerly assistant director of medical services in Nigeria, died on April 24, aged 80. The fourth son of the Reverend David Davies, of Llansilin, Llewelyn Wynne Davies went to school in Oswestry, and studied medicine at King's College, London, and Edinburgh University, where he graduated M.B., Ch.B. in 1897, proceeding to the M.D. in 1903. After holding resident appointments at a number of hospitals, including The Hospital for Sick Children, Great Ormond Street, he continued his postgraduate studies at Heidelberg and Berlin. He also travelled widely as a ship surgeon and was in Japanese waters during the Russo-Japanese War. For some years thereafter he was a general practitioner in Hayle, Cornwall, and then joined the Colonial Medical Service in 1911, being sent to Nigeria, where he did pioneer medical work in unexplored areas of the country. During the first world war he saw active service in German-East Africa, Mesopotamia, India, and Afghanistan, being mentioned in dispatches. He was appointed O.B.E. in 1919. Retiring from the Colonial Medical Service in 1931, he farmed for some years in Llansilin and took an interest in many aspects of country life. Few men were so capable of offering intelligent advice on varied subjects. A keen antiquarian, he was president of the Offa Field Club and a committee member of the Cambrian Archaeological Association. He was also well known as a churchman, being a member of the governing body of the Church of Wales. A justice of the peace, he served on many committees concerned with local government and with the University of Wales. Throughout his life he maintained a fatherly interest in

Llansilin, and his home there was the centre of village life. Although unmarried, he loved family life and was always interested in child care. By young people in particular a visit to his home was never to be forgotten. Two of his nieces are medical practitioners.—I. H.

The death occurred suddenly at Oxford on May 9 of Dr. C. A. R. McCAY, who had been in general practice there for more than 30 years. Charles Alexander Ramsay McCay was born at Castlederg, Co. Tyrone, on May 12, 1890, the son of the late Rev. James McCay, and received his medical training at the Meath Hospital. He took the Irish Conjoint diploma in 1916, and then immediately volunteered for service with the R.A.M.C. in the first world war, attaining the rank of captain. After three years' service in France he returned to Dublin, where he took the D.P.H. at the Royal Colleges in 1919, and the F.R.C.S.I. (in the following year), gaining first place in the latter examinations. He then held resident posts in Dublin and Northampton before settling at Oxford in 1922, in partnership with Dr. Robert Hitchings. He became the senior partner in 1930, when Dr. Hitchings retired, and remained so until the time of his death. He was deeply interested in medical activities of all kinds, and his influence was widely felt. He was a product of the old school, and firmly believed that the doctor should also be the friend and counsellor of his patient. He set himself and his colleagues a very high standard in all medical matters, and strongly opposed any tendency to undermine the responsibility and position of the general practitioner. He was a man of fine character—generous and warm-hearted—and by his passing Oxford has lost a really good doctor, and many people a trusted friend and adviser. He is survived by his widow, three daughters, and two sons.—J. C. S.

Sir ROBERT MCCARRISON writes: As one who enjoyed the friendship of that grand family doctor, Charles McCay, may I quote these lines which so fittingly tell what manner of man he was:

"But once I pass this way
And then—no more.

So while I may,
With all my might,
I will essay
Sweet comfort and delight
To all I meet upon the pilgrim's way."

This might well be his epitaph; for he will long be held in affectionate remembrance by the many to whom, in his pilgrimage, he brought comfort and healing both as friend and as doctor.

The obituary of Mr. R. DAVIES-COLLEY was printed in the *Journal* of April 30 (p. 1097). A.E.S. writes: When "D.C." as he was always known, returned from the first world war he arrived at Guy's arrayed in a grey morning-coat and top-hat. Later, I think, he got a little less formal, but usually wore grey. He was very polite and addressed all nurses (to their gratification and astonishment) as sister. As Mr. T. B. Layton writes, he never showed any emotion. Everybody knew that he had been keen on obstetrics. He was a good surgeon, but had not the tidy and precise habits of Mr. Fagge, whose house-surgeon I was when D.C. was assistant surgeon. A popular, bland, and imposing figure, Davies-Colley will be remembered with affection by all who came under his influence.

Medico-Legal

PSITTACOSIS IN FAMILY

Judgment was entered for defendants with costs by Mr. Justice Gorman in the High Court on May 13 in the action for damages brought by a family of five who alleged they contracted psittacosis from a parrot bought at a pet shop. The defendants were the Regent Pet Stores (Palmer's) Ltd.,

of London, N.W., who denied that any parrot they had sold was suffering from psittacosis or that there was any breach of warranty or negligence by them in connexion with the sale of the bird. The plaintiffs were Mr. W. C. Downes, a trolleybus driver, Mrs. F. A. Downes, his wife, G. W. Downes, now aged 14, Mrs. Daphne Chalk, aged 21, and Elaine Downes, aged 9, all of London, N. Entering judgment for the defendants, his lordship ordered Mr. Downes, who was legally aided, to pay £36 towards the costs. Giving judgment, his lordship said he was satisfied that, while Mr. W. C. Downes, the father, suffered from psittacosis, and it was probable that the boy Graham, Mrs. Chalk, and the girl Elaine had too, he was not satisfied that Mrs. Downes had. The allegation of breach of warranty was that the parrot was weak, dejected, and suffering from psittacosis when it was sold on December 18, 1952, and subsequently died on December 29, 1952. He could not accept this, and preferred the evidence of the defence witnesses that the bird was in good condition when it left the pet stores. It had been stated that the birds in the pet stores were inspected frequently every day, and there had been no indication that this particular parrot was out of condition. In any case, added his lordship, there was a room set aside as a hospital for sick birds. The greatest possible care was given to birds and pets, and there was no evidence whatever that there had been any sort of trouble of any description in respect of pets and their care. He was quite unable to say on the evidence that the bird was suffering from psittacosis at the time of the sale.

FAULTY MCGILL TUBE CAUSES DEATH

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On March 1, 1955, Karen Jennifer Wills, aged 3 years 11 months, was admitted to the Southern Hospital, Dartford, for operation to correct a slight squint of the left eye. Her general health was good, and the operation was performed next day.

Premedication for the anaesthetic consisted of "nembutal" 1½ gr. (100 mg.) and atropine 1/100 gr. (0.65 mg.), followed by ether anaesthesia. After induction and intubation at 10.40 a.m. the operation began at 10.52. Oxygen was slightly increased because of some coughing on the tube similar to hiccups, and the anaesthetist passed his finger into the child's mouth to ascertain that things were all right. Later she became slightly cyanosed, so that the oxygen was again adjusted and a further check with the finger in her mouth was carried out. Her colour was then restored. Five minutes later the operation was concluded. She was then cyanosed and little or no chest movement could be seen. Resuscitative measures were at once applied and maintained for twenty-five minutes, but without avail. Only then was the tube taken out of the child's mouth, and it was found to have a transverse fracture about 1½ in. (4 cm.) from the end nearest the lips, behind the teeth at the back of the tongue.

How this break occurred, and precisely what caused the lack of oxygen contributing to the vagal inhibition which caused her sudden death, did not become clear from the evidence at the inquest held by the coroner for North-west Kent at Dartford on March 8 and 29.

The tube used was a nasal tube, deliberately selected. It was examined by the anaesthetist, who saw no sign of fracture, and no force was used in removing it. A representative of the suppliers said that although tubes had been known to split longitudinally he had never known of a split round the tube. The minimum pull required to break a similar tube on test was 28 lb. (12½ kg.). Although autoclaving tended to harden tubes, this one did not appear to be hard.

Mr. W. H. Stevens, an expert on rubber and plastics, examined the broken tube, which in his view could have broken as it had only by force exerted along its axis. He found that it had perished to some extent, because when he

squeezed it longitudinally cracking was produced, and the cracks contained foreign particles of, he thought, a siliceous character. One crack contained reddish rust. He was unable to break the tube in the way it had broken except by pulling hard along its axis. He did not think that the degree of perishing which he found could have been seen with the naked eye.

A verdict was recorded of death by misadventure from vagal inhibition.

£2,000 DAMAGES FOR RHEUMATOID ARTHRITIS

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

From August, 1950, to April, 1953, Mrs. Maureen McKendrick, a teacher at St. Conval's Junior Secondary School, Glasgow, had as her class-room what had been the back kitchen in the house which formed the school annexe. It was a badly heated and ventilated room, the temperature of which was usually about 50° to 52° F. (10°-11° C.), but as low as 42° F. (6° C.) in winter. It never rose to the 56° F. (13° C.) required by the school regulations. In winter Mrs. McKendrick and her class wore their overcoats in an effort to keep warm, and when conditions were unendurable special arrangements were made for the class to be transferred to the main school building. During this period Mrs. McKendrick's health gradually deteriorated, until she became crippled by rheumatoid arthritis.

Mrs. McKendrick brought an action against her employers, the Glasgow Corporation, alleging that by reason of the conditions in which she was required to work the corporation had failed to take reasonable care for her safety, as a result of which her rheumatoid arthritis had been brought about. The corporation denied that the room was in an unhealthy or dangerous condition, and said that it had had to be used at the time because of shortage of teaching accommodation. Its use had since been discontinued because it was not satisfactory from a teaching point of view.

In the Court of Session evidence was led on behalf of the corporation that damp and cold were not the cause of rheumatoid arthritis. Dr. Dudley Hart, of Harley Street, agreed in cross-examination that for a slim young girl in her twenties conditions of cold and damp in a room in which she had to work would be unsatisfactory, but said that from the point of view of causing rheumatoid arthritis cold and damp had no relevance. Dr. J. P. Currie, of the Glasgow Infirmary, a member of the Empire Rheumatism Council, said that although cold and damp were normally associated with rheumatism in general that was in his opinion a fallacy. Although it was suggested that a prolonged course of exposure to cold and damp working conditions were causative, contributory, or aggravating factors in the progress of rheumatoid arthritis, he believed that in the light of present knowledge of the disease all those conclusions were untenable. He did not think that living in a damp house or sleeping in a damp bed would be positive factors. There was no high incidence of the disease among refrigeration plant workers, and fishmongers and butchers were apparently immune. It was a common disease in Spain, Switzerland, and the Arizona desert.

In his summing up¹ to the jury Lord Walker said that before they could find for Mrs. McKendrick they must be satisfied of three things: that the room was cold, damp, and ill-ventilated throughout the two and a half years she was working there; that these conditions caused or aggravated the rheumatoid arthritis from which she suffered; and that the corporation ought reasonably to have anticipated that rheumatoid arthritis was likely to occur if she was exposed to the conditions in the room.

By a majority of seven to five the jury found a verdict for Mrs. McKendrick and awarded her £2,000 damages.

¹ *Scotsman*, May 18, 1955.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending May 7 (No. 18) and corresponding week 1954.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenzal pneumonia.
‡ Includes puerperal pyrexia.

Vital Statistics

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1946-54 are shown thus ----, the figures for 1955 thus —. Except for the curves showing notifications in 1955, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest fluctuations in the notifications of infectious diseases in England and Wales during the week ending May 7 were a decrease of 3,045 for measles, from 22,537 to 19,492, and increases of 114 for scarlet fever, from 461 to 575, and 82 for whooping-cough, from 1,768 to 1,850.

The largest falls in the incidence of measles were 553 in London, from 1,789 to 1,236, 427 in Yorkshire West Riding, from 2,570 to 2,143, 424 in Warwickshire, from 2,055 to 1,631, 272 in Staffordshire, from 1,268 to 996, 258 in Southampton county, from 993 to 735, and 246 in Surrey, from 971 to 725, and the largest rises were 90 in Glamorgan-shire, from 603 to 693, 83 in Durham, from 719 to 802, 69 in Gloucestershire, from 410 to 479, and 64 in Middlesex, from 1,542 to 1,606. A small rise in the incidence of scarlet fever occurred in most regions, but there were no large local fluctuations. The largest rises in whooping-cough were 38 in Yorkshire West Riding, from 127 to 165, 35 in Durham, from 103 to 138, 34 in Leicestershire, from 55 to 89.

4 cases of diphtheria, 5 fewer than in the preceding week, were notified. The number of notifications was the same as in the 34th week of 1954 and is the smallest number recorded in any week. The four cases were notified in the northern cities of Kingston-upon-Hull C.B. 2, Wallasey C.B. 1, and Liverpool C.B. 1.

24 cases of acute poliomyelitis were notified, and these were 5 more for paralytic and the same for non-paralytic cases as in the preceding week. The largest returns were Lancashire 5 (Liverpool C.B. 3, Longridge U.D. 2), Middlesex 2 (Acton M.B. 2), Worcestershire 2 (Bromsgrove U.D. 2), Yorkshire West Riding 2.

The notifications of dysentery numbered 862 and were 17 fewer than in the preceding week. The largest centres of infection were Lancashire 319 (Manchester C.B. 47, Blackburn C.B. 44, Liverpool C.B. 40, Oldham C.B. 33, Blackburn C.B. 31, Salford C.B. 22, Whiston R.D. 13, Rochdale C.B. 12, Huyton-with-Roby U.D. 11), Durham 135 (Easington R.D. 26, Seaham U.D. 24, Stanley U.D. 17, South Shields C.B. 15, Felling U.D. 13, Whickham U.D. 13), London 71 (Islington 14), Surrey 44 (Woking U.D. 24), Northumberland 38 (Newburn U.D. 10), Yorkshire North Riding 36 (Middlesbrough C.B. 35), Leicestershire 31 (Leicester C.B. 22), and Yorkshire West Riding 28 (Leeds C.B. 10).

In Scotland the number of notifications of dysentery rose from 296 to 393. The largest returns were those of the cities of Glasgow 197, Dundee 61, and Edinburgh 37.

Week Ending May 14

The notifications of infectious diseases during the week included: scarlet fever 571, whooping-cough 1,805, diphtheria 9, measles 20,384, acute pneumonia 441, acute poliomyelitis 16, dysentery 1,038, paratyphoid fever 12, and typhoid fever 2.

Medical News

"Clinical Pathology in General Practice."—The 39 articles on clinical pathology which appeared originally in the *Journal* from October, 1953, to July, 1954, as part of the Refresher Course for General Practitioners are now available as a book. A leaflet describing it is inserted in this issue of the *Journal*. The book sets out to be a practical handbook on clinical pathology. It describes how best to take and preserve specimens, and discusses the value and interpretation of the various tests. It includes details of the laboratory facilities available in Britain and a full index. Written primarily for the general practitioner, this volume is likely to interest equally the hospital worker. Its cost is 21s.

Orthopaedic Accident Service.—From June 1 the Royal National Orthopaedic Hospital, Brockley Hill, Stanmore (Grimsdyke 2900), will operate a twenty-four hour accident service for the treatment of orthopaedic injuries. Facilities are available for the reception of injuries direct from the site of accident. Requests for admission or out-patient treatment should be made to the duty registrar. The service is planned to deal with major and minor injuries, and will supplement the existing special organizations of the Royal National Orthopaedic Hospital for peripheral nerve injuries, hand injuries, rehabilitation, and resettlement.

Joint Annual Meeting.—Members who have resolved to attend the Joint Annual Meeting in Canada on June 20-24 but not yet arranged to do so are asked to communicate before May 31 with the Secretary of the British Medical Association. It may not be possible after that date to reserve either a passage to the meeting or accommodation there.

Carnal Knowledge of Mental Defectives.—When a certified mentally defective patient is found to be pregnant or there is reason to think that sexual intercourse has taken place, the administrative procedure to be followed is set out in a National Health Service communication H.M. (55) 46, sent to hospital boards and committees by the Ministry of Health. The Board of Control should be informed, as before, but the following change in procedure has been made: "Following consultations with the Secretary of State for the Home Department, the Minister is of opinion that it is desirable that in future such cases should be reported to the police, not necessarily with a view to prosecution but to enable the police in consultation with the medical superintendent to decide what is the best course to take in all the circumstances." Medical superintendents are asked to send reports to the local chief constable even when the offence has been committed in another police area.

Eighth World Health Assembly.—Dr. I. MORONES PRIETO succeeded Dr. JOSEPH N. TOGBA as president of the World Health Assembly at its eighth session, which began on May 11 in Mexico City. Dr. Morones Prieto is Mexico's Minister of Health and Welfare. Dr. ANDRIJA STAMPAR, president of the Yugoslav Academy of Sciences and Arts, was awarded the Léon Bernard Foundation Prize in recognition of his "outstanding contribution and practical achievements in the field of social medicine." The prize, which consists of a medal and 1,000 Swiss francs, was presented by Dr. Morones Prieto. He stated that Dr. Stampar had introduced basic concepts of social medicine into the medical schools and health services of Yugoslavia as well as in other countries. Dr. Stampar was chairman of the Interim Commission of the World Health Organization in 1946-8 and president of the First World Health Assembly in 1948.

NAPT Travelling Fellowship.—The Scottish Branch of the National Association for the Prevention of Tuberculosis offers a travelling fellowship, valued at £250, to a doctor working in Scotland in the field of tuberculosis. Details from the Scottish Secretary, NAPT, 65, Castle Street, Edinburgh, 2. The last date for applications is July 15.

Rockefeller Foundation Grants.—Among recent grants are one of \$35,000 to the University of London for research into nucleic acids by Professor J. T. RANDALL and Dr. M. H. F. WILKINS in the department of physics at King's College, and another of \$45,500 (£15,000) to the London School of Hygiene and Tropical Medicine for the investigation of industrial conditions hazardous to health in a new department of occupational health. The present grant brings the total support to this school by Rockefeller funds to about \$2,500,000 since 1922. Professor H. A. KREBS, Nobel Prize winner, recently of Sheffield and now professor of biochemistry at Oxford, will continue to be aided by a grant made to Sheffield University when he was there. This grant for Dr. KREBS's work is a continuation of Rockefeller Foundation support which began in 1935.

Cerebral Palsies.—A century after the publication of Little's classical descriptions of cerebral palsy a Little Committee has been formed to study the clinical features of the disease and the administrative problems of training medical and other staff for work on it. The committee consists of the following members: Dr. W. R. F. COLLIS (chairman), Mrs. EIRENE COLLIS, Dr. WILLIAM DUNHAM, Dr. L. T. HILLIARD, Sir FRANCIS WALSHE, Dr. DAVID LAWSON (secretary at Queen Mary's Hospital for Children, Carshalton, Surrey).

Paediatrician Honoured.—On May 6 at the Dewsbury General Hospital local doctors and nurses entertained Professor C. WILFRED VINING, when a plaque was unveiled to commemorate his work as paediatrician to hospitals in the district from 1930 to 1953.

Medical Patron.—Lord IVEAGH, who is to be invested as a Knight of the Garter on June 13, has been a friend of medicine all his life. As a young man at Cambridge he became interested in research and in 1900 persuaded his father to endow the Lister Institute with a gift of £250,000. He was also associated at an early stage with the work of Wright and Fleming at St. Mary's Hospital. This was the result of a meeting called by Arthur Balfour in his room at the House of Commons to discuss the treatment of influenza by inoculation. It was then decided to form a committee to further the work being done at St. Mary's, of which Rupert Guinness (as he then was) was one of the most active members. In 1921 Lord Iveagh became chairman of the Wright-Fleming Institute of Microbiology and in 1929 presented it with the sum of £40,000 to be spent on new laboratories. He also endowed a ward at the hospital. He was a lifelong friend of Sir Alexander Fleming, who lived for many years as his neighbour in Suffolk. It was on Fleming's suggestion that early in the century he installed a pollenarium on his estate at Pyrford in Surrey. Here for many years the special grasses have been grown to provide the pollen from which vaccines for the treatment of hay fever are manufactured.

Research Fellowships.—The following Beit Memorial Fellowships for Medical Research are announced:

P. C. CALDWELL, D. Phil.: to investigate the mechanism of muscular contraction in Crustacea at the Marine Biological Laboratory, Plymouth.

R.-H. CÔTÉ, D.Sc.: to investigate the chemical constitution of human blood group substances at the Lister Institute of Preventive Medicine.

Miss E. I. B. DRESEL, Ph.D.: to investigate the biosynthesis of porphyrin pigments at University College Hospital Medical School, London.

J. M. LOWENSTEIN, Ph.D.: to investigate the biosynthesis of pyrimidines in mammals at the Department of Biochemistry, Oxford.

R. WHITTAM, D.Phil.: to investigate the metabolism of adenine nucleotides in relation to the active transport of inorganic ions at the Physiological Laboratory, University of Oxford.

Orthopaedic Meeting.—On April 22-23 the President of the British Orthopaedic Association, Professor BRYAN MCFARLAND, and some twenty members attended the spring meeting of the Société Belge d'Orthopédie et de Chirurgie de l'Appareil Moteur at Brussels at the invitation of the society's president, Dr. ROBERT SÈUR.

Ulster Paediatric Society.—A meeting was held on May 7 in the Institute of Clinical Science, Belfast. A demonstration of clinical cases occupied the morning, and after lunch papers were read by Dr. O. D. FISHER, Mr. D. S. GORDON, Dr. W. A. B. CAMPBELL, and Mr. J. A. W. BINGHAM.

Rose Simmonds Memorial Fund.—The first Rose Simmonds Memorial prizes for student dietitians (see *Journal*, July 3, 1954, p. 51) were presented by Miss PAT HORNSBY-SMITH, Parliamentary Secretary to the Ministry of Health, at the annual meeting of the British Dietetic Association on April 30.

Analgesia Research.—The National Birthday Trust Fund has made a grant of £1,200 to Dr. HILDA ROBERTS, lecturer in anaesthesia at the London Postgraduate Medical School, to enable her to do full-time research. The work will be carried out in the Research Unit of Obstetric Analgesia at Hammersmith Hospital.

Honorary Degree.—When QUEEN ELIZABETH THE QUEEN MOTHER is installed as Chancellor of London University on November 24 the honorary degree of Doctor of Laws will be conferred on Viscount MALVERN OF RHODESIA (formerly Sir Godfrey Huggins).

Lady Templer Hospital, Malaya.—Dr. M. R. J. SNELLING, from the King Edward VII Sanatorium, Midhurst, has been appointed first medical superintendent of the Lady Templer Hospital for Tuberculosis at Kuala Lumpur. He will shortly be joined by a thoracic surgical team and 28 Australian nursing sisters. The hospital has 250 beds.

Dr. Scott Thomson has been appointed part-time professor of bacteriology in the University of Wales. Dr. Scott Thomson is director of the Regional Public Health Laboratory (Medical Research Council), Cardiff, and has been lecturer in bacteriology in the Medical School since 1946. He was a major in the R.A.M.C. and was bacteriologist of the penicillin research team set up by the War Office in 1943.

Dr. G. R. Hargreaves has been appointed Nuffield Professor of Psychiatry at Leeds University from October 1. Dr. Hargreaves, who qualified in 1932, was in 1948 appointed the first chief of the Mental Health Section of the World Health Organization.

Dr. K. G. Bergin, B.O.A.C.'s medical superintendent, London Airport, has been elected a Fellow of the Royal Aeronautical Society.

Dr. J. Ferguson Smith, of Glasgow, has been elected an honorary member of the German Dermatological Society "on account of his outstanding scientific services in the domain of dermatology."

Faculty of Ophthalmologists.—At the council meeting on May 13 the following were elected officers for 1955-6: President, Dr. JOHN MARSHALL. Vice-presidents, Mr. T. KEITH LYLE and Mr. J. R. WHEELER. Honorary Treasurer, Mr. A. McKIE REID. Honorary Secretary, Mr. E. F. KING.

COMING EVENTS

"Rehabilitation of the Handicapped."—Two-day course, under joint auspices of British Council for Rehabilitation and Manchester University, at the College of Technology, Sackville Street, Manchester 1. June 6 and 7. Intended for industrialists, industrial M.O.s and nurses, personnel officers, etc. Details from British Council for Rehabilitation, Tavistock House (South), Tavistock Square, London, W.C.1.

Israeli Medical Association.—Third World Assembly in Jerusalem, Haifa, and Tel Aviv, August 10-20. Organized tour from Britain leaves London on August 8 (cost £158). Details and programme from Messrs. D. F. LONG and Co., Travel House, Mornington Crescent, London, N.W.1.

Asian-Pacific Tuberculosis Conference.—In Sydney, August 15-21, the week preceding the Australasian Medical Congress. The programme includes discussions on B.C.G. vaccination and tuberculosis control and treatment. Details from Dr. BRUCE GEDDES, Royal North Shore Hospital of Sydney, Crows Nest, New South Wales.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, May 30

EDINBURGH UNIVERSITY: FACULTY OF MEDICINE.—At Laing Surgical Lecture Theatre, Edinburgh Royal Infirmary, 12 noon, Professor S. F. HAINES (Minnesota, U.S.A.): Thyroid Gland in Relationship to Neuromuscular Disease.

Tuesday, May 31

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. E. M. Wigley: The Alopecias.

●INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—3 p.m., Mr. F. C. Dwyer: Lumbosacral Backache.

OXFORD UNIVERSITY MEDICAL SOCIETY.—At Maternity Lecture Theatre, Radcliffe Infirmary, 8.15 p.m., Professor R. J. Harrison: Origin, Development and Treatment of Human Intersexes.

ROYAL STATISTICAL SOCIETY: STUDY CIRCLE ON MEDICAL STATISTICS.—At Westminster Medical School, 5.45 p.m., annual general meeting. Three short papers: Controlled Trials in Medical Research. Dr. P. Armitage: Sequential Methods; Dr. J. Knowlton: Some Practical Problems; Dr. R. F. Wright: Statistical Inference.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C., 5.15 p.m., Cushing Memorial Lecture by Professor G. M. Bull: Physiology of Osmotic Diuresis and its Clinical Effects.

WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY.—5 p.m., Altmouth Wright Lecture by Professor A. C. Frazer: Studies on Intestinal Function in Man.

Wednesday, June 1

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Diagnosis and Treatment of Tinea Capitis.

●INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—3 p.m., Mr. N. F. Morris: Face and Brow Presentation.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. I. Friedmann: Pathology of the Ear.

Thursday, June 2

HONAN GILLESPIE LECTURE.—At University New Buildings, Edinburgh, 5 p.m., Dr. John Gillies: Induced Hypotension—A Review.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor R. Roaf: Natural History of Deformities as seen in India.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., postgraduate demonstration in neurology.

SURREY INTER-HOSPITAL PSYCHIATRIC ASSOCIATION.—At Horton Hospital, Epsom, Surrey, 8 p.m., clinical meeting. Papers by Dr. A. R. Worters: Problem of Incontinence in the Senile Psychotic; Dr. G. H. A. Chamberlain: Investigation into the Use of Acetylcholine in the Chronic Psychotic.

Friday, June 3

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. L. Forman: Disorders of Hair and Scalp.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., clinical demonstration by Dr. J. G. Scadding.

INSTITUTE OF LARYNGOLOGY AND OTOLARYNGOLOGY.—3.30 p.m., Mr. N. Asherson: Intra-cranial Complications of Ear and Sinus Disease.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—2.30 p.m., visit to Heritage Craft School and Hospital, Chislehurst, Sussex.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Sir Arthur Porritt: Carcinoma of the Breast.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Dr. J. Suchet and Dr. M. W. Lloyd-Owen: Analgesia and Anaesthesia in Labour.

APPOINTMENTS

FAIRLEY, H. BARRIE, M.B., B.S., F.F.A.R.C.S., D.A., Anaesthetist, Toronto General Hospital; Clinical Assistant, University of Toronto.

HENRY, H. S. A., M.B., F.R.C.S.I., D.L.O., Part-time Consultant Ear, Nose, and Throat Surgeon to South Down and South Armagh Group of Hospitals, Northern Ireland Hospitals Authority.

MACDONALD, IAN ALISTAIR, M.D., D.P.M., Consultant Psychiatrist and Medical Superintendent, Highcroft Hall Hospital, Birmingham.

MAKEY, A. R., M.S., F.R.C.S., Part-time Assistant Surgeon, Charing Cross Hospital.

VOIGHT, ETHEL MARY, M.B., B.Ch., Assistant County Medical Officer, School Medical Officer, Wiltshire County Council.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Longstaff.—On May 18, 1955, at Westwood Hospital, Beverley, East Yorks, to Peggy (formerly King-Davies), wife of Dr. John Longstaff, a daughter—Fiona Sarah.

Rose.—On April 20, 1955, at Rotorua, New Zealand, to Flora Rose (formerly Macdonald), M.B., B.S., wife of Benjamin Rose, M.R.C.P., a son—Timothy Julian.

DEATHS

Allott.—On April 29, 1955, at Besborough Heath End, Farnham, Harold Wordsworth Leach Allott, M.R.C.S., L.R.C.P., Lieutenant-Colonel, R.A.M.C., retired.

Bailey.—On April 27, 1955, at Dartmouth, Devon, Charles Henry Farley Bailey, M.R.C.S., L.R.C.P., late of Newport Pagnell, Bucks, aged 81.

Brakenridge.—On April 14, 1955, at Chew Magna, near Bristol, Francis John Brakenridge, C.M.G., M.R.C.S., L.R.C.P., D.P.H., Colonel, late R.A.M.C., retired, aged 83.

Browne.—On April 23, 1955, Hugh Derbyshire Browne, M.R.C.S., L.R.C.P., of Margam Cottage, Haywards Heath, Sussex.

Circuit.—On April 4, 1955, at Little Glemham Rectory, Woodbridge, Suffolk, Kathleen Circuit, M.R.C.S., L.R.C.P.

Clarke.—On April 27, 1955, at the Royal Naval Hospital, Chatham, Kent, Hubert Arthur Clarke, M.R.C.S., L.R.C.P., I.D.S., Surgeon Commander, R.N., retired, of Trincomalee, Poonery Bay, Sussex.

Clarkson.—On April 15, 1955, George Aylwin Clarkson, F.R.C.S., of Oakhurst, Gander Hill, Haywards Heath, Sussex, aged 85.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Vaccination for Genital Herpes

Q.—Could you please give me an opinion on the efficacy of vaccination therapy in a case of recurrent genital herpes? What is the best method of administering vaccination therapy, and how great is the danger of encephalitis?

A.—I am not aware of any published series of cases of the treatment of herpes genitalis by vaccination. My own impression from treating these cases is that vaccination is less effective than in the treatment of recurrent herpes on the face. However, other treatment of herpes genitalis is so unsatisfactory that the vaccine treatment is usually indicated. The vaccination should be carried out at intervals of a fortnight to a total of six or eight inoculations.

The danger of encephalitis seems to be almost entirely confined to primary vaccination in adolescents and adults. Re-vaccination is almost free from this risk.

Gaseous Distension of the Colon

Q.—A man of 60 complains of severe flatulence after a meal. X-ray examination shows gross gaseous distension of the colon by reason of which the stomach, which is of the "cascade" type, seems almost to be pushed up into the chest. What is the best line of treatment?

A.—Excessive gas in the colon may displace the stomach and has a number of causes, but most cases of severe flatulence after a meal are in fact due to air swallowing, with accumulation of air in the stomach under the left diaphragm, and not in the colon. If, as in this case, it is clearly shown in the x-ray picture that the gas is colonic, this may be due to intestinal carbohydrate dyspepsia, provided all causes of obstruction can be ruled out.

The commonest cause of this dyspepsia is undue hurry in the passage of food through the small intestine with resulting bacterial fermentation of starch which has reached the colon undigested. There is sometimes an associated achlorhydria and often an excessive excitability of the autonomic nervous system. The treatment is to cut down drastically all starches in the diet—particularly vegetables—and to give small doses of a sedative such as phenobarbitone, $\frac{1}{2}$ gr. (32 mg.) three times a day, to reduce nervous excitability, and acid, hydrochlor. dil., 15 min. (0.9 ml.), daily, with the two main meals of the day, in a glass of water.

Gas absorption in the small and large intestine may be reduced in cases of portal hypertension or heart failure, and severe meteorism may be due to a small mesenteric thrombosis.

Presumably in the case described all causes of chronic obstruction such as volvulus or peritoneal bands have been excluded, but simple chronic constipation in elderly patients, either of the "dyschezia" type or associated with diverticulitis, may sometimes lead to a considerable degree of megacolon with much gaseous distension. If this is the case a short course of colon washouts might be tried, giving these daily for four or five days to see if relief occurred. Two ounces (56 ml.) of liquid paraffin should first be run into the rectum and retained for one to three hours with the patient lying flat, after which 1 to 2 pints (0.5 to 1 litre) of warm saline should be run into the rectum under low pressure and then allowed to be evacuated.

Abdominal massage is unlikely to be of assistance, and the use of purgatives actually detrimental. Charcoal and other so-called adsorbents are almost, if not entirely, useless. Unless stool cultures show a definitely abnormal flora anti-septics or antibiotics should not be given.

Careers for Tuberculous Patients

Q.—What principles should govern the choice of a career for a patient with tuberculosis? Training colleges will not accept active cases nor, presumably, quiescent ones. Should going to the university be postponed until the disease is arrested? Should careers involving much examination study be avoided? Should office work be avoided, as many offices are stuffy and badly ventilated? Your expert's views would be helpful.

A.—It is possible nowadays to take a much more optimistic view of tuberculosis than formerly. In the writer's opinion, although each case must be judged on its merits, a patient with arrested tuberculosis could in general be accepted for a training college, provided he remains under supervision by a competent chest physician. Nowadays relatively few careers have to be closed to a patient just because he has had tuberculosis. The university certainly need not be postponed for any long period; in the writer's experience most students found to have pulmonary tuberculosis by mass miniature radiography are back at the university the following academic year. They are advised to have 9 to 10 hours in bed and have to forgo strenuous sports, but are quite able to undertake the normal amount of study. It follows, of course, that there is no need to forgo a career which involves examinations. Office work, with its routine hours and lack of physical exertion, is in general very suitable for the ex-tuberculous patient. At present it is wise to advise against jobs involving heavy physical effort or dusty conditions, but it may well be that even these will later be opened to suitable ex-patients. All these remarks apply, of course, only if the patient has been well and thoroughly treated, if he remains under skilled supervision, and if his disease is regarded as securely under control.

Preservation of Fibrinogen

Q.—Solutions of fibrinogen prepared by the method of Jaques appear to become readily injected when stored at 4° C. What is the best method of preserving these solutions?

A.—Solutions of fibrinogen cannot be stored even in the refrigerator at 4° C. for more than two or three days. The reactivity of the fibrinogen deteriorates even if the solutions are not infected. Nor, in my view, is preservation improved by freezing the solution solid at -20° C. The only satisfactory method of storage is to dry the solution by the lyophil drying method immediately the solution has been dialysed. The material can be made in quite large bulk, and suitable amounts weighed out and dissolved as required. Advice on the construction of a satisfactory freeze-drying apparatus can be obtained from any well-equipped university biochemistry laboratory.

Vaginal Pessaries in Virgins

Q.—How does one treat a virgin who has a *Trichomonas vaginalis* infection? Is there not a risk of damage to the hymen if vaginal pessaries are used? I would appreciate your advice.

A.—If the opening in the hymen is wide enough to allow swabs to be taken and the diagnosis to be made, it nearly always allows the patient to insert vaginal pessaries without injury. Even if their regular use does result in slight stretching or tearing of the hymen it does not matter so long as the patient is responsible for it herself.

In cases where the hymeneal opening is exceptionally small and when the patient is nervous, uncooperative, or lacking in self-confidence it may sometimes be necessary to get her permission (or that of her parents if she is under age) to administer a general anaesthetic with a view to vaginal examination: this will inevitably dilate or tear the hymen. It will allow the case to be properly assessed, and has the added advantage that it allows a thorough cleaning of the vagina before the start of the treatment with pessaries.

Anticoagulants in the Puerperium

Q.—Is there any evidence that anticoagulants given to the mother for phlebotrombosis in the puerperium may be passed on to the baby through the breast milk and cause spontaneous bleeding?

A.—Anticoagulants of the heparin group are not absorbed from the intestinal tract and are therefore harmless to the baby even if excreted in the breast milk. The dicoumarol group of anticoagulants (dicoumarol, ethyl biscoumacetate, phenylindanedione) given to the mother are excreted in breast milk and can be absorbed from the intestinal tract. There is therefore the theoretical possibility that the baby might absorb sufficient anticoagulant from the breast milk to disturb its own clotting mechanism. No case of prolonged bleeding in a baby seems yet to have been reported as a result of administering anticoagulants to the mother in the puerperium, and it is not very likely that enough anticoagulant would in practice be absorbed to increase the baby's clotting-time significantly. An injection of vitamin K (5 mg.) would rapidly restore the normal coagulation rate if this was found to be raised.

Nocturnal Epilepsy in a Boy

Q.—What is the best drug for a boy aged 12 who suffers from nocturnal epilepsy? He began to have the fits eight months ago. Physical examination was entirely negative and x-ray examination showed nothing abnormal. He has never had an attack during the day. He was kept free from attacks with phenobarbitone, $\frac{1}{2}$ gr. (32 mg.) at bedtime, until two weeks ago, when the fits began again (he was away from home at the time). Now phenobarbitone, 1 gr. (65 mg.), keeps him all right. I would welcome suggestions as to treatment.

A.—In the treatment of epilepsy it is best to begin with a trial of whatever anticonvulsant may seem to be the most suitable, and, if it is ineffective in the dose first given, to increase this up to the limit of the patient's tolerance. If this should fail, other drugs or combinations of drugs should be tried. In the present case 1 gr. of phenobarbitone appears to be effective, and this should therefore be continued. It is important that whatever drugs may prove effective in controlling the seizures should be continued without reduction of the dose for a long period. This might reasonably be for three years after the last seizure, during which time the growth of the patient will have brought about a reduction of the dosage in relation to body weight. At the end of that time the dose might be halved, and if at the end of a further six months there had been no recurrence of seizures treatment might be stopped.

Intraperitoneal Sulphonamides in Research

Q.—In the course of experimental work on the pathology of certain obscure diseases of animals, in particular reptiles, I want to use a sulphonamide preparation systemically, but the only satisfactory route of administration is intraperitoneal. Can you please suggest the most suitable preparation for this purpose?

A.—It has been the general experience of experimental workers on the pharmacology of sulphonamide and allied drugs that the intraperitoneal route offers a safe and effective method of administration.

The simple sodium salt solutions are too alkaline for administration in this way, and it has been usual to use simple suspensions in saline or in 10% gum acacia of finely powdered (pestle and mortar) drug. The newer carboxymethyl cellulose preparations such as are employed in intramuscular penicillin suspension make excellent suspending agents. A site on the midline, above the bladder and avoiding the spleen, is chosen; a new sharp needle is the best safeguard against penetration of gut or vital tissue. The usual safeguard of withdrawing the needle a few millimetres and then withdrawing the piston before slowly injecting should

be practised. Absorption of sulphonamide drugs from the peritoneum of small laboratory animals and cats and dogs is rapid, approximating more to the intravenous than to the intramuscular route. It seems likely that this would also be true of reptiles.

The wide range of acetylation of sulphonamides among animals, and the possible sequelae of crystallization of acetyl-derivatives in, for example, warm atmospheres, would have to be considered, and this might influence the choice of drug. The writer has seen no reference to acetylation in reptiles, and a cautious experimental approach to dose is suggested. A calculation based on weight (man) should first be attempted; thereafter an increased dose based on surface area should then be used. For small reptiles the latter might well be seven times the former. Sulphathiazole remains the first choice.

Prognosis in Aplastic Anaemia

Q.—What is the longest recorded interval between onset and spontaneous recovery of the marrow in a case of aplastic anaemia? We have under our care a patient with panhaemocytopenia who, in the last four months, has had about 50 pints (28 litres) of blood. The frequent transfusions are causing great distress to the patient, and we are beginning to wonder whether further transfusion is justified. We should be very grateful for your expert's views.

A.—The writer is unable to answer the question as to the longest recorded interval between the onset and spontaneous recovery in aplastic anaemia. In the typical "idiopathic" form of the disease in which the marrow is truly aplastic recovery is undoubtedly extremely unusual. However, patients in whom the marrow aplasia is less complete have been kept alive for several years by blood transfusions, and in the writer's opinion the patient should never be allowed to die from lack of red cells. Even if the chances of recovery are remote, who can say that an individual patient will not recover or have a worthwhile remission? Is the distress to the patient caused by the transfusions psychological, or are the transfusions technically difficult or usually accompanied by reactions? If reactions occur frequently, they might be avoided by careful selection of blood after carrying out investigations for immune iso-antibodies. Possibly, too, transfusions of washed cells might be tolerated better.

Osteo- or Rheumatoid Arthritis?

Q.—My wife, aged 59, has recently developed painful Heberden's nodes on the terminal phalanges. She has fine crepitus in the knee-joints, but otherwise no other signs of rheumatoid arthritis. She has had salicylates and is now having phenylbutazone (1 tablet three times daily). Can you suggest any other treatment to retard the development of rheumatoid arthritis?

A.—Painful Heberden's nodes and fine crepitus in the knee-joints are signs of early generalized osteoarthritis, a condition which is extremely common in middle-aged women and which rarely causes serious crippling. Although the affected joints are painful in the early stages, this is followed by bony enlargement which is relatively painless. A more detailed description of the clinical and radiological features of this type of arthritis was published not long ago in the *British Medical Journal* (1952, 1, 181).

There is no evidence that this form of osteoarthritis predisposes to the development of rheumatoid arthritis, but rheumatoid arthritis is not uncommon in the sixth decade, and the two conditions may therefore coexist. Rheumatoid arthritis should be suspected if the following features are present: (1) Constitutional illness with weight loss; (2) cool, mauve, moist extremities; (3) marked soft tissue thickening around the joints; and (4) severe morning stiffness lasting two or three hours.

When there is any doubt, x-ray examination of hands and feet and a differential agglutination test for rheumatoid arthritis which is now done at most of the major rheumatism centres will help to clarify the diagnosis. Slight elevation

of the sedimentation rate is not uncommon in polyarticular osteoarthritis, but marked elevation will be strongly in favour of a concomitant rheumatoid process.

In generalized osteoarthritis rest of the affected joints and local warmth give the best relief of pain. Drug therapy with salicylates, phenylbutazone, etc., is generally less effective than in other rheumatic diseases.

Stilbamidine and Trigeminal Neuralgia

Q.—Can you give me any information on the use of stilbamidine in the treatment of trigeminal neuralgia? A patient of mine has shown me a cutting from an American newspaper on the subject, and I am anxious to know if there is any authentic basis for the idea.

A.—Stilbamidine has been used in the treatment of leishmaniasis. One author reports that half of a group of patients examined after such treatment had developed a trigeminal neuropathy. The patients complained of hyperaesthesia, paraesthesiae, anaesthesia, and formication in various parts of the trigeminal field. The symptoms arose three months after completion of a course of treatment and in one case had persisted for two years. Examination showed a loss of light touch sensibility with preservation of pain, both deep and superficial. These facts may have led to a trial of the drug in cases of trigeminal neuralgia. However, no reports of a series of such cases so treated (and followed for an adequate period afterwards) have appeared in the literature. The neurological findings above described would suggest that the drug would not be of value. Further, the paraesthesiae which the drug induces might add to the patient's difficulties, since it is well known that sufferers cured of trigeminal neuralgia by sensory root section or alcohol injection of the semilunar ganglion may be greatly troubled by paraesthesiae.

The Elderly Husband

Q.—A widower of 67 has recently married a woman of 35. He was worried beforehand whether he would be able to consummate the marriage successfully, and in the event he has proved impotent despite a course of testosterone propionate. Is his impotence likely to be due solely to psychological causes, solely to physical causes, or to a combination of the two? What treatment is advised?

A.—In view of his age, it is probable that his impotence is mainly physiological, but one would like to know how long he has been a widower, whether or not there was a decline in his sexual capacity in the latter years of his previous married life, whether sexual dreams and morning erections still persist, and a great many other things. The age at which sexuality disappears differs enormously in different individuals, some men retaining their potency well into the 70's and others ceasing to take any interest in sex in the late 50's.

If lack of intercourse is causing his wife distress and some treatment has to be attempted, I would recommend the implantation of tablets of testosterone, a form of therapy more effective than testosterone given by injection. Any psychological factors present will also have to be dealt with. The outlook is not good.

Amoebiasis in Children

Q.—In the treatment of amoebiasis in children (aged 3 years and over) what dosage of emetine is indicated? What other drugs are recommended for oral use or by enema, and in what dosage?

A.—Children between 3 and 8 years may be given one-third of the adult dose of emetine hydrochloride, emetine bismuth iodide, or di-iodohydroxyquinoline, those aged 8 to 10 one-half, children of 10 to 14 two-thirds, and those over 14 full doses. Only acute amoebic dysentery with trophozoites of *Entamoeba histolytica* in the stool should be treated with emetine by injection. Adults should be given 1 gr. (65 mg.) daily for three to four days, and this should

be followed by a full course of emetine bismuth iodide. Children are given proportionately smaller doses. If cysts of *E. histolytica* only are found, emetine bismuth iodide should be given without a preceding course of emetine hydrochloride. The adult dose of emetine bismuth iodide is 3 gr. (0.2 g.) given nightly for 10 nights. This drug may cause nausea and for this reason it should be administered in the evening and preceded by a mild hypnotic. Most patients will then sleep through the period during which nausea is most troublesome. In the unlikely event of nausea and vomiting being severe, emetine bismuth iodide should be replaced by di-iodohydroxyquinoline, the adult dose of which is 0.6 g. thrice daily for 21 days. There is no justification for giving anti-amoebic drugs by enema either to children or to adults, for it is now generally agreed that the results so obtained are not superior to those following routine treatment as here outlined.

Results of Surgery in Lumbar Disk Lesions

Q.—What are the immediate and long-term results of operating on properly selected lumbar disk lesions? Are there any special sequelae or complications to be taken into account when advising a patient?

A.—Where the proper indications for surgery are present skilled operative treatment of lumbar disk protrusions will in most cases bring rapid and lasting relief from symptoms. Crural pain is quickly and completely relieved in the great majority, and though low back pain persists in mild form more frequently, with proper post-operative management it is rarely severe or persistent. The long-term results in several large post-operative series of patients have been satisfactory, and the incidence of recurrent protrusion requiring a second operation has been no more than 5%.

The risks to life and function are extremely small, and where the indications for it are present—in particular when crural pain is severe and persistent—operation can be recommended with confidence.

Treatment of Black Tongue

Q.—What is the treatment of "black tongue"?

A.—The treatment of black tongue will depend upon the cause. If it is due to overgrowth of *Candida albicans* and allied yeasts, painting with 4% to 2% gentian violet will often lead to its rapid disappearance. When it is due to some chemical or other irritant and is associated with overgrowth of the filiform papillae, producing black hairy tongue, painting with trichloroacetic acid (30% to 90%) will frequently be effective. A course of superficial x-ray treatment (50–75 r at weekly intervals, to a total of about 300 r) is also very effective. I have found hydrocortisone lozenges (1–2.5 mg.) locally to be effective in the few cases in which they have been tried.

Books of "Any Questions?"—The second and third volumes of "Any Questions?" are available, price 7s. 6d. (postage 6d.), from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller. Each contains some 200 selected expert answers, and the third volume a cumulative index to the three published books.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: Atitology, Westcent, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 4499. TELEGRAMS: Britmedads, Westcent, London.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association, TELEPHONE: EUSTON 4499. TELEGRAMS: Medisecra, Westcent, London. B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

SIR HENRY DALE'S CONTRIBUTION TO PHYSIOLOGY*

BY

LORD ADRIAN, O.M., M.D., F.R.C.P., P.R.S.

Master of Trinity College, Cambridge

There is no one who could write adequately about the whole field of Sir Henry Dale's scientific work, but no one can write about any part of it without feeling that in this case our conventional labels and signposts are a mistake. Certainly he began in the early years of this century with work which would then have ranked as physiology, and he is now regarded by physiologists in every part of the world with the affectionate veneration we reserve for our greatest masters. But his first researches could be claimed now by the anatomists, his major contributions have enriched the fields of pharmacology and therapeutics, and, as head of the National Institute for Medical Research and President of the Royal Society, he has helped to guide the whole course of scientific work in Great Britain.

Labels, in fact, can only tend to obscure what all of us would wish to emphasize, that he has always been the leader who decides where the advance should go and never the subordinate commander, who must keep to one sector of the field.

No one could have led as Dale has done if his knowledge of the field had been limited to any one sector.

It is true that in the early years of the century, when he began his career in the Wellcome Research Laboratories, the field was a great deal smaller than it is to-day. Biochemistry had scarcely begun, no one measured H-ion concentrations, the hormones were few, and the vitamins had still to arrive. At that time Dale's grasp of the whole range of physiology and of the sciences which could assist it seemed remarkable enough. He could meet

pharmacologists, organic chemists, and clinicians on their own ground; he could use their methods as well as speak their language, and could see the bearing of a discovery in one department on the advance of another. But the marvel has been that he can still do so in spite of all the expansion of medical science in this half-

century, the entry of biochemistry and physical chemistry, the multiplication of hormones and vitamins and enzymes, and the proliferation of technical terms and methods of every sort. The great triumphs of chemotherapy have been in the field which he knows best, but it is difficult to think of any in which he cannot still hold his own.

Clarity of Ideas

Part of the secret must lie in the clarity of ideas which has always made it a pleasure to read his papers. The volumes of the *Journal of Physiology* in the years before the first war contain many classics, for those were the days when physiology could claim an undisputed leadership; there was also Langley's stern editing to make every writer keep to the point. Dale's papers then were among those which every student could

read and remember without any thought of the examinations ahead. They might deal with subjects of forbidding unfamiliarity— β -iminazolyethylamine, for instance—but as soon as one began to read them one could see why Dale thought the subject important, and before one finished it had become evident that he had made it so. He would use the standard techniques of the pharmacologist, the kymographic tracing of blood pressure and respiration and volume change: the records he published left no doubt that his experimental skill was of a very high order, but he avoided unnecessary

Sir Henry Dale, O.M.

Sir Henry Dale is 80 on Thursday, June 9.

The photograph is supplied by Walter Stoneman.

complications and unusual apparatus. There was no need to change the technique so long as it could give decisive answers, and they were decisive because the right questions were asked. In fact, he has been ready to adopt whatever new method would be more effective; but for Dale the technique has always seemed to follow the problem and rarely to suggest it.

Assembling of Evidence

This may do less than justice to the strategy which has led to so many advances. An attack cannot be planned without regard to the arms which can be employed, and Dale has always known where to find them and what to expect from them. His many collaborators and pupils have never found him set in his ways; it is rather that he can develop his theme with such knowledge and authority that in the completed account of an investigation we follow the argument and rarely stop to think of all the difficulties which must have been surmounted in assembling the evidence for it. Yet no one can have seen Dale at work in the laboratory or listened to his communications to the Physiological Society without realizing that it is the evidence which is all-important. Dale has never let his theories take charge: often enough his evidence has led to elaborate theorizing by others—about the role of histamine for instance, or about humoral transmitters in the nerve fibre. When such new horizons are opened it is hard to keep to the solid and familiar ground, but Dale has been more concerned to apply the brake than to be first in the gold rush. The gold he has found will keep its value.

Those who have listened to his lectures must often have been surprised to learn that he has never occupied a professorial chair at a university. He would have shone in teaching as he has in research, and medical education would have profited by his wisdom. But he has taught the whole body of physiologists throughout his career, through the medium of his published work and even more by his personal contact with them at congresses and symposia. For many years he has set the example at the International Congresses of Physiology by showing the rank and file how much more interesting a communication can be when it is clearly presented and illustrated. All of us are agreed that the kymographic records which bear the hall-mark of the National Institute for Medical Research have set a standard which few laboratories can hope to reach.

Such virtues are no doubt of minor account in comparison with Dale's specific achievements in the field of scientific investigation, but his effect on the development of medical science generally has been of major importance. Though he could not serve on the Medical Research Council when he was Director of the National Institute, his ideas have played a large part in the policy of the Council, and his direction of the Institute has led to many developments in fields remote from physiology and pharmacology.

To have remained as fertile in his own researches as Dale has done, as accessible and as encouraging to his juniors, and yet to have made his Institute famous for the variety as well as the standard of its performance is an index of talents and personal qualities which can only arouse our admiration. We cannot feel envy at the power to have accomplished so much; it is too far beyond our reach.

SALUTE TO HENRY HALLETT DALE

BY

OTTO LOEWI, M.D.

Foreign Member of the Royal Society

Sir Henry Dale's eightieth birthday is a welcome occasion for reflections on what science in general and scientists themselves owe to him. Such retrospection is especially gratifying to one who has had the good luck to enjoy Henry Dale's friendship for more than half a century. We met for the first time in 1903, in the small and poorly equipped, yet extremely creative and dynamic laboratory of Ernest Starling. Our interests and aspirations had much in common, and before long a close mutual relationship developed, from which emerged our lifelong friendship. This was deepened when, as time went on, our main interest and work coincided in the field of the chemical transmission of nervous impulses. That such a mechanism existed had been seriously considered first by Elliott (1904) and then by Dale (1914), because of the correspondence they had noted between the effects produced by adrenaline or acetylcholine and those due to the activities of sympathetic or parasympathetic nerves respectively. Later the chemical transmission of impulses from post-ganglionic nerves was established, and then Dale demonstrated, through ingenious planning, methods, and experiments, that the chemical transmission holds good to a much greater extent than I had realized. No better evidence of this can be offered than a quotation from a certain Harvey Lecture (1933): "I personally do not believe in a humoral mechanism in the case of striated muscle." Within the next year Dale demonstrated the chemical nature of transmission from spinal nerves to striated muscles. It was a discovery that made me happy, which may seem strange in view of the sentence just quoted. But it was not strange at all, for the fact stood forth that physiology owed and still owes to Dale the knowledge that the transmission of impulses from all peripheral, efferent nerves to their effector organs is of chemical nature.

It is fascinating to follow Dale's development from the very beginning. He was introduced to experimental medicine by some of the great physiologists of those days: Gaskell, Langley, Anderson, Starling, and Bayliss. At the age of 29 he accepted a post as independent research worker in the Wellcome Physiological Research Laboratories. He has since said: "I was attracted to the offer . . . by an instinctive feeling that it would be a good thing for me, at that stage, to be obliged to stand scientifically on my own feet, to find my own problems, to plan my own experimental attack upon them, to learn and devise methods for myself and to make my own mistakes." Dale's continual development ever since has fully justified the early confidence he had in himself. His scientific achievements, here dealt with in tributes from Lord Adrian and Professor Burn, were of such distinction that soon he became a leader in the fields of pharmacology and physiology and attracted a great number of ardent young associates from many lands. Endowed with imagination, strengthened by self-criticism, and urged on by a contagious enthusiasm and intellectual curiosity, he probed into the very roots of his problems and in doing so became an inspiring educator. He familiarized his students not only with facts, methods, and the art of observing and experimenting, but with ways of scientific thinking and

with the principles applicable to any field of experimental science. And more than all this, Dale became and has remained a scientific father and personal friend to his pupils. Small wonder that every single one of them cherishes a deep, unfaltering devotion to him.

In time the realm of Dale's interests expanded so widely that he became master of the essential problems in nearly every branch of experimental medicine. It became almost a routine for other men of wide scientific knowledge to turn to him for advice or to call upon him—again and again from across the Atlantic—to be the chief speaker at the dedication of research institutes. Hardly anyone else would have dealt with the possibilities of these institutes from so many angles or have so clearly indicated the direction research should take in the future. By such deeds Dale has shown himself to be a pre-eminent elder statesman in science.

For years Dale has been besought to deliver speeches on general themes and to commemorate famous men or anniversaries and to dignify special occasions. By consenting to the publication of a selection of such lectures and addresses in a book called *An Autumn Gleaning*, Dale has given us opportunity to broaden our knowledge of his thought and personality. He is as generous in appreciation of the achievements of others as he is modest about his own. In the introduction to the book just mentioned, he suggests that it may be "a late aftermath of weeds." I agree with the reviewer (Hugh Taylor, *American Scientist*, Vol. 43, p. 36, April, 1955) who calls the book "a golden harvest."

Dale's training at Trinity, one of the foremost humanistic colleges, may in part be responsible for his leaning to the historical aspects of science. He follows up the growth of ideas through the centuries and sees scientific developments in their proper setting. Over and beyond his education he possesses the capacity to grasp what is essential. His flair for the essential in any matter is generally recognized. English friends have related to me more than once that, whenever a scientific discussion becomes entangled, everybody eagerly waits for Dale to rescue it; he always makes the point.

Another characteristic of Dale's is his unusual talent to express the wealth of his thoughts by means of deeply penetrating words. More than that he has an artistic mode of formulation, which should serve the younger generation as a prototype of simplicity, lucidity, and beauty.

I finally desire to emphasize—have tried indeed to do it all along—that Dale's intellectual and aesthetic culture are attended by a strong ethical sense. He has a deep feeling of moral obligation. It shines through everything he writes or speaks. He has a genuine eagerness for any good cause.

To do justice to Dale's personality as a whole would require a big volume. In a short essay like this, only a few of his innumerable facets can be singled out.

The achievements of creative men in science, art, and music originate almost entirely from their aspiration to make the best possible use of their natural endowments. Doing so, they are happy and they do not claim gratitude. Their fellow men are grateful to them, in part because they benefit by their achievements, but for a larger reason as well, because these achievements testify to the heights that can be reached by mankind. Contemplating their deeds, we feel pride, courage, and optimism. On Henry Dale's eightieth birthday I feel joy in saying this to him:

Happy birthday, dear old friend.

SIR HENRY DALE'S CONTRIBUTION TO THERAPEUTICS

BY

J. H. BURN, M.D., F.R.S.

Professor of Pharmacology, University of Oxford

In considering Sir Henry Dale's contributions to therapeutics it is right to mention first his discovery of the action of posterior lobe pituitary extract on the uterus. Though he published no paper dealing specifically with the action of this extract until 1909, there is a record of the stimulant action on the uterus of the cat in his paper on "The Action of Ergot," which appeared in the *Journal of Physiology* in 1906. He pointed out the significance of this effect, since he had shown that the uterus of the cat in the non-pregnant state, unlike that of many other animals, was caused to relax by sympathetic stimulation and by the action of sympathomimetic amines.

Dale's main interest until the end of the first world war was in problems which were at first sight academic; his work on the action of histamine on the capillaries, however, had a great impact on clinical thought. It is hard to remember that up to 1918 the current view was that of Tigerstedt, according to which the capillaries lacked the power to contract and were purely passive structures. Dale and Richards in 1918 were the first to demonstrate that the vasodilator action of histamine seen in the body was due to capillary dilatation, and that a state of capillary constriction could be maintained under certain conditions in a perfused limb. This indicated that the capillaries behaved as though they had a tone of their own. Krogh's work, based on the direct observation of capillary changes and published only a few months later, confirmed and amplified the conception of independent capillary activity in great detail.

While the evidence of Dale and Richards and of Krogh was of interest mainly to physiologists, the work of Dale and Laidlaw on histamine shock brought the importance of capillary dilatation and of capillary permeability to the minds of physicians, surgeons, and pathologists alike. Dale and Laidlaw demonstrated that the injection of histamine into the cat anaesthetized with ether caused a profound and irreversible fall of blood pressure due to stagnation of blood in the widely dilated capillaries of the intestine, and that the blood in the main vessels became concentrated by loss of fluid through the capillary walls.

An interesting observation which is still not fully explained appeared in the first paper of the first volume of the *British Journal of Experimental Pathology*. Dale showed that when a cat was anaesthetized with ether or chloroform for some time, and then without operation allowed to recover, it remained for many hours highly sensitive to the effect of injected histamine. Collapse was caused by an amount of histamine one-tenth of that which was without effect on the cat before it received the anaesthetic.

Biological Standardization

The most important contributions to therapeutics were, no doubt, those which came under the heading of biological standardization. The importance of accurate dosage of drugs was always recognized by those who compiled the various pharmacopoeias, but its full gravity was appreciated only when the number of potent remedies underwent rapid

expansion. The appearance of agents the purity and potency of which could not be determined by chemical means gave rise to special problems, for it was not known how to measure these agents with any accuracy. For the antitoxic sera this did not matter so much. Provided that a patient was given not less than a certain dose of diphtheria antitoxin, no harm was done if he received more, and the doctor was satisfied if the manufacturer could assure him a potency which might be greater than the strength stated on the label but was definitely not less.

When the National Institute for Medical Research was established in Hampstead in 1920 there were two problems urgently needing attention. The one was the provision of a standard for the posterior lobe extract of the pituitary body, which varied widely in potency as made by different firms. A method for comparing the potency of two extracts had been described by Dale and Laidlaw in 1912, but there was no agreement between manufacturers about the strength of the extract which should be made commercially available to medical men. After its effect on the parturient uterus was discovered some doctors used it to accelerate the course of labour, and records appeared in the literature from 1910 to 1920 of patients in whom the injection of posterior lobe extract produced rupture of the uterus. In 1920 Dale therefore arranged an investigation, which established that of the extracts available in Britain the strongest was no less than 80 times the potency of the weakest. This meant that a doctor who used the product made by one firm at one time and the product made by another firm at another time might observe a completely different response on the two occasions. Since uniformity could result only when a common standard of reference was available, Dale investigated standards which had been proposed in the United States, showed that they were unsatisfactory because they were not prepared from the posterior lobe, and he suggested in their place a fresh extract of posterior lobe obtained by following a particular procedure. Actually this standard preparation was superseded in 1925 by the acetone-dried powder prepared in the laboratory of Carl Voegtlin, which was more suited not only to national but also to international use. The work, however, achieved a uniformity of potency in Britain from 1922 onwards.

The second problem which demanded attention at that time was presented by the manufacture of neoarsphenamine. German supplies ceased in 1914, and during the first world war the manufacture in Britain was controlled only by a test to ensure that the preparations administered to patients were not unduly toxic. By 1920 there were numerous reports that British neoarsphenamine was much less efficient in therapy than the original German product had been. Dale therefore arranged for tests for potency to be applied as well as for tests for toxicity, the tests for potency being made on mice infected with trypanosomes according to a method described by Voegtlin and Homer Smith. The results supported the clinical opinions and indicated that some samples of British neoarsphenamine were very weak. Not all manufacturers, however, were at that time willing to accept this evidence, and they protested that tests on trypanosomes in mice were not relevant to the cure of syphilis in man. Dale therefore arranged with Dr. C. F. White for a trial of a series of neoarsphenamine samples on men with a primary syphilitic lesion, in order to compare the results so obtained with the results in mice. The comparison provided a complete vindication of the mouse test, and from that time forward all samples of neoarsphenamine made in Britain were examined not only for toxicity but also for therapeutic action. There can be no doubt that Dale's effort in this matter, as in the matter of pituitary (posterior lobe) extract, was a contribution to therapeutics in Britain of very great importance.

The Introduction of Insulin

When Banting and Best announced the discovery of insulin and Macleod and Collip were assisting them to devise a method of preparing solutions for therapeutic use, Dale,

with H. W. Dudley as his companion, visited Toronto to learn at first hand of the progress of the work. This visit and the work which followed it enabled insulin to be made available in Britain in the shortest possible time as an agent which from the first was of nearly uniform potency.

The situation was full of dangers. The manufacture of a product like insulin was new to pharmaceutical firms in every country, and it seemed too great an adventure for any single firm in Britain. It involved the preparation of an unstable substance in sufficiently purified form for subcutaneous injection, from a tissue rich in an enzyme which could destroy the insulin, and full of other material. The preparation of insulin had defeated many who had attempted it on a small scale. What was now needed was a large-scale process which could be relied upon to produce insulin with regularity and at reasonable cost. This had to be accomplished with little guidance from previous experience of other tissues. For various reasons Dale sought to persuade the manufacturers who were interested to combine their resources, and it was as a result that the two firms Allen and Hanburys and British Drug Houses united to produce the AB brand. Much work was carried out by Dudley at the National Institute which enabled him to obtain insulin as a picrate, and in this way assistance was given in devising a commercial process. Frequent consultation between Dale, Dudley, and F. H. Carr greatly facilitated large-scale production.

Standardization of Insulin

Still more important, however, was the solution of the problem of standardization, which from the first constituted a serious obstacle to progress in purification. It was studied intensively under Dale's direction. The Toronto workers from the first attempted to measure insulin in terms of a rabbit unit, the definition of which was continually modified in the attempt to make such a unit satisfactory. Difficulty arose from the fact that the injection of the same amount of insulin into different rabbits, even when these were of the same sex and of similar weight, caused a fall of blood sugar which differed in magnitude in different animals. The measurement of the hypoglycaemia in different rabbits took considerable time, and for many months it was not obvious how the variation in the response of different animals could be overcome.

Dale's own view from the first was that the method of standardization could not succeed if it was to depend on a rabbit unit, and that it was essential that the method should be comparative, each preparation of insulin being tested in comparison with a standard preparation to determine the difference between them. This was the basis of Ehrlich's method of standardizing diphtheria antitoxin. Using this as the guiding principle, H. P. Marks, working under Dale's direction, finally arrived at an expression of the hypoglycaemic effect on a series of rabbits in terms of the mean effect in the group. This constituted an important advance which had far-reaching consequences. When a given dose of one preparation was injected into several rabbits the hypoglycaemic reaction of each rabbit differed, as has been pointed out. At that time the question seemed to be which of the different responses was to be regarded as the correct one. A revolution of thinking was required before it was realized that all the responses must be taken into account, and that the correct response was the mean of these very varying responses. Once this had been grasped, it was possible to determine a "dose effect" curve for insulin; that is to say, to determine for each of a series of doses of insulin the mean hypoglycaemic response in several animals.

At this stage a firm basis for insulin standardization had been laid down; it was carried out as a comparison of an unknown sample with a preparation specially kept for use as a standard, so that the potency of the unknown sample could be expressed in terms of the standard. The unknown might be four-fifths of the standard, or it might be one and a half times the standard; the number of units the unknown contained was then determined by the number of units

arbitrarily given to a certain weight of the standard. If it was decided to say that the standard contained 8 units in 1 mg., then it followed that if the unknown was four-fifths of the standard the unknown must contain 6.4 units per mg.

International Standardization

This procedure to-day may seem simple and obvious, but in 1923 and 1924 it was entirely new for a substance such as insulin. The success achieved had a very wide influence on the biological standardization of many other substances. Moreover, it came at a time when the establishment of international standards had been under consideration and provided a compelling reason for international agreement. At the International Physiological Congress in Edinburgh in 1923, Dale, Magnus, and others had considered the question of having standard preparations of various kinds, Magnus being specially concerned with a standard preparation of digitalis. As an outcome the Health Organization of the League of Nations arranged a conference in Geneva in 1925, of which Dale was the chairman. At that meeting international standards were agreed upon by the representatives of several countries for insulin, pituitary (posterior lobe) extract, neoarsphenamine and sulpharsphenamine, and for digitalis. This was a great achievement which was based on a careful organization of experimental work in different countries beforehand, and led to close and friendly relations between all the workers concerned. It meant, for example, in the case of insulin that a uniform system of measuring its potency was adopted throughout the world within four years of its discovery. Had Dale not succeeded in persuading the other members to adopt the comparative method of standardization, the meaning of "one unit of insulin" might well have remained obscure and the potency of different samples have shown wide variation for many years.

So successful was the Geneva Conference of 1925 that later conferences in 1928, 1934, 1935, and 1938 extended the list of substances for which international standards were provided almost as a matter of course. Since the second world war the work has continued under the World Health Organization, and the number of international standard preparations has reached fifty, with another fifty under consideration. How great a contribution this has been to therapeutics throughout the world it is quite impossible to indicate or measure. It is very largely due to Dale's skilful persuasion that instead of confusion there is order and co-operation in a field where national prejudices are sometimes just as capable of preventing agreement as in politics generally.

To conclude this account without reference to the changes in the treatment of myasthenia gravis resulting from Dale's work on skeletal muscle would be wrong. Papers by Dale and Gasser in 1925 and by Dale and Gaddum in 1930 pointed the way to the paper by Dale, Feldberg, and Vogt in 1936. The results described in the last paper stimulated Walker to use physostigmine in myasthenia and later neostigmine. Thereafter the symptoms of myasthenia gravis were for the most part brought under control.

"It is so easy to get the impression, from the popular acclaim which greets its real or imagined achievements, that the life of the research worker must be passed at a level of emotional tension rather like that of a gambler. In past years I have had more than one young man come asking for an opportunity to do whole-time research, and to be paid for doing it, with little to show in the way of credentials, beyond a dislike for the idea of teaching or practice, and a feeling that research must, by comparison, be full of excitement and fun. I did my best to correct that impression. The research worker, if he is successful, may indeed have his moments of discovery and seemingly sudden revelation, from which he may experience more than a momentary exhilaration; but, in spite of what popular report may suggest, such moments do not come merely by fortunate accident."—From *Autumn Gleanings*, p. 139, by Sir Henry Dale.

SIR HENRY DALE: HIS INFLUENCE ON SCIENCE

BY

HERBERT S. GASSER, M.D.

*Foreign Member of the Royal Society; Member Emeritus,
Rockefeller Institute for Medical Research*

At the International Congress of Physiology in Boston in 1929 it was easy to arrange a special luncheon in honour of Sir Henry Dale by those whom, at some time previously, he had graciously received as collaborators in his laboratory. The occasion was symbolic of the loyalty and affection of the group as a whole. Those present were holders, or were to be holders, of responsible positions in physiology, pharmacology, biochemistry, and internal medicine. There illustrated was the area of his influence but not its depth. To find an expression for the latter one has to range far from the favoured few who have been with him in his laboratory, and then reflect upon what measuring device can be invoked. In current usage, the adjectives sympathomimetic, cholinergic, and adrenergic enter into descriptions with the readiness of older examples of their kind, as vasoconstrictor or vasodilator. Out in the common domain their influence goes on, though their origin may be forgotten.

Sir Henry's first paper affords us a starting-point. Typical of first papers, its subject matter was probably assigned to him by his professor. It is not one of the sources of the great stream that would develop later and in times of flood overflow its banks to add fertility to the adjoining fields; but it presaged the kind of careful work that makes possible the development of each innovation upon a solid foundation of what has gone before. A half-century later it was to become of great use to me. Also, it supplies us with a date, 1900.

A few years before, the action of an extract of the suprarenal gland had been discovered. It was just becoming associated with the sympathetic nervous system, and the structure of its active principle was still unknown. Acetylcholine had long been in the chemical catalogue, with its pharmacodynamic potency quite unsuspected; and histamine was not yet even a chemical curiosity. Such was the background of the sector of the evolution in the physiological sciences in which Sir Henry Dale's influence was destined to be greatest.

Pure and applied science—why extol one above the other? Where, indeed, is the division? There is but one science: that which, by whichever of its methods, leads to verifiable facts and what can be done with them. For the youthful Dale the course of the main stream was long to follow the saga of ergot. Freedom he had. And it was from the part of his researches that would be called "pure" that the irradiation took place out into the world of physiology and pharmacology, long before the advent of any proper understanding of ergot as a therapeutic agent.

Out of the saga of ergot, as told in the previous papers, now omitting all reference to chronology or collaborators, there can be brought into focus two great sets of contributions: the delineation of the sympathomimetic amines and the description of the actions of the quaternary ammonium bases. Through the whole there had to be carried the theme of adrenaline, which

not long since had been announced. In spite of his early clarifying discovery of the ergotoxin reversal, and in spite of other useful contributions to the mode of its action, again and again he was forced to point out discrepancies in the interpretation of the various experiments.

So fundamental were these developments to an understanding of the control of the circulation, and later to ideas about the nervous system, that each one as it appeared sent its reverberations throughout the laboratories of the world in which these subjects were of interest. To follow them would require a recapitulation of the history of a chapter of the physiological sciences over a half century. But, impossible as is the tracing of irradiation of influence in brief statement, it is still possible to give some hint of how it operated, in an illustration pertaining to the regulation of the vascular system.

Ramifications from Isolation of Histamine

The isolation of histamine and the description of its action, in 1910, may be taken as the point of departure. Here it is convenient also to mention the adduction, seventeen years later, of the proof that histamine is a normal constituent of the body; whereby the growing suspicion that the substance has a physiological significance was confirmed. It was partly the destiny of the analysis of the vasodilator action of histamine to follow a course parallel to that of the vasodilator action of adrenaline. The way of the latter had its rough spots. Annoying differences between the actions of the sympathetic nerves and adrenaline kept obtruding themselves; and the problem of what maintains the vascular tone essential for relaxation by either substance kept resisting a satisfactory solution. Many years were to pass, then at last new light from several of the laboratories of the world: noradrenaline and 5-hydroxytryptamine, each in its way to remove some of the shadows.

In the early experimentation on histamine there occurred a brilliant example of a chance observation appearing before a "prepared mind." Diverted for a time, as the result of a fortunate accident, toward the interpretation of anaphylaxis, Dale in a fundamental contribution not only pointed out the strategy for future work but also supplied an important part of the tactics. The significance of antigen meeting antibody in the organs still stands. The "Dale" bath is still in use. Here is an influence with a history of its own extending throughout a specialty. It might be characterized as pertaining to an offshoot from what I have called the main stream, were it not for the fact that histamine, which opened the front door, again crept in at the back. Its re-entrance, however, is connected with a larger subject: tissue injury.

During the first world war physiologists turned their attention to wound shock. It is not for me to recount Dale's comparisons of histamine shock and wound shock, but to turn to the aftermath. At the time facts were missing, needed for interpretations. A forced conclusion was that there was no justification for assuming that histamine is the only cell constituent which injury liberates. In the subsequent history, with the entrance of heparin on to the scene, the incoagulability of the blood was accounted for. With the second world war came the description of "precapillary sphincters" susceptible to influence by products of tissue injury. More recently has come the claim that ferritin has such an action.

Through work in widely separated laboratories attention has been directed to mast cells. They first came into prominence when heparin was associated with their granules. Their prominence became enhanced when histamine was found in the same location. At last a source of bound histamine in the tissues, long postulated, had been found. Since these cells are widely distributed along the course of the

smaller blood vessels, they are well placed for participation in vascular reactions. Consequently, new perspectives of interpretation are opening up—as, for example, in relation to the triple reaction of the human skin. Histamine research has come to full flower.

In 1910 it would have been impossible for anyone to foresee the number and extent of the ramifications from the description of the action of histamine. Along each of the branches there has been a succession of investigators. Now, the groups situated at the growing ends of the branches, as they look back over their specialized histories, find a meeting-place at a common point.

One, indeed, wonders what some future commentator will have to say in addition; especially in view of the rapidly changing frontier in pharmacology. As a science, pharmacology itself has matured. From its origin, wherein it was devoted to experimental testing of the validity of its inherited accumulation of empirical lore, it has evolved to a stage at which its investigations can be guided by working hypotheses, comprehensive in their scope. Substances identified in the body have contributed largely to the therapeutic armamentarium. Bodies of unrelated facts have been brought together into an understandable whole. Some of the most powerful pharmacodynamic agents, like acetylcholine and histamine, have turned out to be highly important in the operation of physiological mechanisms, while chemical prowess has been able to prepare molecules with actions imitative or antagonistic. For other powerful agents, to the action of which no clue has yet been discovered, patterns of thought have come into existence to point out the way in which solutions are most probably to be found.

Significance of Acetylcholine

In a search for an analogy for the wave of curiosity that swept through the minds of physiologists in the early 'twenties, after Professor Otto Loewi published his famous papers, there rises into view recollections of what happened more than a century earlier. Just as in the earlier time everyone felt impelled to experiment with the Galvani fork, so in the later time there was a strong desire to see personally the experiment on the frog heart. For an understanding of the revolution that had been launched, familiarity with Dale's papers on the amines and quaternary bases had laid a solid foundation. Now his differentiation of the nicotine-like from the muscarine-like action of acetylcholine would mount into a position of enormous importance.

Much as he had done in contributing to the physiological world the basis for a receptive understanding of the rapid surge of events, it was Dale himself who was in the best position to make effective use of those contributions. How he influenced the course of events can henceforth be derived directly, step by step, from the description of the successive accomplishments by himself and his colleagues: finding acetylcholine as a normal constituent of the body, its liberation during synaptic transmission through sympathetic ganglia, and its liberation at myoneural junctions. As experimentation spread to a world-wide scale, sober expressions of doubt appeared on the one hand, and over-enthusiastic extrapolations on the other. These he met or modulated by powerful arguments in a succession of lectures, both at home and abroad. Who can say where we now stand in the history of chemical transmission? Certainly the subject has not evolved to a point whereby it can explain all transmission. If I am not misinterpreting a recent statement by Sir Henry, it amounts to a cautious intimation that there may be transmitters as yet unknown. Such an intimation could well be taken seriously.

International Recognition

As, year by year, Sir Henry's contributions became more and more interwoven in the general fabric of his science, international recognition of the originator of these contributions grew in proportion, expressed by the long list of his

honorary memberships in foreign societies with particular designations and national academies and societies of science and learning devoted to broader purposes. Thus he became an outstanding representative of that ideal of science which knows no frontiers, in an age when political disturbances engendered upheavals of a magnitude without previous parallel. When the storm abated it was apparent to all that not even science had emerged unscathed. To return to its proper position in society it must pass through a healing process. By virtue of his position Sir Henry was favourably situated to come forward effectively on behalf of the restoration; and he did.

The particular occasion to which I would refer, though it is not the only one, is that of his Pilgrim Trust Lecture delivered before the National Academy of Sciences at a joint meeting with the American Philosophical Society, held in Philadelphia in 1946. On his chosen topic, "The Freedom of Science," he talked calmly and objectively; but through his reasoned words there could not fail to shine light from

incandescent feeling behind them. It is always unfair to quote out of context even the choicest passages of a discourse of this sort. For those not among the favoured listeners the whole must be read in order to get its import.

It is the right and duty of every scientist boldly to examine nature without restriction of purpose or fear of outcome, and to communicate the findings openly in order that the aggregate can be tempered under the impact of general criticism. No surer way has ever been invented for determining the laws that cannot be transgressed with impunity in the course of human behaviour. If science has been misused, the misuse is without uniqueness among man's activities; and the way to salvation is not imminent through a study of cause and effect for science alone. True it is that the prime instinct of all living things is for survival. Although at times a retreat may be justifiable for the protection of both civilization and science in the long run, to prevent undue curtailment of the freedom of science in the name of survival, relentless vigilance is needed.

PULMONARY OEDEMA*

BY

GRAHAM W. HAYWARD, M.D., F.R.C.P.

Assistant Physician, St. Bartholomew's Hospital; Physician, National Heart Hospital

Pulmonary congestion and oedema are the most common manifestations of left ventricular failure, and may range in severity from the basal rales of chronic congestive failure to acute pulmonary oedema and attacks of cardiac asthma. More recently an intermediate group of cases with subacute pulmonary oedema has been recognized, caused by uraemia, malignant hypertension, polyarteritis nodosa, and the "rheumatic lung." Although the symptoms, signs, and radiological changes of pulmonary oedema are well recognized, its pathogenesis in heart failure is still uncertain, and until recently there was little information on the circulatory changes in the lungs in man. The occurrence of attacks of pulmonary oedema during the course of cardiac catheterization has enabled these changes to be studied, and the altered distensibility of the congested and oedematous lung has been investigated. These results have thrown new light on the problem of cardiac dyspnoea, and it is my purpose to review this recent work and to attempt to correlate it with the various manifestations of pulmonary oedema.

The subject of pulmonary oedema has been extensively studied by experimental physiologists, who have shown that in animals pulmonary oedema may be produced by increased pressure in the pulmonary capillaries, by increased capillary permeability caused by anoxia, phosgene, and certain other chemicals, notably the thiourea compounds, or by neurogenic vasodilatation of the capillaries with resulting increased permeability, the stimulus arising either from direct excitation of nervous centres, as in head injuries, or reflexly from stimuli arising in the heart or large vessels. The type of pulmonary oedema produced experimentally in a normal animal, however, bears little resemblance to the clinical attack of acute pulmonary oedema which occurs in a patient with a long history of chronic pulmonary congestion, and for this reason caution is necessary in applying the results of these animal experiments to man.

*St. Cyres Lecture, delivered on June 25, 1954, at the Royal Society of Medicine, under the auspices of the National Heart Hospital.

Acute Pulmonary Oedema

I shall use the term "acute pulmonary oedema" to include both cardiac asthma and paroxysmal nocturnal cardiac dyspnoea. These terms merely emphasize particular clinical features of the attacks, but the fundamental mechanism is the same.

Aetiology.—Most cases of acute pulmonary oedema are due to left ventricular failure caused by hypertension, coronary artery disease, or disease of the aortic valve. The group of cases with pulmonary oedema caused by cerebral vascular accidents or fractures of the skull is of particular interest in relation to the pathogenesis of the oedema (Cameron, 1948). In comparison with left ventricular failure, mitral stenosis is an uncommon cause of pulmonary oedema, and the high incidence of this symptom in recently published series of cases of mitral stenosis (Wood, 1954) is due to the recognition of the fact that the most spectacular results of mitral valvotomy are found in this particular group of cases.

Historical.—The clinical features of an attack of acute pulmonary oedema were fully recognized in the early years of the last century, and in 1832 James Hope, who first used the term "cardiac asthma," described the mechanism of the attack, and the circulatory measurements which are reported later are a striking confirmation of at least part of his theory. He wrote that "while the left ventricle was palpitating to disgorge itself, the right, acting in concert with it, deluged the lungs with an inordinate quantity of blood, whence ensued a paroxysm of dyspnoea."

Clinical Features

The clinical manifestations of acute left ventricular failure were fully described by Bedford (1939). Nearly always these attacks occur in patients with a background of chronic pulmonary congestion, as shown by the history of increasing effort dyspnoea and often orthopnoea. A short, dry, frequently repeated cough is usually the earliest symptom and may be associated with a sense

of oppression in the chest. At the height of the attack the most striking feature is intense dyspnoea, often with wheezing, and the increased effort of breathing is shown by the laboured respiration. The chest appears over-distended, and on auscultation a notable feature is the absence of added sounds in the lungs in the very early stages of the attack in spite of the intense dyspnoea.

In short attacks the lung may remain clinically dry throughout or a few rales may appear in the mid-zones or at the bases. In longer-lasting or more severe attacks signs of moisture soon appear and increase until, at the stage when frothy fluid is being coughed up, bubbling rales can be heard all over the chest. In less severe attacks there may be only nocturnal cough and wheezing on lying down, rapidly relieved when the patient sits up. Normal sinus rhythm and pulsus alternans are frequently present. Tachycardia is a constant feature, the rate frequently exceeding 120 a minute. The blood pressure during attacks rises abruptly, particularly in the hypertensive cases, the increase being caused by marked peripheral vasoconstriction as shown by the pallor and coldness of the skin. Cyanosis in the early stages, or in short attacks, is rarely marked, and if present is peripheral in type; during the frothy stage of a severe attack there is increasing cyanosis of central type.

In severe attacks death may occur from asphyxia, or signs of peripheral circulatory failure and shock may appear, cyanosis being replaced by a dusky grey colour of the skin, the blood pressure falls to a low level, and the pulse is rapid and feeble. The breathing now becomes shallow and is no longer laboured, and it is evident that the pulmonary oedema has been decreased by the onset of peripheral circulatory failure.

In mitral stenosis the attacks are sometimes of unusual severity and may fail to respond to the methods of treatment which are usually effective in attacks caused by left ventricular failure, so that an emergency valvotomy may be necessary. More often they are of shorter duration and may be precipitated by emotion, exertion, tachycardia from any cause, or enforced recumbency during cardiac catheterization (Lenègre and Scébat, 1952). During these short attacks dyspnoea is marked and there is often a little frothy blood-tinged sputum.

If acute pulmonary oedema is caused by failure of the left side of the heart there is nearly always a previous history of dyspnoea on effort due to chronic pulmonary congestion, but occasionally it may occur as the first symptom in a previously healthy person as a result of cardiac infarction. The usual pain of infarction may be absent, the patient rapidly becoming dyspnoeic and coughing up large amounts of frothy fluid. These cases should be distinguished from those in which the initial ischaemic pain disappears with the onset of shock and on recovery from shock pass rapidly into acute left ventricular failure with pulmonary oedema. In these patients the blood pressure falls, often abruptly, during the acute phase, and this contrasts with the rise in pressure which is the rule in the attacks due to hypertensive failure. The electrocardiogram will show the typical changes of cardiac infarction, although not infrequently these may not appear until several days after the onset of the attack. An attack of acute breathlessness at night occurring in middle-aged or elderly patients, with no previous dyspnoea and with no history of a recent respiratory infection with bronchospasm, may well be

caused by cardiac infarction, and if the blood pressure falls during the stage of intense dyspnoea this diagnosis is even more probable.

The rare cases of an acquired ventricular septal defect due to rupture of a septal infarct are interesting physiologically, as they illustrate the effect of a combination of a sudden increase in pulmonary blood flow due to the left-to-right shunt and damage to the left ventricular muscle in causing pulmonary oedema. In three cases I have seen in which the diagnosis was made during life, acute pulmonary oedema followed rapidly on the rupture of the septum; in two cases there was little response to treatment, and the patients died 7 to 10 days later. The third lived for a year with orthopnoea, recurrent acute pulmonary oedema, and severe right-sided failure. These cases present a striking contrast to those patients who have an acquired intracardiac shunt due to rupture of a sinus of Valsalva aneurysm into the right heart, with a healthy heart muscle, and in whom the sudden increase in pulmonary flow may not cause oedema of the lung. One such patient lived for over a year and died of a carcinoma of the rectum. A second went successfully through a pregnancy four years after the rupture of her aneurysm, and, even with the increased blood volume of pregnancy and the effect of the placental arteriovenous shunt, developed only minimal signs of basal congestion during the later months of pregnancy.

Rupture of an aortic valve cusp sometimes due to bacterial endocarditis may precipitate acute left ventricular failure, and severe pulmonary oedema may cause the death of the patient.

Physiological Factors

The factors responsible for the formation of oedema fluid in the lungs are fundamentally the same as those concerned in the production of oedema elsewhere in the body, and are (1) hydrostatic pressure relationships, (2) osmotic factors, and (3) the permeability of the capillary wall.

By impaction of the end of a cardiac catheter in a small terminal branch of the pulmonary artery it is possible to obtain pressure readings—"the wedge pressure" or "pulmonary capillary venous pressure"—which reflect with reasonable accuracy the pressure changes in the pulmonary veins and left atrium (Epps and Adler, 1953). The mean left atrial pressure measured in this way is usually 5 to 10 mm. Hg, and the true pulmonary capillary pressure cannot be less than this figure. The intrathoracic pressure variations with respiration will affect pressure in the capillaries and interstitial tissue equally, and so will have little effect on the effective filtration pressure in the capillaries, which in the normal lung is in the region of 5 to 10 mm. Hg.

The osmotic pressure of the plasma proteins in the pulmonary capillaries is the same as that elsewhere in the body—that is, 25 to 30 mm. Hg with the normal plasma protein level of 7 g.%. It is probable, however, that the effective osmotic pressure tending to prevent leakage of fluid through the capillary wall is appreciably lower than this. No information is available on the protein content of interstitial fluid and lung lymph in the normal human, but in normal animals there is considerable leakage of protein, which reaches a concentration of 2.5 to 3 g.% in the lung lymph with an osmotic pressure of about 11 mm. Hg (Warren and Drinker, 1942). If, as seems likely, the same happens in man, the effective osmotic pressure will not be more than 200 mm. Hg.

Studies of lymphatic flow in animals show that significant amounts of protein and fluid escape from the vessels into the interstitial tissue of the lung and are removed by the lymphatics. If the permeability of the capillaries is increased, either by anoxia or by capillary toxæmia, a

considerable increase in the amount of fluid escaping occurs and pulmonary oedema results, the oedema fluid having the same protein content as normal lung lymph (Drinker, 1945). The effect of neurogenic factors on the permeability of the capillary membrane has been the subject of much experimental work. Parts of the pulmonary vascular bed are certainly supplied with functionally active vasomotor fibres, and there is evidence, both clinical and experimental, pointing to some influence of the nervous system in the permeability of the lung capillaries (Daly, 1946), but the importance of this factor in human pulmonary oedema is still conjectural.

In the normal person the relatively low filtration pressure and higher osmotic pressure will reduce the transudation of fluid in the lung to a minimum, and any fluid which may escape is efficiently removed by the lymphatics. If, however, the filtration pressure in the pulmonary capillaries exceeds the effective plasma osmotic pressure, or if the permeability of the capillaries is increased in any way, fluid may pass through the capillary wall into the interstitial tissues of the lung. The barrier separating the plasma in the capillaries from the alveolar spaces in the normal lung is extremely thin, about 0.8 μ , composed of the capillary wall, thin interstitial tissue, alveolar lining membrane, and

FIG. 1.—Thickening of alveolar and capillary lining in mitral stenosis. ($\times 700$.)

mucin layer (Macklin, 1954); so that if the lymphatic channels, which start in this region, are unable to remove the fluid as fast as it is formed, it can readily escape into the air passages, to produce the frothy fluid of pulmonary oedema.

In mitral stenosis or chronic left ventricular failure transudation of fluid from the capillaries may be hindered by thickening of the basement membrane and the barrier layer may be much thicker, often as much as 15 μ (Fig. 1), due to thickening of the alveolar epithelium and structural changes in the interstitial tissue (Parker and Weiss, 1936), so that, even if there is interstitial oedema, fluid may not be able to pass readily into the air passages, and the lungs may be clinically dry. The absence of structural changes in the lung may be one reason why larger amounts of frothy fluid are frequently coughed up in attacks due to cardiac infarction than in those due to chronic left-sided failure, where intense dyspnoea may dominate the clinical picture of cardiac asthma.

Circulatory Changes During Acute Pulmonary Oedema

Until recently no accurate measurements of the circulatory changes in the lungs during attacks of pulmonary oedema have been possible, although the presence of pulmonary hypertension during the attacks has been inferred from the marked pulsation over the ventricle and pulmonary artery and the loud pulmonary

second sound (Bedford, 1939). A number of patients with mitral stenosis have developed acute pulmonary oedema during the course of pre-operative cardiac catheterization, and circulatory measurements have been made during these attacks. They were precipitated by a variety of causes, such as anxiety, prolonged recumbency, or exercise, and were usually short-lasting, but were apparently identical with the spontaneously occurring attacks; with cough, dyspnoea, and expectoration of frothy sputum. From personally observed cases and from reports in the literature (Gorlin *et al.*, 1951; Lenègre and Scébat, 1952; Lenègre *et al.*, 1953) measurements in 23 cases of pulmonary oedema have been collected, and in 6 cases studies before and during the attacks have been made (Fig. 2). Details of a small number of attacks of acute pulmonary oedema occurring in the course of physiological studies on patients with left ventricular failure have also been obtained from the literature.

In attacks due to mitral stenosis (Fig. 2) there is usually a slight to moderate increase in the pulmonary artery pressure before the attacks, and during the attacks the pressure

FIG. 2.—Haemodynamic studies in 23 cases of mitral stenosis with acute pulmonary oedema.

rises abruptly. The "pulmonary capillary" pressure before the attack was raised to between 25 and 30 mm. Hg and during the attack rose to a level between 32 and 54 mm. Hg. In 15 of the 23 cases the pressure was between 35 and 38 mm. Hg. The cardiac output before the attack was usually slightly below the average normal of 3 litres per minute per square metre. During the attack a slight rise in output is common, but this figure may be inaccurate because of the obvious difficulties of measuring the factors necessary for its calculation according to the Fick principle during an attack of acute dyspnoea. The pulmonary arteriolar resistance before the attacks shows a slight to moderate increase, and changes in resistance during the attack are variable. No case of acute pulmonary oedema occurred in patients with a very high resistance. The work of the right ventricle was increased in all cases, and its ability to carry out the work without any significant increase in the end-diastolic pressure is in keeping with the clinical observation that marked systemic venous engorgement is unusual during an attack of pulmonary oedema.

Catheter studies on patients during acute pulmonary oedema due to left ventricular failure are infrequent, but in all recorded cases the pattern is the same—that is, an abrupt rise in pulmonary artery and “pulmonary capillary” pressure, the latter in all cases exceeding 30 mm. Hg, and a slight rise or no change in cardiac output. The pulmonary artery/pulmonary capillary pressure gradient is usually unchanged during an attack. The arterial oxygen saturation before the attack was usually reduced—with figures between 84 and 96% saturation. In these short attacks a slight fall in arterial oxygen saturation sometimes occurred, as was to be expected, but it was surprising to find a number of patients with an initially somewhat low saturation who actually increased their arterial oxygen saturation during an attack which caused intense dyspnoea. In severe attacks there is profound arterial anoxia, with levels sometimes as low as 45% saturation.

Mechanism of the Attack

The level of the “pulmonary capillary” pressure in all recorded attacks of pulmonary oedema due to left ventricular failure or mitral stenosis has exceeded the plasma osmotic pressure, often by a considerable margin, and this would seem to be a clear demonstration of the mechanism of the attack. In the cases presented here this margin has been an appreciable one, as the effective plasma osmotic pressure is probably not more than 20 mm. Hg and the “pulmonary capillary” pressure has usually been over 35 mm. Hg. This may not, however, be the sole mechanism, as will be seen if the effects of exercise in patients with mitral stenosis or left ventricular failure are studied. In a group of patients with mitral stenosis, whose disability varied from Grade 1 to Grade 4, and many of whom gave a history of attacks of nocturnal dyspnoea, exercise for three to five minutes in the recumbent position produced changes in cardiac output, pulmonary artery pressure, and pulmonary capillary pressure which are exactly comparable to those recorded during acute pulmonary oedema, and yet in no patient did such an attack occur (Fig. 3). In patients with left ventricular failure, effort produces exactly the same change (Lewis *et al.*, 1953). Many patients tolerated this mild exercise well, and, in spite of a considerable elevation of “pulmonary capillary” pressure, in several cases to over 50 mm. Hg, no acute oedema developed.

There are several possible explanations for this discrepancy. One is that the thickening of the pulmonary capillary wall or alveolar lining described earlier hinders the escape of fluid from the capillaries into the air passages, and that this enables some patients to withstand the high pressures without clinical oedema developing (Araujo and Lukas, 1952). Another is that in acute pulmonary oedema the speed of transudation of fluid from the capillaries is suddenly increased, and in the absence of a significant increase in the rate of blood flow through the lungs this must be due

to an increase in capillary permeability. The lung capillaries usually allow some protein to escape, and in acute pulmonary oedema the protein content of the frothy sputum, the lung oedema fluid, and fluid from a hydrothorax, if this is present, contains from 2.5 to 3.5 g. of protein%. The idea that increased capillary permeability is responsible for acute pulmonary oedema has long been favoured by experimental physiologists, but the only factor, excluding drugs and poisons, which is known for certain to produce this effect is anoxia, and in the early stages of the attacks there is no evidence of anoxia. It is in the later stages of the attack that anoxia becomes important, and then it may well augment or perpetuate the clinical attack.

The idea of neurogenic factors altering capillary permeability is still a theoretical one, and many of the experiments which purported to demonstrate such an effect, such as injecting substances into the floor of the fourth ventricle (Cameron and De, 1949), have subsequently been shown to cause an increase of left atrial pressure to a level of over 30 mm. Hg (Sarnoff and Sarnoff, 1952). Clinically, the view that increased capillary permeability causes acute pulmonary oedema has always had many supporters, and this factor is often invoked to account for the occurrence of attacks in sleep or as a result of excitement, emotion, or anxiety. So far as the last factor is concerned, it is common to find that if during cardiac catheterization the patient is apprehensive the pulmonary capillary and pulmonary artery pressures rise, and with reassurance or sedation will fall to much lower levels. The action of morphine or the barbiturates in stopping attacks is commonly explained on the basis that they damp down pulmonary vasomotor reflexes, but the true explanation of the action of morphine may equally well be that it lowers capillary pressure by decreasing anxiety, decreasing the muscular movements which are increasing the venous return to the heart, and decreasing metabolism, which will lower the oxygen needs of the tissues and hence lower the cardiac output.

Factors Responsible in Mitral Stenosis

The factors responsible for this high pulmonary capillary pressure in mitral stenosis have been discussed by Gorlin *et al.* (1951), who showed that in the presence of severe stenosis a high left atrial pressure is necessary to produce a rate of flow through the narrowed valve sufficient to fill the ventricle in diastole and to maintain the cardiac output. In acute pulmonary oedema when the cardiac output is almost unchanged, tachycardia is a constant feature during the attack, and Gorlin *et al.* have shown that even a slight increase in heart rate of 10 to 15 a minute will shorten the diastolic filling period of the left ventricle and render necessary a higher pressure gradient across the mitral valve. Momentary disproportion between the output of the right

and left ventricle is a factor which may elevate the pulmonary capillary pressure, but with present techniques this cannot be detected. These changes in pulmonary capillary pressure are brought about by only a slight increase in pulmonary blood volume, owing to the relatively inelastic pulmonary venous and left atrial compartments (Ball *et al.*, 1952). These patients usually have only slight to moderate enlargement of the left atrium, and in patients with massive left atrial enlargement, commonly due to mitral incompetence, large volume changes are possible with relatively little change in pressure and attacks of acute pulmonary oedema are uncommon.

In attacks due to left ventricular failure the high left atrial

pressures are probably associated with a high left ventricular filling pressure, which is necessary to maintain the output of the failing left ventricle. The contrast between the performances of the right and left ventricles in pulmonary oedema is striking, the right ventricle carrying out increased work with a normal filling pressure and the left doing so only because of considerable increase of filling pressure.

It has recently been suggested (Burch and Romney, 1954) that active constriction of the pulmonary veins may be partly responsible for the rise in pulmonary capillary pressure—the so-called “pulmonary venous throttle mechanism.” In mitral stenosis the pulmonary veins at necropsy are often small and contracted (Holling, 1951), and in life have been shown by tomography often to be smaller than usual (de Bettencourt *et al.*, 1953). There is certainly a plentiful supply of nerve fibres to the pulmonary veins, but there is no proof that pulmonary venous constriction does in fact occur.

The conclusion to be drawn from this haemodynamic study is that acute pulmonary oedema in patients with cardiovascular disease does not occur unless the left atrial and pulmonary capillary pressures exceed by a considerable margin the effective plasma osmotic pressure. The additional factor of increased pulmonary capillary permeability may in some cases be responsible for the sudden outpouring of fluid, which eventually escapes into the air passages. The probable sequence of events is that there is initially acute interstitial oedema of the lung, but that the fluid is removed by the lymphatics and none escapes into the alveoli. This corresponds with the attacks of paroxysmal dyspnoea, during which the absence of moist sounds in the lungs is a striking feature. If transudation persists the lymphatics become unable to deal with the fluid, which then escapes through the barrier layer of alveolar epithelium and mucin to enter the air passage, and a frank attack of acute oedema with frothy sputum results.

The cause of the actual attack of acute pulmonary oedema can in most instances be explained by these haemodynamic changes, which increase pulmonary capillary pressure. Tachycardia, whether caused by emotion, anxiety, exertion, or infection, is responsible for many of the attacks, particularly in mitral stenosis. Attacks occurring during sleep are sometimes caused by the orthopnoeic patient slipping down in the bed and increasing the pulmonary congestion and oedema. Another explanation which has some evidence to support it is that sudden movement while asleep following a period of muscular relaxation may cause a considerable increase in the venous return to the heart. Continuous recordings of heart rates show that even in the healthy individual a transitory increase in the heart rate of 30 to 40 beats a minute may occur during sleep, and if this occurs in a patient with heart failure it may precipitate an attack (Christie, 1938).

Treatment

The recognition of the fact that acute pulmonary oedema does not occur unless there is a considerable increase in pulmonary capillary pressure places on a rational basis most of the methods of treatment which are effective in this condition, as anything which decreases the venous return or lowers the capillary pressure is likely by itself to stop an attack if given before the stage when there is severe anoxia which has increased capillary permeability. Venesection, limb tourniquets, or drugs such as theophylline with ethylenediamine act in this way, the latter also relieving bronchospasm. The ganglion-blocking drugs, such as hexamethonium, which produce peripheral vasodilatation and a fall in systemic pressure, are often remarkably effective in stopping attacks of acute pulmonary oedema, the dyspnoea being relieved soon after the blood pressure has been lowered by slow and cautious intravenous injection of the drug. The method of action of morphine has already been described.

Digitalis would seem to have an obvious place in the treatment of acute pulmonary oedema, as it increases the

efficiency and improves the emptying of the failing left ventricle. If given intravenously, for speed of action, it may sometimes have a marked pressor effect; and Bayliss *et al.* (1950) have described three cases of acute left ventricular failure which were caused in this way by digoxin. For this reason it is best given orally, and some additional more rapidly acting drug is necessary during the acute stage of the attack. General anaesthesia in patients with pulmonary oedema, prior to either mitral valvotomy or emergency surgery, often produces a remarkable improvement in the patient's condition and signs of oedema decrease and may disappear. The combination of a good airway, high oxygen content of inhaled air, and muscular relaxation with low venous return is probably responsible for this improvement. The frothy character of the oedema fluid due to its high protein and mucin content has led to the use of anti-foaming agents, given by inhalation, in the treatment of acute pulmonary oedema, and good results have been reported (Goldmann and Luisada, 1952).

Direct evidence of the value of lowering the pulmonary capillary pressure is given by the effect of a successful mitral valvotomy in relieving attacks of acute pulmonary oedema. The left atrial pressure is lowered, often to normal figures, immediately after valvotomy (Munnell and Lam, 1951), and the effect of this can be observed at the time of operation, when the congested and oedematous lung becomes dry and the dilated subpleural lymphatics shrink.

Any procedure which reduces chronic pulmonary congestion will diminish the danger of acute pulmonary oedema. Treatment between attacks with digitalis, salt restriction, and the regular use of the mercurial diuretics, with a sedative at night, will often lessen the frequency of attacks, and may stop them altogether.

Subacute Pulmonary Oedema

An unusual type of pulmonary oedema which is subacute in its clinical course is seen in several diseases, all of which are associated with left ventricular strain. It occurs in uraemia, acute nephritis, polyarteritis nodosa, malignant hypertension, and as the “rheumatic” lung in acute rheumatism. The pathological, clinical, and radiological changes are identical in all these diseases with the exception of some cases of polyarteritis. The lungs are solid and rubbery in consistency, particularly in the perihilar region. Histologically there are an early interstitial oedema and an intra-alveolar fibrinous exudate, later infiltration of the exudate with mononuclear cells and fibroblasts, and dilatation of the alveolar ducts, which are lined by a hyaline membrane (Hadfield, 1938; Doniach, 1947).

The fundamental difference between subacute and acute pulmonary oedema is that in the former the exudate clots and is then organized. Clinically there is intense dyspnoea, although the lungs may show no abnormality on clinical examination, and the scarcity of added sounds in the chest is in striking contrast to the extent of the lesion seen radiologically. Episodes of acute pulmonary oedema may be superimposed, often as a terminal event. The scarcity of added sounds in the lungs in this group is explained by the organization of alveolar exudate which has a high fibrin content. Occasionally in polyarteritis nodosa there may be extensive radiological and pathological changes in the lungs, although the patient has no signs or symptoms referable to the chest. In one such case the organizing exudate was almost entirely confined to the interstitial tissue of the lung. The histological and clinical picture of subacute pulmonary oedema suggests that it is due to a combination of altered capillary permeability and left ventricular failure.

Radiology

The radiological features of acute pulmonary oedema have been reviewed by Jackson (1951). The typical appearance consists of dense cloudy opacities spreading outwards from the hilar into the central parts of the lung, obscuring

FIG. 3.—“Pulmonary capillary” pressures in acute pulmonary oedema (A) and at rest and on exercise in mitral stenosis (B), and in left ventricular failure (C). (C drawn from data taken from Lewis *et al.*, 1953.)

the lung markings, and leaving the peripheral parts of the lung clear. If the lungs of patients dying with pulmonary oedema are x-rayed after removal from the body the opacities are seen to be much more extensive, clouding those parts of the lung which appear translucent in the ordinary film. The rapidity with which these changes disappear, often in less than 24 hours, and the distressed state of the patient account for the difficulty in getting adequate films in acute pulmonary oedema. In subacute pulmonary oedema the opacities are rounded and more definite, corresponding to the rubbery areas which are found at necropsy, and in addition the changes of ordinary acute pulmonary oedema may be superimposed.

Relationship between Pulmonary Oedema and Dyspnoea

Dyspnoea is the chief symptom of left heart failure and is seen in its most extreme form in acute pulmonary oedema, where the intense effort of breathing is obvious. The intensity of respiratory effort or the force exerted on the lungs can be measured in patients made dyspnoeic by exercise by recording changes in intrathoracic pressure, using an oesophageal catheter; and in heart failure this force may be almost as great as in the normal person, although the resultant volume of pulmonary ventilation is much less owing to the increased rigidity of the lung (Marshall *et al.*, 1954). The cause for the increased rigidity at rest is probably the structural changes in the lung previously described, and the further increase in effort is usually ascribed to passive congestion of the lung, although from animal experiments (Hayward and Knott, 1954) it seems probable that pulmonary oedema is a more potent factor than pulmonary congestion in increasing the rigidity of the lung.

The amount of blood in the pulmonary capillaries at any one time is only about 50 to 60 ml. in the normal subject (Roughton, 1945) and the amount of extra blood in them during passive congestion may be small. Kopelman and Lee (1951) measured the intrathoracic blood volume in patients with mitral stenosis and left ventricular failure and showed that, whilst in mitral stenosis it is normal and in left ventricular failure increased, no significant change takes place when recovery from failure occurs. Studies on the effects of exercise (Fig. 3) on patients with heart failure show that even with mild exercise the pulmonary capillary pressure may exceed the effective plasma osmotic pressure, so that interstitial oedema may well be occurring in this early stage in development of failure, but the lymphatics may be able to remove it before it enters the air passages. This is supported by the well-recognized clinical fact that the dyspnoea of early hypertensive heart failure can occur without signs of moisture in the lungs, although the chest x-ray film shows an increase in hilar markings, and the mercurial diuretics will cause a diuresis and improve the dyspnoea. The concept that lung oedema is responsible for the altered distensibility of the lungs and cardiac dyspnoea is supported by measurements of lung rigidity before and after mitral valvotomy.

Hayward and Knott (1955) showed that after a successful mitral valvotomy the distensibility of the lung is improved, and that on exercise the lung behaves as does the normal lung, no increase in rigidity occurring. The improvement can be attributed to the fall in left atrial and pulmonary capillary pressure, and these measurements provide one explanation for the marked improvement in dyspnoea which often occurs in spite of no significant change in cardiac output or pulmonary artery pressure or in the result of lung-function studies. Pre- and post-operative chest x-ray films in successful cases often show no appreciable difference, and this again suggests that changes in the pulmonary capillaries which are invisible in the chest film are responsible for the improvements in effort tolerance.

In acute pulmonary oedema the rigidity of the lung may be enormously increased and the intense respiratory effort may produce only a small amount of lung ventilation. Thus

in one patient the intrathoracic pressure swing was 30 cm. H₂O for each breath, with a pulmonary ventilation of only 18 litres a minute, in comparison with the usual figure in normal individuals of 5 cm. H₂O pressure swing at rest, increasing to 40 to 50 cm. H₂O on effort causing dyspnoea with a pulmonary ventilation of 90 to 115 litres a minute. An additional factor decreasing lung distensibility in pulmonary oedema may be surface tension changes in the lung due to the presence of the sticky mucinous fluid in the air passages and the congested alveoli. Bronchospasm, which is often a striking clinical feature of acute pulmonary oedema, is an important contributory cause of the dyspnoea by increasing respiratory resistance. The bronchial veins drain either directly into the left atrium or into a main pulmonary vein, and swelling of their small tributaries lying in the submucosa of the bronchioles, caused by a high left atrial pressure, may contribute to the bronchial narrowing (Marchand *et al.*, 1950).

Summary

Studies on the formation and removal of oedema fluid in the lung show that in cardiovascular disease pulmonary oedema does not occur unless the left atrial and pulmonary capillary pressures exceed the effective plasma osmotic pressure by a considerable margin.

Exercise in patients with mitral stenosis or left ventricular failure produces circulatory changes identical with those found during attacks of acute pulmonary oedema. The fact that acute pulmonary oedema does not necessarily occur in spite of a high pulmonary capillary pressure suggests either that the fluid is hindered in its escape into the interstitial tissue of the lung and air passages by the structural changes in the capillary wall and alveolar epithelium, or that it is rapidly removed by the extensive pulmonary lymphatic system.

In acute attacks of pulmonary oedema, in addition to the high pulmonary capillary pressure some unknown factor, possibly neurogenic, may suddenly increase the capillary permeability. All those procedures which are effective in the treatment of the acute clinical attack lower the pulmonary capillary pressure, which is invariably raised during it.

Subacute pulmonary oedema due to uraemia, malignant hypertension, polyarteritis nodosa, and the "rheumatic lung" is characterized by clotting and organization of the interstitial and alveolar exudate, and is probably caused by a combination of left ventricular failure and altered capillary permeability.

The increased rigidity of the lung which occurs on exercise in patients with heart failure and is responsible for the increased respiratory effort when the patient is dyspnoeic, and the low minute volume of ventilation, may be caused more by interstitial oedema of the lung than by pulmonary capillary congestion.

TREATMENT OF INTRACTABLE PAIN WITH LARGE DOSES OF MORPHINE AND DIAMINO-PHENYLTHIAZOLE

BY

F. H. SHAW, M.Sc., Ph.D.

AND

A. SHULMAN, M.B., B.S., B.Sc.

(From the Departments of Pharmacology and Physiology, University of Melbourne, Australia)

Morphine given as its salts has the world-wide reputation of being the most effective agent for the relief of pain and associated mental anguish. Its use in large doses for the relief of severe pain, of either medical or surgical origin, has been hindered by the risk of producing severe respiratory depression.

To date, the only substances known clinically to be active in combating this respiratory depressant effect have been N-allylnormorphine ("lethidrone," "nalorphine," "nalline") and, more recently, levallorphan (Eckenhoff and Funderberg, 1954). Lasagna and Beecher (1954) have studied the analgesic potentialities of mixtures of morphine and nalorphine, but, to date, no satisfactory clinical combination of these two drugs has been found that, in adequate therapeutic doses, does not produce some toxic effect.

In this paper we wish to discuss the clinical use, in 35 cases, of a morphine antagonist—namely, 2:4-diamino-5-phenylthiazole hydrobromide (D.A.P.T.) (Davies *et al.*, 1950)—which, while having in therapeutic doses little effect on the analgesic properties of morphine, reveals marked and lasting antagonism to its respiratory depressant effect and thus renders the clinical use of large doses of morphine a safe procedure.

The use of D.A.P.T. as a morphine antagonist in animals has been previously reported (Shaw and Bentley, 1949, 1952; Shaw and Shulman, 1955), and D.A.P.T. has also been used as a synergist with $\beta\beta$ -methylene-glutarimide (NP13, "megimide") in the treatment of barbiturate intoxication (Shulman *et al.*, 1955).

Pharmacology of D.A.P.T.

From the above animal experiments and from the clinical results obtained it would appear that the following are the facts of pharmacological importance regarding D.A.P.T.

1. It is a specific antagonist of morphine (Shaw and Bentley, 1955). It has been found to be specially effective in relieving the respiratory depression caused by excessive

doses of morphine, heroin, "omnupon," and the synthetic analgesics, pethidine, and methadone hydrochloride. The depth of respiration is increased rather than the rate. It appears sometimes to antagonize the vomiting and, usually, the constipation associated with morphine.

2. It appears to be a non-specific respiratory stimulant, especially by the parenteral route. Its use in barbiturate poisoning has been discussed already (Shulman *et al.*, 1955).

3. Prolonged administration of large doses of morphine—1½–2 gr. (80–130 mg.) thrice daily—in the presence of D.A.P.T. demonstrated that these doses did not lose their analgesic effect—or, at the most, the morphine dosage had to be increased by 30%. We feel it would be unwise on this evidence to claim that D.A.P.T. prevents the onset of tolerance, but in our series (30 cases continuing, some up to five months) there were no signs of development of tolerance or addiction. In two cases the injection of large—2-gr. (130-mg.)—doses of morphine thrice daily enabled us to reduce the total daily requirement when this had been given in small—½-gr. (32-mg.)—amounts at frequent intervals.

4. Whereas therapeutic doses will antagonize the respiratory depressant effect of morphine, an increase in the dosage will also antagonize its soporific action. A still higher dosage may leave the patient awake and mentally restless. This may be associated with transient muscular twitches, prolonged and forced expirations, and occasionally vomiting. Mental disorientation has been produced occasionally in the aged.

5. It seems to have a high therapeutic index (about 10) when used in animals or clinically, either as a morphine antagonist or as a synergist to $\beta\beta$ -methylene-glutarimide in the treatment of barbiturate intoxication. In the latter case doses of more than 0.5 g. have been given over a two-hour period with the production of neither acute nor delayed toxic symptoms.

6. It has no analgesic properties of its own when given by either the oral or the parenteral route.

7. Small doses have little effect on the blood pressure, but with a large intravenous dose (75 mg.) there may be a rise in blood pressure.

8. It is a stable white crystalline powder readily soluble in water (4%) at room temperature. Physiological solutions slowly hydrolyse, but refrigerated solutions have been shown to retain their activity for periods up to one week.

Some preparations of D.A.P.T. contain a toxic impurity, and it has been our practice to check all samples for toxicity by means of a "rat test"—that is, the LD₅₀ of a standard pure sample is compared with that of the new preparation.

Treatment of Severe Pain

Principle.—Before the new treatment can be successfully applied it is essential to discard an ancient concept—namely, that morphine is a dangerous drug. Up till now the use of morphine has been attended by the immediate risk of respiratory depression and the long-term inconvenience of tolerance. Both these dangers are now banished by the use of the thiazole derivative. Accordingly it is recommended that the present practice of the administration of small dosages of morphine at frequent intervals be abandoned. One should aim at large—1–2-gr. (65–130-mg.)—doses of morphine, which are sufficient to produce an analgesia of six to eight hours' duration and which nevertheless still keep the patient alert. These doses should be given at the initiation of the treatment. The great psychological advantage of never having the patient suffer severe pain cannot be too strongly stressed. The principle of the treatment therefore consists in giving gradually increasing amounts—½-gr. (16-mg.) increments—of morphine accompanied by D.A.P.T. (15 mg.) over a period of one (or two) days until the desired degree of analgesia is obtained.

Detail.—The patient will probably be receiving ½–1 gr. (16–22 mg.) of morphine. In the following, "treatment" means the injection of both morphine and D.A.P.T. and

the subsequent observations of respiration, etc. Inject $\frac{1}{2}$ gr. (32 mg.) of morphine, and 15 mg. of D.A.P.T. 30 minutes later—that is, when the maximum effect of morphine is being exerted—both injections being intramuscular. Observe respirations (and sedation) every 15 minutes for two hours. If the pain returns before the termination of six hours and the respirations have not fallen below 6–8 a minute, repeat the "treatment" with $\frac{1}{2}$ gr. (50 g.) of morphine and 15 mg. of D.A.P.T. (observe respirations as before). If the degree of respiratory depression should cause concern a dose of 10 mg. of D.A.P.T. may be repeated at 10-minute intervals (see Note 3). If the pain returns before the expiration of six hours, and the respirations have not fallen below 6–8 a minute, repeat the "treatment" with 1 gr. (65 mg.) of morphine and 15 mg. of D.A.P.T. (observe respiration as before).

At this stage pain of mild-to-moderate intensity should be receiving up to eight hours' relief per "treatment" without any undue sedation. The patient is now said to be stabilized.

In cases of very severe pain it may be necessary to give doses of morphine of up to 2 gr. (130 mg.) three or four times a day, in the following manner.

Inject $\frac{1}{2}$ gr. (90 mg.) of morphine and 15 mg. of D.A.P.T. (intramuscularly) and observe respiration, etc., as before. Repeat this "treatment" when pain returns or at the end of six hours. If the analgesia is still inadequate and the respirations have not fallen below 6–8 a minute give two "treatments" of $\frac{1}{2}$ gr. (100 mg.) of morphine and 15 mg. of D.A.P.T. If adequate analgesia is not obtained inject 2 gr. (130 mg.) of morphine and 15 mg. of D.A.P.T. When the patient has been stabilized, usually on the second day of treatment, the intramuscular injection of D.A.P.T. is replaced by the oral administration. A dose of 20 mg. (one tablet) of D.A.P.T. is given at the same time as the morphine injection. If the patient is unduly sedated during the day, the oral dose of D.A.P.T. may be increased up to 30 or 40 mg., and reduced to 20 mg. at night.

Notes

1. The plan of the procedure is simple. The patient is given graded doses of morphine (with D.A.P.T.) until respiratory depression (or sedation) is evident or an analgesia of from six to eight hours is obtained.

2. D.A.P.T. is an extremely safe drug. The dose is 15 mg. intramuscularly; as much as 100 mg. has been given without ill effect, but careful administration is advised as these high doses are approached.

3. Slow and irregular breathing is not a sign of respiratory danger, provided that the respirations are deep and cyanosis is not present. Under these conditions a rate as slow as 6 a minute is not dangerous. If at any time the respiration of the patient should cause concern—that is, if the rate should fall below 6–8 or the breathing be shallow, with cyanosis—further intramuscular injections of 10 mg. of D.A.P.T. may be made at 10-minute intervals until 60 mg. of D.A.P.T. has been given. It must be stressed that

D.A.P.T. will increase the depth rather than the rate of respiration. For more rapid action the D.A.P.T. may be injected intravenously.

4. It has been found easier to prevent the onset of pain than to alleviate it once it has occurred. Accordingly it is better to give four treatments a day rather than three if pain tends to recur at about seven hours.

5. Care should always be exercised in the treatment of the aged.

6. At night it is desirable to give a barbiturate cover or an injection of hyoscine—1/150–1/100 gr. (0.43–0.65 mg.).

7. If the patient has not received sufficient relief from a large injection (over 1 gr.—65 mg.) of morphine it is safe to repeat the injection (with D.A.P.T.) at any time after two hours.

8. If the patient's condition worsens as death approaches and the period of analgesia shortens, the dose of morphine may be increased by $\frac{1}{2}$ gr. (16-mg.) increments. The need to increase the D.A.P.T. is unusual, but it may be increased by 5–10 mg. in the presence of respiratory depression or undue sedation.

9. D.A.P.T. given in therapeutic doses to a morphinized patient causes practically no side-effects. Slight irregular flickers of the fingers, shoulder, and neck were occasionally observed, but these could not be differentiated from identical movements seen in the drowsy and deeply morphinized patient to whom no D.A.P.T. had been given.

In some of our early cases morphine and thiazole were given cautiously by continuous intravenous therapy. Such procedure has not been necessary in our later cases.

The Concomitant Use of Other Drugs

There are no pharmacological contraindications to the use of the following drugs with D.A.P.T.

1. Hyoscine.—This drug in larger doses (1/100 gr. (0.65 mg.) intramuscularly) increases the drowsiness and may extend the period of analgesia. It should be used only at night or in cases of very severe pain.

2. Atropine has a similar action to that of hyoscine, but less marked.

3. Barbiturate.—This drug may be used where it is felt to be of benefit, especially at night if sleep does not come easily.

4. Chlorpromazine ("Largactil").—This drug has been used in about 10 of our cases. Vomiting is usually lessened and the period of analgesia increased, but the patient is much drowsier.

5. "Marzine".—This new anti-emetic has been used in six cases of hyperemesis. The vomiting is usually prevented until the terminal stages are reached, when it appears to lose its efficacy.

A brief synopsis of two of the 35 cases investigated appears below. Further summaries are given in Table I. A list of the dosages required for complete relief is given in Table II. In all but four cases these dosages remained unaltered until death supervened. In the four cases mentioned—dose 1– $\frac{1}{2}$ gr. (65–80 mg.)—the dose had to be increased to 2 gr. (130 mg.) during the final two days.

TABLE I

Age and Sex (Years)	Condition	Before Treatment		Treatment		After Treatment Duration of Analgesia (Hours)	Duration of Treatment (Weeks)	Comments
		Dose of Morphine gr. mg.	Duration of Analgesia (Hours)	Morphine (gr.)	D.A.P.T. (mg.)			
F 35	Ca. breast, oedema arm	$\frac{1}{2}$ 22	2–3	2 I.M. q.d.	20–40 P.O.	6	18	Excellent relief of pain. No side-effects with large dose morphine over 4 months' period
F 42	Ca. cervix	$\frac{1}{2}$ 22	2–4	1 I.M.	8 I.M.	8–12	2	Slight mental disorientation due to secondary in brain or to morphine (?)
F 69	Melanoma of toe	$\frac{1}{2}$ 16	2	1 I.M. b.d.	8 I.M.	8–12	2	
F 65	Ca. breast, oedema left arm	$\frac{1}{2}$ 16	2	$\frac{1}{2}$ I.M. q.d.	20 P.O.	6–7	4	
F 55	Ca. breast	$\frac{1}{2}$ 22	1 $\frac{1}{2}$	1 I.M. t.i.d.	20 I.M.	8	1	Complete relief from severe pain. No side-effects
F 55	" femur	$\frac{1}{2}$ 32	2	1 I.M. t.i.d. 2 I.M. (terminal two days)	20 P.O.	8	12	
F 85	Gangrene left foot	$\frac{1}{2}$ 11	2–4	1 I.V.	6 I.V.	10–12	2	8 mg. D.A.P.T. gave signs of mental disorientation in old patient

				2 I.M. q.d.	20–40 P.O.	6–7	10	No mental disorientation. Hospitalized at commencement. One month later returned home
F 78	" breast	$\frac{1}{2}$ 16	1	$\frac{1}{2}$ I.M. t.i.d.	20 P.O.	8	13	
F 55	" femur	$\frac{1}{2}$ 16	2	1 I.M. t.i.d.	40 P.O. (day); 20 P.O. (night)	8	12	

TABLE II

Dose of Morphine to Give 8 Hours Analgesia	No. of Patients Receiving Relief
$\frac{1}{2}$ gr. (32 mg.)	2
$\frac{1}{2}$ gr. (48 mg.)	3
1 gr. (65 mg.)	8
$1\frac{1}{2}$ gr. (77 mg.)	10
$1\frac{1}{2}$ gr. (110 mg.)	6
2 gr. (130 mg.)	5
2 $\frac{1}{2}$ gr. (160 mg.)	1
	35

Case 1.—A woman aged 52 had cancer of the lower jaw with extensive metastases and was greatly emaciated. When seen she was receiving 8 gr. (0.52 g.) of morphine a day, in divided doses, with less than two hours' relief from pain. Vomiting and constipation were troublesome. The patient was stabilized with $\frac{1}{2}$ gr. (110 mg.) of morphine and 15 mg. of D.A.P.T. intramuscularly. During the next two days she was free of pain for six hours at a time and the vomiting and constipation were relieved. The dosage of morphine was then increased to 2 gr. (130 mg.) and 20 mg. of thiazole was given orally. Pain was relieved for eight hours, and she did not feel drowsy. The treatment continued for five weeks until the patient died. There were no untoward symptoms other than a transitory mild mental disorientation. This disorientation has been observed in other cases: it is mild and transitory, and appears to be due to the large doses of morphine rather than the D.A.P.T., as it has been observed only in the older patients.

Case 2.—A woman aged 38 with cancer of the breast, marked oedema of the left arm, and intolerable pain received no more than two hours' relief from $\frac{1}{2}$ gr. (16 mg.) of morphine. Treatment was begun, and the patient stabilized, on $\frac{1}{2}$ gr. (110 mg.) of morphine and 15 mg. of D.A.P.T. intramuscularly three times a day. There was complete absence of pain with a decrease in the incidence of vomiting, and the constipation was rectified. On the fourth day oral administration of D.A.P.T. (20 mg.) was substituted for intramuscular injection. Later the dose of D.A.P.T. given during the day was increased to 40 mg. at each "treatment" to combat slight sedation (the nightly dose remained at 20 mg.). Two months later the dose of morphine had to be increased to 2 gr. (130 mg.) three times a day; it is impossible to say whether this was due to development of tolerance or the increasing severity of the pain. There were no untoward side-reactions. The patient died after 18 weeks' treatment.

At the beginning of treatment this patient was very depressed. About one week after initiation her mood changed to one of cheerfulness and remained so until within one week of death. In about one-quarter of our cases we have noticed this favourable change in outlook. It does not appear to be a euphoria due to the morphine, but rather owes its origin to the D.A.P.T. This aspect is still under investigation.

Discussion

The adequate relief of prolonged and severe pain still remains one of the unsolved problems of medicine. To date, morphine and its analogues have been the drugs used, and these have been only partially effective in producing relief from severe pain. This is due to the fact that it has not been possible to administer sufficiently large doses to produce complete analgesia without evoking dangerous and undesirable side-effects such as respiratory depression, tolerance, vomiting, and constipation; especially in old and cachectic patients with poor hepatic and renal function.

The method here described, incorporating the use of 2:4-diamino-5-phenylthiazole hydrobromide (D.A.P.T.), permits the use of large doses of morphine, adequate to effect satisfactory analgesia, without the associated production of these dangerous and undesirable side-effects.

Special mention must be made of the apparent ability of D.A.P.T. to prevent or delay the onset of tolerance. This clinical observation, if substantiated by further work in progress, would make the action of D.A.P.T. unique in this regard.

As it is rare to have the opportunity of safely administering doses of morphine of the order of 1–2 gr. (65–130 g.) in a single injection, the following few points of physiological interest arising therefrom are worthy of mention.

The slow intravenous administration (20 minutes) of 1 gr. (65 mg.) of morphine sulphate with 1/150 gr. (0.43 mg.) of hyoscine hydrobromide exerts its maximum clinical effect

within 20 minutes. Given intramuscularly, the full effect is not exerted for 40 minutes. These observations are also borne out in dogs under electroencephalographic control.

The slow intravenous or intramuscular administration of 1 gr. (65 mg.) of morphine sulphate and 1/150 gr. (0.43 mg.) of hyoscine hydrobromide usually has little depressant effect on the blood pressure or pulse rate. An occasional fall in the systolic pressure of 5–15 mm. Hg. associated with a transient pallor of the skin and a subjective feeling of cold, is sometimes observed, but this is quickly followed by a warm, flushed, and slightly sweaty skin with a return to normal blood pressure and an accompanying subjective feeling of warmth.

It would be natural to compare the action of D.A.P.T. with that of N-allylnormorphine (nalline). A full clinical comparison will be given in a later paper (Shulman, in preparation).

Nalline by itself has certain opiate properties and is not free from undesirable side-reactions when given in therapeutic doses (Payne, 1954; and several others). D.A.P.T. in doses at least five times the therapeutic is almost without side-reactions of any kind.

Nalline produces withdrawal symptoms in patients who have received only a few doses of morphine. This we have never observed with D.A.P.T. in therapeutic cases. Indeed, if it were so, our method of treatment of intolerable pain would not be possible, as all our patients had been receiving morphine before the beginning of treatment.

Nalline itself may cause vomiting, and does not appear to antagonize that due to morphine.

Nalline would appear to antagonize the analgesic action of morphine. This is certainly not the case with D.A.P.T. in therapeutic doses. Lasagna and Beecher (1954) have tried unsuccessfully to evolve a combination of nalline and morphine in post-operative patients and healthy volunteers which would give the desired therapeutic effect of analgesia without the concomitant production of the associated unpleasant side-reactions of morphine, and have discussed the difficulties involved in obtaining such a clinically useful mixture.

In addition to the extensive series of cases given above, D.A.P.T. has been used in a few cases of neonatal asphyxia, in methadone hydrochloride poisoning, and for the relief of post-operative pain. In the last-mentioned example the ability of the patient to cough painlessly was important. It should now be possible to use larger doses of morphine pre-operatively in conjunction with D.A.P.T., perhaps by intravenous administration. Finally, the removal of the risk of respiratory depression due to morphine should lead to an extension of this drug's use in the fields where it is already of value—namely, "shock," coronary occlusion, obstetrics, etc.—and may open up new fields in anaesthesia.

We wish to express our thanks to the superintendent and staffs of the Alfred, Austin, Royal Melbourne, and Women's Hospitals, and the Peter MacCallum Institute, Melbourne, for their kind co-operation in this investigation. We are indebted to Professor W. Davies, of the Chemistry Department of the University of Melbourne; Mr. E. T. Rosenblum, of Felton Grimwade and Duerdins Pty., Ltd. (Melbourne); Monsanto Chemicals (Australia) Ltd., and Nicholas Pty. Ltd. (Australia) for their gifts of 2:4-diamino-5-phenylthiazole hydrobromide. We are most grateful to Miss M. Bell, Miss S. Loewe, Miss M. Parker, and Mr. W. Straffon for their kind assistance with this work. Finally, we especially wish to express our thanks to Professor R. D. Wright, Dr. Kaye Scott, and Dr. W. P. Holman, for their kindly interest and advice during this investigation. This work was partly aided by a grant from the National Health and Medical Research Council of Australia.

BLOOD CHOLINESTERASE VALUES IN EARLY DIAGNOSIS OF EXCESSIVE EXPOSURE TO PHOSPHORUS INSECTICIDES

BY

J. C. GAGE, Ph.D., B.Sc., F.R.I.C.

From the Imperial Chemical Industries Ltd., Industrial
Hygiene Research Laboratories, Welwyn, Herts

The phosphorus insecticides are a group of substances which owe their high mammalian toxicity to their inhibitory action on the enzyme cholinesterase located in the central and peripheral nervous system. Precautions to protect those engaged in the application of these insecticides are prescribed by the Agriculture (Poisonous Substances) Regulations, 1953, and similar action should be taken with regard to those engaged in their manufacture. If the precautions taken are inadequate, or are temporarily relaxed, the first sign of excessive exposure will be a diminution of the activity of cholinesterase circulating in the blood. Several surveys of the blood cholinesterase values of large groups of normal individuals have been published; these are necessary in order to provide a standard of reference whereby abnormally low values may be recognized. The results obtained reveal a wide scatter in both the plasma and the red-cell enzyme activities, though the coefficients of variation obtained by the various authors are consistent with one another (Callaway, Davies, and Rutland, 1951; Wolfie and Winter, 1952; Fleisher and Pope, 1954).

Callaway *et al.* (1951) have suggested that a better indication of a significant fall in blood cholinesterase activity would be obtained if a measurement on an individual is referred, not to the average value of a normal population, but to a series of readings on the same individual prior to exposure to an anticholinesterase, and they have recommended a statistical procedure for doing this. The present investigation was undertaken to extend this treatment by a study of the nature of the temporal variation of cholinesterase activity in normal individuals and thereby to establish criteria for the recognition of significantly low blood cholinesterase values.

Experimental

The selection of the individuals who took part in these tests was not random. Volunteers were requested, and from those who offered themselves were selected the ones who showed the widest range of cholinesterase values. The sex and occupations of the subjects are shown in Table II. The technique of taking finger-tip blood samples and the procedure for measuring cholinesterase activity were similar to those used by Wolfie and Winter (1952); wherever possible, duplicate blood samples were taken to permit the calculation of the experimental error. The tests were made only when the subjects were in sufficiently good health to continue their normal employment, and none at any time came into contact with phosphorus insecticides or any other known cholinesterase inhibitor.

Experimental Results.—The results obtained from the cholinesterase measurements are displayed graphically in the Chart. Where duplicate blood samples were available, the points on the graphs are the mean of the pairs of determinations.

Experimental Error.—For the calculation of the experimental error, 119 duplicate pairs of red-cell samples and 135 duplicate pairs of plasma samples were available. From these duplicate measurements red-cell and plasma variances due to combined sampling and measurement error were found to be 24.3 and 33.3 respectively, corresponding to

Monthly red-cell and plasma cholinesterase values, showing individual average values. The reference letters correspond with those in Table II.

standard deviations of 4.93 and 5.77. In order, therefore, that two single determinations should be regarded as significantly different ($P=0.05$) they must differ by at least 14 units for red cells and 16 units for plasma, or, if the averages of duplicate determinations are being compared, by 10 and 12 units.

Monthly Averages and Variances

Table I shows the averages of the monthly groups of determinations and the monthly variances which are a measure of the variation of the individual values within these groups. There is no evidence to suggest, and no reason to suppose, that these variances are not homogeneous, and the combined variance within the monthly groups can be shown by the usual method of analysis of variance to be 99 for red cell and 283 for plasma. These two terms are a measure of the scatter of cholinesterase activities in normal individuals; the coefficients of variation derived from them are 12.8 and 21.3 respectively, which are within the range of the figures quoted by Callaway *et al.*

TABLE I.—Monthly Averages and Variances

Month	Red Cell		Plasma	
	Average	Variance	Average	Variance
June, 1953	79.7	92.1	79.6	185.8
July	82.3	69.6	83.3	297.0
August	75.6	145.0	75.2	376.6
September	76.1	192.4	81.6	425.8
October	72.3	138.8	77.6	297.3
November	71.9	146.8	80.2	257.4
December	79.2	93.0	80.7	271.3
January, 1954	80.0	62.9	82.0	366.0
February	77.4	71.4	78.8	246.2
March	82.2	105.5	81.1	190.1
April	77.9	49.5	76.8	194.5
May	76.1	78.7	73.6	254.2

A comparison of the monthly averages gives no indication of any real seasonal variation in the cholinesterase values, nor any change in the quantitative interpretation of the method of measurement. Analysis of variance does not conflict with this impression; there is no evidence of any significant difference between the monthly averages of the plasma values, while the red-cell averages show a difference with a low order of significance (P between 0.05 and 0.1).

Individual Averages and Variances

It is evident that if a series of measurements of a variable property, such as enzyme activity, are made on an individual, the results will approximate more closely to one another the shorter the interval between the measurements. As the interval increases, the dependence of a result on that of the previous determination decreases, and when the interval exceeds any periodicity in the fluctuation of the enzyme activity the results will be scattered randomly round the average value. An inspection of the graphs in the Chart reveals that this interdependence or serial correlation does occur to some extent and is manifest by a secular drift around the average value, but it is broken up by completely random variations. The individual variances reported in Table II range between 165 and 18.8 for red cell and 158

TABLE II.—Individual Averages and Variances

and 15.3 for plasma cholinesterase. The Bartlett test fails to show any significant difference between these variances; the conclusion should not be drawn from this that the variances are equal for all individuals, but that the evidence is not sufficient to discriminate between them. Nevertheless, the usual method of analysis of variance is sufficiently valid, and this reveals the expected highly significant differences between the individual averages, although the scatter of these averages is considerably less than that of single determinations.

The variance between the groups of individual figures, calculated by analysis of variance, may be regarded as an estimate of the variance of the basic individual red cell and plasma values, independent of temporal variation; these variances were calculated to be 43 and 211 respectively. These figures give rise to coefficients of variation of 8.4 and

18.3 compared with 12.8 and 21.3 derived from the variances of single individual values quoted above. These observations demonstrate that the scatter of single enzyme measurements on a large number of individuals derives from differences in the basic cholinesterase activities of the individuals, amplified by the deviations from these basic values which operate at the time of measurement. These deviations are themselves compounded of the variation due to experimental error and temporal changes in the blood cholinesterase activity due to causes at present unknown. There is an indication from the graphs in the Chart that for most individuals the same general trends exist in the temporal variation of both red-cell and plasma cholinesterase, yet there is clearly no close correlation between them.

The method derived by Callaway *et al.* for the recognition of significant decreases in blood cholinesterase activity may now be examined in the light of the above observations. These authors considered that the significance of the deviation of a value from the mean of n previous values on the same individual is given by the expression $s\sqrt{(n+1)/n}$, where s is an estimate of the standard deviation of the distribution of values round the individual average; s was calculated from repeated measurements of the blood cholinesterase activity of a limited number of young Service men. This treatment is based on the assumptions that the individual values are randomly scattered round the individual averages and that the variances are homogeneous, both of which are not entirely in accordance with the experimental findings described above. An alternative statistical treatment of the results, involving an attempt at a mathematical study of serial correlation, can hardly be justified, as all the information contained in the experimental figures which is relevant to the application of these cholinesterase measurements may be extracted from the Chart by inspection.

Criteria for the Assessment of Excessive Exposure

From the information derived from the present investigation it is possible, when confronted by one or more cholinesterase values in an individual, to form an opinion whether the values are so much below the average value for the population or a decrease between two successive readings is so large that an abnormal fall in blood cholinesterase activity has occurred. Such a procedure would enable the non-observance of safety precautions, or faulty operation of plant or of apparatus used in the production or application of phosphorus insecticides, to be deduced from blood cholinesterase measurements on those engaged on these operations. If, however, the tests are regarded as a method of diagnosis of the early stages of poisoning and as a means of deciding whether a man should or should not continue in his employment, then it is necessary to define a value below which the symptoms of poisoning may be expected to manifest themselves. This is a matter of considerable difficulty, as there is little agreement in the literature on this point (Garlick, 1950; Brown and Bush, 1950; Grob, Garlick, and Harvey, 1950; Barnes and Davies, 1951; Williams and Griffiths, 1951; Kay *et al.*, 1952).

Moreover, there is evidence that a man with a decreased cholinesterase value may remain without symptoms and yet be in a hypersensitive state which will cause him to react strongly to a further absorption of the anticholinesterase, to which, in the absence of a previous exposure, he would not be susceptible (Davies and Nicholls, 1955). It is therefore desirable, when there is reason to suspect an abnormally low value, not only to search for the cause but to remove the subject from the range of the phosphorus insecticide until his blood cholinesterase value has returned to normal.

In applying cholinesterase measurements to control the manufacture and use of phosphorus insecticides it is understandable if, in order to gain a larger margin of safety, somewhat narrower limits of normality are defined than the experimental evidence justifies, and a number of normal individuals are thereby classed as victims of excessive

exposure. Yet it must be remembered that this method will fall into disrepute, and lose that energetic co-operation from management and men which is essential to it, if men are too frequently taken off work or there is an interruption of production or application processes when no clinical symptoms are apparent, nor any evidence of unsatisfactory working conditions.

Owing to differences in technique and in the definition of units it is not always possible to make direct comparisons between cholinesterase activities measured in different laboratories. Nevertheless, the ratio between two values determined in the same laboratory should be comparable; a statistic such as the coefficient of variation, which is itself a ratio, can be regarded as a property of the population under investigation and independent of variations in technique. In order that the deductions from the present investigation should be generally applicable, all quantitative terms have been presented as ratios based on the relevant average value for the population; and before any laboratory can apply these or any other recommendations of a like nature it is necessary that an adequate estimate of this statistic should be determined. This should be based on cholinesterase determinations on as many randomly selected normal individuals as possible; the number should not be less than 20.

The approach to the significance of a single blood cholinesterase measurement on an individual varies according to the previous history of cholinesterase measurements. If no value previous to contact with phosphorus insecticides is recorded, then the distribution of single measurements of cholinesterase activity on a normal population must be invoked. The present investigation gives population averages of 77.7 and 79.2 for red-cell and plasma cholinesterase values respectively, with standard deviations of 9.9 and 16.8. There is therefore a one in forty chance that a normal individual will have a plasma and red-cell cholinesterase value less than 57.8 and 45.6—that is, 74.3% and 57.5% of the average values respectively. It is suggested that if a red-cell or plasma cholinesterase value of an individual in contact with phosphorus insecticides is found to be less than one-half of the population average, it should be regarded as a sign that appropriate action should be taken—that is, he should not be allowed to continue in his employment and the process and precautionary measures should be carefully scrutinized. If a value between 50% and 60% of the population average is encountered it should be regarded as an alerting signal to stimulate an active supervision of the process; in particular, frequent blood cholinesterase measurements should be made in those concerned in the process. If the single cholinesterase determination has been made in order to confirm suspected symptoms of anticholinesterase poisoning, then there need be no hesitation in accepting a value below 60% of the population average as confirmatory evidence.

The procedure just outlined is bound to miss small but significant decreases in cholinesterase in subjects whose normal activity is high. If one or more pre-exposure values on an individual are known, these provide some indication of the individual's normal value, and it seems desirable to modify the above recommendations by requiring that appropriate action be taken if an individual is found to have a cholinesterase value one-half of the population average or one-half of the average of his pre-exposure values, whichever is the higher.

Regular Testing

The most desirable procedure is the regular testing of all individuals engaged upon, or likely to be engaged upon, the manufacture or handling of phosphorus insecticides. From an inspection of the graphs obtained by plotting the results obtained from such regular tests, the pattern of the normal cholinesterase values may be determined and any departure therefrom recognized. The individual graphs of the Chart reveal drifts around the individual average interspersed with random fluctuations of varying magnitude. In no case is

any value inferior to that of the previous month by more than 30 units, nor are any of those approaching this value maintained into the subsequent months. It is recommended, therefore, that if in such a systematic series of tests a decrease of more than 40% of the population average is encountered it should be regarded as a reason for taking the appropriate action defined above, and if the fall is between 30 and 40% of the population average then supervisory measures should be made stricter. There is not sufficient evidence to indicate the extent of any likely downward drift in normal individuals, but it is suggested that the condition should be suspected if the value approaches 60% of its pre-exposure value.

The separate determination of red-cell and plasma cholinesterase has been stated to present a diagnostic advantage in cases of poisoning by anticholinesterases (Grob *et al.*, 1950). If the experimental procedure is restricted to the enzyme activity of whole blood there is a considerable saving of time; the criteria suggested above would equally apply to such measurements.

Summary

The red-cell and plasma cholinesterase values of 19 normal individuals have been measured at monthly intervals for a period of one year. The distribution of the monthly values on each individual is not entirely random, there being some measure of serial correlation. There is no clear evidence of any seasonal variation in the values.

The distribution of all the values on all the individuals has a coefficient of variation of 12.8 and 21.3 for red cell and plasma respectively. The contributory factors to this variation are discussed, and it is shown to be compounded of a basic individual variation, increased by the experimental error of measurement and individual temporal variations of unknown origin.

The establishment of limits of cholinesterase activity, whereby excessive exposure to phosphorus insecticides may be recognized, is discussed.

I am indebted to Dr. O. L. Davies for valuable advice and criticism of the statistical treatment of the results, to the subjects for their patient co-operation, and to Miss Sylvia Morrissey and Mr. Z. S. Berczy for technical assistance.

Claimed to be Britain's first secondary school for spastics, the Thomas Delarue School was opened recently by the National Spastics Society at Dene Park, Tonbridge, Kent. This is the first of five special schools which the Society and its groups will open this year. Eighteen children from a number of towns and cities in England and Wales will be admitted to the Thomas Delarue School this term, and it is hoped eventually to accommodate 45 handicapped boys and girls. Education up to general certificate level, combined with treatment, will be provided. A second school was opened on May 11 at Craig-y-Parc, Cardiff. Twelve children aged from 5 to 16 from towns and cities in Wales and the West of England will be the first pupils, but it is hoped that facilities will eventually be available for 35 to receive education and treatment.

A FIELD TEST FOR THE ASSAY OF HUMAN WHOLE-BLOOD CHOLINESTERASE

BY

D. R. DAVIES, M.Sc., F.R.I.C.

AND

J. D. NICHOLLS

The Chemical Defence Experimental Establishment,
the Ministry of Supply, Porton

The level of cholinesterase (ChE) in the blood is a valuable index of the amount of anticholinesterase which has been absorbed into the system, and it has in fact been used for this purpose (Metcalf, 1951; Davies, 1952a; Marchand, 1952). Since anticholinesterases are being used extensively in agriculture and for insect vector control—very often far removed from laboratory facilities—the determination of such an index under field conditions would be useful. The essential requirement of a field test is simplicity. The procedure and equipment required should be simple, few reagents be necessary, and the time taken for the performance of the test be reduced to a minimum. Finally, the test should be sufficiently uncomplicated to be carried out by non-specialist personnel.

Aldridge and Davies (1952) have discussed the possibility of applying the generally used techniques for ChE assay to field conditions, and came to the conclusion that, for reasons given, these were unsuitable. They did, however, suggest that the electrometric method of Michel (1949) was satisfactory under certain circumstances. They based their suggestion on the fact that this technique lent itself to the rapid and easy estimation of considerable numbers of samples. While subsequent experience has shown this to be true, there are two major disadvantages. The pH meter is not reliable enough to use in the field; and the glass electrode is most certainly too fragile for this purpose.

Fleisher and Pope (1954) have applied the Hestrin (1949) colorimetric method to the estimation of whole-blood ChE. Their method possesses the advantage that it is a colorimetric technique and that single estimations can be completed, including the collection of the blood sample, in twenty-five minutes. Its disadvantages as a field test are (1) relatively few tests can be performed in a given time, and (2) at least six reagents and an equally large number of manipulative processes are involved. Furthermore, the technique requires the use of a spectrophotometer.

Limperos and Ranta (1953) have described a test which they have used under field conditions and which approximates to the requirements. The principle is the same as that of the electrometric method. The differences are (1) that changes in pH are followed by changes in a bromthymol blue (B.T.B.) solution incorporated in the reaction mixture, and (2) the test is carried out in an unbuffered medium. The levels of enzyme activity are assessed by the colour of the solution after a given interval of twenty minutes, and these colours are green, olive green, olive brown, and orange. In practice the distinction between the first two and the second two is difficult. This is a serious disadvantage, since (as is shown below) this is the important range. A second major disadvantage is that under certain conditions of illumination the combination of blood and B.T.B.

appears to fluoresce. When this happens colour assessment is almost impossible. Despite these difficulties a relatively slight modification of procedure has been shown to give a workable and satisfactory test. If a fixed colour change is taken—for example, from green to orange—and the time for the change to occur is observed, these difficulties are overcome.

Experimental

Apparatus.—Tubes 3 by $\frac{1}{8}$ in. (7.5 by 1 cm.) (one for each test). Pipettes: 10 ml. graduated in 1 ml.; 5 ml. graduated in 0.5 ml.; 20 c.mm. haemoglobin pipette. Rack to hold ten 3 by $\frac{1}{8}$ -in. tubes. Watch to read accurately in minutes. Triangular needles, 1 packet. Thermometer.

Reagents.—Two solutions only are needed. (1) Acetylcholine chloride ampoules (Roche Products), 0.6% solution. Dissolve the contents of six 0.1-g. ampoules in 100 ml. of distilled water. This solution can be stored at 20° C. for a period of five or six days without deterioration, and provides sufficient solution for 200 tests. (2) Bromthymol blue: (a) Stock solution, 0.04 g. of powder is dissolved in 1 ml. of N/20 sodium hydroxide. Approximately 90 ml. of distilled water is added and then sodium hydroxide, dropwise, until the solution just turns blue. The total volume is made up to 100 ml. The pH of this solution should be 7.7, and if it is possible, since this solution can be made up in the laboratory, it should be checked with a pH meter. (b) For use, dilute two volumes of stock solution with one volume of distilled water.

Technique.—Collect 20 c.mm. of blood in a haemoglobin pipette and wash it out into 1 ml. of dilute B.T.B. solution contained in one 3 by $\frac{1}{8}$ -in. tube. Add 0.5 ml. of acetylcholine chloride solution and note the time of addition. Note the exact time at which the colour of the reaction mixture becomes deep orange. The interval is a measure of the enzyme activity. To facilitate the determination of the end-point, a standard* is easily prepared as follows: Blood and B.T.B. solution in the above proportions are added to a tube and then 0.15 ml. of N/100 acetic acid. The volume is then made up to 1.5 ml. (The pH should be 6.7.)

Results

If the time interval over which the requisite colour change occurs is determined precisely, then the assessment of whole-blood activity correlates closely with determinations made by the electrometric method. This is shown in Fig. 1. In this figure the reciprocal of the time

(T) taken to effect the given colour change at temperature (t) is plotted against the activity of the sample in $\Delta pH/\text{hour}$ always determined at 25° C. (For convenience the actual ΔpH value has been multiplied by 100 throughout.) In this case t was between 19 and 22° C. The close correlation between $\Delta pH/\text{hour}$ and T is obvious from the graph.

The relative activities of different specimens at varying temperatures have been plotted against the temperature, the activity at 20° C. being taken as equivalent to 100. The relative activity increases with temperature in a non-linear fashion from 10° to 40° C. Above 40° C. results become uncertain. At 10° C. the relative activity is about 65, whilst at 30° C. it is 137.

*A permanent glass standard is obtainable from Tintometer Ltd., Salisbury.

FIG. 1.—The relationship between ChE activity measured as (1) the reciprocal of the time necessary to effect given colour change (that is, A/T), and (2) in electrometric units (that is, ΔpH). A/T determined at temperatures between 19 and 22° C., ΔpH determined at 25° C.

The information yielded by these two series of experiments allows us to simplify the test for field conditions. If in addition it is possible to relate enzyme levels to zones which will permit clear-cut executive action, then a very useful test may be evolved. The latter idea is possible, for three critical levels of whole-blood ChE activity; (1) The lower level of normal whole-blood ChE activity; (2) the level of hypersensitivity; (3) the clinical danger level.

Lower Level of Normality.—There have been very many determinations of normal values of red-cell, plasma, and whole-blood ChE, and the limits of variation have been extensively worked out (Callaway *et al.*, 1951; Wolfie and Winter, 1952; Fleisher and Pope, 1954). These are consistent with each other. For the present purpose the values for the whole-blood ChE as determined in this laboratory have been used to define the lower limits of normal activity. On a recently determined series the mean value of whole-blood ChE was 133 (Δ pH/hour) with a standard deviation of 12 (Δ pH/hour). The lower fiducial limit of normality is therefore 109 (Δ pH/hour).

Level of Hypersensitivity.—No symptoms of systemic poisoning are obvious until a very significant reduction of the blood ChE has occurred. Callaway *et al.* (1954), however, have shown that when the whole-blood ChE of rabbits has, by previous exposure to anticholinesterase, been reduced to half the pre-exposure value, there is a significant reduction in the LD₅₀, thus demonstrating that a reduction in the blood ChE level is indicative of an increased sensitivity towards further doses of anticholinesterase. Their data did not permit an extrapolation which would have indicated the exact point at which this increased sensitivity is first obvious. In the absence of such precise data, and bearing in mind the main purpose for which this test is being evolved, we therefore suggest that the level of clinical significance could be set at 50% of the mean normal level—that is, at Δ pH/hour of 67.

Clinical Danger Level.—Davies (1952b) noticed that the blood cholinesterase of animals dosed with anticholinesterase by the intravenous, intramuscular, or percutaneous route had to be reduced to at least 20% of normal before the onset of serious clinical symptoms. In his experience the critical whole-blood cholinesterase level is about 20% of normal, although it does not follow that symptoms automatically appear when this level of blood cholinesterase is reached (Frawley *et al.*, 1952). The clinical danger level may therefore be set at 20% of the mean normal level—that is, at Δ pH/hour of 26 units.

Effect of Temperature

The most difficult problem has been to evolve a method of temperature compensation without the use of a constant temperature bath or enclosure. This was done as follows. As indicated above, several simultaneous observations were carried out on the same sample at various temperatures, together with electrometric determinations at 25° C. These results were then summarized in a family of straight lines corresponding to each temperature and relating $1,000/A_T$ and Δ pH/hour, where T is the time taken for the completion of the colour change. From these, T was determined for each critical level at varying temperatures, and a new family of curves constructed relating T and temperature. By plotting these on one diagram, as in Fig. 2, a chart showing various zones has been constructed, each zone corresponding to the interpretation shown on the right side. (See also Table I.)

TABLE I

	Lower Level of Normality Δ pH 109	Upper Level of Hypersensitivity Δ pH 67	Level of Serious Poisoning Δ pH 26
10° C.	41 minutes	63 minutes	111 minutes
15° C.	32 "	49 "	98 "
20° C.	26 "	40 "	87 "
25° C.	22 "	34 "	74 "
30° C.	19 "	30 "	62 "
35° C.	14 "	23 "	53 "

The *modus operandi* of the test is therefore as follows: The temperature of the ambient air is noted. An ordinate of the chart is then drawn corresponding to this temperature, and the time read off at the point where it cuts each curve.

The tubes are prepared as described earlier—that is, 1 ml. of B.T.B., 20 c.mm. of blood, and 0.5 ml. of acetylcholine chloride—and then the colours noted at each of these times, obtained from the chart (Fig. 2). In all the tubes in which the colour has changed to deep orange at the time of inspection the reaction is complete. For example, if the temperature was 23° C., the test with all normal blood samples would be complete in 21 minutes. Blood which changed colour in less than

Fig. 2.—Chart relating time of colour change with temperature and degree of poisoning.

34 minutes but longer than 21 minutes would possess whole-blood ChE levels lower than normal, and the level would indicate a slight absorption of anticholinesterase. Such levels would, however, be of little clinical significance. They would, on the other hand, indicate indifferent safety procedures or personal carelessness on the part of the individual.

If the time taken is longer than 34 minutes this indicates that the individual is hypersensitive, and will come into the appropriate zone. If even after 72 minutes the test is not complete, at least 80% inhibition is indicated, implying danger of clinical symptoms.

It should be emphasized that an exact colour match with the standard is seldom necessary, since the criterion at the critical time is whether the colour change is complete at that time.

One other point with reference to temperature needs to be discussed. The test may in extreme circumstances—that is, at 10° C.—take 100 minutes to complete, and if no constant temperature bath is to be used it is rather important to know what temperature fluctuation may be permitted during the period of the test itself. The experiments on which the relationship between field test and the electrometric method (shown in Fig. 1) were based were carried out at 19° C., 20° C., and 22° C., hence a variation of 3° C. during the period of the test would seem to be permissible. Lowry *et al.* (1954) confirm this suggestion, for they state that to measure cholinesterase to within 3% the permissible temperature range is 3° C. This is, however, a point that ought to be checked under a wide variation of conditions, or at least kept in mind during the period of the test.

A series of experiments were carried out at different temperatures to check the chart that has been produced. The procedure was exactly as described. Forty-eight samples of blood were prepared by diluting normal blood with inactivated blood. Thirty samples (obtained from eight individuals) were examined on different occasions in the climatic chamber at 31° C. and 85% relative humidity. A further 16 samples (from four individuals) were tested in a constant temperature bath at 31° C. The results are shown in Table II.

Of the 47 samples so tested, 45 conform precisely to the pattern described in the test. Of the discrepant samples those with Δ pH/hour—116, T_{31} —19 minutes are only just outside the expected zone. A sample of Δ pH—116 should have a reaction time of 18 minutes or less.

TABLE II.—The Confirmation of Reaction Times at 31° C.

Normal Range Δ pH hr.—109		Range of Slight Absorption Δ pH hr.—109-67		Hypersensitive Range Δ pH hr.—67-26	
T_{31}	18 min.	T_{31}	18-29 min.	T_{31}	29-67 min.
130	15	108	20	66	31
126	15	104	20	63	32
146	14	103	21	59	42
132	15	103	20	58	39
123	15	102	20	56	40
140	14	100	22	55	33
129	15	100	22	53	40
148	15	96	22	52	40
136	16	95	23	49	35
133	15	88	23	36	47
127	15	87	23	36	50

116	19	78	27		
110	18	76	27		
		75	27		
		75	28		
		73	28		
		67	27		

Δ pH hour values and reaction times grouped according to the clinical zones described in Fig. 2.

Summary

The field test of Limperos and Ranta for the assay of human whole-blood ChE has been modified to facilitate its more extensive use. A chart has been constructed which permits adjustments in the conditions of the test to compensate for temperature variation and to relate ChE levels to the degree of poisoning.

We thank the Chief Scientist of the Ministry of Supply for permission to publish this paper. We also thank Dr. Donald Hunter, Director for Research in Industrial Medicine, for seconding one of us (J. D. N.) to C.D.E.E., Ministry of Supply, Porton, to facilitate the development of this work.

Speaking at a largely attended council meeting of the Invalid Children's Aid Association on May 13, Dr. F. S. COOKSEY, director of the department of physical medicine at King's College Hospital, London, described the rehabilitation of the physically handicapped child under three heads: medical care, education of the mind and body, and "settlement," both at home during school life and later at work. With regard to the first, Dr. Cooksey stressed the importance of early diagnosis, particularly in cases of cerebral palsy, and of integrating the medical care under one doctor. "Only one man can integrate the treatment of the child, and he is the family doctor—who frequently does not," said Dr. Cooksey. So far as education is concerned, he thought that too many children with potentially normal brains were suffering from lack of education because they are segregated on account of their physical handicaps. "We should realize that the physically handicapped child should earn its living with its brain, not necessarily with its hands." Craft work was emphasized too much. Speaking of settlement in the home, Dr. Cooksey drew attention to permissive regulations under the National Assistance Act which allow for alterations to be made in the home so that the handicapped child can live more comfortably—such things as the widening of doors, the erection of ramps, and special appliances and furniture.

Medical Memorandum

Female Circumcision and the Age of the Menarche

From previous observations (Ellis, 1950; Wilson and Sutherland, 1953) it is evident that in tropical countries the onset of menstruation may be early or late compared with that for English children, but that it is not determined solely by the climate.

Studies in African ethnopsychiatry (Carothers, 1953) suggest that environmental factors may be of importance in the development of personality and constitution. It is of interest, for example, that exophthalmic goitre (Graves's disease), which may be associated with personality type (Martin and Fisher, 1945), is rare in Africans (Gillman and Gillman, 1951; Carothers, 1953; Davidson, 1954; Wilson, 1954). It is well known, too, that changes in environment which directly or indirectly modify glandular function may affect menstruation in English girls (Browne, 1950).

During nutritional investigations in Sierra Leone which extended from December, 1953, to February, 1954, the opportunity arose to investigate the influence of initiation rites, which include female circumcision, on the age at menarche of Africans. A comparison was made between Creole girls who are Colony-born Africans, among whom no circumcision is practised, and girls belonging to native tribes in the Protectorate, who at the age of about 12-13 years retire into seclusion for ceremonies of initiation. These rites are characterized by an operation on the clitoris and labia minora, which may vary from small incisions to total excision, with the object of restricting sexual pleasure. After this the girl is ready for marriage; without the operation she will not obtain a husband. This initiation and operation usually precedes the menarche; in view of the high emotional content of the ritual it therefore seemed possible that the onset of menstruation might be affected.

Records for the tribal girls were particularly difficult to obtain, and data were available for only 33. The number of Creole girls studied was 129. The present age of each girl was recorded, together with a note whether or not her periods had started. With this information the average age of the menarche and its standard deviation may be calculated, using the statistical technique of probit analysis. The results obtained may be compared with corresponding results for 2,590 girls in the South of England (Wilson and Sutherland, 1953). None of the differences is statistically significant (see Table). Although the number of tribal girls is small, it may be concluded that there is no evidence that the initiation and operation has any substantial effect upon the age of the menarche.

	No. of Girls	Average Age of Menarche (years)	Standard Deviation (years)
Tribes	33	13.44	1.30
Creoles	129	13.65	0.94
S. England	2,590	13.49	1.19

Reviews

HOWELL'S PHYSIOLOGY

A Textbook of Physiology. Edited by John F. Fulton, M.D., with 12 collaborators. 17th edition. (Pp. 1,275+xliv; illustrated. 94s. 6d.) Philadelphia and London: W. B. Saunders Company. 1955.

The seventeenth edition of what was originally *Howell's Textbook of Physiology* appears under the editorship of Professor Fulton and twelve other distinguished American physiologists; altogether, however, it is the work of thirty contributors. A conscientious review of a book containing over 1,200 pages is neither feasible nor expected by the editor, so I can only express an opinion of its merits based on a cursory glance through the whole and a careful reading of those parts about which I know more than the ordinary run of physiologists.

A general word of praise may be uttered at once: if I were going to teach physiology in some obscure medical school in the heart of Africa, isolated from the modern literature and given the opportunity to take only one book with me, then the textbook under review would be the ineluctable choice. I say this with a strong feeling of disloyalty to an old favourite and the only other large textbook with which a comparison is invited—namely, Starling's *Principles of Human Physiology*; and I say it, furthermore, in spite of the poor literary presentation, the immature judgment, and the obvious lack of any guiding spirit that are revealed by some of the contributions in the book under review. It is unfortunate, but true, that the cause of these defects—the multiple authorship—constitutes the very reason why the book should be the more valuable as an aid to teachers; the author of each section is, or should be, familiar with the literature relevant to his subject-matter, whereas the single author of a large text must, for most of the time he is writing, be dealing with subjects to which, in the course of his everyday activities, he does not normally devote much thought. Scientific writing is not, and should not be, a whole-time task; rather should it be the occupation that fills up idle hours when the day in the laboratory or clinic is over.

Treated in this way, there is an obvious limit to what may be expected of a single author, and it may well be argued that the writing and keeping up to date of a large textbook covering the whole field of physiology are a task beyond the capacities of anyone who is not a complete slave to his work. This consideration, whilst it emphasizes the necessity for multiple authorship, raises the question of the place of large comprehensive textbooks in modern physiology; if the treatments of individual aspects were thorough, up to date, and authoritative, they would occupy a welcome place on the shelves of all research workers and teachers, although their use to medical students—the people for whom they were primarily written by their original authors—would be negligible on account of their size. Unfortunately, an inspection of those parts of Fulton's book on which I feel justified in expressing an opinion reveals that these standards are not always attained; the authors have not always taken the trouble to master the details of the work they describe, and one has the suspicion that they have not always had recourse to the original literature, taking their facts and opinions at second-hand from reviews. (An obvious exception is that part of the book dealing with the nervous system; constituting nearly half the book, it is in itself a scholarly monograph.) Since it fails, therefore, as an introduction to most subjects for the research worker, and since it is unsuitable on account of its size for the medical student, the remaining function—namely, as a source of ready knowledge for teachers in a hurry to prepare a lecture—stands as its sole justification for existence.

The alternative to such a book is a series of monographs covering the whole field of physiology; such a conception has everything to recommend it, and only begs the question

of its execution. The difference between hastily throwing together a chapter or two on demand and constructing an exhaustive and well-considered monograph is the difference between a few weeks' and a year's work; moreover, the ability to write, and the inclination to sacrifice the time required for it, are becoming rarer, while the expenses of producing a scientific book are rising rapidly to the point where it will be impossible to publish at a reasonable price books with the limited circulation one must expect for such specialized works. Thus the modern medical and scientific publisher is confronted with a problem which will not resolve itself easily; meanwhile the large textbooks of physiology remain as anachronistic survivals from a day when research was, perhaps, more leisurely; when the scientist did not, as he seems to do to-day, spend his spare time growing vegetables or usurping the functions of a builder and decorator; when the ability to express oneself with ease was one that was taken for granted in most men of science; and, finally, when the medical student was treated as a reasoning human being instead of as a sausage-skin, to be stuffed full of miscellaneous information by over-zealous preclinical departments, competing among themselves to squeeze in the most of their particular brand of knowledge.

HUGH DAVSON.

NEUROSURGERY

Correlative Neurosurgery. By Edgar A. Kahn, Robert C. Bassett, Richard C. Schneider, and Elizabeth Caroline Crosby, with eleven other contributors. Foreword by Kenneth G. McKenzie, M.B., F.R.C.S.(C). (Pp. 413+xv; illustrated. £7.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1955.

Designed as a textbook for the younger neurosurgeon, this volume has been compiled by a number of authors, most of whom were associated with the late Dr. Max Peet. It therefore reflects largely the views of a single school of neurosurgeons. There are excellent opening chapters on the aids to diagnosis of radiology, electroencephalography, and the use of radioactive isotopes, which are clear and up to date. When dealing with the actual intracranial surgery a great amount of fine detail of operative technique is given together with quite admirably clear, simple diagrams, drawings, and photographs. It is perhaps in the finer points of technical detail that the book is at its best.

Many of the chapters dealing purely with surgery are followed by a neuro-anatomical study of the part of the central nervous system concerned. These are a most valuable addition, and are both clear in content and very well and simply illustrated.

All fields of neurosurgery are amply covered in the book, but it would perhaps have been more satisfactory if the actual figures with survival and mortality rates had been given in all the chapters concerned with methods of treatment, for it is highly important to be aware of the exact volume of experience which has been responsible for the views expressed.

The book is superbly produced and well put together, and the standard of the frequent illustrations is very high indeed.

W. MCKISSOCK.

ACUTE POLIOMYELITIS

Treatment of Acute Poliomyelitis. Edited by William A. Spencer, M.D. Second edition. (Pp. 134+xi; illustrated. 27s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1954.

The recent news from the United States of a partially successful vaccine for poliomyelitis must not be allowed to distract attention from the need to improve provision for treatment of the acute disease, and we must always be prepared for severe outbreaks. Some of the American clinics for the treatment of acute poliomyelitis have for many years led the world as regards their methods, and this small book is specially welcome, for it brings to the clinician a wealth of detailed information about treatment techniques

from a first-class U.S. Poliomyelitis Respiratory Centre, and is published in co-operation with the National Foundation of Infantile Paralysis.

The book is presented like the notebook of a student attending a course of lectures, and consists of nearly 90 short sections from 23 authors. These include such subjects as laboratory guides to respiratory management, indications for tracheotomy, body positioning, care of paralysed muscles, and home care for the respiratory patient. Of special interest to the British reader are the sections on machines for assisted coughing, and the astonishing glossopharyngeal breathing by which patients can be taught to force a series of mouthfuls of air into their lungs by a manoeuvre of the tongue and throat. Positive-pressure intratracheal breathing has not yet been adopted in the U.S.A., partly perhaps because anaesthetists are not playing much part in the treatment of poliomyelitis, and partly because the technique of having a tracheotomy in a tank respirator has been developed much more than in this country, to provide an efficient method of treating the "combined" case.

W. RITCHIE RUSSELL.

WORK OF THE CASUALTY OFFICER

The Casualty Department. By T. G. Lowden, M.A., B.M., B.Ch., F.R.C.S. (Pp. 278+viii; illustrated. 37s. 6d.) Edinburgh and London: E. and S. Livingstone, Ltd. 1955.

Whilst in some hospitals the work of the casualty department is recognized to be of considerable importance, there are still many places where relatively junior men undertake this responsible work without adequate supervision or training. Mr. Lowden's book should be of particular value to the junior casualty officer, and it is likely to prove helpful to more senior people as well.

Starting with a short chapter on sepsis and antibiotics, the author goes on to describe common septic lesions. Primary suture of some septic wounds is recommended, and, although this may be a reasonable proposition in the hands of the discerning and experienced surgeon, some may question the wisdom of such advice in a book of this type. Then follows a long chapter on the septic hand, which is sound and in accordance with modern enlightened opinion. The chapter on soft-tissue wounds with skin loss encourages the casualty officer to think of early skin replacement without stimulating an unnecessarily officious desire to graft all such wounds. There are further useful chapters on burns and on minor non-emergency surgery. The author mentions the simple method of removing a lipoma by cutting into it and separately shelling out the two halves, and it would have been useful had he described that simple method of dealing with a sebaceous cyst by expressing the contents through a small incision and gently withdrawing the cyst wall. The last few chapters, on organization of the casualty department, anaesthesia, disposal of cases, and legal responsibilities, will all prove of value to the casualty officer.

Certain criticisms of this book must be made. The incorrect spelling of Bunnell and Wolfe is of but minor importance. However, much of the book is written in a rather awkward style which does not make for easy reading, and one may hope that the author will give this matter his attention in any future edition of a work which should prove popular in the casualty department.

R. S. MURLEY.

PHYSIOLOGICAL ACOUSTICS

Physiological Acoustics. By Ernest Glen Wever and Merle Lawrence. (Pp. 454; 148 figures. 80s.) Princeton, New Jersey: Princeton University Press. 1954.

With the possible exception of nuclear physics, there have in recent years been greater advances in acoustics than in any other branch of the physical sciences, and in consequence the literature on the subject is vast. Even to the professional physicist acoustics has the reputation of being difficult, while to those doctors whose work demands that

they should keep abreast of events in acoustics much of what is written to-day is a closed book, and many must wish that they had paid more attention to physics during the year in which it formed part of their studies.

To-day physiologists, psychologists, and of course otologists need to have a good up-to-date knowledge of the properties of sound, of how it is conducted to and perceived by the ear, how it reaches the conscious level, and finally the physical basis for the various forms of deafness. Dr. Wever and Dr. Lawrence, from Princeton University, have in their book *Physiological Acoustics* provided a contemporary and authoritative account of the mechanism of hearing which is easy to read and above all is interesting. Nothing of importance is left out, and to the scientific worker interested in acoustics, the physiologist, or the otologist this work is likely to become a standard source of reference. To the otologist in particular the book should appeal, for, despite its title, it does contain some interesting physical facts concerning deafness; and there is a chapter devoted to the forms of conductive deafness and to otosclerosis and the fenestration operation. This puts in a simple form the physical reason for the success of the fenestration operation, and indirectly it helps to explain some of the failures. For the research worker there are details of the general layout and management of animal experiments. Perhaps the most attractive feature of the book is the easy style in which it is written, and this, combined with the experience and authority of Dr. Wever, makes it a book which should be read by all interested in acoustics.

TERENCE CAWTHORNE.

MEDICO-HISTORICAL BIBLIOGRAPHY

Garrison and Morton's Medical Bibliography. An Annotated Check-list of Texts Illustrating the History of Medicine. By Leslie T. Morton. 2nd ed. (Pp. 655+xiii. £5 5s.) London: Grafton and Co. 1954.

How ungrateful we all are to those who serve us best! We daily consult dictionaries, year-books, and bibliographies without a thought of the high skill of those who made them and the vast labour that they involve. There should be a form of short prayer for the souls of the compilers of these works to be muttered when we find just what we want—a rarer event than some might think. Certainly Mr. Morton's "mountain of merit" would have reached a good height by now had we all been as grateful to him as we should be.

The history of this admirable book is as follows. In 1912 Fielding H. Garrison, editor of the *Index-Catalogue of the Library of the Surgeon-General's Office*, published at Washington an extract from that great work as a bibliography of the most important contributions to the literature of medicine and the allied sciences. He used it as a scaffolding for his well-known *Introduction to the History of Medicine*. Later he revised the list and published it in the *Johns Hopkins Bulletin of the History of Medicine*, in 1933. After Garrison's death in 1935 Mr. Morton set to work to revise it. He was in a good position to do this as a result of his experience in the libraries of University College, London, and St. Thomas's Hospital Medical School. In 1943 he produced a complete revision, admirably arranged, of Garrison's original plan. This *Medical Bibliography* has ever since been in constant use by teachers and historians of medicine and has become a standard reference work essential to every library, medical or other, of any importance. It has been the constant companion of the reviewer since it first appeared, and he can heartily recommend it as the most efficient and reliable guide to its subject that is known to him. The book has been for some time out of print, and Mr. Morton, now Information Officer of the *British Medical Journal*, has produced a second edition with nearly 7,000 entries as against the 5,500 of the first. For conciseness, convenience, accuracy, and accessibility of its vast store of information the book has no rival. We wish it the success that is its just due.

CHARLES SINGER.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JUNE 4 1955

SIR HENRY DALE

Sir Henry Dale's eightieth birthday, which falls on June 9, will bring to him messages of good will from throughout the world of medicine and science, and indeed from far beyond it. To those who are familiar with Sir Henry's apparently boundless energy and enthusiasm the fact that such a young man has now completed nearly eighty years of active life will be a matter for admiration and even astonishment. To those who know of him only from his publications, and especially from the classical papers which appeared from his pen in the early years of the present century, it might be surprising that Sir Henry Dale is not already an honoured member of the pantheon of the past. Those who are acquainted with him personally realize that in him exists the living embodiment of a most interesting period of medical history; and history that lives is always entrancing.

But Sir Henry has always been much more than an outstandingly successful investigator. He almost alone now has claim—a claim that he himself would undoubtedly reject—to be a polymath in the world of medical sciences. True, he has had the good fortune to grow in stature during a period of unprecedented expansion in scientific knowledge, and he has himself contributed to the advance of knowledge in so many different aspects of medical science that familiarity with his own publications alone is a liberal education in itself. But nobody can fail to be awed at the range of knowledge he commands. Indeed, nobody can again hope to attain the degree of understanding and experience in every aspect of medical research such as Sir Henry can bring to bear upon any problem before him, whether it be biological standardization, the properties of chemotherapeutic agents, or synaptic transmission of the nerve impulse. As Lord Adrian writes in our opening pages this week, conventional labels fail to apply to Sir Henry, whose achievements can be claimed by anatomists, physiologists, pharmacologists, biochemists, and even, let it be said, by chemists, for he was at one time Fullerian Professor of Chemistry at the Royal Institution, London.

Claude Bernard was described by Professor Charles Singer as "a severe and powerful thinker with an

Olympian intellectual aloofness." "Aloofness" is a word that could never be applied to Sir Henry Dale, appropriate though the rest of the quotation may be. Although Sir Henry valued greatly the time he spent in Germany during his early years, and particularly his period in Ehrlich's laboratory, he never became a "Geheimrat." As director of the National Institute for Medical Research and President of the Royal Society during the dark early years of the war, his responsibilities were tremendous, but always he remained a friend as well as a mentor of those colleagues, senior and junior, who had the good fortune to be associated with him. His personal laboratory (F4) at the National Institute, whence came so much of scientific importance between the wars, was not a laboratory alone. F4 was indeed a nursery from which emerged many whose inspiration and accomplishment owe much to a director who continued to work with his own hands for as long as a laboratory was available. His care for and interest in the work of all those who were associated with him was witnessed by the frequency with which Sir Henry's itching pencil clarified and illuminated the many publications which came from the Institute during his tenure of the directorship. The rounded periods—reminiscent both of the Prayer Book and of Gibbon—of his own publications have set a standard of lucidity and precision in scientific writing which has influenced many but which none can equal.

Many years ago the late Sir Frederick Gowland Hopkins wrote: "Up to near the end of the last century nearly every expert looked to the influence of the nervous system alone as concerned with the co-ordination of functions in the body; the conception of chemical regulation and co-ordination had achieved no place in the mind of the majority." How the researches of Sir Henry Dale have resulted in a blending of the idea of chemical regulation and co-ordination with that of the role of the nervous system will be clear from the contributions of Professor J. H. Burn (page 1357), Professor Otto Loewi (page 1356), Dr. Herbert S. Gasser (page 1359), and Lord Adrian (page 1355) in the *Journal* this week. A point that stands out in these accounts is the significance of a mind prepared to evaluate the unexpected and seemingly irrelevant result. The apparently casual use of post-pituitary extract in control experiments which formed part of an investigation concerned with the biological effects of preparations from ergot led surely, in Dale's hands, to the recognition and investigation of the powerful and beneficial oxytocic effects of the posterior pituitary gland. Who would expect that an examination of the pharmacological properties of an extract or ergot could lead also to the

recognition of acetylcholine as a chemical transmitter of nervous impulses, or of histamine as a substance of such wide biological significance as is now recognized? Fortunately Sir Henry Dale was there to appreciate the import of these apparently insignificant initial observations, and to rear thereupon such a structure of knowledge that now each step in the development of it seems to have been inevitable. But it was inevitable only because Sir Henry with his agile and unprejudiced mind was there to seize upon the significance of the apparently irrelevant event. The final demonstration in 1936 that acetylcholine is a transmitter of impulses passing along voluntary motor nerves was the culmination of a series of papers on the subject which stretched over nearly a quarter of a century. From this developed the use of neostigmine in myasthenia gravis and as an antagonist of D-tubocurarine in anaesthesia. The demonstration of humoral transmission in ganglia led naturally to the investigation of the pharmacology of methonium compounds and to the use of a hexamethonium to ensure a bloodless field in surgery. The recognition of the relationship of histamine to anaphylaxis by Dale and Laidlaw in 1919 ultimately resulted in the development of the antihistamine substances which are now of value in many allergic and related conditions. And so the process continued; particular and apparently casual laboratory observations leading to general ideas of significance in medicine as a whole.

Throughout long periods of international distinction and responsibility Sir Henry has been ably supported by his gracious wife, and Lady Dale is known to investigators of all ages throughout the world as a kindly and generous hostess. To Sir Henry and Lady Dale we send our greetings on this most joyous occasion.

PULMONARY OEDEMA

Cardiac asthma and acute pulmonary oedema are commonplace medical emergencies, and it usually falls to the family doctor to treat the distressing attacks of paroxysmal nocturnal dyspnoea which are so alarming to the patient and his relations. Though the bedside diagnosis of pulmonary oedema presents little difficulty, and orthodox treatment is usually successful, the underlying mechanism of the attacks has hitherto been a matter of conjecture and treatment has been largely empirical. In the St. Cyres lecture, published at page 1361 of this issue of the *Journal*, Dr. G. W. Hayward reviews many of the problems of pulmonary oedema in the light of experimental data obtained by modern cardiological technique.

Acute pulmonary oedema occurs most often as a complication of hypertensive heart disease or aortic valvular disorders, but it is also seen not uncommonly in the course of mitral stenosis. It is perhaps not fully appreciated that acute pulmonary oedema may be the only manifestation of acute myocardial infarction, the underlying disease often being overlooked because of the absence of the characteristic substernal pain. The onset of pulmonary oedema depends on changes in the balance between the hydrostatic pressure within the capillaries and the osmotic pressure of the plasma and in the permeability of the capillary walls. An additional factor in patients with chronic venous congestion is that the pathological thickening of the barrier between capillaries and alveoli greatly impedes transudation of fluid into the alveoli. Studies of the pressures in the pulmonary circulation by means of cardiac catheterization confirm that pulmonary oedema occurs only when the pulmonary capillary pressure is greater than the effective plasma osmotic pressure. In the early stages this gives rise to interstitial oedema of the lung, and Hayward believes that a similar state probably exists in a more chronic form in patients with congestive heart failure, when it is responsible for the dyspnoea of cardiac failure by preventing normal lung distension. In acute pulmonary oedema the interstitial fluid is at first removed by the lymphatics, but eventually the fluid breaks through the barrier into the alveoli, and there is a sudden flooding of the respiratory tract. At some stage in this process the additional factor of increased capillary permeability also helps to cause oedema, and it may be that this is the additional impetus enabling the oedema fluid to break through into the alveoli. It is not certain what leads to the increased capillary permeability: in the late phases of pulmonary oedema it is probably aggravated by anoxia, but at the beginning of the attacks anoxia is not severe enough to have this effect, and it is possible that there is a neurogenic cause for the early increase in permeability. The clinician is aware that many attacks of acute pulmonary oedema seem to be aggravated by emotion, by unusual exertion, and by infection, and it now appears that all these factors exert their deleterious effect by increasing the pulmonary capillary pressure. The attacks, which so often occur in the early hours of the morning, are caused by an increase in pulmonary congestion when the orthopnoeic patient slips down in the bed, or by a sudden increase in venous return to the heart when a sudden muscular movement takes place during sleep.

Recent studies have thrown no new light on the treatment of acute pulmonary oedema, but they have confirmed the soundness of traditional therapy and

supplied a logical explanation for many forms of treatment already known to be effective. Any measure diminishing either the venous return to the heart or the pulmonary capillary pressure can relieve the attack in the early stages before capillary damage from anoxia has taken place. In this way venesection and administration of aminophylline exert their good effect. Morphine has long been a stand-by in the treatment of pulmonary oedema, and although there is no direct proof of its mode of action it probably lowers capillary pressure by allaying anxiety. It may also act by depressing muscle tone and thus diminishing venous return to the heart, and at the same time the cardiac output falls, since metabolism is lowered. The use of digitalis requires some caution. There can be no doubt of the value of digitalis in the treatment of hypertensive heart failure, but the intravenous use of digoxin has been known to precipitate acute left ventricular failure by its vasopressor effect. In patients with mitral stenosis, attacks of pulmonary oedema usually disappear altogether after the operation of mitral valvotomy. It remains important to treat chronic venous congestion between the attacks of pulmonary oedema by digitalis, by the mercurial diuretics, and by limiting the intake of salt. It is remarkable how effective these simple measures are in delaying, or even in preventing, further attacks of acute pulmonary oedema.

TRIETHYLENE-MELAMINE

Three years ago we discussed in these columns¹ attempts to find substitutes for nitrogen mustard in the treatment of Hodgkin's disease, lymphomas, and chronic leukaemias. Nitrogen mustard itself has serious disadvantages. It must be given intravenously, and it often causes severe nausea and vomiting; even when every care is taken the veins tend to become thrombosed; some degree of bone-marrow depression is almost always produced and is occasionally a danger to life. Triethylene-melamine at first seemed a promising substitute, for it could be given by mouth, and gastrointestinal upset was less severe and less frequent. Early clinical trials²⁻⁷ showed that its therapeutic effects were similar to those of nitrogen mustard and it was thought to be more useful in the chronic leukaemias. Now

from further experience it has become clear that triethylene-melamine has grave drawbacks. In cases of generalized Hodgkin's disease quite striking remissions may be obtained with it, but it is difficult to predict in advance which patients will respond. E. K. Blackburn and G. M. King⁸ state that complete therapeutic failures are less frequent than with nitrogen mustard, but M. M. Wintrobe *et al.*⁹ prefer to administer nitrogen mustard first and use triethylene-melamine only for maintenance therapy. L. M. Meyer *et al.*¹⁰ thought the results were inferior to those obtained with nitrogen mustard. On the other hand, most workers find that in chronic lymphatic leukaemia much better control is possible with triethylene-melamine. Patients are extremely sensitive to the drug and a single dose of 2.5 mg. may have a significant effect.⁹ Blackburn and King consider that triethylene-melamine is probably the treatment of choice in many cases of chronic lymphatic leukaemia. However, this malady is often symptomless for many years even when generalized lymph-node enlargement, high lymphocyte counts, and heavy infiltration of the bone marrow are present. There is no satisfactory evidence that treatment of such patients defers the onset of symptoms or increases the expectation of life. Symptoms resulting from a group of large nodes are probably better treated by local radiotherapy than by chemotherapy, and once anaemia or thrombocytopenia supervenes none of the chemotherapeutic agents available are of any significant value.⁹ Triethylene-melamine has given benefit in cases of chronic myeloid leukaemia; much larger doses are required than in the lymphatic variety, and although good remissions can be induced they are difficult to maintain.^{6, 10, 11} "Myleran" (1,4, dimethanesulphonyloxybutane) appears to be far more effective in this condition,⁹ particularly in maintenance therapy, but administration of it is probably better postponed until radiotherapy has lost its effect. However, it may be justifiable to give myleran first if x-ray facilities are not available.¹²

The greatest danger of triethylene-melamine is its extreme toxicity to the bone marrow—its narrow margin of safety and the "unpredictable vulnerability of the marrow."¹⁰ Even with the most scrupulous precautions irreversible damage of the bone marrow may follow treatment. The doses recommended in almost all of the earlier reports have since proved to be far too high, and, because of fatalities after doses well within the therapeutic range, all investigators have become extremely cautious. Deaths have been recorded following total doses as small as 10 mg.¹⁰ and 7.5 mg. (0.124 mg. per kg. body weight).⁸ Furthermore, patients who have received two or three courses of treatment without experiencing depression of bone marrow have sometimes succumbed to a subsequent course.^{13, 14}

The capricious behaviour of triethylene-melamine is explained by its chemistry. The molecules tend to polymerize, with resulting loss of activity. Samples thus vary in potency, and P. Alexander and W. C. J. Ross have shown wide variation in laboratory tests which include hydrolysis rates, capacity to combine with desoxyribose-nucleic acid, and ability to gelate soluble proteins. It

is most unsatisfactory for clinicians to have to depend on so unstable and toxic a compound. Yet no satisfactory substitute is available, though many substances are undergoing clinical trials, especially in the United States. "Thio-tepa" (triethylene-thiophosphoramide), closely allied to triethylene-melamine but chemically less reactive, has been very effective in an experimental leukaemia¹⁵; but clinical trials are still at an early stage, and some workers have found it less beneficial than triethylene melamine.⁹ W. C. J. Ross and his colleagues¹⁶ have synthesized a series of water-soluble aromatic nitrogen mustards which are powerful inhibitors of the transplanted Walker rat tumour. One of these, known as "CB1348" (di-2-chloroethyl-*p*-amino-phenylbutyric acid), has been tried clinically; preliminary results have shown that the drug may be effective in Hodgkin's disease, lymphosarcoma, and lymphatic leukaemia.¹⁷ CB1348 is given orally, is said to be free of side effects, and unlikely to produce irreversible damage to the bone marrow unless large doses are given. But toxic substances of this class cannot do more than palliate, and a solution of the problem of radical therapy in this distressing group of diseases certainly lies elsewhere.

SWELLINGS OF THE SALIVARY GLANDS

Recurrent swelling of a salivary gland is a familiar clinical problem, but except when calculi are present the aetiology of the condition is often obscure and treatment difficult. This is particularly true of the parotid, where stone formation is uncommon and recurrent parotitis is more often seen. In a recent Hunterian Lecture S. S. Rose has reported his findings in 192 cases of recurrent swelling of the parotid and submandibular salivary glands.¹ Careful radiological examination of these patients, including sialography, has done much to clarify the aetiology of the condition. In this series of patients, 74 had recurrent swelling of the submandibular gland, and in only two of these was the obstruction of the duct not due to a stone. Rose has produced a satisfactory classification for the causes of recurrent parotitis. Among the 118 patients in his group, duct obstruction accounted for 42 and recurrent infection for 66. Less common causes included congenital dilatation of the ducts of the gland and Sjögren's syndrome. Calculi were present in less than 3% of patients with swelling of the parotid.

Obstruction of the parotid duct is usually near its orifice at the papilla. In young adults the obstruction occurs about the time of eruption of the third molar tooth. It is believed that the papilla becomes damaged as a result of alteration in the mechanism of mastication. In patients over the age of 40 the papilla may be damaged by an ill-fitting denture. Recurrent pyogenic parotitis is usually related to inhibition of the normal secretion of saliva, which is decreased or sometimes absent, and may be associated with xerostomia.

Treatment of recurrent parotitis depends in the first instance on an accurate diagnosis, and here sialography is a helpful investigation. Duct obstruction is treated

by removal of the underlying cause, such as an ill-fitting denture, and dilatation of Stensen's duct with a lacrimal dilator. Often one dilatation is sufficient to cure the condition. In cases of recurrent infection general treatment is directed towards the correction of anaemia, achlorhydria, and oral sepsis. Patients are advised not to eat dry food, and chewing-gum is beneficial to patients with xerostomia. Infection is treated by injecting 1 g. of streptomycin in 2 ml. of solution into the duct daily for six days. This injection acts not only because of its antibiotic effect but also by mechanically dilating and washing out the duct.

INTERNATIONAL NON-PROPRIETARY NAMES

About five years ago a Subcommittee on Non-proprietary Names, attached to the Expert Committee on the International Pharmacopoeia, was appointed by the World Health Organization, and its sixth report was recently issued. The purpose of the subcommittee was the establishment of an international system of common nomenclature for new pharmaceutical products comparable to the activity in the national field of the British Pharmacopoeia Commission for the last fifteen years and to the American Medical Association for a longer period. Since 1950 the Scandinavian Pharmacopoeia Council has issued lists of non-proprietary names known as N.F.N. names (Nordisk Farmakopoei). The World Health Organization invited national pharmacopoeia commissions, drug manufacturers, and others to report on drugs for which international non-proprietary names were required and to suggest names for them. The subcommittee of three members were required to deal with the proposals by correspondence, and the chairman, Professor R. Hazard, of Paris, after consultation with his colleagues, was to decide on the names. The international non-proprietary names so selected were sent to pharmacopoeia commissions and other interested bodies with a recommendation that they be adopted and protected from registration as trade marks. Early in 1951 a first short list of names was issued, and a second list appeared towards the end of the year; few of the names were novel, most being already well established in national pharmacopoeias or works of reference.

By the end of 1952 a total of 430 names had been issued, many of them newly coined, but about this time very strong criticisms were made, especially in the United States, of the procedure used for the selection and publication of the names. This led to the issue by the Executive Board of the World Health Organization of a new procedure and a list of guiding principles to be followed by its subcommittee. In effect, all names previously issued were withdrawn and a three-stage process for publication was applied. Names proposed are first considered by the subcommittee, and, if acceptable within the "guiding principles," then published in the *Chronicle of the World Health Organization* as "proposed international non-proprietary names." During the six months after publication any interested person may raise formal objection to a proposed name,

and, in so far as objection is sustained, the name must be withdrawn by the World Health Organization. If no objections remain at the end of six months the name is then issued as a "recommended international non-proprietary name." By these means legitimate interests in private property in names are safeguarded, but there can be no prospect of meeting the essential need for a reasonably quick decision on a new name. The period of six months allowed for formal objection was recently reduced to four months, but although a list of "proposed" names was published in October, 1953, none attained the status of "recommended" names until the end of April, 1955.

The difficulties in the way of agreement at the international level are no doubt immense, but it can scarcely be possible for the national bodies responsible for the issue of non-proprietary names to withhold decisions for 18 months or more until "recommended" names are available from Geneva. To achieve its objective, the World Health Organization will need to provide the facilities for quicker decisions. Failing this, the sub-committee may come to function only in a general advisory capacity and as a clearing-house of information on national drug-naming activities.

TRYPSIN IN THROMBO-EMBOLIC DISEASE

For many years the proteolytic enzyme trypsin has been of interest to people studying blood coagulation. Its *in vitro* properties in promoting clotting were the first to be investigated. Ferguson and Erickson¹ showed that the addition of trypsin and calcium to plasma caused clotting in 16 seconds; after the addition of calcium alone the plasma took 95 seconds to coagulate. Whether it can be concluded from this that proteolysis plays a part in physiological blood coagulation is not known. It is perhaps significant that inhibitors of trypsin, such as soya-bean trypsin inhibitor, also oppose coagulation. In recent times it is not so much the coagulant properties of trypsin which have been of interest, but rather its action as an agent for the destruction of fibrin; such dissolution of fibrin is referred to as fibrinolysis. I. Innerfield and his co-workers^{2,3} and M. E. Peck⁴ have reported on the therapeutic trial in man of trypsin preparations for intravenous and intramuscular administration. The object of therapy with heparin and drugs of the coumarin group is to stop the spread of intravascular clotting; in contrast, trypsin is intended to remove intravascular thrombus when it has formed.

Our knowledge of human fibrinolysis is incomplete, but *in vitro* activation of proteolytic enzyme systems in plasma capable of destroying fibrin has been produced by various methods. The active enzyme is called plasmin, and it is believed to have a precursor plasminogen. Plasminogen can become plasmin *in vitro* under the influence of culture filtrates of *Strepto-*

coccus haemolyticus (streptokinase).⁵ The system can be activated also by certain inorganic solvents such as chloroform or ether, which possibly remove inhibitors.⁶ It is thought that trypsin activates plasminogen to plasmin,⁶ and that it may in addition have a direct action on fibrin itself.⁵ Innerfield *et al.*⁵ have studied the effect of intravenous administration of trypsin on experimentally produced thrombi in rabbits and dogs. They have described evidence suggesting restoration of circulation with diminution and even disappearance of thrombus. Microscopical examination showed removal of fibrin with the enclosed cellular and platelet masses without damage to the vessel wall. The same workers did not confirm previous observations of intravascular clotting after injection of trypsin intravenously. Such intravascular clotting is to be expected in view of the readily demonstrable *in vitro* coagulant action of trypsin. They attribute this failure of trypsin to produce coagulation *in vivo* to circulating antitryptic substances; it was not due to significant reduction of clotting proteins by proteolysis, which occurred only after very large intravenous doses of trypsin. Such large doses, therefore, had an anticoagulant activity. The object of trypsin therapy was to administer sufficient to lyse fibrin without unduly affecting the coagulation mechanism. Since carrying out these animal investigations Innerfield *et al.*² and Peck⁴ have reported the use of trypsin in man. They report favourably on the results of administering intravenous trypsin for thrombophlebitis. As an incidental finding during these observations, they noticed that trypsin had an apparently dramatic effect on inflammatory processes quite apart from its action on intravascular thrombus. Minor general reactions were not uncommon after intravenous administration of trypsin. They included immediate flushing of the face, a general feeling of warmth, and occasionally a sense of suffocation. Sometimes a delayed reaction appeared some hours after the injection, with nausea, vomiting, and abdominal pain. At the site of intravenous injection a local phlebitis was occasionally found. More recently Innerfield³ has reported on the favourable effect of intramuscular trypsin on the prevention of relapse in cases of chronic recurrent thrombophlebitis.

The assessment of any therapeutic agent in thrombo-embolic disease is difficult, and the results of further trials are awaited with interest. It can be shown *in vitro* that fibrinolytic activity is most successful when the enzyme is given optimal opportunity for contact with the fibrin. In a completely occluded vessel the greater part of the thrombus will be beyond the reach of administered trypsin. The work, however, is important in that it represents a renewed interest in the dissolution of fibrin rather than the prevention of its formation by anticoagulant drugs.

We record with regret the death on May 28 of Dr. C. W. Buckley, the distinguished rheumatologist, at the age of 80. He was formerly consulting physician to the Devonshire Royal Hospital, Buxton, and editor of *Annals of the Rheumatic Diseases*.

EMERGENCIES IN GENERAL PRACTICE

ACUTE HEPATIC FAILURE

BY

SHEILA SHERLOCK, M.D., F.R.C.P.

Physician and Lecturer, Postgraduate Medical School of London

"Wandering and uncertain shiverings . . . follows a most fatal putrefaction of that noble entrail."

—BOERHAAVE (1742).

Failure of liver-cell function may occur suddenly with deep coma, or its onset may be insidious and associated with a perplexing combination of mental and neurological signs. In either category its early recognition is important because it is often reversible and its recurrence can be anticipated and prevented.

The features common to all forms of acute hepatic failure are cerebral changes, fetor hepaticus, and mild fever.

The cerebral changes are diffuse, and all parts of the central nervous system may be involved. Mental disturbances are the most conspicuous; change in personality, confusion, mania, and sometimes screaming are followed by stupor and eventually coma ("hepatic coma") resembling a deep sleep. Disordered motor activity is shown by the "flapping" tremor reminiscent of the beating of a bird's wings. When the patient holds his arms in front of him with his fingers separated, rapid irregular movements occur in bursts, with flexion extension of the wrists and metacarpo-phalangeal joints. There is also a fine 6-9-per-second tremor of the outstretched hands. The movements disappear in repose and are apt to be overlooked if the patient is observed only at rest and not asked to hold his hands in front of him.

Fetor hepaticus is a sweet, slightly faecal odour detected in the breath. It has been likened to the smell of mice or to a freshly opened corpse. It is of intestinal origin.

The temperature may be raised to 100-101° F. (37.8-38.3° C.).

The two commonest causes of acute hepatic failure are acute virus hepatitis and portal cirrhosis of the liver.

Virus Hepatitis

Of the patients with virus hepatitis, 99.8% recover uneventfully. The unfortunate complication of severe liver-cell necrosis is therefore rare and correspondingly difficult to recognize.

In the jaundiced patient mental disturbance provides the earliest warning of this grave turn of events. The patient becomes disorientated, confused, and rambling. Fetor hepaticus and the flapping tremor are present. Jaundice is deep, and persistent vomiting is a bad sign. The temperature rises. Daily percussion of hepatic dullness reveals shrinking of the liver under the right costal margin. Ascites may be present if the illness is of longer than two to three weeks' duration.

Acute hepatic failure can also occur early in the course of virus hepatitis, and is then extremely difficult to diagnose, for jaundice is inconspicuous or absent. The predominant clinical features are mental, and the patient may be admitted to a mental hospital without the hepatic disease being recognized. Helpful diagnostic points are a history of

epidemic jaundice in the community or recent injection therapy giving the opportunity for transmission of the hepatitis virus. There is anorexia, the liver edge is tender, and percussion over the right lower ribs posteriorly causes sickening right upper quadrant abdominal pain. The urine contains bilirubin, but sensitive tests may be needed to demonstrate it. Fouchet's method or the new tablet test are equally satisfactory.

Portal Cirrhosis

When hepatic failure complicates chronic portal cirrhosis it is important to know why it has developed. An effort must be made to determine any factor which has depressed the liver function. Gastro-intestinal haemorrhage may have occurred from oesophageal varices, and evidence of haemorrhage must be sought. The bleeding is often slow and occult, and melaena may be detected only by rectal examination. Acute infections such as pneumonia, minor surgical operations such as paracentesis abdominis, and acute alcoholism are other possible precipitants.

When mental or neurological changes complicate well-documented cases of portal cirrhosis, the problem of recognition of the syndrome should not be difficult. Episodes of confusion, flapping tremor of the hands or arms, fetor hepaticus, or stupor can be detected by careful examination. Indeed, if the portal cirrhosis is well recognized, it is difficult to know what else could cause this strange, episodic, neurological picture. Difficulty in diagnosis arises when cirrhosis has not been considered as the underlying cause and the patient is believed to be suffering from one of the other organic dementias, arising from conditions such as cerebral atherosclerosis, cardiac failure, uraemia, Parkinsonism, and disseminated sclerosis, or from the abuse of drugs. The recognition of the underlying cirrhosis, therefore, becomes the key to the diagnostic problem. A history of alcoholism or previous jaundice should be sought, and clinical features of cirrhosis such as mild jaundice, spider naevi on the skin, palmar erythema, ascites, distended abdominal wall veins, and enlargement of liver and spleen noted.

Rarely, the neurological changes in the cirrhotic patient are chronic, and episodes of tremor, confusion, stupor, and coma may occur for years before the correct diagnosis is made. This concept of "chronic intermittent hepatic coma" has been recognized only recently. In the intervals between the episodes the patient is almost normal. Deterioration can often be related to increased amounts of nitrogen-containing substances in the intestines and may therefore follow medication with ammonium chloride, methionine or other amino-acids, or even a high protein diet. The relationship of this observation to the treatment of patients with liver disease is discussed later.

Other Causes

When acute hepatic failure occurs in pregnancy the commonest causes are virus hepatitis and eclampsia. Virus hepatitis of serum type is common in pregnancy because of the many injections performed during antenatal supervision. Cirrhosis is an unlikely diagnosis because patients with chronic liver disease are usually infertile.

Certain poisons cause acute hepatic failure, and suicidal or accidental ingestion of such chemicals as carbon tetrachloride or phosphorus must always be considered.

Prognosis

Acute hepatic failure complicating virus hepatitis has a worse outlook than that complicating cirrhosis of the liver. The mortality rate in patients with virus hepatitis and hepatic coma is about 70%. However, the liver possesses such an enormous power of regeneration that even the deeply comatose patient may resume consciousness and ultimately recover completely, with apparently no residual liver damage or shortened expectancy of life. In speaking to the relatives a reasonably hopeful attitude must therefore always be maintained.

The prognosis for acute hepatic failure complicating cirrhosis is very variable and hence difficult to predict. When there has been a clear precipitating factor such as alcoholism or infection the outlook is fairly good because such features can be corrected. When the acute failure follows haemorrhage the prognosis is poor, for the bleeding may be difficult to control.

Insidiously developing hepatic failure in the cirrhotic patient carries a reasonably good prognosis, especially if the patient is not jaundiced and neurological changes can be related to increased amounts of nitrogen in the intestines. With correct dietary management the patients can be maintained in mental equilibrium for years.

Pathogenesis of Acute Liver Failure

All the clinical features of acute hepatic failure are probably due to absorption into the blood stream of intestinal contents which have not been detoxicated by the liver (see diagram). Normally, the liver acts as a useful intermediary

The mechanism of neurological changes leading to hepatic coma (modified from Sherlock, Summerskill, White, and Phear, 1954, *Lancet*, 2, 453). The three important factors are: (1) Nitrogenous substances in the intestines. (2) Portal-systemic collateral veins diverting blood past the liver. (3) Depressed hepato-cellular function.

filter, which prevents gastro-intestinal poisons reaching the systemic circulation and the brain. The failing liver of hepatitis or cirrhosis is unable to fulfil this function adequately and the by-pass may even be accentuated by the presence of collateral vessels connecting the portal and systemic circulations, as in cirrhosis with portal hypertension. If the portal vein is thrombosed, a not uncommon complication of hepatic cirrhosis, the whole portal blood flow is deviated through collateral channels. Poisons which are apt to gain entrance to the general circulation include bacteria causing pyrexia, various intestinal toxins producing fœtor hepaticus, and certain nitrogenous substances causing cerebral disturbance. The actual cerebral poisons present

in portal venous blood are unknown, but undesirable effects may follow such nitrogen-containing substances as a high-protein diet, ammonium chloride, urea, methionine, or choline. The portal vein and cerebrospinal fluid contain a high concentration of ammonia in hepatic coma. However, the relation between the neurological changes in man and blood "ammonium" concentration is not close enough to assume that ammonia toxicity is the cause. The patients are not hypoglycaemic and no other constant biochemical abnormality has been demonstrated.

This theory of "auto-intoxication" or *portal-systemic encephalopathy* may appear to be an old one, but it certainly accounts for many of the clinical features which commonly occur in hepatic failure, and it suggests a regime of management which has proved satisfactory in these patients.

Treatment

There is little active treatment that can be undertaken before hospital admission. Therefore admission is urgent and should be arranged as soon as the diagnosis is made. It is important to resist the use of drugs which are detoxicated by the liver, because their prolonged and undesirable action may contribute to the coma. Such drugs include morphine and most barbiturates. If the patient is restless and sedation is indicated, paraldehyde may be given per rectum in a dose of 16-20 ml. emulsified in 60 ml. of normal saline. Otherwise, glucose drinks will suffice as a temporary measure.

The management of the patient in hospital is here given only in outline. The initial care should always be undertaken in an establishment where constant supervision, a suitable dietary regime, and clinical and biochemical assessment of liver-cell function are all available. The basic principles, however, apply equally when the cirrhotic patient is discharged home to the practitioner's supervision.

Treatment in hospital is directed along two lines: (1) eliminating potentially toxic nitrogenous substances from the intestines; and (2) improving hepato-cellular function.

Elimination of Intestinal Intoxicants

Possible toxic nitrogenous compounds include a high-protein diet, methionine, choline, and ammonium chloride, and these are all avoided. The physician is torn between the policy of a liberal protein diet as a general principle in liver disease and the avoidance of protein because of its potential toxicity. When the patient is first observed, protein should not be given, but he should be maintained for one week on glucose and a little fat. This alone may produce a striking remission of the neurological sequelae and permit more adequate assessment of liver-cell function. Such a protein-free diet can be used only temporarily until symptoms are brought under control; thereafter, protein must be gradually increased. A diet containing 25 g. of protein is introduced for one week, and this should be raised by 25 g. during successive weeks. It is usually found that patients with cirrhosis and chronic neurological complications can tolerate only 50 g. of protein daily. It must not be thought that all patients with cirrhosis of the liver should have such a low-protein diet; it is recommended only for those with neurological complications.

During the initial protein-free period, adequate caloric intake must be maintained, otherwise endogenous protein breakdown produces amino-acids and a further metabolic strain on the liver. So long as the patient remains co-operative 2,000 calories can be administered daily by mouth in the form of 20% glucose in fruit juices. Should he be unco-operative, it may be necessary to resort to gastric tube-feeding or intravenous infusions. An intragastric tube supplying 20% glucose in water at a rate of 20-30 drops a minute provides 2 litres or 1,600 calories during 24 hours; 1 g. of potassium chloride is added to each litre.

Intravenous feeding is recommended if persistent vomiting or uncooperation makes the intragastric drip method impracticable. In order to provide sufficient calories without

fluid overload, 20% glucose in water is employed, 2 litres a day being given. Since this would irritate small veins, with a resulting phlebitis, it is delivered into a large venous channel, such as the innominate vein or superior vena cava, by means of "polythene" tubing. This method ensures continuous intravenous feeding for several days.

Since toxæmia from the effect of intestinal bacteria on nitrogen-containing substances may play a part in the genesis of these changes, temporary sterilization of the gut is worthwhile. It is best to choose a broad-spectrum antibiotic such as chlortetracycline or tetracycline, giving 0.5 g. six-hourly orally, or if necessary by stomach tube, as long as the coma lasts or to a maximum of one week. Parenteral antibiotics are not effective.

After an enema initially, daily motions should be ensured with magnesium sulphate.

Improvement of Hepato-cellular Function

This implies the energetic treatment of any factor which is depressing liver function and precipitating failure. Infection is treated with antibiotics, anaemia is controlled by blood transfusion, and alcohol is forbidden. A carbohydrate diet allows the maximal metabolic rest to the liver.

Intravenous glutamic acid has been advocated for the treatment of patients with hepatic coma. Wide experience of it in many parts of the world has failed to show any consistent improvement in patients suffering from a condition remarkable for its day-to-day variation.

Results of Treatment

Any treatment advocated for hepato-cellular failure is difficult to assess, for the cause of the syndrome is uncertain and the clinical state so variable from time to time. Using the above conservative regime, I have treated 21 patients with the syndrome of acute hepatic failure due to virus hepatitis or portal cirrhosis. Two of five patients with virus hepatitis and 11 of 16 with portal cirrhosis have survived episodes of coma.

If the patient with acute virus hepatitis survives acute hepatic failure, recovery is usually complete. The cirrhotic patient, however, is liable to recurrences, and the general practitioner must then decide whether readmission to hospital is necessary. Gastro-intestinal haemorrhage, rapidly accumulating ascites, or deep coma are clear indications for immediate admission to hospital. If, on the other hand, the changes described above are recognized early, conservative management can be employed in the home. Improvement can be reasonably expected within 36 hours, and this may avert unnecessary readmission to hospital.

Next article on Emergencies in General Practice.—
"Pulmonary Embolism," by Professor R. B. Hunter.

CHILD WELFARE CENTRE**"PROVINCE OF NATAL" WELFARE CENTRE
OPENED IN LONDON**

The High Commissioner for the Union of South Africa (Mr. G. P. JOOSTE) on May 26 opened the "Province of Natal" Centre for Child Health in London. The centre is a handsome and spacious erection in Guilford Place, on the dividing border between the boroughs of Holborn and St. Pancras, and adjacent to the Hospital for Sick Children, Great Ormond Street. In addition to serving as a welfare centre, it is to house the Institute of Child Health, hitherto located at the hospital, and it seems to have a fair amount of space unallocated and available for future developments.

The ground floor is planned for maternity and child welfare work, with a hall for lectures and meetings, a kitchen for demonstrations, and a creche open on certain afternoons a week in which busy mothers may leave their children. The first floor is given over to school health work, and here all the activities of a school health service which are more conveniently carried out at a clinic than in the school itself will proceed. On this or the floor above there are a dental department, an orthoptic clinic, a clinic for minor ailments, an audiology room, and a child guidance centre, where a psychiatrist and psychiatric social worker will be engaged. Elsewhere in the building are two large laboratories and all their accessories. Special attention was drawn to the system of benches cantilevered from the wall and provided with continuous service racks, while each of the under-bench units is independent and removable.

A South African Benefaction

At the opening ceremony Professor ALAN MONCRIEFF, Director of the Institute of Child Health, explained how this new venture had come about. He reminded the company that the University of London Institute of Child Health was founded in 1946, with a generous gift from the Nuffield Foundation to establish a chair in child health and with the warm support of the university authorities on the one hand and the board of management and staff of the Hospital for Sick Children on the other. Investigations then began to be made into where and how a model welfare centre could be established. In 1947 the Mayor of Durban, Mr. Rupert Brown, came to London, and in an interview with Professor Moncrieff said how sorry he was that the National Health Service newly instituted in Britain prevented the people of Natal from helping Great Ormond Street. "I remember gripping my chair hard as I launched into a tactful explanation to him of how the money could still be used—for our model welfare centre." He had a dreadful feeling that he was too late, but fortunately the Mayor was convinced, the South African Gift Committee was communicated with, and before the end of the year a grant of £106,888 had been made. Then ensued a period of planning and architects' conferences. The University had acquired land, a portion of which was available, and the London County Council signified its willingness to pay 90% of the cost of maintenance and all the salaries of medical and nursing staff. A house committee, with representatives of the L.C.C., the two borough councils from whose areas most of the children will be drawn, and the Institute of Child Health, will control general matters of policy, voluntary help, clinic sessions, amenities, and so forth. Professor Moncrieff added that it was a stipulation at the time of the original gift that the name "Province of Natal" should be associated with the centre.

The object was first to give a model service to the children of this part of London, and also as a university centre to undertake teaching and research. Postgraduate doctors and student nurses would come from Great Ormond Street to learn what was going forward, also health visitors, and it was hoped that the L.C.C. would use the centre in the training of their medical and nursing staffs.

The HIGH COMMISSIONER then formally declared the Centre open and unveiled a commemorative plaque. He explained that the financial assistance which came from the people of Natal was from a fund originally called the "Salute to Britain" fund, expressive of the deep feeling of sympathy for the people of Britain in their ordeal during the war. It was difficult to conceive a more fitting manner in which the money could have been used than in the construction of this Centre to alleviate suffering and promote knowledge in the service of children, in whom lay the future of any nation.

The thanks of the London County Council for the facilities provided by the centre were voiced by its chairman, Mr. NORMAN PRITCHARD, and His Excellency was thanked by Lord WAVERLEY, chairman of the governing body of the British Postgraduate Medical Federation.

MEDICAL MEMBERS OF PARLIAMENT

Below are biographical notes of the members of the medical profession who were successful at the General Election held on May 26. Altogether 20 candidates with medical qualifications stood for election.

Dr. R. F. B. Bennett

Dr. R. F. B. Bennett (Conservative, Gosport and Fareham) was born in July, 1911, and was educated at Winchester, New College, Oxford, and St. George's Hospital, London. He qualified in 1937, and graduated B.M., B.Ch. in 1942. During the war he served in the R.N.V.R., and subsequently with the Fleet Air Arm, first in the Western Approaches, where he was twice torpedoed, and then in Tanganyika and Ceylon, completing more than 500 hours' flying as a pilot. Towards the end of the war he was attached to the R.N. Psychiatric Hospital at Knowle. After the war he was a psychiatrist

for South Hampshire. Dr. Bennett contested the East Woolwich constituency in the 1945 election. In 1950 he had a majority of 10,584 at Gosport and Fareham, and a similar majority in 1951. He was Parliamentary Private Secretary to the Home Secretary from 1951 to 1954, and to the Minister of Fuel and Power from November, 1954, to this year's General Election. He has been secretary of the Conservative Parliamentary Committees on Air and Civil Aviation since 1951; psychiatrist to the Institute for the Study and Treatment of Delinquency since 1950; and a member of the South-west Metropolitan Regional Hospital Board since 1953. He was a member of the Steering Committee of the Parliamentary and Scientific Committee from 1952 to 1954. He is a member of the Inner Temple, and holds the rank of surgeon lieutenant-commander in the R.N.V.R.

Dr. R. F. B. BENNETT (Conservative) 30,918
Mr. S. J. Surrey (Labour) 18,432

Dr. A. D. D. Broughton

Dr. A. D. D. Broughton (Labour, Batley and Morley) was born on October 18, 1902. He was educated at Rossall School, Cambridge University, and the London Hospital. He qualified in 1929 and graduated M.B., B.Chir. in 1937. He took the D.P.M. in 1936 and the D.P.H. a year later. Dr. Broughton held appointments as casualty officer at Poplar Hospital and as receiving-room officer at the London Hospital before returning to Rossall School for a few years as resident medical officer. He entered general practice in Batley in 1932. During the war he served in the Medical Branch

of the Royal Air Force. Dr. Broughton was elected a member of the Batley Borough Council in 1946 and held office as vice-chairman of the public health and of the maternity and child welfare committees. He took his seat in Parliament in February, 1949, after winning the Batley and Morley by-election, and was returned with a majority of 9,885 in the 1950 election, and with only a slightly reduced majority in the 1951 election.

Dr. A. D. D. BROUGHTON (Labour) 27,178
Mr. H. Watson (Conservative) 17,970

Mr. J. D. Cronin

Mr. J. D. Cronin (Labour, Loughborough) was born on March 1, 1916, and received his medical education at St. Bartholomew's Hospital, qualifying in 1939. In the following year he graduated M.B., B.S. at London University, and in 1947 he obtained the F.R.C.S. Mr. Cronin is orthopaedic surgeon to the French Hospital and is an adviser on industrial injuries to a number of trade unions. He is examiner in surgery for the General Nursing Council. During the second world war he served from 1942 to 1946 in the R.A.M.C., attaining the rank of captain.

Mr. J. D. CRONIN (Labour) 24,044
Mr. M. V. Argyle (Conservative) 19,781

Mr. Walter Elliot

Mr. Walter Elliot (Conservative, Kelvingrove) was born on September 19, 1888, and was educated at Glasgow Academy and the University of Glasgow. He took the B.Sc. in 1910, graduated M.B., Ch.B. in 1913, and proceeded D.Sc. in 1923. The honorary degree of LL.D. has been conferred on him by the Universities of Aberdeen, Edinburgh, Glasgow, and St. Andrews, and Leeds and Manchester, and he is an honorary D.Sc. of the University of South Africa. From 1933 to 1936 he was Lord Rector of Aberdeen University, and he was Rector of Glasgow University from 1947 to 1950. Mr. Elliot was elected F.R.S. in 1935 and F.R.C.P. in 1940. During the war of 1914-18 he served with the R.A.M.C. Mr. Elliot was returned to Parliament as Member for the Lanark division in 1918 and again in 1923, and he was a Member for the Kelvingrove division of Glasgow from 1924 until the General Election of 1945, when he lost his seat by 88 votes to the Labour candidate. In 1946 he was returned to Westminster by the Scottish Universities after a spectacular contest in which all his opponents lost their deposits.

The Representation of the People Act of 1948 abolished the university vote, and Mr. Elliot therefore returned to the Kelvingrove division of Glasgow for the General Election held in 1950, when he had a majority of 1,224, and he was re-elected in the following year with an improved majority. Mr. Elliot became a Privy Councillor in 1932, and from 1923 onwards he held in succession the offices of Under-Secretary of Health for Scotland, Under-Secretary of State for Scotland, Financial Secretary to the Treasury, Minister of Agriculture and Fisheries, Secretary of State for Scotland, and Minister of Health. In 1941-2 he was a director of Public Relations at the War Office.

Mr. WALTER ELLIOT (Conservative) 14,854
Mr. J. L. Williams (Labour) 11,966

Mr. Somerville Hastings

Mr. Somerville Hastings (Labour, Barking) was born on March 4, 1878. He is consulting aural surgeon to the Middlesex Hospital. A student at Middlesex Hospital and University College, London, he graduated M.B., B.S. in 1902 and took the F.R.C.S. in 1904. Mr. Hastings has been interested in medical politics for many years. He was a member of the B.M.A. Planning Commission, whose report was published in 1942. In 1929 he assisted in the formation of the Socialist Medical Association, of which he is a past president. He is also a member of the public health advisory committee of the Labour Party. He was returned as Labour M.P. for Reading in 1923, and again in 1929, and was Parliamentary Private Secretary to the Board of Education in the first Labour Government.

Mr. Hastings has been a member of the London County Council since 1932, and he became chairman of the hospitals and medical services committee of the council in 1934, holding this post for 10 years until he became chairman of the council itself. He was a member of the Curtis Committee, and is now vice-chairman of the children's committee of the London County Council. He is an alderman of the council. At present, at the age of 77, he is a member of the North-east Metropolitan Regional Hospital Board. Mr. Somerville Hastings was returned in 1945 as the Member for Barking with a majority of 18,911; in 1950 with a majority of 20,030; and in 1951 with a still larger majority.

Mr. SOMERVILLE HASTINGS (Labour) 27,129
Mr. B. Massey (Conservative) 12,082

Dr. Charles Hill

Dr. Charles Hill (Liberal and Conservative, Luton) was born on January 15, 1904, and was educated at St. Olave's School, Trinity College, Cambridge, and at the London Hospital. He qualified in 1927, and graduated M.B., B.Chir. in 1929, proceeding M.D. in 1936. For a time he was a London University extension lecturer, and then spent two years as deputy medical officer of health for Oxford before coming to the B.M.A. as assistant secretary in 1932. Three years later he was made deputy secretary, and in 1944 he became secretary, which post he held until his resignation in 1950. He has been active in the affairs of

the World Medical Association, of which body he was president in 1949-50. He was formerly chairman, and is now vice-president, of the Central Council for Health Education. He first stood for Parliament in 1945, when he unsuccessfully contested the Cambridge University constituency as an Independent. In 1950 he was returned for Luton as a Liberal and Conservative with a majority of 1,086, which figure he improved upon at the 1951 General Election. He was Parliamentary Secretary to the Ministry of Food from 1951 to April 7 this year, when he was appointed Postmaster-General, becoming also a Privy Councillor.

Dr. CHARLES HILL (Liberal and Conservative) ... 24,722
Mr. M. Janis (Labour) 20,304
Miss J. Henderson (Liberal) 3,140

Dr. Donald McI. Johnson

Dr. D. McI. Johnson (Conservative, Carlisle) was born on February 17, 1903. He was educated at Cheltenham College and at Gonville and Caius College, Cambridge, and St. Bartholomew's Hospital, qualifying in 1926. He was in general practice when war broke out in 1939, when, as a Territorial officer, he was mobilized for service in the R.A.M.C. Since the end of the second world war he has founded a publishing firm and has written a number of books. He is a member of Sutton and Cheam Borough Council. He has stood for Parliament on four previous occasions as a Liberal candidate.

Dr. D. McI. JOHNSON (Conservative) 20,071
Mr. A. Hargreaves (Labour) 19,701

Colonel Malcolm Stoddart-Scott

Colonel Malcolm Stoddart-Scott (Conservative, Ripon) was born on September 23, 1901. He was educated at Elmfield College, York, Ashville College, Harrogate, and Leeds University, where he graduated M.B., Ch.B. in 1926, and proceeded M.D. in 1929. Colonel Stoddart-Scott served as D.A.D.M.S. and A.D.M.S. 48th Division in the second world war. He has been honorary secretary of the Conservative Parliamentary Health Committee, and he sat on the Standing Committees which dealt with the National Health Service Bill, Analgesia in Childbirth Bill, Nurses Bill, Milk Designation Bill, and other measures. He was first elected to Parliament in 1945 as the Conservative Member for Pudsey and Otley with a majority of 1,651. In 1950 he was returned for Ripon with a majority of 10,975, and in 1951 he increased his majority to 12,420.

Colonel M. STODDART-SCOTT (Conservative) ... 21,977
Mr. E. Brierley (Labour) 9,912

Dr. Barnet Stross

Dr. Barnet Stross (Labour, Stoke-on-Trent Central) was born on December 25, 1899, and was educated at Leeds Grammar School and at Leeds University. He graduated M.B., Ch.B. in 1925, and was engaged in general practice in Stoke-on-Trent until 1948. Dr. Stross was elected councillor of the City of Stoke-on-Trent in 1937, and in the following year he accepted an invitation to stand as Parliamentary candidate for the Hanley division of Stoke-on-Trent. In 1945 he entered Parliament, representing this division. Dr. Stross served on the Standing Committees responsible for con-

sidering the National Health Service Bill, the Nationalization of Coal Bill, and the Criminal Justice Bill. He was returned as the Member for Stoke-on-Trent (Hanley) in 1945 with a majority of 11,602; for Stoke-on-Trent Central in 1950 with a majority of 16,547; and in 1951, again for Stoke-on-Trent Central, with a slightly reduced majority.

Dr. BARNET STROSS (Labour) 28,452
Mr. G. B. Price (Conservative) 16,097

Dr. Edith Summerskill

Dr. Edith Summerskill (Labour, Warrington), who was born in 1901, was a student of King's College, London, and Charing Cross Hospital. She qualified in 1924. She served on the Middlesex County Council from 1932 to 1938, fought a Parliamentary by-election in Putney in 1934 (reducing the majority against Labour from 22,000 to 2,000), contested Bury at the 1935 General Election, and was returned in 1938 as the Member for West Fulham. In 1945 she was again returned by West Fulham, and was Parliamentary Secretary at the Ministry of Food from then until 1950, when

in the next Government she became Minister of National Insurance. In 1946 Dr. Summerskill represented Great Britain at the Food and Agriculture Organization's conference at Washington, and again in 1947 in Geneva. She was one of the organizers of the Socialist Medical Association. In the 1949 New Year Honours List it was announced that Dr. Summerskill had become a Privy Councillor. In 1945 Dr. Summerskill had a majority of 7,521; at the 1950 election she had a majority of 2,849; and in 1951 2,583. She was adopted as the Labour candidate for Warrington at this election in place of Dr. H. B. W. Morgan, the retiring Member, who did not seek re-election.

Dr. EDITH SUMMERSKILL (Labour) 22,721
Mr. H. Davies (Conservative) 17,075

Acknowledgments

The photographs of Dr. Charles Hill and Dr. A. D. D. Broughton are by Elliott and Fry Ltd.; that of Mr. J. D. Cronin by Wakefields of Chiswick; Colonel Malcolm Stoddart-Scott by Bassano; Mr. Walter Elliot by Davis (Streatham); Mr. Somerville Hastings by Illustrated; Dr. D. McI. Johnson by Cumberland News; Dr. Edith Summerskill by London News Agency; Dr. R. F. Bennett by Barrett; and that of Dr. Barnet Stross was taken privately.

Radiotelephony is being used by many local health authorities in the control of their ambulance fleets, and is to be introduced on a limited scale into the London ambulance service. The health committee of the London County Council proposes to equip six ambulances and a staff car for two-way radio-transmission, and to adapt three more ambulances as reserves, with a control set at headquarters. These ambulances will be used primarily to reinforce general ambulance stations working under pressure; their crews will be able to receive instructions without returning to base, to verify doubtful information quickly, and to report immediately any special circumstances, such as births in ambulances. They will also be a valuable means of controlling operations at any major disaster. The estimated cost of initial equipment is £2,975.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Environmental Cancer Research

SIR.—Sir Ernest Kennaway in a recent article (*Journal*, May 7, p. 1107) called attention to the significance of studying cancer in man from the epidemiological point of view. He emphasizes that this type of cancer research, though it may be empirical, can well lead to the identification of carcinogenic factors for man whose avoidance would be followed by a reduction in incidence of certain cancer types.

For many years Sir Ernest has played a leading role in cancer research, covering many phases of this field. It is thus of interest that of late he has given so much emphasis to the study of cancer as it is influenced by our environment as a practical means of combating cancer. He has pointed out that environmental factors do not only play a role in certain limited occupational fields, but can also affect large segments of the population as, for instance, cancer of the lung and cancer of the cervix. On my visits to London I always look forward to a discussion with Sir Ernest and to learning from him about his latest research in cancer epidemiology. He has contributed greatly to my own interests in this field. This admiration, however, does not prevent us from having occasional differences of opinion.

Sir Ernest believes that the circumcision factor may not account for the low rate of cervical cancer in Jewish women because of the great differences in cervix and penile cancer rates in England, which should both be influenced by smegma application. This view does not consider that differences in tissue susceptibility may account for such variances in rates. Furthermore, there may be co-factors affecting the cervix but not the penis. Similarly, smoking affects both lung and larynx cancer, though here, too, the incidence rates vary greatly.¹ It is important, however, that the incidence pattern be similar among different population groups as far as penile and cervical cancer are concerned for these two types of cancer, as is the case. It is for this reason, added to the statistical evidence available, that we felt the circumcision factor to be consistent with the belief that it aids in lowering the rate of cancer of the cervix.

In respect to the abstinence after menses data, we had no proof that such abstinence was a factor in the low incidence of cervical cancer in Jewish women. Ten out of twenty Jewish women with cancer of the cervix (not five as erroneously stated in the *British Medical Journal* article) did not abstain after menses, whereas five abstained for the full period of seven days.² We pointed out that these were insufficient cases to allow statistical analysis, though they were in line with the controls. As our other reason as to why we felt that the abstinence period was probably not as important as proposed, we found that the rate of abstinence in Jewish women in New York City in the early fifties, and certainly in the forties and younger age groups, has decreased so markedly that the rate of cervical cancer should have been increasing significantly among Jewish women in this city, a fact which has not been observed. As the younger Jewish women advance into the cancer age, the answer to this question will be even more apparent. Perhaps the abstinence factor could be more easily examined if it could be studied independently from the factor of circumcision. We believe that, since Jews continue circumcision and as long as there are not many inter-racial marriages, the rate of cancer of the cervix will remain low in Jewish women in spite of the fact that they no longer significantly practise the abstinence period. Subsequent years will prove or disprove this concept. We have

repeatedly emphasized, furthermore, that circumcision represents only one of the factors that seems to affect the risk to develop cancer of the cervix. However, in environmental factors, as Sir Ernest has so frequently pointed out, it suffices if we successfully halt exposure to one given factor.

To those who, in addition to carrying out laboratory research, also have the task of caring for cancer patients, the need for preventive measures becomes increasingly clear. Some day it is hoped, of course, that what Sir Ernest calls fundamental research will give us the basic answer and cure for all cancers. However, such an answer and such a cure do not seem within our reach at present. It is therefore important that we must concentrate on the study and modification of environmental factors which seem to influence the development of a majority of our cancers. In this field international co-operation is of first-rate importance. It is along these lines that Sir Ernest Kennaway has made so many significant contributions which have stimulated research in many parts of the world.—I am, etc.,
New York, 21, U.S.A.

Measles

SIR.—Dr. J. F. Lund (*Journal*, May 21, p. 1279) raises certain important and urgent principles which require a considerable amount of further thought and attention from all those engaged in the practice of medicine. The subject is the use (and abuse) of antibiotics not only in general practice but also in other branches of medicine.

We seem to be confused over the whole matter. How much of the vast amounts of these drugs, which are now being used and which are costing the nation so much money, are really necessary? It seems impractical and a sign of inexperience that we should immediately think in terms of antibiotics when confronted with all types of infections, irrespective of whether they be severe or slight. We are all agreed that the more severe conditions, such as the pneumonias, meningitis and osteomyelitis, require urgent and adequate treatment with the antibiotics, but is it necessary to treat sore throats indiscriminately with "25 g. of aureomycin, 36 penicillin lozenges and a gargle," as was seen on one prescription handed to a chemist? We seem to have forgotten that these same infections used to settle down without a great deal of trouble, in most instances, a decade or so ago. A further factor which has apparently escaped notice is that it is probable that the virulence of the infecting organisms has altered. There is no question that scarlet fever is now both less frequent and less severe, and that ear infections are also less virulent. Whether this has come about because or in spite of the use of these drugs is a matter for conjecture, discussion, and research. A further question to be answered is: What is the best route for their administration, with special reference to oral penicillin? Are the wide-spectrum antibiotics as necessary as prescribing costs suggest? It may not have been such a bad idea to have retained the restrictions which were previously applied to the use of these drugs in general practice. Another aspect which merits consideration is the steadily rising numbers of fatalities and ill effects attributable to the use of these substances. Yet another thought is to the future. The proportions of resistant organisms are mounting, especially so in the hospitals. It would be disastrous to think that in the future we might run out of antibiotics which would control these resistant organisms.

To return to Dr. Lund's question. In the same measles epidemic, and only some few miles from him, I had in my own practice 135 cases of measles and I did not use any prophylactic chemotherapy or antibiotics. Of all these, only four children eventually needed selective treatment with intramuscular penicillin: two catarrhal children who developed an acute chest infection which settled within five days and two other children needed similar therapy for acute otitis media—these also cleared up rapidly with no after-

effects. It is most important to know whether these drugs are or are not necessary in view of the almost equally good results with these two differing forms of therapy. We await therefore with great interest and expectation the results of the College of General Practitioners' investigation into this very subject.

To show that antibiotics are not necessary in the vast majority of other common infections in general practice I would like to quote from some figures which I have been keeping over the past few months. I have followed the rule that non-specific therapy be given unless there are definite indications for their administration. The two conditions which have been observed are acute otitis media and acute exudative throat infections. In acute otitis media, out of 80 cases antibiotics (penicillin only was used) were considered necessary in only 39% of cases; there were no complicating after-effects in any of these 80. In the acute sore throats, antibiotics (again intramuscular penicillin was the only one used) were required in only 25% out of the 50 cases seen.

I hope that I have made the issues clear—namely, that we need a reassessment and reorientation in clarifying the indications for the use of antibiotics, especially in reference to their use for minor conditions in general practice.—I am, etc.,

Beckenham, Kent.

JOHN FRY.

SIR.—I was interested in Dr. J. F. Lund's letter (*Journal*, May 21, p. 1279) describing his experiences with prophylactic penicillin in measles. Between January and April of this year I treated 100 cases, ranging in age from 5 months to 7 years. They all received an oral penicillin suspension in a dosage of 100,000 units to 200,000 units four-hourly, depending upon age. The only complication I encountered was in the case of a boy aged 3½ years who developed appendicitis seven days after the appearance of his rash. I gather this is a recognized complication of measles, which is a disease primarily affecting the mucous membranes. Incidentally, it was not mentioned as a complication in your interesting leading article on measles in the *Journal* of April 23 (p. 1018).—I am, etc.,

London, S.W.4.

G. J. GRAINGER.

SIR.—I would like to endorse Dr. J. F. Lund's remarks in his letter on the prophylactic use of sulphonamides in measles (*Journal*, May 21, p. 1279). I personally have seen just over 80 cases during the recent epidemic with an age range of 6 months to 7 years. In addition there have been about another 100 cases dealt with by the practice. All have had prophylactic sulphonamides and none have developed complications. We may, or may not, have been lucky, but propose to continue with our present routine.—I am, etc.,

Spondon, Derbyshire.

R. G. G. TAYLOR.

SIR.—I am afraid Dr. J. F. Lund (*Journal*, May 21, p. 1279) and his principal, Dr. R. G. Wigoder, have drawn false conclusions from a mere coincidence. My partner Dr. T. D. Reilly and I have notified 56 cases of measles since January 1. We have used no prophylactic sulphonamides or penicillin and we have had no case with complications. It is to be hoped that none of the organisms in Dr. Lund's patients will prove resistant to penicillin in later illnesses, otherwise its already expensive use will require increased expense in the use of newer antibiotics.—I am, etc.,

Liverpool, 22.

F. R. CRADDOCK.

Disseminated Sclerosis

SIR.—We feel that Dr. Hugh Garland did not do full justice to the book by Drs. Douglas McAlpine, Nigel D. Compston, and Charles E. Lumsden on *Multiple Sclerosis* in the review in the *Journal* of May 14 (p. 1197). It is a valuable book, the first of its kind in this country on this important subject. We calculate that there is approximately one case of disseminated sclerosis per thousand of the adult

population in Northern Ireland, which emphasizes how common is the disease. Dr. Garland implies that one should not make a diagnosis of disseminated sclerosis in two or more members of one family. In a controlled study¹ we have found 6.5% familial incidence and we know of no controlled study which refutes this finding. We cannot, however, claim that the familial factor is important in the aetiology. A similar familial incidence is found in diabetes mellitus; yet no one would consider changing the diagnosis of diabetes mellitus on account of a positive familial history.

Dr. Garland mentions Professor Platt's valuable suggestion that artificial feeding in infancy may play a part in the aetiology of disseminated sclerosis. We inquired into breast-feeding in our survey, and where a definite answer could be obtained we found that 90% of our patients had been breast-fed. However, we did not inquire how long this had been carried on. However, recently we came across a young woman in her twenties with undoubted disseminated sclerosis, who gave the startling information that she had been nursed at the breast for three years.—We are, etc.,

Food-poisoning

SIR,—I think that doctors in the public health service will have been struck by an air of unreality in Dr. Christopher Hardwick's article on "Acute Food-poisoning" (*Journal*, May 14, p. 1205). To say that "single cases and outbreaks of food-poisoning still occur with some frequency" seems a marked understatement to the M.O.H. who is recording them week by week without much intermission. Dr. Hardwick also says that outbreaks of bacillary dysentery due to *S. sonnei* "occur occasionally" and that various institutions provide the bulk of the cases. In actual fact, this is a constant disease, occurring week by week in the general population of a large town, much as scarlet fever and whooping-cough occur, all the year round.

We in the public health service are constantly saddened and baffled by the complete detachment of our clinical brethren from the wider aspects of medicine, and here is yet another example of the way in which clinical teachers seem to be quite unaware that facts and figures about the present situation await them at the end of a telephone in the local town hall.—I am, etc.,

Cambridge.

CYRIL G. EASTWOOD.

The Changing Face of Medicine

SIR,—I read with interest Professor Kennedy's presidential address as delivered to the Edinburgh Obstetrical Society and reported in the *Journal*, April 30, p. 1045. It contains a reference to the problem of National Service and the doctor, which I am sure was not made in a bad spirit but which would seem to indicate that the two years thus spent is a complete and utter waste of time in the majority of cases. I feel that this is an opinion widely held and upon which a little illumination is well overdue.

What has the R.A.M.C. to offer to the National Service medical officer? It cannot be denied that it provides for the regular and short-service officer facilities for post-graduate specialist study which are unrivalled in the civilian medical world. Obviously these facilities cannot be made available to the man who is there for two years only, and he has to be used exclusively to fulfil the military commitments of the country. But every effort is made to give the National Serviceman the sort of work he would like, if this is at all possible and provided he has sufficient experience to be able to carry it out.

He may go to a military hospital to serve in whichever specialty he may have had experience in. Here he will find abundant clinical material with every opportunity to learn and every encouragement to do so. Should he take advantage of this and mark his work with the attainment of a higher degree or part of it, he will find genuine pleasure

at his success. There is no lack of helpful teaching and advice. Such special facilities which do exist he may make free use of. He may be posted as a general duty medical officer. Here he is virtually a general practitioner. Considering the age group of his patients it is not surprising that chronic ill-health is uncommon and many conditions practically non-existent—but he should find plenty to occupy his attention. For the rest, many will find themselves in close proximity to a civilian hospital. There is no Army regulation to stop them visiting such a place. It must be remembered that there is no compulsion on the National Service medical officer to improve his knowledge and ability beyond that necessary in the performance of his duties—much depends upon himself as it does in civilian practice. As a National Service officer myself I can say in all sincerity that I have received nothing other than help and encouragement during my period of service.

In conclusion I would like to make it clear that I do not suggest that a period of National Service is a benefit from the purely professional point of view, or that it is intended that it should be. It is a matter of personal initiative. If a man has no desire to learn and is content to vegetate then he has every right to do so and no one will compel him. In such circumstances, however, he is in no position to grumble and say that he has learned nothing and forgotten much. If a refresher course is needed on the completion of his service then it is completely and utterly his own unaided fault, and any vacuum which may exist is confined solely to that space between his ears.—I am, etc.,

London, S.W.1.

G. T. TATE.

The Ban on Heroin

SIR,—As some of the small fry of Dr. R. Hale-White's letter (*Journal*, May 21, p. 1277) we, too, wonder what is "the perfectly good substitute for heroin." It certainly is not morphine, amidone, pethidine, or codeine. We wonder whether the chairman of the Central Health Services Council and Lord Haden-Guest have heard of the Brompton mixture of heroin and cocaine for the relief of suffering of, for example, cancer of the lung, and, if they have, we wonder what they would substitute for it.—We are, etc.,

E. H. V. HENSLEY.

F. C. HEATLEY.

H. J. BLISS.

G. SWIFT.

J. A. PATERSON.

G. FISHER.

Winchester

SIR,—I am very concerned about the proposed Government ban on heroin (diamorphine) and would like to add my voice of protest to that of Dr. A. H. Douthwaite (*Journal*, April 9, p. 907). Here is our most potent weapon for the relief of pain to be denied us. Not only is heroin the most potent but often it is an irreplaceable drug. And heroin has other uses besides analgesic.

May I recall the case of a patient of mine—the victim of Buerger's disease? In the course of eight years this man had over forty operations, mostly amputations of major or minor extent and a sympathectomy, and now he has lost both legs and parts of all his fingers. During those eight years he suffered continuous pain of greater or less severity. When at its worst nothing could control it but heroin. Everything was tried—pethidine and the modern synthetic analgesics were useless, morphine was ineffective and made him sick. And he needed heroin in heroic doses. When the pain was at its worst he was taking heroin $\frac{1}{2}$ gr. (22 mg.) by injection every two hours, day and night for days on end—he and his wife gave the injections—4 gr. (0.26 g.) of heroin a day. At that he did not appear drugged, but felt and acted like a normal man; and it abolished his pain. One will say that he had become addicted to it. That is not so. If his pain eased up he would drop it in a day or two and do with something milder. Two years ago his disease became arrested, since when he has had no pain and no drugs. And the Government propose to deny us the use of this unique drug.

Fortunately my patient's disease is now quiescent, but it may flare up again.

Fortunately Buerger's disease is a rare condition, but there are others who suffer it. And there are other painful

conditions besides this. Our most powerful ally for the relief of pain is to be outlawed, but why is this being done? Because heroin addiction is a problem in America. I contend that this is not a justifiable reason for banning its use in this country. For one thing, it will not stop drug addiction in America. Further, there are other and better ways of controlling their addicts without interfering with us. Britain manufactures and exports heroin; there is no problem of addiction in this country. Surely American interests could be served by banning the export of the drug, though continuing its manufacture for home consumption.

Furthermore, note that all this has been done behind our backs. There was an annotation in the *Journal* of July 25, 1953 (p. 196), to the effect that W.H.O. had recommended that production and importation of diamorphine be abolished throughout the world. Since then nothing. Surely a step of such importance deserves some announcement in anticipation, perhaps a leading article in our official journal. The first printed word concerning it was a letter of protest by Dr. Douthwaite, after the Government decision had been made.

Also our legislators are being deceived. The subject has been brought up in the House of Lords (reported in the *Journal* of May 7, p. 1163), where Lord Mancroft said that "adequate supplies of a perfectly good substitute were now available." He has been deceived. There is no substitute for heroin. And, again, Lord Haden-Guest asserted that "the whole medical profession, so far as could be ascertained, was behind the order." That is untrue. Not only were the profession never consulted or asked their opinion, they were never even informed that such a step was being contemplated.

A week or two ago I placed these points before a meeting of the local Division of the British Medical Association—mainly to find out whether other doctors thought in this matter as I did. I was greatly gratified by the support my ideas received from them, and it was largely at the instigation of this meeting that I was encouraged to place my views before you.—I am, etc.,

Moffat, Dumfriesshire.

W. J. GILLIES.

SIR,—Maybe those who favour the ban on heroin are also heroic in disapproving of any attempt to relieve nocturnal cough by prescribing a linctus. Some of us, however, will wonder what to give our coughing diabetics at night if our old friend and stand-by linct. diamorph. et hyoscyam. is to disappear. Probably one or other of the big drug firms will come to our rescue, but, as they seem to have run out of names which are easy to remember, we may find ourselves, particularly the older among us, groping vainly when we try to recall the title of their products.—I am, etc.,

Launceston.

DONALD M. O'CONNOR.

Clinical Staging of Cancer of the Breast

SIR,—I would be grateful if you would allow me to comment upon the response to my letter on this subject which you, Sir, and the Editor of the *Lancet* were good enough to publish recently (*Journal*, March 26, p. 790). A copy of the letter and a covering note were sent to a surgeon and a radiotherapist at each of the teaching hospitals in Great Britain and to a number of interested clinicians. In all, sixty-five people were written to, and I asked not only for their personal views but suggested that they might feel inclined to bring the matter forward for discussion at their hospital medical committees. Forty-three replied, with varying degrees of enthusiasm, that they favoured the plan to establish an international staging and wished me luck, though several said it would be an uphill struggle. Two said it was hopeless trying and one said the attempt should not be made at all. The opinions most frequently expressed were that the British Empire Cancer Campaign, the Royal College of Surgeons, and the Faculty of Radiologists were the most appropriate bodies to deal with the matter. Mr. R. M. Blaikley has informed your readers (*Journal*, April 16, p. 970), and this has also been pointed out to me

by individual correspondents as well as by the reports from medical committees which are beginning to reach me, that a committee of the General Register Office under the chairmanship of Dr. A. H. T. Robb-Smith is considering this subject at the moment. It seems, therefore, that the problem is actively exercising learned opinion, and it is certainly not the wish of my colleagues at the Royal Marsden Hospital, on whose behalf I first wrote, to complicate the issue further at present.

I think it is generally agreed that any staging must be clinical, although, as Dr. H. J. G. Bloom and Dr. W. W. Richardson point out (*Journal*, May 21, p. 1276), a pathological staging of the regional lymph nodes is much more accurate. But it is a fact that this information is not available in a high proportion of the cases, and their graph indicates that within each clinical stage what one loses in pathological grade 3 cases one gains in grade 1 cases. My personal view is that staging should only be clinical but that in the presentation of results the histology should also be considered when this is known. Dr. Robert Morrison's staging (*Journal*, May 7, p. 1153), employing as it does eleven groups, looks complex but is in fact an application of the T.N.M. system, which will undoubtedly form the basis of any international staging, not only for cancer of the breast but for other sites as well. I feel confident myself that an acceptable staging will emerge in the not-too-distant future.—I am, etc.,

London, W.1.

MICHAEL HARMER.

Treatment of Severe Asthma

SIR,—In the article "Treatment of Severe Asthma" in the "Emergencies in General Practice" series (*Journal*, May 21, p. 1269) considerable space and attention have been given to A.C.T.H. and cortisone, remedies which are not likely to be available to the general practitioner called to treat an attack. Intravenous infusion is also often impracticable, as is the administration of oxygen.

In a short article for general practitioners I find it depressing that nearly a third of the space is devoted to the above-mentioned remedies whilst several useful and easily available drugs are omitted. Every doctor has his own particular drill for treating an acute asthmatic attack, but surely pethidine and paraldehyde warrant at least half as much space as cortisone and A.C.T.H.—I am, etc.,

London, S.E.2.

PETER H. SHERWOOD.

Insecticide Vaporizers

SIR,—Your annotation on "Insecticide Vaporizers" (*Journal*, May 14, p. 1202) has over-simplified the case and fails to distinguish black from white. The impression is given that insecticide vaporizers originated in America and are only now coming into use in this country. The contrary is the case, for the first test of such equipment was made in the course of Admiralty trials of new insecticides in 1946, and as part of the programme the mammalian toxicity of a "continuous-flow aerosol" was investigated.¹

Arrangements were soon made for manufacture in the U.S.A., and in both countries this original apparatus has been in use on an ever-increasing scale with great success and no single recorded case of harm to a human being.

Your annotation is, of necessity, based on American sources, and it is a regrettable fact that the situation in the U.S.A., following the introduction of the original British-designed apparatus, rapidly got out of hand, and it is believed that there are now over 90 different and indifferent copies of the original. At this point the vital importance of discriminating between correctly designed equipment and copies based on insufficient technical and scientific knowledge must be very strongly stressed. The A.M.A. Committee on Pesticides noted that few machines conformed to what was considered to be a reasonably safe design, and herein lies the reason for such cases of illness attributed to the "vapours" that have so far been reported in the U.S.A. The reverse is the case in Britain, for by far the greatest number of vaporizers in use in this country are the

product of very careful design and strict control over the output and insecticides used. All these units conform to, and in performance are well within, the limits stated by the A.M.A. Committee for insecticide vaporizers and the Canadian Standards Association.

Your statement on the fluctuating performance of a unit subjected to local air currents is misleading, for the essential point has been entirely missed, as the outputs referred to a unit in which the thermostat was known (and stated) to be wrongly placed. This was, in fact, part of the experimental work carried out at the University of Massachusetts on behalf of the original American company.²

Barnes³ and Brown⁴ testify to the safety of both D.D.T. and B.H.C. in general use, and Princ⁵ sums up recent work on D.D.T.: "Most scientists to-day agree that the danger of chronic toxicity from D.D.T. exposure is negligible," and more recently still in a leading article on "Agricultural Poisons" (*Journal*, April 2, p. 836) you commented as follows: "Although D.D.T., chlordane, B.H.C., and similar substances have been used in considerable quantities in many parts of the world, there is no evidence to suggest that persons using them as insecticides suffer any serious risk of acute or chronic poisoning." The experiment cited in which rats were affected when exposed to continuous inhalation falls into its proper perspective when it is realized that the dosage was appreciably greater than that possible with the majority of British vaporizers correctly sited and installed, and the fact that they have been used for much longer periods in a number of laboratory animal houses for the control of flies and body parasites with great success and perfect safety, and that one important installation has been in continuous use for nearly two and a half years.

Finally, I must refute your statement as to the ineffectiveness of such vaporizers. It is impossible in the space permitted to do more than state that the continuous-flow aerosol is a highly effective method of pest control in enclosed spaces and to give a few references, in particular the generalized account of the method in its application in many fields which has been published in *The Times Review of Industry*.⁶⁻¹²—I am, etc.,

Labelling the Container

SIR,—I wonder whether the time has not come to do away with the custom—peculiar to this country, I believe—to label medicine containers so that neither patient nor doctor can assess their contents. May I suggest that, on the contrary, it should be made compulsory for the chemist to label every medicine in such a way that its composition is clearly and fully described on the container?

As far as I can see it serves no useful purpose to keep the patient in ignorance of the nature of the medicine he is taking. The time should have passed when ignorance may have been thought to have therapeutic value, and to be a welcome help to ensure the superiority of the doctor. If the doctor's prescription does not satisfy the possibly critical mind of the patient nothing is lost by explaining the matter, or even by thinking twice before prescribing. Conversely, I cannot see any possible harm arising from the fact that the patient knows the ingredients of the medicine he is taking. There is no place in present-day medicine for the use of coloured water or other miracle drugs;

besides, in the case of placebos or for special reasons, the chemist could always be advised how to label the medicine. It happens not seldom that medicines are mixed up in the household and that the wrong drug is taken or given to children. This would occur less frequently. Even errors in dispensing may more easily be discovered if the container is labelled by the chemist.

Much of the doctor's time and mental energy would be saved if he were not so often confronted with bottles of tablets or medicine and expected to decide on sight which of them should be continued and which should be stopped; or if he were not asked to repeat the prescription for the "medium-sized" white tablets of which the patient has run out; or if he were spared the efforts he has to make when he wants to know which drugs other doctors or the hospital had previously prescribed. The patient would less often be treated with drugs which had already proved to be useless, and the State and the private patient would save appreciable sums of money if the identity of the medicine in the private medicine cupboard, in which highly expensive drugs such as antibiotics and hormone preparations often live a long and useless life, could be assessed, and if these drugs could be used when they are again needed.—I am, etc.,

London, W.1.

H. UCKO.

Cases Wanted

SIR,—In October, 1954, Kurtzke and Berlin¹ reported favourably on the use of isoniazid in a small series of cases (30) of multiple sclerosis. The results were sufficiently encouraging to warrant a therapeutic trial, and this is now being carried out in four hospitals—Middlesex Hospital, London, W.1; the Maida Vale Hospital for Nervous Diseases, London, W.9; Bristol Royal Infirmary (Dr. A. M. G. Campbell); and the Royal Victoria Hospital, Belfast (Dr. R. S. Allison).

The trial is limited to cases of recent onset, including retrobulbar neuritis, and those with a recent relapse who were capable of walking half a mile before the relapse. Cases are admitted for a period varying from two to four weeks. The trial is blind—that is, the clinician in charge of the case does not know if the patient is receiving isoniazid or the control drug, arsenic, since both substances are used in identical tablet form.

In order to expedite the entry of cases into this trial it is hoped that general practitioners will refer suitable cases to one of the above hospitals.—I am, etc.,

London, W.1.

DOUGLAS McALPINE.

Technique of Psycho-analysis

SIR,—In view of the extremely friendly and laudatory nature of Dr. Ernest Jones's review of my *Technique of Psycho-analysis* (*Journal*, May 21, p. 1261) it may seem a little ungracious to correct him on a minor point of fact. Dr. Jones maintains that, since the first edition of this book was published in 1928, "Dr. Glover has severed his connexion with other psycho-analysts." This is not quite accurate enough. In 1944, owing to my conviction that the orientations of an increasing section of the British Psycho-analytical Society, and consequently of its training system, had become profoundly unscientific, I demitted my offices in, and membership of, that Society. To mark the continuance of my relations with other psycho-analysts and with the International Association, I sought for and obtained membership of the Swiss Psycho-analytical Society. About the same time I was made an honorary member of the American Psycho-analytical Association, and subsequently was appointed chairman of the then Research Committee of the International Association. A small point, perhaps, but of some scientific and professional moment to me.—I am, etc.,

London, W.1.

EDWARD GLOVER.

Obituary

E. A. RENNER, O.B.E., M.B., Ch.B.

Dr. E. A. Renner, director of medical services of Sierra Leone, died in London on April 28 at the age of 60.

Edowo Awunor Renner was born at Freetown, Sierra Leone, on June 3, 1894, the son of Dr. W. A. Renner, who had served for 33 years in the medical service of the Colony and who had acted as principal medical officer, as the director was then termed. E. A. Renner's early education was received at the Boys' High School, Freetown, and was interspersed with regular visits to his grandparents, who had retired to Jersey, in the Channel Islands. Later he was a pupil at Park Field School, Sefton Park, Liverpool, and he went on to become a medical student at Edinburgh University, where he graduated M.B., Ch.B. in 1919.

Renner was always interested in the welfare of his own people, and he joined the Sierra Leone medical service in 1920. During his 35 years of devoted service he was medical officer in many of the medical stations throughout the Colony and Protectorate, and at one period of his career he was in charge of the pathological laboratory. During the latter part of his clinical career he was stationed at Freetown as senior medical officer in charge of the Maternity Hospital, and was also a much sought after and highly respected private practitioner in that city. For his public-spirited work he was appointed O.B.E. in 1948. Apart from his clinical acumen, he displayed outstanding administrative ability, which, combined with great tact and a very pleasant manner, endeared him to everyone. He was promoted deputy director in 1950, and a year later director of medical services of Sierra Leone, and was therefore the first African director of medical services in any of the West African colonies.

Renner was appointed director at a very difficult time, when the post-war shortage of staff and constitutional changes in the Colony added to the responsibilities of the director. His tact and preparedness to appreciate the views of the other man without sacrificing his own principles were no doubt of great value to the Colony and to the medical department, and without him much could not have been accomplished. Despite his onerous duties he found time to interest himself in the Red Cross, to which he rendered valuable service, and he was also a very keen freemason and churchman. "Teddy" Renner, as he was affectionately called by all his friends, will be greatly missed, and it is a tragedy that he died before he could enjoy a well-earned retirement with his family in England. He leaves a widow and four children, his eldest son being in medical practice in Beaconsfield.—F. McL.

A. J. WILSON, M.D., F.R.C.P.Ed.

The obituary of Dr. A. J. Wilson was printed in the *Journal* of May 21 (p. 1285). We are indebted to Dr. J. SHULMAN for the following appreciation:

By any assessment Arthur J. Wilson was remarkable. By rigid assessment he was a man of unusual talents and character. During the first world war his medical studies were interrupted by service in the Royal Flying Corps, in which he was for a time an instructor in aerial gunnery. I first met him in 1922, when we were fellow residents at the Coventry and Warwickshire Hospital. I am proud to

think that our friendship, established then, endured to the time of his death. From the very onset of his professional career he was outstanding. His life was a model of spartan simplicity—even as a young hospital resident it was obvious that he had a definite objective in life which nothing could deter him from achieving. Self-discipline was so firmly established in his character in these early days that he rapidly earned an enviable reputation for early rising, punctuality, precision, and accuracy—neatness and tidiness dominated every activity. His very handwriting was so neat and legible that throughout his life it was always a pleasure for others to read his medical notes. Clinical work followed the same pattern, and so careful and accurate were his observations that in all the 33 years of our acquaintance I have not known a diagnosis, once established by him, ever amended by anyone else. Ill-health unfortunately dogged his early professional career, and, advised by Sir Robert Philip, he showed rare courage in deciding to practise as a physician consultant at a time when it was almost a dangerous experiment so to do. He was by this time honorary physician to the Coventry and Warwickshire Hospital and was a pioneer in establishing the department of cardiology there. It was only natural, with his sound knowledge, accompanied by the most scrupulously careful and patient clinical observations, that he rapidly built up an undisputed reputation for reliability among practitioners and colleagues. Simple spartan tastes never deserted him. Apart from music and photography, medicine was his only hobby. Self-discipline was so firmly engendered that no one ever knew him to utter an angry or unkind word. This gentleness, accompanied by a charming simplicity of manner, always made him a most delightful listener, and he extended this quality to all his patients. For those who knew him his memory will be green for many a day.

Dr. W. J. GRANT, who was in practice at Shrewsbury for nearly 33 years, died at his home there on March 28 at the age of 63. William James Grant was born in Prince Edward Island, Canada, on January 31, 1892, and was educated at St. Dunstan's College, Charlottetown, Prince Edward Island, and at Laval University, Quebec, where, in 1909, he obtained the certificate of B.A. which entitled him to begin his professional studies in medicine. He entered McGill University, Montreal, for this purpose, and graduated M.D., C.M. in 1914, after which he held a resident appointment at the Western General Hospital, Montreal. From 1915 to 1919 he served first in the R.A.M.C. and then in the R.C.A.M.C., and on return to civilian life he decided to make his home in England, and for a short time was honorary assistant surgeon at Croydon General Hospital. He obtained the F.R.C.S.Ed. in 1921, and in the following year entered into partnership with Dr. J. D. Williams at Shrewsbury. When Dr. Williams retired soon afterwards Dr. Grant took over the whole of the practice. Dr. Grant was exceptionally knowledgeable and well read in medico-political matters. While his views were not always shared by his colleagues in Shropshire, his presence at local meetings never failed to add interest and fire to the proceedings. For some time he was a member of the executive committee of the Fellowship for Freedom in Medicine, and, although he had to resign from the committee because of the distance he had to travel to attend meetings, he remained a staunch supporter of the Fellowship. He will be remembered for his determined fight to secure better remuneration under the Danckwerts award for the single-handed practitioner with a small list of patients, a fight which was crowned with success. He was one of the signatories to the requisition which, in 1953, called for an extraordinary general meeting of the British Medical Association, and it was he who submitted the main pleading on behalf of the small-list practitioner at that meeting. Dr. Grant was chairman of the local committee of the British Medical Guild; he was also a member of the Shrewsbury medical board and for the past few years its chairman, and a member of the Industrial Injuries

Disablement Board of the Ministry of Pensions and National Insurance. With the full knowledge of the hopelessness of his final illness, he bore it with great fortitude. He is survived by his widow, two sons, and two daughters.—A. G. W.

Medico-Legal

"AUTOMATISM" AS A DEFENCE

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On February 11, 1955, Stanley Charlson was tried before Mr. Justice Barry and a jury at Chester Assizes on charges of causing grievous bodily harm with intent to murder or with intent to cause grievous bodily harm, and of unlawfully wounding his 10-year-old son Peter.¹

Charlson's family medical background was that his mother had died of a cerebral haemorrhage, his aunt of a cerebral tumour, and his sister of meningitis. He himself some six years before had had trouble with his legs, which he had been told was neuritis, and since then had had increasing weakness in his legs and difficulty in co-ordinating their movements if he tried to walk fast or run. He also had had persistent headaches, sometimes of great severity. On examination by the prison doctor he was found to have signs of organic disorder of the nervous system pointing to the possibility of a cerebral tumour, though the doctor did not make a definite diagnosis. There was no question of any "disease of the mind."

Charlson, who was a devoted husband and father and on excellent terms with his son, had called Peter into the back room of their home to see a rat which was standing on a stone in the river. He then for no apparent reason picked up a wooden mallet from the floor, struck him twice on the head, breaking the skin of the scalp and causing blood to flow, and then threw him out of the window 25 ft. (8 m.) into the river, severely injuring his arm and leg. When interviewed by the police later in the day, Charlson was dazed and bewildered and knew that he had done something dreadful. He remembered hitting Peter with the mallet in the back room, but could not think why he had done so.

Mr. Justice Barry in summing up to the jury told them that no defence of insanity was raised in the case. It was, however, for the prosecution to prove on the first two charges that Charlson had had the intent specified in the charge—namely, to murder Peter or cause him grievous bodily harm. On the third charge, of unlawful wounding, the prosecution would have to prove no more than that when he struck the blows he knew what he was doing. However, if he did not know what he was doing, if his actions were purely automatic and his mind had had no control over the movement of his limbs, if he was in the same position as a person in an epileptic fit, then no legal responsibility for his act rested upon him at all. The prison doctor had given evidence that someone suffering from a cerebral tumour is liable to outbursts of impulsive violence over which he would have no control and which would be quite without motive, and that Charlson's conduct was wholly consistent with such a condition.

The jury returned a verdict of "Not Guilty" on all three charges.

FEMUR FRACTURED DURING E.C.T.

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On March 31, 1955, Mr. Israel Weingott, a tailor, withdrew an action against Dr. Dalton E. Sands and the Board of Governors of King's College Hospital on the second day of the hearing. Mr. Weingott's case had been that electric convulsion therapy had been administered to him under Dr. Sands's supervision while sitting in a chair instead of lying down, resulting in a fracture of his left femur.

Mr. Weingott gave evidence that he was sitting in a chair before the treatment, in the course of which he became unconscious. Dr. Rossiter Lewis, called as expert witness on his behalf, said that the essential principles to be observed during E.C.T. were that the patient should be flat on his back on a bed or couch of firm consistency and in a position to be properly controlled by assistants at his head and feet or in some kind of restraining jacket to prevent violent movements of the legs. It was possible for the patient to suffer a broken femur during treatment even if these principles were observed. The risk would be greatly increased if the treatment were given to the patient sitting in a chair.

A former porter at the hospital gave evidence that on the day on which the treatment was given he took Mr. Weingott straight to the cubicle in which he was to have his treatment, and that this contained a wooden armchair but no couch. He said that later he collected him from the cubicle on a trolley and took him to the casualty department for his fractured femur to be treated. In cross-examination he was unable to explain how he came to do this when his time sheets showed that he was not on duty on the day in question.

Announcing the withdrawal of the case Mr. Weingott's counsel said that Mr. Weingott having heard the evidence was satisfied that there was no foundation for any of the charges of negligence he had made against the doctor and the hospital. The Lord Chief Justice said that the most serious thing was the allegation against the doctor, and he had been very glad to hear it withdrawn. Although he felt that the plaintiff had been entirely honest in bringing the action, he had obviously suffered from mental trouble, and his evidence was not such that he would have acted on it. There would be judgment for the defendants with costs.

The Medical Defence Union instructed Messrs. Hempsons, solicitors, to act for Dr. Sands.

Universities and Colleges

UNIVERSITY OF OXFORD

Dr. R. M. Acheson has been elected to a Radcliffe Travelling Fellowship, and Dr. R. G. Tucker has been awarded the Radcliffe Prize.

Mr. H. J. R. Beveridge (Ampleforth College) has been elected to a Nuffield Scholarship in Medicine at Pembroke College.

In Congregation on April 28 the degree of D.M. was conferred on Mrs. Zaida M. Hall and, in absence, on Constance L. Simpson.

Dr. J. L. Gowans has been elected to the Staines Medical Research Fellowship at Exeter College as from October 1, 1955.

UNIVERSITY OF CAMBRIDGE

The following degrees were conferred in Congregation on April 30:

M.D.—E. H. R. Ford.
M.B.—J. R. Burwell.

In Congregation on May 14 the following degrees were conferred:

M.A.—R. A. Parker, M.B., B.S.
M.B., B.Chir.—L. M. Barrett.
M.B.—J. S. Garfield (by proxy).

Drs. John Hugh Ross and Richard Hume Adrian have been elected to Fellowships at Corpus Christi College.

UNIVERSITY OF GLASGOW

The following degrees were conferred on April 30:

M.D.—M. C. Macleod (with honours), R. C. MacLeod.
Ph.D.—T. C. D. Whiteside, M.B., Ch.B.

UNIVERSITY OF DUBLIN

SCHOOL OF PHYSIC, TRINITY COLLEGE

The following degrees were conferred on May 12:

M.D.—Margaret K. B. Knox, E. du P. Meiring.
M.B., B.Ch., B.A.O.—P. R. D. Black, Jean R. Ellis, A. C. A. Hempel.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending May 14 (No. 19) and corresponding week 1954.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

† Includes primary and influenzal pneumonia.
‡ Includes puerperal pyrexia.

Vital Statistics

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in April was 116, compared with 113 (revised figure) in the previous month and 107 (revised figure) in April, 1954.

The numbers of cases of industrial diseases in the United Kingdom reported during April, 1955, were as follows: lead poisoning 5, anthrax 1, epitheliomatous ulceration 15, chrome ulceration 26; total 47. There were no deaths.—*Ministry of Labour Gazette*, May, 1955.

Week Ending May 21

The notifications of infectious diseases during the week included: scarlet fever 620, whooping-cough 1,613, diphtheria 17, measles 23,655, acute pneumonia 377, acute poliomyelitis 19, dysentery 1,232, paratyphoid fever 7, and typhoid fever 3.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1946-54 are shown thus -----, the figures for 1955 thus ———. Except for the curves showing notifications in 1955, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

¹ 1955 1 *Weekly Law Reports*, p. 317.

Infectious Diseases

The largest rises in the number of notifications of infectious diseases in England and Wales during the week ending May 14 were 892 for measles, from 19,492 to 20,384, and 176 for dysentery, from 862 to 1,038, and the largest falls were 58 for acute pneumonia, from 499 to 441, and 45 for whooping-cough, from 1,850 to 1,805.

The largest increases in the incidence of measles were 427 in Leicestershire, from 472 to 899, 303 in Glamorganshire, from 693 to 996, 256 in Kent, from 600 to 856, and 213 in Southampton County, from 735 to 948, and the largest decreases were 292 in Middlesex, from 1,606 to 1,314, 276 in Yorkshire West Riding, from 2,143 to 1,867, 232 in Warwickshire, from 1,631 to 1,399, and 216 in Essex, from 1,269 to 1,053. 571 cases of scarlet fever, 4 fewer than in the preceding week, were notified, and there were no large fluctuations in the local trends. Only small changes were reported in the returns for whooping-cough. 9 cases of diphtheria were notified, being 5 more than in the preceding week. The areas with more than one case of diphtheria were Kingston-upon-Hull C.B. 3 and Liverpool C.B. 2.

16 cases of acute poliomyelitis were notified, and these were 3 fewer for paralytic and 5 fewer for non-paralytic cases than in the preceding week. The largest returns were Yorkshire West Riding 3, London 2, Wiltshire 2, Warwickshire 2 (Birmingham C.B. 2).

The rise in the notifications of dysentery was mainly due to a large outbreak in Surrey, Croydon C.B. The largest centres of infection were Lancashire 339 (Liverpool C.B. 53, Blackburn C.B. 49, Manchester C.B. 45, Oldham C.B. 39, Middleton M.B. 19, Blackpool C.B. 18, Whiston R.D. 16, Crompton U.D. 13, Salford C.B. 11, Rochdale C.B. 10), Surrey 162 (Croydon C.B. 147), Durham 107 (Easington R.D. 23, Stanley U.D. 19, Seaham U.D. 17, South Shields C.B. 10), Northumberland 75 (Castle Ward R.D. 36, Newcastle-upon-Tyne C.B. 22), Yorkshire West Riding 62 (Huddersfield C.B. 29, Leeds C.B. 11), London 53 (Islington 16), Yorkshire North Riding 42 (Middlesbrough C.B. 38), Warwickshire 24 (Coventry C.B. 14), and Middlesex 22.

In Scotland the number of notifications of dysentery increased by 16 to 409. The largest returns were those of the cities of Glasgow 224, Edinburgh 46, and Dundee 37.

Medical News

Westminster Hospital Old Students' Dinner.—The annual Westminster Hospital dinner was held on May 27 at the Royal College of Surgeons. A large gathering, said to be a record, assembled to support the chairman, Dr. F. M. ALLCHIN. In proposing the toast of Westminster Hospital and Westminster Medical School, the chairman said that the school was full and that there were 500 applications a year for the 60 vacancies. Mr. F. A. D'ABREU proposed the toast of the guests, for whom Sir DANIEL DAVIES replied. Sir STANFORD CADE proposed the health of the chairman, and his speech, like Dr. Allchin's in reply, was a mixture of sentiment and reminiscence suitable to such an occasion.

Prison M.O.s.—The Annual Conference of Prison Medical Officers and Psychologists was held at the Home Office on May 20, the chair being taken by Dr. H. K. SNELL, Director of Medical Services, Prison Commission. Dr. J. D. W. PEARCE, of St. Mary's Hospital, and Mr. EDWARD CLARKE, barrister-at-law, spoke on "The Value of Statements Elicited During Conditions of Altered Consciousness Artificially Induced." Dr. I. A. ANGUS, Dr. W. A. NORTON, and Mrs. A. SMITH, of the Brixton Prison staff, contributed a paper on "Observations on Eleven Cases of G.P.I. at Brixton," and Dr. C. F. T. SAVILLE, medical officer at Aylesbury Borstal Institution, read a paper on "A Visit to Some Spanish Prisons."

The Society of Physicians in Wales held its sixth meeting at Tenby on May 13-14 under the chairmanship of Dr. JOHN DE SWIET. The following papers were read: "Leptospirosis in Pembrokeshire," by Dr. GLAN DAVIES. "Carpal Tunnel Syndrome," by Dr. GEOFFREY LLOYD. "Treatment of Severe Hypertension by Oral Medication," by Dr. JOHN FORBES. "Some Observations on Thrombocytopenia," by Professor SCARBOROUGH. "Experimental Embolic Carditis," by Dr. ANEURIN HUGHES. "Perforation of Interventricular Septum in Myocardial Infarction," by Dr. J. M. SWITHINBANK. "Electrocardiographic Changes in Pulmonary Embolism," by Dr. J. DE SWIET.

Royal Society Awards.—Under the Royal Society and Nuffield Foundation Commonwealth Bursaries Scheme, Mr. D. H. COLLESS (University of Malaya) receives an award to enable him to study the systematics of mosquitoes at the Natural History Museum; Dr. A. A. KINNEAR (University of Pretoria) to enable him to study endocrinological techniques at Birmingham; and Dr. J. H. D. MILLAR (consultant neurologist, Belfast) to enable him to study electrocortigraphy at the Montreal Neurological Institute.

R.S.I. Elections.—The following medical men have been elected to the council of the Royal Sanitary Institute: Dr. E. HUGHES, Dr. A. G. G. THOMPSON.

Dr. J. H. F. Brotherston has been appointed professor of public health and social medicine at the University of Edinburgh in succession to Professor F. A. E. Crew, F.R.S., who retires on September 20. Dr. Brotherston is aged 40, and qualified at Edinburgh in 1940. After service with the R.A.M.C. during the war, he worked at the London School of Hygiene and Tropical Medicine, and at Guy's Hospital.

Dr. C. V. Harrison, of the London Postgraduate Medical School, has been appointed professor of morbid anatomy in the University of London.

New French Neurosurgical Journal.—Messrs. Masson and Co. announce the publication of a new quarterly journal, *Neuro-Chirurgie*. The journal is sponsored by the Société de Neuro-Chirurgie de Langue Française, but will also publish papers by authors who are not members of this society. Subscription is £4 12s. 6d. per annum, and the journal is published from 120, Boulevard Saint-Germain, Paris, 6.

COMING EVENTS

Hammersmith Hospital and Postgraduate Medical School.—The golden jubilee of Hammersmith Hospital and the twentieth anniversary of the founding of the Postgraduate Medical School are being celebrated next week. The Queen is to visit the hospital and medical school on June 5, and June 8 will be an "open day" (from 2.30 to 5.30 p.m.), when special arrangements are being made to show interested doctors the work which is going on. Points of interest will include a new metabolic unit for the investigation of metabolic disorders, the Medical Research Council's cyclotron and linear accelerator, an exhibition illustrating the research work of the medical school, and a radio-isotope laboratory. Medical films will be shown in the lower lecture theatre, which will be the assembly point from which groups will be collected for conducted tours of the medical school and hospital.

A celebration ball will be held at the Park Lane Hotel on Thursday, June 9. Tickets (30s. including supper) can be obtained from Mr. J. G. BRICE, F.R.C.S., Hammersmith Hospital, London, W.12.

Royal Society of Tropical Medicine and Hygiene.—The Annual General Meeting will be held on June 15 (changed from June 16) at Manson House, 26, Portland Place, London, W.1, 7.30 p.m.

NEW ISSUES

Journal of Clinical Pathology.—The new issue (Vol. 8, No. 2) is now available. The contents include:

- HISTOLOGICAL DIFFERENTIATION BETWEEN PHAEOCHROMOCYTOMA AND MELANOMA OF THE SUPRARENAL GLAND. John C. Dick, Grace M. Ritchie, and Henry Thompson.
- RETICULUM-CELLLED MEDULLARY RETICULOSIS IN A YOUNG ADULT. F. G. J. Hayhoe.
- NASOPHARYNGEAL PLASMACYTOMA WITH EXTENSIVE SKIN METASTASES. D. Enslie-Smith, J. M. Johnstone, and I. C. Whyte.
- GLYCOGEN STORAGE IN THE LIVER IN DIABETES MELLITUS. R. Winston Evans, T. R. Little, and H. S. Pemberton.
- CYTOLOGICAL EXAMINATION OF SPUTUM IN RELATION TO ITS MACROSCOPIC PURULANCE. G. A. Rawlins.
- THE DRIED DISC TECHNIQUE WITH BACITRACIN, CARBOMYCIN, ERYTHROMYCIN, POLYMYXIN B, AND TETRACYCLINE. R. W. Fairbrother and R. C. Jennings.
- SENSITIVITY TESTS FOR THE POLYMYXINS. S. R. M. Bushby.
- FURADANTIN IN PROTEUS BACILLURIA. S. J. Heffernan, P. W. Kippax, and W. A. V. Pamplin.
- A CHROMATOGRAPHIC METHOD FOR THE DETERMINATION OF THE THREE BILE PIGMENTS IN SERUM. Barbara H. Billing.
- THE THREE SERUM BILE PIGMENTS IN OBSTRUCTIVE JAUNDICE AND HEPATITIS. Barbara H. Billing.
- AN INVESTIGATION OF SERUM LIPIDS AND LIPOPROTEINS BY PAPER ELECTROPHORESIS. W. G. Dangerfield and E. B. Smith.
- THE RELIABILITY OF THE DETERMINATION OF URINARY PROTEINS BY ELECTROPHORESIS ON FILTER PAPER. D. Wolvius and J. C. M. Verschure.
- AN APPARATUS FOR PAPER ELECTROPHORESIS. G. T. Franglen, N. H. Martin, and J. D. Treherne.
- THE USE OF BORATE BUFFER IN PAPER ELECTROPHORESIS OF SERUM. R. Conden and Myfanwy N. Powell.
- AMINO-ACID COMPOSITION OF SERUM PROTEINS IN HEALTH AND DISEASE. A. J. Cummings and F. V. Flynn.
- PLASMA CREATININE. Mary Ralston.
- AN ASSESSMENT OF NEW TESTS FOR DETECTING BILIRUBIN IN URINE. Daphne Bryant and F. V. Flynn.
- UPTAKE OF SULPHATE ³⁵S BY LEUKAEMIC HUMAN BONE MARROW *in vivo*. F. Ellis, L. G. Lajtha, and R. Oliver.
- HAEMORRHAGIC DIATHESIS DUE TO A CIRCULATING ANTICOAGULANT INVESTIGATED BY THE THROMBOPLASTIN GENERATION TEST. D. M. D. Evans.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, June 6

- GUY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Carbutt Memorial Lecture by Dr. J. M. H. Campbell: Cyanotic Congenital Heart Disease.
- INSTITUTE OF DERMATOLOGY.—June 6 to 30, semi-permanent exhibition: Some Interesting Photographs and Moulages (Department of Medical Illustration).
- INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—4.30 p.m., Mr. W. Hawks-worth: Utero-vaginal Prolapse.

Tuesday, June 7

- INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. J. Wallace: Vulval Atrophy.
- WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY.—5 p.m., Alroth Wright Lecture by Professor B. Ephrussi (Paris): Intrinsic Factors Controlling the Synthesis of Cytochromes in Yeast.

Wednesday, June 8

- INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Moniliasis and Related Diseases.
- LONDON SCHOOL OF ECONOMICS AND POLITICAL SCIENCE.—3 p.m., University Extension Lecture by Dr. J. A. Scott: Public Health in an Urban Community.

Thursday, June 9

- BRITISH SOCIETY FOR RESEARCH IN AGEING.—At Ciba Foundation, 41, Portland Place, W., 2 p.m., symposium: Endocrinology and Ageing. Dr. V. Korenchevsky: Endocrinological Factors in Ageing; Dr. J. A. Lorraine: Hormonal Relations in the Menopause; Dr. P. L. Krohn: The Ageing Ovary; Dr. P. J. Thung, Dr. L. Boot, and Dr. O. Muhlbock (Amsterdam): Old Age Changes in the Morphology and Functions of the Mouse Ovary.
- INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Benign Epithelial Tumours.
- NORTH-WESTERN TUBERCULOSIS SOCIETY.—At Wrightington Hospital, Appley Bridge, Wigan, 3 p.m., summer meeting.
- NUFFIELD ORTHOPAEDIC CENTRE.—At Windfield-Morris Orthopaedic Hospital, 8.30 p.m., Mr. W. Gissane: Some Problems in the Treatment of Injuries.
- POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. Felipe de la Balze (Buenos Aires): Some Histological and Functional Aspects of Normal and Pathological Testes.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor Milroy Paul (Colombo): Haemorrhages from Head Injuries.
- ROYAL SOCIETY.—11 a.m., discussion to be opened by Professor H. S. W. Massey, F.R.S.: Radiative Balance in the Atmosphere.
- ST. ANDREWS UNIVERSITY.—At Physiology Department, Medical School, Small's Wynd, Dundee, 5 p.m., Professor H. A. Salvesen (Oslo): Relation of the Parathyroids to Bone Metabolism and Bone Disease.
- ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., postgraduate demonstration in psychiatry.

Friday, June 10

- INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. G. B. Dowling.
- INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., clinical demonstration by Dr. J. G. Scadding.
- INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—3 p.m., Mr. A. H. C. Walker: Obstetric Fistulae.
- POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Mr. P. McG. Moffatt: Use of the Ophthalmoscope in Medicine (I).
- UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C., 5.30 p.m., Professor O. Krayer (Harvard Medical School): New Aspects of the Pharmacology of Veratrum Alkaloids: The Anti-accelerator Cardiac Action of the Secondary Amines.
- WHITTINGTON HOSPITAL.—At Archway Wing, N., 5.15 p.m., clinical pathological conference. Dr. J. M. Alstow: The Community, the Profession, and the Hospital.

APPOINTMENTS

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—B. H. Brock, M.B., B.Chir., F.R.C.S., Registrar in Orthopaedic and Traumatic Surgery at Windfield Orthopaedic Hospital and United Bristol Hospitals; T. Galla, M.B., Ch.B., D.P.M., Senior Registrar in Psychiatry at the Bristol Mental Hospitals; S. Haroon, M.B., B.S., D.G.O., Registrar in Obstetrics and Gynaecology at Gloucestershire Royal Hospital, Gloucester; J. J. Y. Dawson, M.D., M.R.C.P., Senior Consultant Chest Physician to Plymouth Clinical Area; B. M. Hibbard, M.B., B.S., D.Obst.R.C.O.G., Registrar in Obstetrics and Gynaecology to Bath Group of Hospitals; W. Lumsden Walker, M.B., Ch.B., D.P.H., D.P.M., Medical Superintendent to the Hortham-Brentley Hospital Group, Bristol; T. C. Leahy, M.B., B.Ch., Senior Hospital Medical Officer to the Hortham-Brentley Hospital Group, Bristol; R. V. Walley, M.B., B.Chir., Deputy Resident Physician (Infectious Diseases), at Ham Green Hospital, near Bristol; J. R. Moyle, M.R.C.S., L.R.C.P., D.M.R.D., Consultant Radiologist to Plymouth Clinical Area; B. Chudecki, Med.Dipl., Cracow, Assistant Radiologist to Exeter Clinical Area.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

- Jacobs.**—On May 11, 1955, at Arnold House, Arnold, Notts, to Jean (formerly Thwaites), wife of Dr. Brendan Jacobs, a son—Stephen Brendan.
- Perren.**—On May 4, 1955, at Battledown Manor, Cheltenham, Glos, to Mary, wife of Dr. John F. Perren, R.A.F., a son—Timothy John (corrected announcement).
- Picken.**—On May 23, 1955, at Cardiff, to Lisel (formerly Regensteiner), wife of David K. W. Picken, M.B., F.F.A.R.C.S., a brother for Charles—Ralph.

DEATHS

- Cobb.**—On April 15, 1955, at Lymington Hospital, Lymington, Hants, William Ernest Stanley Cobb, M.R.C.S., L.R.C.P.
- Fisk.**—On April 27, 1955, at Fairland House, Beccles, Suffolk, Harry Hope Fisk, M.R.C.S., L.R.C.P.
- Hill.**—On April 18, 1955, at the White House, Laverstock, Salisbury, Wilts, Horace Bryden Hill, M.B., B.S., M.R.C.P., Surgeon Captain, R.N., retired.
- Hudson.**—On May 17, 1955, at Watermillock House, Ulswater, Cumberland, James Hudson, M.D., formerly of Newcastle-upon-Tyne, aged 90.
- King.**—On April 15, 1955, at Carmarthen, Leslie Reginald King, M.B., B.Chir., late of Stow-on-the-Wold, Glos.
- Kingdon.**—On April 2, 1955, at Trehunsey, Hillside Road, Sidmouth, Devon, Clement Thomas Cory Kingdon, M.D., aged 86.
- Mitchell.**—On April 28, 1955, at his home, Holmhurst, Greystones, Co. Wicklow, Robert Hollingsworth Mitchell, M.B., B.Ch., aged 51.
- Patterson.**—On April 19, 1955, Elizabeth Patterson, M.B., B.S., of 50, Weymouth Street, London, W.
- Renner.**—On April 28, 1955, in London, Edowo Awunor Penner, O.B.E., M.B., Ch.B., of Sierra Leone, West Africa, and Fintny House, Penn Road, Beaconsfield, Bucks, aged 61.
- Trubridge.**—On April 11, 1955, at his home, Lennox, Mass., U.S.A., Luigi Walter Trubridge, M.D.

Any Questions ?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Rapid Suppression of Lactation

Q.—What is the best method of suppressing the milk, if an immediate cessation of breast-feeding is required ?

A.—If the decision against breast-feeding is already taken by the time delivery is complete, oestrogen therapy should be commenced immediately. Every hour counts and the sooner it is given after delivery the more effective it is. The aim is to give not less than 50 mg. stilboestrol (or 1.5 to 2 mg. ethinyl oestradiol) during the next four to seven days, and the dose should be high (say 5 mg. stilboestrol three times a day) during the first one or two days, and then gradually reduced. Bandaging of the breasts, aperients, and fluid restriction are unnecessary. Sometimes, at the end of the course of treatment, there is slight filling and secretion from the breasts, but this is not usually enough to require treatment. If it is, however, a supplementary modified and shortened course of oestrogen therapy can be given.

Once lactation is established it is much more difficult to suppress it with oestrogens. In such a situation a similar course of treatment is given in the hope that it will help. The breasts should be emptied at the commencement of treatment, but thereafter suckling, expression, the use of a breast pump, and any sort of local stimulation of the breasts are to be avoided.

Emotional Sweating

Q.—Is there any treatment for excessive under-arm perspiration? My patient is a healthy young woman of 20 who has to change her clothing several times a day because of drenching sweats.

A.—Though we know a good deal about sweat, the physiology of sweating, and the mechanism involved in disorders of sweating, it is unfortunately true that such knowledge is not readily translated into practical measures for the treatment of the suffering patient. Sweating may be a consequence of heat or of emotional disturbance, mental effort or sensory stimulation. Emotional sweating particularly affects the axillae, palms and soles, and forehead. The channel along which these disturbances act is nervous, and interruption of continuity of that channel at various levels may abolish the function of sweating.

Atropine, methanthelinium ("banthine"), and similar drugs are acetylcholine-inhibitors and so may protect the secretory mechanism from excessive stimulation, but they are usually effective only in doses so close to those producing untoward side-effects that they are not suitable for continuous use. They may with advantage be employed on particular occasions. Tincture of belladonna, 10–12 minims (0.6–1.2 ml.), may be taken half to one hour before the occasion and will usually be tolerated. In the last resort surgical interruption of the nervous channel by sympathectomy may be performed, usually with excellent results in the hands and feet but less successfully in the axillae. In a proportion of patients in whom the operation is performed in the upper sympathetic chain a more or less troublesome gustatory sweating of head or face has been reported as a sequel. It would be ideal if a similar blocking of impulse could be achieved by the use of those drugs which are known to be ganglion-blocking agents, such as the hexamethonium group. Unfortunately, as with the acetylcholine inhibitors, the effective dosage is so near the toxic dose that the continuous administration is dangerous. How-

ever, it may help to prescribe a tolerated dose of methylphenobarbitone, 3 gr. (200 mg.) twice daily, or amylobarbitone sodium, 1 gr. (65 mg.) thrice daily, which are the more effective of the barbiturates as ganglion-blocking agents.

While many patients suffer excessive sweating as a simple aberration of the normal physiology without any more significant psychological component than temperamental sensitiveness, a proportion are dependent upon psychological experience in childhood or adolescence, and such patients can with advantage be treated by the psychiatrist.

Routine treatment of patients with hyperhidrosis is largely empirical and symptomatic and relies upon local measures. These are often not very successful. Most local measures depend in part upon a blocking of the gland orifice, and thus carry with them the risk of inflammatory and infective sequelae such as occur with any retained secretions. Others closely approach a direct irritant effect and have therefore to be used with caution. The patient should try a variety of remedies and in varying concentrations to discover which is most helpful and most acceptable. Bathing twice daily for ten minutes in a solution of bleaching powder, a teaspoonful to a quart (2.3 litres), increasing to a teaspoonful to a pint (0.6 litres), is helpful, care being taken to avoid producing a dermatitis. Formalin solution, aluminium acetate and chloride, each starting with a concentration of 1% and 10% sodium hexametaphosphate, are other astringents of value. In some patients the use of the constant current (15 to 20 mA for 20 minutes twice a week) is effective, the negative pole being placed in the axilla. X rays (300 r at 90 kV through 2 mm. aluminium on three occasions at monthly intervals) should be prescribed only by those experienced and expert in this field and should not be repeated.

In conclusion, every patient with axillary hyperhidrosis presents an individual medical problem, and should not be treated along routine or empirical lines until the medical and often the psychosomatic aspects have received attention.

Management of a Transverse Colostomy

Q.—About three months ago a transverse colostomy was performed on a male patient aged 55 on account of a perforated diverticulum. Can you assist me towards (a) reducing the number of "actions" of the colostomy; and (b) increasing the solidity of the faeces? The patient has been instructed about diet and fluid restriction and takes "isogel" water-absorbing granules.

A.—The "control" of a transverse colostomy can never be as good as that of an iliac operation. Since in this case the operation was done for a perforated diverticulum there is a possibility that the colostomy may later on be closed, but not, of course, until careful radiological studies of the distal bowel have shown its condition and patency. It is true, too, that all colostomies tend to settle down and become more manageable with the passage of time.

So far as diet is concerned each patient is a law unto himself; it requires painstaking observation on the part of the patient to find out the reaction of his bowel to various foods. It is usually thought best to give a comparatively non-residue-forming diet so that there is little bulk left to stimulate the colon, and, of course, as has been done already in this case, to keep the fluid intake down to a minimum. Kaolin is probably the most reliable material to make the bowel contents more solid and might be used instead of the "isogel." Green vegetables, onions, and so on tend to give a malodorous flatus and so should be avoided; activated charcoal in the form of biscuits is useful here. Habit-forming drugs to help control would naturally be used with great caution, but in the early stages of colostomy life the administration of a small dose of chlorodyne with meals is sometimes of help. In the case of a transverse colostomy, washing out the bowel is rarely of help and may even stimulate the bowel to greater activity.

Sobering Up with Aspirin

Q.—What effect might 50 gr. (3.3 g.) of aspirin have on the clinical signs and symptoms of alcoholic intoxication, and on the alcohol content of the urine? Locally, the "boys" when out on a drinking round commonly use aspirin, as well as amphetamine and "oblivon," to help them sober up.

A.—Individuals vary greatly in their sensitivity to aspirin. A dose of 50 gr. (3.3 g.) might produce nausea and vomiting in an average individual, and in a hypersensitive person might also give rise to tinnitus and deafness. It would not alter the signs or symptoms in a person who had been drinking nor make him appear to be more sober than if he had not taken it. The concentration of alcohol in the urine would not be affected by aspirin, and a knowledge of this figure or of the amount of alcohol consumed could be used as evidence in the usual way. Salicylates tend to interfere with the Cavett method for the assay of alcohol in urine, but accurate results are given by the Kozelka and Hine method. The "boys" would be well advised not to use "oblivon" (methylpentynol) as a means of sobering up, since its effects resemble those of alcohol and its use would tend to increase their apparent degree of intoxication. Aspirin would have no effect except through psychological mechanisms. Amphetamine taken after a patient has ceased to drink has a distinct sobering effect, and, taken the morning after, prevents or abates the usual symptoms of hangover.

Brown Tongue

Q.—A man aged 39 complains of a foul taste in his mouth and a brown patch on his tongue for two years. On two occasions during that time the patch disappeared completely without treatment, and with it the foul taste. On examination four weeks ago there was an ulcer about one inch (2.5 cm.) long down the middle of the tongue at the junction of the anterior two-thirds and posterior third of the tongue. In and around it was a friable brown material removable by scraping. A barium swallow and meal showed no abnormality, but a swab gave a pure growth of a fungus of the genus *Candida* on culture. I treated him with tyrothricin lozenges for a week, which produced no improvement, so I followed this with 1% aqueous gentian violet as a paint night and morning for two weeks. This has resulted in amelioration of the foul taste, but the brown patch is still present on the anterior two-thirds to a slight extent, while the posterior one-third remains unchanged, for the patient cannot paint that without gagging. I should be grateful for advice on further treatment.

A.—The brown patch may well be caused by infection with *Candida*, but it should be remembered that this yeast may be present only as a secondary invader or even as a harmless saprophyte. The ulceration suggests that there is an active infection, and the improvement with gentian violet would support the view that *Candida* is playing a pathogenic role. Tyrothricin has some fungicidal activity, so that improvement could occur, but one would expect more benefit from gentian violet.

Spontaneous change in the flora of the mouth is quite common in the healthy mouth. Van Leeuwenhoek, in his pioneer studies with the microscope, observed changes in his own buccal micro-flora after drinking hot coffee. It is not surprising, therefore, to find that spontaneous recovery from brown tongue occurs.

The foul taste is probably the result of some change in the enzymes in and near the taste buds, rather than the production of an evil-tasting substance by the invading organism. Why this is not a more frequent accompaniment of brown tongue has not been explained.

Treatment should be carried out by the doctor, and the posterior part of the tongue should be painted with gentian violet. If this is not successful it might be worth trying with 33% trichloroacetic acid. Superficial x-ray treatment

to the posterior part of the tongue is difficult and may be impossible, so that local application will have to be persisted in; it would be worth giving the patient a lozenge containing benzocaine or other local analgesic to suck before attempting to paint the remaining brown areas.

Right of Disposal of Wife's Dead Body

Q.—In the case of a wife's death, who has the right of disposal of the body? Does a son or a daughter take precedence over the husband? Is the position in Scots law the same as in English law? If not, please indicate the difference.

A.—In England, if a wife leaves a will, her executors (whoever they may be) have a statutory responsibility for her burial and they have the right of disposal of her dead body to the exclusion of her husband and family. If she leaves no will, her husband will be the next of kin, and the duty of burial and its complementary right of disposal rest on him.

In Scotland the English statutes do not apply and there is no reported decision of the courts on the subject: in consequence the position is far from clear. The best opinion appears to be that the husband's wishes would take precedence over those of the family of the deceased.

Lack of Beard

Q.—A 33-year-old man is worried by his lack of beard. Each morning he shaves, but the soft texture of his beard and the sparsity of its distribution are a source of embarrassment to him. On examination he is well built. He has normal distribution of body hair with male configuration. He leads a normal sex life. The genital organs appear normal, if slightly below average size. What is the reason for the lack of beard? What is the possible treatment?

A.—Normally the growth of the beard is dependent on a sufficiency of testosterone produced by the testicular interstitial tissue. Since, however, this man's sexual life and growth of body hair are normal, his lack of beard is unlikely to be due to deficiency of androgens. His condition is probably what is termed "resistance of the target organ"—that is, insensitivity of the hair follicles to androgenic stimulation. In such a case treatment will probably be ineffective, but a trial might be made of the daily local inunction of testosterone cream.

Some Problems of an Adolescent Girl

Q.—I should be grateful for advice on the treatment of a healthy girl of 17, whose peripheral circulation is very poor. She has chilblains in winter, but her main complaint is the purplish discoloration of her legs and cheeks, worse in winter but never completely absent. There is also adolescent acne, a very coarse skin over the buttocks and outer surface of the arms, and a rather sour body odour in spite of daily baths and strict attention to hygiene.

A.—A pernicious type of circulation with erythrocytosis of the calves is a constitutional condition (unless acquired after acute poliomyelitis). It is often congenital, sometimes inherited, and is not very amenable to treatment. Small doses of thyroid extract (e.g., $\frac{1}{4}$ gr.—16 mg.—daily) are sometimes useful. The body must be kept warm to lessen peripheral vascular tone, and sudden considerable changes of temperature should be avoided. Central heating is a help, and on going out in cold weather warm clothing is essential. It is difficult to get a girl of 17 to wear woollen stockings, but she might be persuaded to put them on over nylons when she goes out of doors. Otherwise jeans should be worn. Elastic stockings are helpful because they are warm, and because they lessen the chronic oedema so often present with erythrocytotic legs.

The other complaints are associated with adolescence, and time will effect a cure. Acne vulgaris can usually be improved by simple measures. The greasiness of the skin

requires the frequent use of soap and water or rinsing with weak cetrimide solution ($\frac{1}{4}$ -1%). No grease should be applied to the skin, and if make-up is used a "liquid powder" is best. Chocolate and fried food must be avoided and the intake of starch reduced. Precipitated sulphur (6%) in calamine lotion may be applied at night. Fractional doses of x rays are helpful.

Watercress Cultivation

Q.—I would be grateful if you can tell me whether any standards for the purity of water used for commercial watercress beds have ever been formulated. Is there any literature on the subject to which I could refer?

A.—The Ministry of Agriculture and Fisheries has had two schemes governing the grade and designation of watercress. Under the National Mark Scheme certain physical qualities were demanded, but there was no mention made about water purity. In a trial scheme, first suggested in 1950, the same physical qualities were mentioned and extended to include a declaration that the ingoing water to the cress beds should be of drinking-water quality. Neither the National Mark Scheme (suspended at the beginning of the second world war) nor the trial scheme is at present in operation. The inquirer should refer to a paper¹ read before the Royal Sanitary Institute's Health Congress at Scarborough in 1954, which is an excellent review of information concerned with the hygiene of watercress cultivation.

The best policy to aim at would be to insist on a standard of purity for the water similar to the prevailing standard for rural water supplies, but in any case, as watercress is eaten in the fresh state, its consumption is somewhat hazardous, because it may be exposed to contamination from sources other than the water supply in which it is grown.² It is recommended by some authorities that watercress should be cleansed by soaking in a chlorine solution (free chlorine 150 parts per million) for about 10 minutes and then washed thoroughly in mains tap water. There is no wilting of the leaves and no appreciable taste after this procedure.

Drug Treatment of Ménière's Disease

Q.—What place have vasodilators, antihistamine drugs, vitamins, and streptomycin in the treatment of Ménière's disease? How successful are they? Are there any measures that will improve the hearing loss when the degree of loss does not appear to be static?

A.—The morbid anatomical basis of Ménière's disease of the labyrinth consists in a dilatation of the endolymphatic system resulting from some disturbance in the circulation of the endolymph. The cause of this disturbance is as yet unknown. The beneficial effects of histamine and nicotinic acid described by Shelden and Horton¹ and Miles Atkinson²⁻⁴ are likely to be dependent upon some improvement in the circulation of the endolymph, brought about by vasodilatation within the labyrinth. The good effects of cervical sympathectomy, described by Garnett Passe,⁵ are likely to be brought about in the same way. The therapeutic effect of certain antihistamines—for example, dimenhydrinate, mepyramine, and promethazine—is probably dependent, like that of phenobarbitone, upon its depressant action upon the vestibular centres. Vitamin therapy has been recommended by a number of authors, in particular with vitamins A and B. The good results claimed have not been substantiated. Streptomycin has also been prescribed for Ménière's disease in view of its destructive effect upon the vestibular neurones. The use of streptomycin has, however, certain serious disadvantages. There is evidence that in addition to its effect upon the vestibular neurones it also brings about widespread pathological changes in the vestibulo-cerebellar pathways. The effect of this is a persistent state of general imbalance which in elderly people may be very serious.

Improvement of hearing sometimes follows vasodilator therapy—for example, intravenous infusion of histamine. It must, however, be added that similar improvements in hearing sometimes appear to occur spontaneously in the natural course of the disease.

Irritation of Tip of Penis

Q.—I have a patient aged 76 years who complains of intense irritation of the tip of the penis. The irritation is apt to come on at any time of the day or night, and is extremely embarrassing, as the desire to scratch is almost unendurable. I would welcome some suggestions on diagnosis and treatment.

A.—I assume that the urine has been tested for sugar, and that there is no urethritis or balanitis to account for the irritation. Also that the meatus appears normal and that there are no disturbances of micturition such as difficulty, frequency, or pain. If nothing can be found to account for the meatal irritation, I should give the patient a course of testosterone intramuscularly on the supposition that it is due to senile tissue changes. Testosterone is often very effective in the treatment of senile pruritus. It might also be worth while giving the patient some 1% cinchocaine ointment for local use.

Ritual Circumcision

Q.—My son, now aged 2 years, had a ritual circumcision performed when he was 7 days old. I was very worried at the time, as there was practically no penile skin left, but I was assured that this was quite in order. As a matter of fact the wound healed quite well, and we have had no trouble: the shaft of the penis is almost completely covered by good scar tissue and there remains a small area of normal skin at the root. Is this in fact in accordance with the established principles of ritual circumcision, and will the scar tissue give rise to any trouble in future years?

A.—To remove so much skin is certainly not in accordance with ritual ceremony, and it is fortunate that the wound healed so well. The skin of the penis is very elastic, and it is quite easy for a priest (or medical man) to pull down too much at the time of circumcision. But the scar should not cause trouble in future years.

Corrections.—The late Dr. John Lowe did much research on the treatment of leprosy by sulphones, not sulphonamides as inadvertently stated in Sir Arthur MacNalty's appreciation (May 21, p. 1283).

In announcing a research grant to Dr. Hilda Roberts (May 28, p. 1351) we described her present appointment as lecturer in anaesthesia in the Postgraduate Medical School. Dr. Roberts resigned from that post on March 31 and is now an honorary research assistant of the Institute of Obstetrics and Gynaecology at Hammersmith Hospital.

Books of "Any Questions?"—The second and third volumes of "Any Questions?" are available, price 7s. 6d. (postage 6d.), from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller. Each contains some 200 selected expert answers, and the third volume a cumulative index to the three published books.

*In cases of
osteo- and
rheumatoid
arthritis*

BUTAZOLIDIN

Phenylbutazone

has given considerable relief

BUTAZOLIDIN has now been used in the treatment of many hundreds of thousands of cases of osteo- and rheumatoid arthritis, and in a great number it has resulted in considerable relief from pain and in increased mobility. There is reason to believe that its action is more than analgesic, for the increased movement obtained is greater than that resulting from simple analgesia alone. This is noted particularly in cases of osteoarthritis.

GEIGY

For optimal results with minimal risk of side reactions, physicians are urged to consult the detailed literature on BUTAZOLIDIN available on request.

BUTAZOLIDIN is available in tablets of 100 mg. and 200 mg. and in 5 ml. ampoules containing 1,000 mg. phenylbutazone.

THE EVOLUTION OF THE TREATMENT OF ADDISONIAN ANAEMIA*

BY

Sir LIONEL WHITBY, C.V.O., M.D., F.R.C.P.

Regius Professor of Physic in the University of Cambridge

The rational treatment of any disease is governed entirely by the depth of understanding of its fundamental cause and of the factors which may contribute. The treatment of Addisonian anaemia has therefore evolved with the accumulation of knowledge through the century since 1855, when Addison, in the preamble to his classical monograph, *On the Constitutional and Local Effects of Disease of the Suprarenal Capsules*, wrote his few brief paragraphs on an "idiopathic anaemia."

It would not be within the terms of my title to enter into a long discussion on whether the first recognizable clinical descriptions of Addisonian anaemia should be ascribed to James Scarth Combe, of Edinburgh, to Thomas Addison, of Guy's, or to Professor Anton Biermer, of Zurich. But it would be appropriate to mention that Addison recognized that the malady was fatal, the onset was insidious, the usual symptoms of anaemia were present, that the body fat was often well preserved, and that treatment was ineffective. He stated that the condition arose from "no discoverable cause whatever," but speculated that "from the disease having uniformly occurred in fat people" he was "naturally led to entertain a suspicion that some form of fatty degeneration might have a share at least in its production."

Addison's most clear description—though submerged in his classical monograph on suprarenal disease, and consequently open to the criticism that the author was confusing two diseases—is nevertheless far superior to that given by Combe (1824), whose patient had, indeed, a severe anaemia, but with no convincing features suggestive of Addisonian anaemia.

There is no doubt, however, that the account of 15 cases of fatal anaemia which he had met with in the course of five years, given by Biermer in 1872, came nearer than any other that had previously appeared to depicting Addisonian anaemia as it is recognized to-day.

Addison's position was, however, firmly established some years after his death by two staunch advocates: first, his devoted pupil—Samuel Wilks—who in 1874, in a letter to the *British Medical Journal*, asserted that Thomas Addison had lectured about the disease as far back as 1843; and, secondly, William Pepper, professor of clinical medicine in the University of Pennsylvania, himself greatly interested in the disease, who gave, in 1875, some of the first reports of the bone marrow—

albeit not very convincing, since they suggest leukaemia rather than pernicious anaemia—and who considered that "the older and equally clear description by Addison of idiopathic anaemia was one and the same affection as the progressive pernicious anaemia reported by Biermer."

Addison as a Diagnostician

Addison was outstandingly famous as a diagnostician; his obituary notice in the *Medical Times and Gazette* (1860, 2, 20) says: "Diagnosis was his forte, and those who knew him best are aware that he stood unrivalled in his power of searching into the complex framework of the body and dragging the hidden malady to light. His very meagre and simple prescriptions—if he remembered to prescribe at all—showed that he made no study of therapeutics."

Nevertheless, in what is always regarded as his first public pronouncement on Addisonian anaemia, his communication to the South London Medical Society in 1849, there are some scant descriptions of treatment, but it is difficult to know whether Addison was then speaking of suprarenal disease or his "idiopathic anaemia." The probability is the former, but there is clearly confusion of both. Whatever may have been the nature of these cases, the somewhat non-specific treatment can be regarded as appropriate to all of them.

In referring to two patients who recovered, he says of one, "A man below the middle period of life, who was looked upon as past all hope, and suspected to be suffering from some latent malignant disease, slowly, but steadily, recovered under the free use of brandy, but with the singular result that the hair on one side of his head turned permanently grey, whilst the other side retained its original brown colour."

Treatment of anaemia at that time had not progressed since the time when Sydenham wrote, "We give Mars in the pale colours, the pallor disappears, and once again the face is rosy and ruddy." Then, as now, the iron-deficiency anaemias would have responded to iron in the form of the oxide, the sulphate, and the carbonate, provided sufficient was given, and this irrespective of mercury and other metals, the astringents, diet according to the powers of the stomach, as well as formidable purgings, which were put into operation at the same time.

Pepper (1875), however, appreciated that Addisonian anaemia was in a class by itself, and doubtless he had found, like others, that iron was ineffective. Unhindered by our modern knowledge of such trivialities

*Addison Centenary Memorial Lecture delivered at Guy's Hospital Medical School on March 23, 1955.

as blood groups, he made at least a rational if somewhat perilous approach to symptomatic treatment by advocating and practising blood transfusion, with reactions and results which strike terror into the heart of the modern reader.

Approach to Rational Treatment

At this time—the 'seventies—the current views on aetiology can hardly be regarded as pointing the way to rational treatment, but even then the possibility of a psychosomatic influence was being seriously considered.

Samuel Wilks (1874), in the letter to which I have already alluded, and in which he succinctly established the priority of Addison over Biermer, said: "I express an opinion that nervous shock may be the starting point of the morbid process, and I know of a case where a young lady poisoned her father, and was so overwhelmed with grief that she took to her bed, became anaemic and died. Two of my cases gave a distinct history of moral shock, and a young lad, who died in one of Sir W. Gull's beds, with extreme anaemia, had never been well since he had been attacked by a sheep in a field." He then delivers the knock-out blow to the Continental claim: "The German and the Swiss doctors do not allude to this probable cause."

The last quarter of the nineteenth century provided a steady accumulation of clinical detail about Addisonian anaemia, but relatively little in the way of fundamental understanding, with the one exception of the finding of changes in the stomach, which, however, were not properly comprehended at that time. Consequently, though the clinical entity itself became clearer, the approach to rational and specific treatment was wanting. Glossitis, a number of characteristic changes in the peripheral blood, the hereditary factor, retinal haemorrhages, and neurological changes all came to be built into the picture of the disease.

It was Samuel Fenwick (1877), physician to the London Hospital, who supplied the first appreciation of the importance of stomach function. In a lecture on "Atrophy of the Stomach" he made a clear distinction between Addison's anaemia and Addison's disease, and he described four cases of the former which, after death, had a well-marked lesion of the glandular structure of the stomach. He says: "The stomach showed no signs of post-mortem solution; the whole of the glandular structure of the organ was in a state of atrophy." He actually tested an infusion of the stomach with half a drachm of hydrochloric acid for its power to digest hard-boiled egg. This observation—the failure of stomach function—was, as we now know, the key not only to the proper understanding of the disease but also to its specific treatment as practised to-day.

However, the correct interpretation of these findings was side-tracked—in fact, obscured—for almost half a century after Samuel Fenwick's lecture, largely as the result of the work of William Hunter (1901), a physician at Charing Cross Hospital, who in an incisive and convincing monograph postulated a septic origin for the disease.

A Septic Origin?

Hunter's thesis was based on the belief that Addisonian anaemia was essentially haemolytic by reason of infection of the alimentary canal with haemolytic organisms. The preface to his monograph contains a table in the form of a genealogical tree emanating from the question "What is Pernicious Anaemia?" and evolving to be answered in the later "generations" by confident statements that the disease must originate in the gastro-intestinal area from a "special poison" in the liver, from "infection" in the intestine and stomach, the latter with *Sireptococcus longus*, and a "special infection" with associated dental cario-necrosis and glossitis.

Hunter's monograph, convincingly written, greatly influenced the treatment of Addisonian anaemia. First, he

advocated the prevention and removal of the infective cause of the disease by paying attention to the hygiene of the teeth and of the mouth. Secondly, he said it was essential to change such conditions in the gastro-intestinal tract as favoured the operation of the infective cause. This was done by washing out the stomach, by administering what was regarded as a gastric antiseptic—salicylic acid or bismuth salicylate—as well as intestinal antiseptics, such as salol, naphthol, calomel, or mercuric chloride, and, not least, enemata containing salicylic acid. Thirdly, there were certain measures designed to combat the chief symptoms, of which the most important and most widely used was arsenic in the form of Fowler's solution. This had been introduced by Byrom Bramwell (1877), with high hopes of effecting permanent cure, though experience had shown that it had only a temporary beneficial influence.

It is perhaps interesting to note that Minot and Castle (1935) took the trouble to investigate the action of arsenic in pernicious anaemia when they were carrying out their studies on the significance and interpretation of the reticulocyte count. They found that arsenic would produce an irregular and often sustained reticulocyte response in pernicious anaemia, sometimes associated with showers of nucleated cells, but that the reaction was not physiological, since any subsequent rise in the red-cell count, if such occurred at all, was irregular, disorderly, and incalculable. It is now known that arsenic has no real blood-building value and that it acts as a bone-marrow depressant rather than as a stimulant.

Hunter also practised dietetic treatment, stating as his view that "the most important factor regulating the amount of blood destruction in health is the nature of the diet, a nitrogenous diet causing a much greater destruction than a farinaceous one." He also made a very limited trial of antistreptococcal serum, but even though most of the cases which he records seem to have had a remission he clearly rated this remedy quite low.

Hunter's views dominated the treatment of pernicious anaemia for a quarter of a century, and were supported by Arthur Hurst (1923), who showed that, as the result of oral sepsis, the *Str. longus* became implanted in, and could be recovered from, both stomach and duodenum. Hurst is best known for his emphasis upon the loss of stomach function, particularly the complete achlorhydria so characteristic of Addisonian anaemia, which permitted the implantation of the toxin-producing streptococcus in the upper part of the alimentary tract. Hurst realized the primary importance of the achlorhydria, since it preceded the anaemia and was not, therefore, a secondary phenomenon, whilst it persisted even in remission. He held the view that the anaemia and nervous system changes were both toxic in origin.

When I entered the wards of the Middlesex Hospital in the early 'twenties, the main treatment of Addisonian anaemia followed the views of William Hunter, as expanded by Hurst. Wholesale dental extractions, the administration of arsenic, dilute hydrochloric acid three times a day before meals, for life, together with acidophilus milk. Splenectomy had also a considerable vogue, especially following the reasonably favourable report of Krumbhaar (1916).

Transfusion, with or without splenectomy, was also widely practised, especially in America, with, however, no more than a temporary effect, and this method of treatment must have given George Minot (Minot and Lee, 1917) some of his first experience with pernicious anaemia.

The Work of Whipple, Minot, and Murphy

Meanwhile, in the year following the first world war the way was being prepared for one of the most far-reaching discoveries in medicine. As early as 1918, George Whipple, first in California, and later in Rochester, began a long-term fundamental study upon the power of different foodstuffs—meat, liver, and other substances—to effect the regeneration of haemoglobin in dogs, otherwise maintained on a

standard basic diet, and exsanguinated to a fixed degree. This original and ingenious programme was both simple and effective.

During the period from 1918 to 1925, in association with his colleagues C. W. Hooper and Mrs. Robscheit-Robbins, Whipple published a series of papers, unravelling the basic physiology of haemopoiesis in a systematic and orderly manner, and with a thoroughness and pertinacity which can scarcely have been equalled before or since. The most significant papers in relation to my theme are entitled: "Blood Regeneration following Simple Anaemia: Influence of Meat, Liver and Various Extracts Alone or Combined with Standard Diets" (Hooper, Robscheit, and Whipple, 1920); "Favourable Influence of Liver, Heart, and Skeletal Muscle in Diet on Blood Regeneration in Anaemia" (Whipple and Robscheit-Robbins, 1925). It should also be noted that Whipple (1922) had suggested that, "In pernicious anaemia, there may be a scarcity of the material from which the stroma of the red-blood cells are formed or that a disease of the stroma-forming cells of the marrow exists."

Critics have sometimes said that though Whipple and his colleagues clearly demonstrated the virtues of liver and other substances in blood regeneration, their standard of reference, a dog rendered anaemic by bleeding, bore no resemblance whatever to pernicious anaemia. But no one can read the first fully documented paper of Minot and Murphy (1926) without feeling Whipple's influence, and, indeed, the paper contains this significant paragraph: "Following the work of Whipple and Robscheit-Robbins, we made a few observations on patients, concerning the influence of a diet containing an abundance of liver and muscle-meat, on blood regeneration. The effect appeared to be quite similar to that which they obtained in dogs. These observations, together with the information given above, led us to investigate the value of a diet with an abundance of food rich in complete proteins and iron—particularly liver—and relatively low in fat, as a means of treatment for pernicious anaemia."

The award of the Nobel Prize in 1934 to Whipple, Minot, and Murphy expressed the judgment of an impartial world towards these great men.

Looking back over the intervening period and re-reading Minot and Murphy's simple conclusion that "the dietetic treatment of pernicious anaemia is of more importance than hitherto recognized," one must greatly admire their modesty and the care with which they attempted to control their remarkable results. Their most commendable caution in interpreting therapeutic successes in a disease well known to be subject to one or more spontaneous remissions ought to be blazoned as an example to all who undertake therapeutic trials. After a most critical discussion of results with other remedies, they say, in relation to the obvious constancy and endurance of their own: "There is no data to indicate whether the remission in these 45 cases will last longer than those of others." This simple paper, patently honest and diffident in the extreme, resembles the gentle opening bars of a great unfinished symphony, of which some movements have even now not yet been composed, much less played.

A Developmental Sequence

The developments have been remarkable: In therapeutics, the sequence from liver itself to oral and parenteral extracts, crude and refined, to folic acid, folinic acid, and vitamin B₁₂. In clinical medicine, the comprehension of much about the megaloblastic anaemias—not only pernicious anaemia, but also the nutritional anaemias of pregnancy, infancy, and alimentary disturbances such as sprue. In physiology and pathology, a steady advance in knowledge of the fundamental processes of blood formation, including the cytochemistry and biochemistry of erythropoietic metabolism, all of which has illuminated the field of protein chemistry far beyond the haemopoietic system.

With the discovery of the efficacy of liver the true pathology and aetiology of Addisonian anaemia was shown to be not a haemolytic phenomenon but a maturation defect causing dyshaemopoiesis—a shift from a destructive process to a deficiency disease. Nevertheless, there is ample evidence that excessive red-cell destruction contributes to the anaemic state, even though this haemolytic aspect is of quite secondary importance compared with dyshaemopoiesis (Singer *et al.*, 1948).

The concept of Addisonian anaemia has, however, been greatly extended, so that it is now regarded as a generalized cellular disease, and not simply as a dyshaemopoietic anaemia with neurotrophic complications. Cellular degenerations or changes are found not only in the erythroblasts of the bone marrow and the tissue of the central nervous system, but also in the granular leucocytes of the marrow giving rise to macropolycytes, in the megakaryocytes, in the epithelial cells of the tongue, oesophagus, stomach, and even the respiratory tract (Graham and Rheault, 1954). These multiple changes are all rectified with liver or vitamin B₁₂.

Many times during the past hundred years has diet been considered important in the treatment of Addisonian anaemia. Many times also has the fashion changed, as is so frequently the case with dietetic measures for any pathological condition even to this day. Fenwick (1880), for example, recommended protein foods rather than farinaceous, whereas Hunter advocated the reverse. It should also be appreciated that others (Gibson and Howard, 1923) before Minot and Murphy—some also basing their work on that of Whipple and his colleagues—had prescribed liver for patients with Addisonian anaemia, and had reported improvement, but none had recognized that liver possessed a complete curative effect.

What is remarkable is not that Minot and Murphy thought of trying the effect of liver, since there were a number of pointers, from the well-known beneficial effect of liver-soup in sprue to the experimental work of Whipple, but that they had the foresight or instinct or courage to exhibit it in sufficient amount—half a pound or more of raw or lightly cooked liver a day for life—and with sufficient persistence to obtain and maintain the required effect.

There should be a plaque somewhere to record the fortitude and faith of the first 45 patients with Addisonian anaemia whom Minot and Murphy treated, who endured this nauseating treatment and so gave this great boom to mankind.

When I was in Boston in 1946 there was a dramatic clinical demonstration of two cases of Addisonian anaemia at the Peter Bent Brigham Hospital. Minot and Murphy were both present. The first case was one of the original series of 45 reported in 1926; the patient, a woman, had reached the age of 80, and was dying of carcinoma of the stomach; she had had more than twenty years of happy life, and had graduated through all the advances in liver therapy to that time. The second case, a newly identified one, presented as a contrast, had, with one single parenteral injection of a concentrated extract, shown a maximum reticulocyte response and all the other expected features of a complete remission.

Minot's technique for estimating an early response to treatment by means of a reticulocyte count was a neat and most effective clinical method for control. It was probably crucial in the discovery of liver, since the occurrence of a reticulocyte crisis encouraged persistence and indicated dosage. It has since found numerous applications in clinical haematology, as well as in the elucidation of the pathology of blood disease and the evaluation of methods of treatment.

Castle's Hypothesis

The remarkable investigations of William B. Castle and his colleagues, which began in 1929 and continue even to this day, have clearly shown the role of the stomach in the production of Addisonian anaemia. The experiments,

brilliantly planned and faultlessly executed, showed the relationship between normal haemopoiesis, the diet, gastric secretion, and liver function.

Castle's work can be accounted among the greatest advances in the study of disease processes. It called attention to the vital point in Addisonian anaemia—that certain stomach secretions were essential for fundamental nutrition. The weak antiseptic action of the normal stomach juices in preventing the implantation of a haemolytic organism in the intestine, the basis of twenty-five years of treatment for Addisonian anaemia, ceased to be important almost overnight.

Castle's experimental work led him to propose (Castle *et al.*, 1930) his hypothesis that normal erythropoiesis depended upon a substance of unknown composition generally referred to as the haemopoietic or anti-pernicious anaemia principle. This principle, he suggested, was formed in the normal stomach or in the small intestine by the interaction of two factors—an extrinsic factor present in certain protein constituents of food, and an intrinsic factor secreted by the epithelial cells of the fundus of the stomach.

The haemopoietic principle, absorbed from the alimentary tract, was stored in the liver, whence it ultimately reached the bone marrow by way of the blood stream. Castle's hypothesis explained Addisonian anaemia by an absence of intrinsic factor; it had also the merit of supplying a rational explanation for most megaloblastic anaemias either by other deficiencies or by failure in the processes of absorption, transport, or storage of the haemopoietic principle.

The treatment of Addisonian anaemia quickly evolved from Minot and Murphy's great announcement, largely as the result of the work of Edwin J. Cohn and his associates, who in 1928 introduced a refined and highly potent liver extract for parenteral injection which was subsequently improved through the following decade. Somewhat later, Sharp (1929), Sturgis and Isaacs (1929), and Wilkinson (1930) showed that hog's stomach contained a substance active in the treatment of Addisonian anaemia. This factor, at first thought to be the same as that present in liver, was found to have different properties; it can now, in the terminology of Castle's hypothesis, be regarded as intrinsic factor, and can, in fact, be used to effect absorption of vitamin B₁₂ from the stomach.

With increasing knowledge, however, it became clear that Castle's hypothesis was not a complete explanation, since it did not always fit new facts as they were discovered. It was, for example, found that a number of megaloblastic anaemias would respond to crude liver extracts, but not to refined and concentrated products, and this suggested that liver contained more than one substance, each or all of which might be necessary for supplying the deficiency in different types of megaloblastic anaemia.

Folic Acid and Vitamin B₁₂

This belief was eventually confirmed by the synthesis of folic acid in 1945 by Angier and his team, and the isolation of vitamin B₁₂, almost simultaneously, in 1948, by Lester Smith in England and Rickes and his colleagues in America. Studies with these substances have shown that the anti-anaemic properties of liver itself, as well as the crude extracts or products, can be attributed to both folic acid and vitamin B₁₂, whereas the refined liver extracts owe their activity to vitamin B₁₂ alone. Addisonian anaemia, including the neurological complications, is now known to be due essentially to a deficiency of vitamin B₁₂, whereas most if not all of the other megaloblastic anaemias of similar haematological type are due to a deficiency of both folic acid and vitamin B₁₂, or, in some cases, of folic acid alone.

So far as Addisonian anaemia is concerned, the limitations of folic acid are now fully appreciated. Notwithstanding haemopoietic activity, folic acid fails to prevent or cure the nervous lesions associated with the disease. Indeed, exces-

sive administration would seem to precipitate neurological complications in advanced and untreated cases of the disease by rapidly immobilizing any traces of vitamin B₁₂ in the tissues, thereby creating an acute and sudden shortage of essential neurotrophic material.

Vitamin B₁₂, or cyanocobalamin, the unique cobalt-containing material which was isolated by modern methods of chemical separation, was originally prepared by an expensive process from ox-liver. It is now obtained from the metabolism fluids of a number of bacteria.

In Addisonian anaemia it is active in a daily dose as low as 1 µg., whilst a satisfactory haematological response can be obtained with as little as 20 µg. a day, and a maintenance dose of some 45 µg. every six weeks. It is also protective against the neurotrophic complications in the same somewhat uncertain and unpredictable manner as occurs with liver extracts. Experience has shown that a dosage higher than the minimum should always be used, and especially in arteriosclerotic subjects or those in whom an infection supervenes. Something of the order of 100 µg. a day is advisable until remission is complete, with a maintenance dose of 50 µg. every two weeks. Maintenance by means of massive doses at long intervals is unsatisfactory.

It is now also appreciated that most cases of Addisonian anaemia require to take iron in order to complete recovery, whilst a number may be thyroid-deficient.

Some Difficulties in Treatment

The evolution of liver treatment for Addisonian anaemia from 1926 to the present day has emphasized certain therapeutic principles, has revealed a number of complications or difficulties, and, above all, has brought to light something of the nature and mode of interaction of various related substances in the processes of haemopoiesis, especially with regard to the synthesis of substances which are fundamental constituents of a biological cell—namely, nucleic acid and its derivatives.

None would now question that Addisonian anaemia, a deficiency disease due to failure of stomach function, is incurable, and that adequate treatment must be maintained for life if haematological relapse and, above all, neurotrophic complications are to be avoided. A critical analysis (Wilkinson, 1932) of such cases as have been reported to have re-established the essential gastric function has shown quite clearly that most, if not all, are likely to have been sprue or some other alimentary disease, rather than Addisonian anaemia. Fully restored cases usually relapse in two to ten months if treatment is omitted, but some have remained well for nearly two and a half years.

Proper maintenance, with haematological control, is, however, a prime requirement, since it is really no kindness to cure a patient of Addisonian anaemia if he is afterwards to develop, and die from, preventable spinal paralysis.

Clinical experience has shown that the dosage of vitamin B₁₂, whether as such or as liver extract, should be increased in the aged, or the arteriosclerotic, and in such as develop an infective process; while septic foci should be removed. Other deficiencies may also complicate the picture, so that some with Addisonian anaemia may be found to need regular courses of iron or thyroid extract, and sometimes vitamin C, while those with neurotrophic disturbances are the better for large doses of the complete vitamin B complex, which, with calcium pantothenate, may be very effective in relieving other deficiency symptoms, such as glossitis.

In brief, the treatment of Addisonian anaemia has evolved to the point where specific curative treatment is available, with which the physician can ensure that no patient who is co-operative need die of the disease *per se*. But this is not to say that the treatment has reached a mechanical stage where neither skill nor art is required. Optimum dosage differs from patient to patient. Constant haematological and clinical supervision are necessary. Minor difficulties, such as sensitivity to liver extract, may be troublesome, and

the possibility of other incidental deficiencies should always be borne in mind, since their treatment can greatly increase the comfort and well-being of the patient.

Pathology and Biochemistry of Erythropoiesis

So much for the evolution of treatment. This survey would not, however, be complete without some short and simple account of the revelations arising from this evolution in respect of the fundamental pathology and biochemistry of erythropoiesis.

Knowledge has come from many sources, but above all from the clinical field (which would have pleased Addison), since no satisfactory technique for assay and evaluation in an animal has ever been devised. Castle, for example, had to carry out the whole of his classical work on the human subject, and likewise with the primary testing of various extracts of liver, as well as folic acid and vitamin B₁₂.

Throughout the years the hypothesis of Castle has provided an invaluable working basis for the clinician in all cases of megaloblastic anaemia. It has to be admitted, however, that the hypothesis is no longer acceptable in its original form, even though in the clinical field it still has most valuable applications, and has also provided a focusing point for new discoveries which might otherwise have become inextricably confused.

But vitamin B₁₂, which, at the outset, was thought to be the haemopoietic principle, has the natural distribution and all the properties of extrinsic factor. It cannot be absorbed in active form without gastric intrinsic factor, but, once absorbed, it behaves like the haemopoietic principle. Evidence has now accumulated to show that vitamin B₁₂ itself is microbiologically active, but not haemopoietically so unless it becomes bound to intrinsic factor, possibly a mucoprotein, in the gastric juice or its counterpart in the tissues. The bond is heat-labile, and when dissociated by heat the vitamin B₁₂ is no longer haemopoietically active. In Addisonian anaemia vitamin B₁₂ is highly active by parenteral injection by reason of a tissue-binding substance, since it appears in the serum in bound form, but it is only active by mouth when given in massive dose (3 mg.) or in association with normal gastric juice (Ungley, 1949).

Knowledge concerning erythropoiesis has also come from studies in bacterial metabolism and animal nutrition, and, indeed, the fact that intestinal bacteria may immobilize such substances as vitamin B₁₂ has an influence on therapeutics, which may be profoundly altered by a change of flora brought about by an antibiotic. Thus, the binding of vitamin B₁₂ so that it is no longer available to bacteria may, in fact, be one of the essential functions of Castle's intrinsic factor, irrespective of conversion of vitamin B₁₂ to a haemopoietically active form.

Functional Relationship between Folic Acid and Vitamin B₁₂

A problem of fundamental importance is a determination of the functional relationship between folic acid and vitamin B₁₂, particularly whether they are independent haemopoietic agents or whether their actions are inter-related so that the presence of one is necessary for the functioning of the other. Folic acid was at one time thought to correspond to Castle's extrinsic factor, but this obviously is not the case; and, indeed, it is difficult to fit folic acid into Castle's hypothesis at all.

The activity of folic acid seems to be dependent upon its conversion to folinic acid, otherwise known as the citrovorum factor, and so called because it is an essential growth factor for *Leuconostoc citrovorum*. Folinic acid has been shown to be therapeutically active in certain megaloblastic anaemias (Davidson and Girdwood, 1951), but, unfortunately, attempts to throw light on the relationship of folic acid, folinic acid, and vitamin B₁₂ by *in vivo* and *in vitro* studies of bone marrow have produced confusing and inexplicable results. When vitamin B₁₂ is injected into the bone marrow of a case of Addisonian anaemia in relapse

the material is utilized by the cells, but this is not the case with either folic acid or folinic acid. On the other hand, when the materials are tested *in vitro* with megaloblastic marrow cultures, folic acid can bring about normal maturation, whereas vitamin B₁₂ will not do so unless associated with normal gastric juice.

Studies of the metabolic requirements of bacteria have also shown that the pyrimidine base, thymine, can replace folic acid, and that the desoxyriboside of thymine, thymidine, can replace vitamin B₁₂ in satisfying certain essential growth requirements of organisms. Both of these substances, as well as a number of others (Welch and Heinle, 1951), possess some haemopoietic activity in megaloblastic anaemias.

This rapidly accumulating tangle of facts has not as yet been unravelled, but from the angle of basic biochemistry the views of Vilter and his colleagues (1950) offer a logical and rational approach to the problem, particularly in the co-ordination of bacteriological metabolic experiments with therapeutic results in the megaloblastic anaemias.

In brief, it is suggested that all the substances which I have considered are concerned in the formation of nucleic acid, which is essential for haemopoiesis. The synthesis of nucleic acid is thought to be brought about by a "chain reaction" in which, in the first stage, folic acid, probably first converted to folinic acid, exercises a coenzyme function in the formation, from uracil and other simple substances, of purines and pyrimidines (such as thymine). In the second stage, vitamin B₁₂ is thought to act as the coenzyme for the conversion of pyrimidines to nucleosides (such as thymidine) which are available for the formation of nucleotides, and so of nucleic acid. On this theory a deficiency in either folic acid or vitamin B₁₂ may cause a breakdown in nucleic acid metabolism.

These views point to there being some interplay between folic acid and vitamin B₁₂ in certain metabolic processes, and it may well be that the riddle of the interchangeable haemopoietic roles of these substances in Addisonian anaemia will be solved only through detailed studies of biochemical reactions.

We know that we have not yet solved all the therapeutic problems of Addisonian anaemia, much less drawn all the dividends from the discoveries which have been made since Addison first lighted a beacon a century ago. At that time he could hardly have been aware of the magnitude of the vista which he was about to illuminate, even as we do not know what will happen in the next century.

Conclusion

In a brief hour I have tried to look over the past, including the near-past in which the tempo of advance has so rapidly increased. In so doing, one remembers with gratitude the heritage of this great hospital through its many sons whom Addison inspired, most of whose contributions in the field of my subject can be found in succeeding volumes of the *Guy's Hospital Reports*.

I think of Wilks, Pye-Smith, Taylor, French, Campbell, Hurst, John Conybeare, Izod Bennett, whose pupil I once was because he came to us at Middlesex, and John Ryle, who was my immediate predecessor at Cambridge.

"Let us now praise famous men."

ARTERIAL REPLACEMENT BY "ORLON" CLOTH*

A PRELIMINARY REPORT OF ITS EXPERIMENTAL AND CLINICAL USE

BY

J. B. KINMONTH, M.S., F.R.C.S.

Surgical Professorial Unit, St. Thomas's Hospital

G. W. TAYLOR, M.B., F.R.C.S.

AND

R. H. LEE

Surgical Professorial Unit, St. Bartholomew's Hospital

During the years since the second world war it has gradually become clear that the grafts used as substitutes for arteries served chiefly as scaffolding on which the tissues of the host developed a new vessel. The survival of cells from the donor has not proved essential for success. Indeed, good results may be obtained where no effort is made to maintain the viability of the cells of the graft. K. Nakayama (1953, personal communication) has used human homografts preserved in alcohol to replace the aortic bifurcation. In our own hands the results with heterografts sterilized and preserved in neutral formalin and used in animals have been most satisfactory over considerable periods of time. It therefore seemed a logical consequence that artificial materials might be used as a scaffold, and Voorhees and his colleagues (1952) reported the successful use of an inert plastic cloth, "vinyon-N."

Experimental Studies

Vinyon-N was difficult to obtain in England, and so we chose for trial "orlon," a plastic developed by duPont and available in Great Britain from Zurrer Silks (Darwen) Ltd., Anchor Mills, Darwen, Lancs. It was one of a variety of woven plastic materials which were easily available and likely to be chemically inert in the body. The choice was made chiefly on the naked-eye appearance of the weave and its power to hold sutures. Its ability to prevent excessive leakage of water, or blood through its pores was also tested on the laboratory bench before it was used surgically. It was found to be more suitable in these ways than other materials that were tried.

Orlon is an acrylic resin, a polymer of acrylonitrile, and possesses the qualities of strong resistance to acids, alkalis,

FIG. 1.—Orlon replacing portion of abdominal aorta of dog. Carrel suture used (see text).

salts, and greases. The fabric used was 175 on the weft and 260 on the warp. It was inelastic, soft, and pliable, and sewed easily without tearing.

Mongrel or greyhound dogs were anaesthetized with intravenous pentobarbitone sodium, and under aseptic conditions the peritoneum was opened through a long midline incision. The posterior peritoneum was incised, exposing the distal abdominal aorta, the lumbar arteries were ligated, and 2 to 3 cm. of aorta was resected after Blalock clamps had been applied to it above and below. The tube of orlon fabric was then sutured end-to-end to the aorta with over-and-over continuous stitches of 5/0 silk moistened with liquid paraffin, and the clamps were temporarily removed to allow blood to fill the tube and test for leaks at the anastomoses. Blood oozed through the orlon fabric for about a minute while clotting was occurring in the interstices of the fabric.

FIG. 2.—Aortogram two months after insertion of orlon. Carrel suturing not used. The upper anastomosis (arrow) is not used. The thickness of collagen is barely discernible, the lower is located by the small notch.

† All prostheses were inserted in the aorta, except in G.11 (aorta to external iliac).

FIG. 3.—Interior of orlon tube inserted end-to-side two months previously. The interior of the host aorta is visible at either end, and that of the orlon, covered by transparent new "intima," in the centre.

FIG. 4.—Microscopical section (x55) of orlon and collagen four months after insertion. Spaces near the orlon are artefacts. The thickness of collagen is greater on the exterior (see text).

possible a larger stoma than would end-to-end anastomosis, in which the stoma would, of course, be limited to a diameter equal to that of the host artery. A large stoma, and particularly one in which the suture line did not completely encircle the host vessel, should be less liable to closure by thrombosis. The end-to-side and side-to-side anastomoses worked well in the aortas of dogs in which they were tried.

The posterior peritoneum was closed over the prosthesis and the abdomen closed in layers. Penicillin and "plasman" were given post-operatively. At a later date patency of the grafts was determined by an aortogram performed by injecting diodone into the aorta above the prosthesis through a cardiac catheter which had been passed down into the aorta from the common carotid artery (Fig. 2).

The results in the dogs which had orlon prostheses are shown in the Table. The prostheses were implanted in their abdominal aortas or as shunts around an aortic or iliac obstruction. One (G.10) died 10 hours after operation without recovering from the anaesthetic. The prosthesis was patent and lined internally by smooth fibrin. The anastomosis was intact. Another (G.3) died at 16 weeks post-operatively from rupture of a false aneurysm that was surrounding the prosthesis and which had formed from an anastomotic leak. The orlon tube was floating in the centre of the false aneurysmal sac and had no fibrous reaction within or around it. The significance of this lack of reaction

is discussed below. The suture material was found to have pulled out of the aorta at the distal anastomosis. In one animal (G.11) a 5-in. (12.5-cm.) long shunt had been placed from the aorta to the left common iliac artery, bridging a tape ligation on the iliac artery. The shunt thrombosed in the early post-operative period, and on sacrifice at four weeks the graft was found to be thrombosed and one of the distal anastomotic sutures had constricted the iliac artery. All the other orlon prostheses have remained patent. The two failures were due to technical errors which were in no way peculiar to the material or the method.

The tubes become lined with a smooth glistening layer of hyaline collagenous tissue, the innermost layer indistinguishable from intima (Figs. 3 and 4). They are surrounded by a thick layer of fibrous tissue which encases and grows into the meshes of the cloth (Fig. 5). They are tolerated without ill effect. The collagen lining and surrounding the tube results from the vascularity and activity of the surrounding tissues. This was well shown in dog G.3. Rupture of the distal suture line occurred soon after operation, and blood continued to flow through and around the tube and into the false aneurysmal sac, in which it lay almost free for several months before death. Despite this, the orlon tube looked almost as fresh as when it was inserted. There was a little fibrin deposited on it, but no collagen formation whatever. This suggests that contact with surrounding living tissues may be necessary for the collagen to form. Mere contact with circulating blood is insufficient.

Another interesting point that emerged at necropsy was the way in which the orlon retained its strength. After several months in the tissues the tensile strength of the fabric appeared to be quite unchanged. This is of great practical importance, because mere unsupported collagen would be expected to stretch under pressure and with the passage of time.

None of the prostheses and their surrounding tissues have shown evidence of calcification on x-ray examination.

Clinical Application

Encouraged by these results, we placed orlon tubes in three patients. Brief case summaries are presented.

Case 1

A 58-year-old male Civil Servant was admitted to St. Bartholomew's Hospital complaining of epigastric pain of three months' duration. For four years he had had intermittent claudication of the left calf, which appeared after 150 yards. For the past 18 months he had noticed increasing epigastric discomfort, which for three months had been severe and was associated with nausea, morning vomiting, and weight loss. Two months before admission he noted the appearance of a tender mass in the left mid-abdomen that had more recently increased in size.

On examination he was noted to be a thin ill-looking man who appeared older than his age. The blood pressure was 210/108. The veins in the neck were distended; the heart was enlarged and there was an apical systolic murmur. In the abdomen there was a visible swelling in the left upper portion which had an expansile pulsation, measured 5 by 12 cm., extended from the left of the umbilicus to just

FIG. 5.—Exterior of aorta and collagen-surrounded orlon removed from an animal three months after operation.

*Based on a communication to the Surgical Research Society, London, November 26, 1954.

below the costal margin, and was compressible, tender, movable from side to side, but not superiorly and inferiorly. Peripheral pulses were decreased bilaterally and neither posterior tibial pulse was palpable.

Aortography showed a large aneurysm of the abdominal aorta extending from just below the kidneys down to and involving both common iliac arteries. It was evident that the aneurysm was expanding, that rupture was imminent, and that intervention was necessary. Operation was performed through a long midline incision. The aneurysm extending from 1 cm. below the kidneys to 2 cm. below the bifurcation was excised and an orlon prosthesis anastomosed end-to-end to the aorta above and to each common iliac artery below. After operation the femoral pulses were good. He experienced a fall in blood pressure during the first 30 minutes of the operation and afterwards passed little urine. His blood urea rose to 332 mg. per 100 ml. by the fourth day, and he became comatose and died. Necropsy revealed marked renal fibrosis and atheroma of the renal arteries. The orlon prosthesis was patent and the anastomosis intact. Death was due to failure of the diseased kidneys to function following the period of hypotension during operation.

Case 2

A 62-year-old male clerk of works was admitted to St. Bartholomew's Hospital complaining of pain in the leg on walking. Two years previously he had noticed that pain developed in the left calf after walking about 200 yards.

FIG. 6.—Orlon prosthesis in place on iliac vessels of Case 2 after completion of side-to-side anastomoses.

It had steadily increased in severity until the present, when it occurred after 75 yards of slow walking. He had been forced to stop work because of the pain. There was no rest pain or ulceration.

On examination the blood pressure was 200/100. Major abnormal findings were limited to the extremities, where the left foot was colder than the right, and paled quickly on elevation to 20 degrees. Pulses were completely absent on the left, but present though diminished on the right. Aortography revealed obstruction of the left external iliac artery.

The ischaemia was considered to be too severe for relief by ganglionectomy alone, and it was decided to use an arterial prosthesis. Operation was performed through a left paramedian incision. The left iliac vessels were exposed and a tube of orlon 5 in. (12.5 cm.) long was anastomosed to the left common iliac artery above the block and to the left common femoral artery below it (Fig. 6). The anastomoses were done side-to-side to make larger stomata. The existing collateral circulation was not disturbed. A left lumbar ganglionectomy was also performed. Post-operatively the pulses were all present in the left leg and stronger than in the right. Six months after operation he was able to walk three-quarters of a mile without claudication and the pulses remained present and strong.

Case 3

A 67-year-old company director was admitted to St. Bartholomew's Hospital complaining of a large pulsating swelling in the left groin. For many years he had noticed

a small lump in the left lower abdomen, which three weeks before admission had suddenly enlarged and started to pulsate and had become very prominent. There was a history of three myocardial infarctions at ages 64, 65, and 66, and moderate exertional dyspnoea and angina since the last infarction.

On examination the pulse was 88 and grossly irregular; the blood pressure was 180/105. The heart was not enlarged, but auricular fibrillation was present. In the abdomen there was a large pulsating visible mass in the left lower quadrant just below the umbilicus and extending down to the inguinal ligament. Its most prominent part was pushing out the anterior abdominal wall. The pulses were diminished bilaterally and absent distal to the popliteal artery on the left. Because of its possible harmful effect on renal function, aortography was not done. Operation was performed through a long left paramedian incision and a huge abdominal aneurysm was excised. It was 8 in. (20 cm.) in antero-posterior and 5 in. (12.5 cm.) in lateral extent. A λ-shaped orlon graft was placed from 2 in. (5 cm.) below the renal arteries to 3 in. (7.5 cm.) beyond the bifurcation and anastomosed end-to-end to the aorta above and to the common iliac below. Post-operatively he has had good pulses in both legs, and the prosthesis has functioned perfectly in the five months since operation.

Preparing the Prostheses

1. *The Seam*.—Ordinary fine white nylon sewing thread (No. 102) has been used to sew the seam, as orlon thread was not available to begin with. More recently pure orlon thread has been used. No difference has been discernible in the results from the two materials. A sewing machine is used to sew the seam and three rows of stitches are inserted close together and about 5 mm. from the free edges of the cloth. The ways in which the cloth is folded and sewn can be seen in Fig. 7. Prostheses for end-to-end or side-to-side anastomosis need only one longitudinal seam, for they are made from a single piece of cloth folded upon itself. The ends of the prosthesis intended for side-to-side use are closed by seams which lie close to the stomata. This avoids having a blind bag at each end (Fig. 7). Two pieces of cloth of the same shape are placed one on the other and sewn together when a branching prosthesis is needed. More seams are then required. A prosthesis for the aortic bifurcation is shown in Fig. 7. The same principle may be used for a greater number of branches.

2. *The Ends*.—Sutures placed close to the edge of a single thickness of cloth may pull out; therefore the ends are folded over. The folding is done before sewing the seams to avoid narrowing the ends of the tube.

3. *Size*.—Rough dimensions may be obtained from angiograms. The length is estimated without great difficulty. The diameter measured from the arteriogram tends to be smaller in obliterative disease and larger in aneurysmal disease than is needed in the operation. The diameter of the prosthesis as it lies flat and undistended needs to be

FIG. 7.—Diagrams to show folds and seams of prostheses for (from left to right) end-to-end, bifurcation, and side-to-side insertion.

approximately twice the diameter measured on the arteriogram film. It is convenient to have two or three prostheses of slightly different dimensions prepared before operation. One of them is usually found to be of the correct size. Should it prove too long it is easy to unpick some of the seam and trim it to the required length.

4. *Sterilization*.—The completed tubes are sterilized by boiling or autoclaving before operation. The latter is preferable. It is important to avoid folds or wrinkles in the cloth. The completed prostheses are smoothed with an electric iron before autoclaving. This is particularly helpful in keeping the folds at the stomata turned conveniently backwards so that suturing is facilitated when the time comes. Glass rods or small test-tubes are inserted inside the prostheses to prevent wrinkling during autoclaving.

Discussion

The advantages of these cloth prostheses over homografts are obvious. They are far more easily obtained and there is no anxiety about their sterility. They have, however, limitations. They cannot be used across the line of flexion of a joint, or certainly not if the joint is to be acutely flexed in the immediate post-operative period, for if this is done the tube is folded, the lumen obstructed, and thrombosis follows. This was the result when a prosthesis was inserted in a dog from the aorta to the femoral artery and the hip-joint flexed. Perhaps if flexion was avoided by splintage or other means until a firm collagenous wall had formed success might be obtained. Until this point is elucidated further we have avoided using a prosthesis below or across the inguinal ligament in patients, relying still upon homografts for this region.

A point of technical interest became evident when the aortograms were examined. When the classical Carrel everting suture was used a definite constriction was always produced at the anastomosis. This did not occur when a simple over-and-over running suture was used without eversion of the inner surfaces. The latter type of suture also has the advantage of greater speed and ease of execution.

The idea of using seamless tubes soon comes to mind when considering prostheses, and through the kindness of Messrs. Ethicon Sutures we have had some of these for preliminary trial. Certain disadvantages came to light which were not at first obvious. A turnover at the ends is desirable, and this necessarily produces some constriction, which is undesirable in the smaller-lumen tubes. Also, where branches are involved they are less adaptable for use compared with the prostheses made to measure. However, there is no doubt that with further trial still better prostheses will be evolved.

Summary

Experimental studies using "orlon" cloth prostheses to replace arteries of dogs are described.

The prostheses can be inserted end-to-end, end-to-side, or side-to-side into the arterial tree of the host. Branching prostheses may also be used.

Their clinical use in the treatment of arterial disease is reported.

Technical points in preparing the prostheses are outlined.

Advantages and disadvantages of prostheses compared with homografts are discussed.

We are grateful to many colleagues who have helped with this work. Professor Sir James Paterson Ross has given advice and encouragement, and Professor E. C. Amoroso has given us hospitality and facilities at the Royal Veterinary College for the animal studies. Dr. Hugh Cleland has helped with some of the operations. Miss D. Aitken has given skilled technical help, particularly in preparing the prostheses.

SENSITIVITY TO FIVE ANTIBIOTICS OF A FURTHER 200 STRAINS OF STAPH. PYOGENES ISOLATED FROM OUT-PATIENTS

BY

E. G. REES, M.B., M.R.C.P.

R. A. SHOOTER, M.D.

(From the Department of Bacteriology, St. Bartholomew's Hospital)

AND

G. D. H. SHAW, M.B., B.S.

Surgical Registrar in Charge of the Casualty Department, St. Bartholomew's Hospital

Three years ago a report was made from this laboratory of the sensitivity to five antibiotics of strains of *Staphylococcus pyogenes* isolated from out-patients (Birnstingl, Shooter, and Hunt, 1952). It was found that, although the majority of staphylococci isolated from in-patients at that time were resistant to penicillin, resistant staphylococci were isolated from only 32 of 200 out-patient infections. No strains were resistant to streptomycin, chlortetracycline, oxytetracycline, or to chloramphenicol. In view of the continued prevalence of penicillin-resistant staphylococci in hospital wards, and the increasing number of strains found to be resistant to the later antibiotics, we have again examined 200 strains of *Staph. pyogenes* isolated from out-patient infections to see if resistant staphylococci are responsible for more of these infections than was the case three years ago.

Sources of Staphylococci

Swabs were taken from patients with acute infections of the skin and subcutaneous tissues attending the casualty department between October, 1954, and March, 1955. Whenever possible, swabs were taken on the first attendance, or, if this was not possible, when a lesion was opened. Swabs taken from patients attending other out-patient departments of this hospital, such as the skin and ear-nose-and-throat departments, were not included in the series, and care was also taken to exclude patients attending other hospitals, or who had recently been discharged from hospital wards.

Methods of Isolation and of Testing Sensitivity

All the swabs were sown direct on to two horse-blood-agar plates from which cups had been cut with a cork-borer. After inoculation these cups were filled with penicillin 10 units/ml., streptomycin 250 µg./ml., oxytetracycline 50 µg./ml., chloramphenicol 250 µg./ml., and erythromycin 100 µg./ml. respectively. Staphylococci which coagulated plasma in a tube were regarded as *Staph. pyogenes*: those which were inhibited by antibiotics to approximately the same degree as the Oxford H staphylococcus were described as sensitive.

Dilution sensitivity tests were carried out for all the antibiotics used with the exception of penicillin. For these tests stock solutions of streptomycin calcium chloride complex (1,000 µg./ml.), oxytetracycline (100 µg./ml.), chloramphenicol (1,000 µg./ml.), and erythromycin (100 µg./ml.) were prepared in distilled water and stored at -8° C. The solutions of streptomycin and chloramphenicol were replaced every two months; solutions of oxytetracycline and erythromycin were made up weekly. For testing, series of two-fold dilutions of each of the four antibiotics in nutrient agar plates were prepared immediately before use, each plate

containing 14 ml. of nutrient agar and 1 ml. of a solution of antibiotic of such strength as to give the required concentration when uniformly diffused in the medium. Each plate was divided by diamond marking into 12 approximately equal sectors of just over 5 square cm. An 18-hour nutrient broth culture of each staphylococcus was used as the inoculum, a 1-mm. loopful of the undiluted culture being spread over each sector. (For streptomycin, tests were also made using this inoculum diluted 300 times.) The plates were incubated at 37° C. for 18 hours, and the end-point was determined by inspection of the surface of the medium.

Results

For *Staph. pyogenes*, resistance to penicillin is dependent on the production of penicillinase, and as this can be detected in primary culture no further examination was thought necessary. Of the 200 strains isolated, 43 produced penicillinase and were resistant. Sensitivity to the

Sensitivity of 200 Strains of *Staph. pyogenes* to Streptomycin, Oxytetracycline, Chloramphenicol, and Erythromycin

other antibiotics is shown in the Table. With one exception strains found sensitive by the dilution method had already been so described on primary isolation.

We have deliberately used a heavy inoculum when testing sensitivity, partly to enable a comparison to be made with previous work, and partly in the belief that the results obtained may be more applicable to conditions in the body (Spink, 1951). In a small pilot experiment involving 12 strains it was found that for oxytetracycline, chloramphenicol, and erythromycin, the difference between an inoculum of undiluted culture or a 1 in 300 dilution of undiluted culture amounted to only one serial dilution of the antibiotic. For streptomycin the difference was greater, and the results are accordingly reported as those obtained with undiluted culture or its 1 in 300 dilution.

Discussion

Penicillin.—In the three years since the last survey much penicillin has been prescribed in general practice, and many members of the public have entered and left hospital wards. A considerable number of this last group of patients must have taken with them to the outer world penicillin-resistant hospital staphylococci, and it is gratifying and perhaps a little surprising that we have isolated only 43 resistant strains (21.5%), as compared with 16% three years ago. The spread of resistant staphylococci within hospitals has been so rapid that it might be thought that there is some special feature of the hospital environment which encourages them in preference to sensitive strains. Perhaps in the outer world sensitive staphylococci are better able to hold their own, and a 21.5% rate represents a state of equilibrium.

Streptomycin.—With the use of a heavy inoculum two of our strains were relatively resistant to streptomycin, but that this represents the selection of a few resistant variants is suggested by the finding that all the strains were sensitive when tested with a dilute inoculum. There are few indications for the use of streptomycin in the treatment of staphylococcal infections, and it was included as a matter of theoretical interest.

Other Antibiotics.—Resistance to oxytetracycline, chloramphenicol, erythromycin (and streptomycin) is the result of

exposure of staphylococci to these drugs, and resistance, once acquired, is permanent. This type of resistance is becoming an additional characteristic of hospital staphylococci, and its occurrence is related to the frequency with which the newer antibiotics are prescribed. That we have found only one staphylococcus to be resistant to chloramphenicol and none to be resistant to the other antibiotics presumably reflects the relatively restricted use of antibiotics in general practice, and the dilution among the general public of resistant hospital strains.

If *in vitro* sensitivity tests can be taken as a guide to the likely outcome of treatment—and for most infections and drugs there is general agreement that they can—our findings would suggest that some 80% of staphylococcal infections originating outside hospital will respond to treatment with penicillin, and almost all to treatment with oxytetracycline, chloramphenicol, and erythromycin.

Summary

Two hundred strains of *Staph. pyogenes* isolated from out-patients with acute staphylococcal infections of the skin and subcutaneous tissues have been tested for their sensitivity to penicillin, streptomycin, oxytetracycline, chloramphenicol, and erythromycin. Of the strains tested, 21.5% were resistant to penicillin. One strain was resistant to chloramphenicol, and none to the other antibiotics.

Comparison of these results with those of a similar investigation carried out three years ago has shown that there has been a slight increase in the proportion of strains resistant to penicillin, but virtually no increase in strains resistant to the other antibiotics.

We are indebted to Professor L. P. Garrod for advice, and to Miss M. Rhodes for technical assistance.

TREATMENT OF THE PREMENSTRUAL SYNDROME

VALUE OF ETHISTERONE, MEPHENESIN, AND A PLACEBO COMPARED

BY

G. I. M. SWYER, D.M., D.Phil., M.R.C.P.

Consultant Endocrinologist, Department of Obstetrics, University College Hospital

In a recent penetrating contribution on the premenstrual syndrome Greene and Dalton (1953) reached the conclusion that the wide variety of distressing symptoms from which many women suffer during the final week or so of the menstrual cycle, and occasionally at other points of the cycle, are probably due to water-retention. This, in turn, they felt was very likely the result of an abnormal elevation of the oestradiol/progesterone ratio. Claims for the beneficial results of treatment aimed either at dehydration or at correcting the alleged hormonal disturbance have, they point out, been made by a number of writers. They themselves found treatment by a progestogen to be almost invariably successful, in mild cases relief usually being obtained by the oral administration of ethisterone in a dosage of 25 mg. twice daily during the second half of the menstrual cycle. Still more effective was the intramuscular injection of progesterone, 25 mg. on alternate days during

the same phase of the cycle, or the implantation of progesterone, which then remained available for many months.

My own experiences with ethisterone, used in much the same way as above, had been less convincing of its efficacy. Moreover, it has seemed probable that psychological factors, leading to the tension-pain syndrome, might constitute a not unimportant part of the premenstrual syndrome, so that the administration of a muscle-relaxing drug might be expected to have some value in the management of the condition. There have already been reports that mephenesin ("myanesin"; 3-(2-methylphenoxy)propane-1:2-diol) administered orally to patients with disturbed psychic functions manifested as anxiety could produce sedation without soporific effect (Schlan and Unna, 1949); and Ström-Olsen (1951) found this drug to be of value in combination with psychotherapy in relieving tension states. There seemed to be good reason, therefore, for submitting the use of mephenesin orally in the treatment of premenstrual symptoms to clinical trial, and at the same time to compare its value with that of ethisterone.

Plan of the Experiment

Since the assessment of the patients' symptoms could only be subjective, it was clearly necessary to adopt a plan which would eliminate, so far as possible, both patient and observer bias. The use of a placebo, indistinguishable from the active tablets, was a prime requirement, and ignorance of the nature of each set of tablets, both by the patient and, at least until after the result had been recorded, by the observer, was equally important. The scheme employed therefore consisted of four groups of treatments: placebo; ethisterone, 10 mg.; mephenesin, 0.5 g.; and ethisterone, 10 mg., + mephenesin, 0.5 g. All the tablets, of course, looked alike and were put up in numbered boxes, a complete set of the four treatments, in prearranged order, being contained within a larger numbered box. It was intended that each patient in the trial should have each of the four treatments in successive months, in random order, the actual order remaining unknown to the observer until the end of the trial. This therefore called for 24, that is 24 patients for a complete series.

The patients were women attending the Fertility and Endocrine Clinics of the Obstetric Hospital, University College Hospital, and employees of the Savings Bank division of the General Post Office (kindly referred by Dr. Mary Parkes). The nature of the trial was explained to them—namely, that they would be having four different treatments in successive months, and would be asked which seemed to be effective. A record was made of their age, parity, the duration of their premenstrual symptoms, whether the latter were mild or severe, and whether they were constant or inconstant from one cycle to another. They were entered into the trial in the order in which they presented themselves and were given the first box of tablets from the appropriate large container. They were told to take one tablet five times a day for 10 days, starting on the 15th day of the cycle, and to return a month later.

On their return the effect of treatment in the cycle just finished was scored as ++ if symptoms were completely abolished; + if there was some, but incomplete, improvement; 0 if the symptoms were unchanged; and — if the symptoms were worse, or additional symptoms, thought to have been caused by the treatment, were noticed. They were then given the second box of tablets, and so on until all four months of treatment had been accomplished. Naturally, in a trial of this kind, it is inevitable that, for one reason or another, not every patient completes the planned series of treatments.

Results

The clinical details of the patients, and their results with the individual treatments, are shown in Table I. From this it is at once clear that there is considerable variation in the severity and variability of the symptoms from patient to patient, and in the same patient from cycle to cycle. This naturally makes the assessment of the value of different treatments more difficult.

Table II shows the results of treatment for each successive month, regardless of the treatment actually used. It would

TABLE I.—Details of Patients and Their Individual Results

No.	Age	Parity	Duration of Symptoms	Symptoms	Months of Treatment			
					1	2	3	4

A = Mephenesin. B = Ethisterone. C = Mephenesin + ethisterone. D = Placebo. ++ = Very good. + = Good. 0 = No effect. — = Side-effects.

TABLE II.—Results of Treatment by Months Irrespective of Actual Treatment

Month	Very Good	Good	Total	No Effect	Side-effects	Total
1	3	7	10	7	7	14
2	4	6	10	8	4	12
3	4	12	16	4	1	5
4	5	7	12	4	4	8

TABLE III.—Comparison of Results in First and Second Months with those in Third and Fourth

Months	Good	No Good
1+2	20	26
3+4	28	13

TABLE IV.—Results of Treatment by Different Treatments, Irrespective of Months

Treatment	Very Good	Good	Total	No Effects	Side-effects	Total
Mephenesin	8	6	14	5	4	9
Mephenesin + ethisterone	3	10	13	4	4	8
Ethisterone	3	10	13	8	2	10
Placebo	2	6	8	6	6	12

TABLE V.—Comparison of Mephenesin versus the Rest

Treatment	Good	No Good
Mephenesin + (mephenesin + ethisterone)	27	17
Ethisterone + placebo	21	22

TABLE VI.—Comparison of Ethisterone versus the Rest

Treatment	Good	No Good
Ethisterone + (ethisterone + mephenesin)	26	18
Mephenesin + placebo	22	21

appear that fewer good results were obtained during months 1 + 2 than during months 3 + 4; this is more apparent in Table III. The difference is not significant ($\chi^2=1.302$); nevertheless it seems possible that the suggestibility of the patients may have been heightened towards the latter part of the trial, so that those who had not yet experienced relief from the treatments they had had so far presumably thought that some of the later treatments ought to be effective.

Table IV sets out the results of the different treatments, irrespective of months. It will be seen that complete relief of symptoms occurred most often with mephenesin, but that when the "very good" and "good" results combined were compared with the poor results, there was not much to choose between mephenesin, ethisterone, or mephenesin + ethisterone. The placebo, though less effective than the above, was by no means devoid of apparent value.

Tables V and VI compare mephenesin with the rest and ethisterone with the rest. The similarity in these groups of figures will be noticed. None of these differences is statistically significant.

Discussion

The results of this limited trial suggest that both ethisterone and mephenesin have some value in the treatment of the premenstrual syndrome, but that neither can be expected to help more than about 60% of patients. The combination of mephenesin and ethisterone appears to be no better than either substance alone. Mephenesin alone completely relieved eight patients, whereas ethisterone and ethisterone + mephenesin had this effect on only three each, and the placebo did as well in two patients. Table I shows that of the 21 patients who had all four treatments, only 3 had no relief from any treatment, 10 benefited from either ethisterone or mephenesin, and 8 appeared to be helped by both.

The incidence of side-effects was notably low both with mephenesin and with ethisterone; in point of fact, more complaints of these were recorded for the placebo than for the other tablets.

Since in this trial either ethisterone or mephenesin alone helped some 60% of patients, and one or the other was of some value to about 90% of the patients, it is apparent that hormonal imbalance may not be the sole cause of the symptoms in at least some of the patients. The evidence suggests that psychological factors, manifesting themselves in tension states, may be an important part of the premenstrual syndrome in some cases, and where successful treatment does not follow from ethisterone therapy the use of mephenesin might well be considered.

Summary

A clinical trial of ethisterone and of mephenesin, alone and in combination, for the treatment of premenstrual symptoms has been carried out by means of a random block design, whereby the effects of the various treatments could be compared with each other and with those due to a placebo.

While mephenesin produced complete relief more often than ethisterone, an overall analysis suggests that there is little to choose between them. Either substance alone helped only some 60% of patients, and a combination of the two was no more effective; but one or the other was of some value to about 90% of the patients.

My thanks are due to Dr. Mary Parkes for referring the majority of the patients to me for the purposes of this trial; and to Dr. B. M. Merriman, of British Drug Houses Ltd., for supplying the sets of tablets.

ANTERIOR TIBIAL SYNDROME FOLLOWING ARTERIAL EMBOLISM

BY

D. C. WATSON, M.C., M.D., M.R.C.P.

Senior Medical Registrar, United Liverpool Hospitals

(From the Liverpool Royal Infirmary)

Carter *et al.* (1949) described a syndrome consisting of ischaemic necrosis of the muscles of the anterior tibial compartment of the leg, with a lesion of the anterior tibial nerve. Their 10 patients were fit young men, in eight of whom the onset was clearly related to strenuous unaccustomed exercise involving the use of the leg muscles. The condition developed in their two remaining cases after transfusion into the affected limb. The main clinical features were pain, swelling, redness, and tenderness in the front of the leg. There was inability to dorsiflex the foot and toes. The peroneal muscles were not affected. Involvement of the anterior tibial nerve produced paralysis of the extensor digitorum brevis muscle and sensory loss on the dorsum of the foot. The degree of residual foot-drop was lessened by the development of contracture in the affected muscles.

Vogt (1943) described the first similar case. Sirbu *et al.* (1944) described one case in which both legs were affected after marching, and another which followed repair of a small muscle hernia through the anterior crural fascia. Horn (1945) reported two cases in young soldiers after marching, and Phalen (1948) described the case of a young man who developed the syndrome after walking half a mile. The case of a young Greek who showed the same condition in both legs after long-jumping on a concrete pavement was recorded by Pearson *et al.* (1948). Hughes (1948) described three cases of "ischaemic necrosis of the anterior tibial muscles due to fatigue." Two were in healthy men who played football before the onset of their symptoms, and the third case occurred in a young man suffering from a febrile systemic illness, possibly polyarteritis nodosa. Tillotson and Coventry (1950) described a case in a hiker following his first walk of the season. Horn and Sevvitt (1951) reported a case in which the syndrome was included in the sequelae of a traumatic rupture of the popliteal artery. Similar symptoms were noted by Psaki and Schields (1952) in a soldier who sustained a twisted ankle.

Below, two cases are described in which the syndrome followed arterial embolism.

Case 1
