Erythema Marginatum

At the start of therapy there were 29 cases with erythema marginatum (A.C.T.H. 12, cortisone 11, aspirin 6). The proportion with new episodes developing during treatment and observation was similar for all treatment groups (Table 18). At 13 weeks, erythema marginatum had persisted in two A.C.T.H. cases and one aspirin case.

Among the cases without erythema marginatum at start of treatment, the number developing episodes for the first time during treatment or observation was also similar for all treatment groups (A.C.T.H. 10, cortisone 15, and aspirin 11). Among these cases only one remained at 13 weeks—a cortisone case which first manifested erythema marginatum during the observation period. In addition there was one aspirin case in which erythema marginatum appeared for the first time at the 13th week (Table 19).

Thus the rate of appearance or disappearance of episodes of erythema marginatum seemed to be unrelated to therapy.

Heart Size

Variations in heart size were analysed by three methods:

1. The proportion in each treatment group with a cardiothoracic ratio of 0.55 or more; this method described extreme grades of cardiac enlargement.

2. The frequency of change in transverse cardiac diameter of 0.6 cm. or more, between 0-3, and 3-6, and 6-9 weeks and 0-1 year; this method, although starting from an abnormal base line, was more sensitive than method 1 to temporary changes of a lesser degree.

3. The proportion of cases with a cardiothoracic ratio of 0.50 or more; this method yielded no additional information and will not be further discussed.

In Cardiac Group A the proportion with a cardiothoracic ratio of 0.55 or more in any treatment group at any time was insignificant (Table 20). In Cardiac Group B (exclud-

† Excluding cases with failure and/or pericarditis at start of therapy.

ing those with failure or pericarditis or both) the approximately equal distribution among the three treatment groups persists throughout. In Cardiac Group C (excluding those with failure or pericarditis or both) there was a smaller proportion of cases initially in the aspirin group with extreme grades of cardiac enlargement. This inequality persists at three, six, and nine weeks, but disappears at one year. In the group of cases with failure or pericarditis or both, the relative inequality persists throughout.

Using the more sensitive index of change in heart size of 0.6 cm. or more, a larger proportion showed an increase over the 0-9 weeks period in each hormone compared with the aspirin group. This difference appeared early, since analysis of the 0-3 and 3-6 weeks intervals showed the same result, but at one year it had disappeared (Chart V). In contrast, the proportion showing a decrease in heart size was similar for all treatment groups. Cardiac groups A, B, and C all showed this difference between each of the hormones and aspirin early in treatment and the same equality at the end of one year. Among cases with failure and/or pericarditis (in which the proportion of enlarged hearts was

CHART V.—Changes in heart size and average weight gain in specified time intervals.

high at start of therapy), approximately one-third showed an early decrease regardless of therapy, and few (16%) showed an increase during treatment.

Considering gains in body weight, increases in heart size were more frequent in each hormone group than in the aspirin group during 0-3 and 3-6 weeks, but not during 6-9 weeks. In each period, however, both hormone groups had an average weight gain two to three times as great as the aspirin group; in other words, there was no clear relationship between weight gain and increase in heart size.

In summary, when heart size is measured by the proportion with a cardiothoracic ratio of 0.55 or more, the cardiac subgroups and the total cases reveal no differences between treatments. Using the more sensitive index of change in heart size of 0.6 cm. or more, there is a tendency for cases treated with A.C.T.H. or cortisone to show a temporary increase in heart size.

Atrioventricular Conduction Time

The course of the atrioventricular conduction time* (measured by the P-R interval in the electrocardiogram) was analysed, using:

1. The percentage with a P-R interval of 0.18 sec. or longer.
2. The percentage with a P-R interval of 0.16 sec. or longer.
3. The average P-R interval.

*The diagnostic criteria for admission of patients to the study defined normal P-R intervals as corrected for age and heart rate according to the Ashman-Hull tables. These corrections were not used in evaluating the course of the disease because the P-R intervals were unduly influenced by marked pulse rate changes, and because recent unpublished studies of the P-R interval in normal children by the Child Research Council of Denver question the corrections proposed by Ashman and Hull.

4. The percentage with an increase or decrease in the P-R interval of 0.03 sec. or more during the interval of 0-3, 0-6, 6-9, and 0-9 weeks.

The four methods led to the same conclusions, and only the percentages with a P-R interval of 0.18 second or longer are presented here.

The proportions of cases with a P-R interval of 0.18 second or longer are distributed fairly equally at start of therapy in each of the treatment and each of the cardiac groups (Chart VI, Table 21). They decreased initially more

CHART VI.—Atrioventricular conduction time. Percentage of cases with P-R interval of 0.18 second or more.

† Includes cases with failure and/or pericarditis at start of therapy.

rapidly among those receiving A.C.T.H. or cortisone than among those receiving aspirin, with the A.C.T.H. group showing a very rapid fall at the end of the first week from 33.3% to 8.7%, and in the second week to 6.9%. At the third week the A.C.T.H. and cortisone groups were at the same level, with the aspirin group clearly lagging behind. This difference was maintained to the end of the treatment period, after which, at 9 weeks and at one year, all three groups were in the same range (13% to 19%). This decrease during treatment in the hormone-treated cases occurred in all cardiac groups, but was less marked in cardiac group C.

The hormones appear to decrease the P-R interval to values below those at 9 weeks and at one year. The values at these later times might well be expected to be closer to normal than those recorded during the acute illness. It may be questioned, therefore, whether the early decrease in P-R intervals is an effect of the hormones on the disease or merely a direct effect on the atrioventricular conduction time.

Apical Systolic and Basal Diastolic Murmurs†

The development and course of significant heart murmurs are among the most important aspects of rheumatic fever. They are analysed during the acute attack (0–13 weeks) and at one year, according to the status of the heart at the start of treatment—that is, Cardiac Group A, those without pre-existing heart disease or carditis; Cardiac Group B, those with carditis and without pre-existing heart disease; and Cardiac Group C, those with pre-existing heart disease.

Cardiac Group A

Each treatment group included approximately the same number of cases without carditis or pre-existing heart disease. None of these had an apical systolic or basal diastolic murmur on admission to the study. During the nine-weeks period of treatment and observation it was unusual for either of these murmurs to appear, and at 13 weeks few cases had either an apical systolic or a basal diastolic murmur or both, regardless of the type of therapy (Table 22). At 13 weeks,

TABLE 22.—*Cardiac Group A (no Carditis, no Pre-existing Heart Disease): Murmurs Present at Specified Times. U.K. and U.S., all Cases*

	Total Cases	No. with Murmurs at			
		End of Therapy (Week 6)	End of Observation (Week 9)	Follow-up (13 Weeks)	Follow-up One Year
A.C.T.H. ...	40	3	5	5	5
Cortisone ...	39	2	1	3	4
Aspirin ...	38	3	2	2	5

among 40 A.C.T.H. cases there were five with apical systolic murmurs; among 39 cortisone cases there was one with an apical systolic murmur, one with a basal diastolic murmur, and one with both; and among the 38 aspirin cases there were two with apical systolic murmurs. At one year apical systolic murmurs were still few: five A.C.T.H., four cortisone, and five aspirin. One of the cortisone cases also had a basal diastolic murmur. In other words, if a case of rheumatic fever meeting the criteria for admission to this

†In this study the following grades were adopted for reporting apical systolic murmurs: Grade 0—No murmur, or a murmur considered to be "functional" on the basis of its apparent origin at the pulmonary area or along the left sternal border. Grade 1—Murmur apparently localized to the apical area, but so faint as not to be transmitted to or toward the axilla. Grade 2—Soft apical systolic murmur transmitted to or toward the axilla. Grade 3—Louder similar murmur. Grade 4—Very loud similar murmur, usually transmitted to the back. In the analysis of the data, the "P" murmurs were included under Grade 0.

study had no apical systolic or basal diastolic murmur at that time the chance of developing either murmur during the acute attack or at one year was only approximately 1 in 8 regardless of treatment.

Cardiac Group B

Among the cases with carditis without pre-existing heart disease, the distribution of apical systolic murmurs by grade was not the same in the three treatment groups at start of therapy; there were relatively more Grade 0 and Grade 2 murmurs among the aspirin, Grade 1 among the cortisone, and Grade 3 among the A.C.T.H. cases. For this reason, analysis of the group as a whole becomes complicated and each grade is analysed separately.

The Group B cases without an apical systolic murmur at start of therapy (included in Group B on account of other murmurs, increase in heart size, failure or pericarditis) behaved much like the cases without carditis (Group A). It was unusual for them to develop an apical systolic murmur during the first 13 weeks following the start of treatment or at one year, regardless of the treatment employed (Table 23).

In Group B cases, Grade 1 apical systolic murmurs at start of treatment appeared to respond differently during the acute attack in hormone-treated cases compared with the aspirin-treated cases. In the majority of the cases treated with A.C.T.H. or cortisone the Grade 1 murmur disappeared by the end of six weeks of treatment. There was a slight increase in their frequency among the cortisone cases at nine weeks, but otherwise there was no appreciable change at the 9th and 13th weeks. By contrast, in only 4 of 18 aspirin cases did the Grade 1 apical systolic murmur disappear at six weeks and in only seven by the 13th week. There were relatively few Grade 1 murmurs that increased to Grade 2 or 3 during the 13-weeks period in any of the treatment groups. At one year following the end of the observation period, the differences between the three treatment groups were no longer significant (Table 23).

Grade 2 apical systolic murmurs in cases with carditis (Group B) presented a somewhat different pattern. These murmurs disappeared in slightly more cortisone than A.C.T.H. or aspirin cases. Thus by the end of 13 weeks they had disappeared in about one-sixth of the A.C.T.H., one-fifth of the aspirin, and one-third of the cortisone cases. Considering murmurs which decreased as well as those which disappeared, the differences among the treatment groups are not so great. At the end of 13 weeks in one-half of the A.C.T.H. and aspirin cases the Grade 2 murmur had diminished or had disappeared, in comparison with five-sevenths of the cortisone cases. With the number of cases studied, none of these differences reached the 5% level of

significance. By the end of one year, only minor differences remained. Thus in the Group B cases there were no striking differences in the effect of A.C.T.H., cortisone, or aspirin on Grade 2 apical systolic murmurs during the acute attack or at one year.

Grade 3 apical systolic murmurs in cases with carditis did not disappear, except in a few instances, during the 13-weeks period or at one year, regardless of the type of treatment (Table 23). Some of these loud murmurs became less intense, particularly in the aspirin group, but this difference again was not significant.

Summarizing, the apical systolic murmurs in Group B cases responded in relatively the same way to the three forms of treatment, except when the apical systolic murmur was of minimum intensity (Grade 1). In these cases a larger proportion of such murmurs disappeared during therapy with A.C.T.H. and cortisone than with aspirin, but there was little difference between treatment groups at the end of one year.

In 11 centres, basal diastolic murmurs in cardiac Group B cases were recorded in 20 of 201 (10%), while in one U.K. centre they were present in 41 cases (80%), absent in 8, and undetermined in 2. Two separate analyses are therefore presented.

In the 11 centres, basal diastolic murmurs were present at the start of therapy in 7 of 58 A.C.T.H., 8 of 70 cortisone, and 5 of 73 aspirin cases (Table 24). At 6, 9, 13 weeks, and one year the disappearance of these murmurs or their appearance in cases originally without them was approximately the same for all treatment groups.

In the one U.K. centre, of eight cases initially without basal diastolic murmurs one developed a transient murmur. In 41 cases where the murmur was initially present it had disappeared by nine weeks more frequently from the A.C.T.H. (14 of 15) than from the cortisone (6 of 13) and aspirin groups (4 of 13). The difference was still present at one year (13 of 15 A.C.T.H., 4 of 12 cortisone, and 5 of 12 aspirin).

terms—namely, mid-diastolic murmur, third heart sound, and gallop rhythm—were recorded inconsistently from centre to centre and from observer to observer of the same case in the same centre. Further, in acute rheumatic carditis this murmur is rarely heard in the absence of an organic apical systolic murmur, which was consistently recorded. The U.S. investigators therefore agreed that the mid-diastolic murmur in the U.S. cases should not be analysed.

In the U.K. no such murmur developed during the year in Group A cases. In Group B, where the murmur was initially absent it appeared in only a few cases, equally in all treatment groups. Where it was initially present it persisted up to the 13th week to a greater extent in the aspirin group (9 of 17 cases) compared with A.C.T.H. (3 of 19) and cortisone (5 of 18). At one year, however, there was little difference between the three groups (1 of 17 A.C.T.H., 3 of 18 cortisone, and 3 of 16 aspirin). In Group C cases, where the murmur was initially absent it appeared in a few cases in all treatment groups by the end of one year. Where the murmur was initially present it persisted in all treatment groups at the ninth week (13 of 20 A.C.T.H., 12 of 19 cortisone, and 15 of 19 aspirin), becoming slightly less at one year (9, 10, 9 cases, respectively).

Presystolic Murmurs

Apical presystolic murmurs were not included in this analysis, as they result from slowly progressive scarring of the mitral valve and are not evidence of acute carditis. In this study they were present in only 16 of 497 cases (3.2%) on admission, and they appeared for the first time in very few (12 additional cases during the following 13 weeks).

Summary of Murmurs

Summarizing the effects of treatment on murmurs during the acute attack and at the end of the first year, the following conclusions appear justified:

1. The development of an apical systolic murmur among those without such murmurs at start of therapy, regardless of the presence or absence of carditis, was infrequent and was not related to the treatment.
2. The disappearance of softer apical systolic murmurs was more rapid among those receiving A.C.T.H. or cortisone than among those receiving aspirin, but at the end of one year the treatment groups did not differ significantly. Similar results were found for the apical mid-diastolic murmur for the U.K. centres only.
3. The disappearance or diminution of loud apical systolic murmurs rarely occurred, regardless of therapy.
4. The appearance or disappearance of basal diastolic murmurs occurred in a relatively small proportion of cases, and in 11 of 12 centres was not related to therapy.
5. At the end of one year there was no evidence that the treatment groups differed in the frequency with which murmurs had appeared or disappeared.

§ In the one U.K. centre where an abnormally high proportion of basal diastolic murmurs was heard at entry, they disappeared more frequently in the A.C.T.H. group.

Seriously Ill Cases

Cases here described as seriously ill are those with congestive failure, pericarditis, or both, present on admission or occurring during the 13-weeks period of treatment and follow-up, and those cases terminated by death during the one-year period of this report.

Congestive Failure and/or Pericarditis

At the start of treatment, 23 of 162 A.C.T.H., 15 of 167 cortisone, and 10 of 168 aspirin cases had congestive failure (Table 27). Among these cases, failure disappeared

13th week	3 (2)	1	1	—	—	1

N.B.—Figures in parentheses indicate number of cases on given day in which failure had reappeared after previous disappearance.

at about the same rate, regardless of therapy. In all but one case in each treatment group failure disappeared by the 13th week. After initial disappearance it reappeared in only three cases, all in the A.C.T.H. group.

Among the cases without congestive failure at the start of therapy, 7 of 139 A.C.T.H., 7 of 152 cortisone, and 10 of 158 aspirin cases developed failure during the 13-weeks period (Table 27). In 21 of these (7 A.C.T.H., 6 cortisone, and 8 aspirin), failure appeared during the treatment period but disappeared in all but five cases during the observation period. One of these, a cortisone case, had a fatal outcome during the observation period, and four (two A.C.T.H., two aspirin) had persistent failure at the ninth week. In three cases (one A.C.T.H., two aspirin) failure was present at the 13th week. In one of these aspirin cases treatment had been changed to A.C.T.H. on the 28th and continued to the 70th day.

Thus among the cases with or without failure at the start of therapy there were no marked differences among the treatment groups in the behaviour of congestive failure.

Pericarditis was present at the start of therapy in 13 of 162 A.C.T.H., 16 of 167 cortisone, and 9 of 168 aspirin cases, and disappeared at approximately the same rate regardless of therapy (Table 28). In only four of these (two cortisone and two aspirin) did the symptom reappear following its disappearance.

Among the cases without pericarditis at the start of therapy (Table 28), there were 3 of 149 A.C.T.H., 3 of 151 cortisone, and 5 of 159 aspirin cases which developed pericarditis for

13th week	—	—	—	—	—	—

N.B.—Figures in parentheses indicate number of cases on given days in which pericarditis had reappeared after previous disappearance.

the first time during the 13-weeks period. In nine of these (three A.C.T.H., two cortisone, and four aspirin) pericarditis appeared during the treatment period. In all 11 cases it was of short duration, persisting in no case until the ninth week, and never reappearing after disappearance.

Thus among cases with or without pericarditis at start of therapy it appeared and disappeared regardless of treatment.

Deaths

Among the 497 cases, 6 deaths occurred during the one year of follow-up. Their case histories were as follows:

Case 1.—A 12-year-old girl was admitted to a U.K. centre in her first attack, with fever, carditis with apical systolic murmur and gallop rhythm, erythema marginatum, and elevated sedimentation rate. She was treated with A.C.T.H. on the 24th day of her disease, with symptomatic improvement but with progressive carditis. A basal diastolic murmur, noted intermittently during the first week of treatment, later was constantly present, becoming associated with a basal systolic murmur. In the fourth week an apical mid-diastolic murmur was heard and nodules appeared, rapidly increasing in number. The acute disease was obviously not controlled by A.C.T.H. No additional symptoms appeared during the three-weeks observation period. The patient was kept in bed thereafter throughout her slow but progressive downhill course, death occurring five months after the beginning of treatment and one day following her removal from the hospital against advice.

Case 2.—A 7-year-old boy with a four-days history of precordial, pleural, and joint pains was admitted to his local hospital, where his sedimentation rate was found to be elevated and a diagnosis of rheumatic fever was made. He was treated with penicillin, sulphonamides, and 60 gr. (4 g.) of aspirin and 30 gr. (2 g.) of sodium bicarbonate a day for 12 days without improvement. During this period he is said to have developed "a murmur" of gradually increasing loudness. He became dyspnoeic and was transferred to a U.S. centre. On admission he was extremely ill, with fever, orthopnoea, dyspnoea, cyanosis, muffled heart sounds, apical systolic murmur, gallop rhythm, and tachycardia (146/min.). Bronchial breathing and rales were heard over both lung fields. A diagnosis of rheumatic pancarditis with mitral valvular disease and congestive heart failure was made and rheumatic pneumonia suspected. The patient was treated with digitalis and mercaptopurine ("thiomerin"), and admitted to the study in the cortisone group. He died 20 hours after admission, having received 300 mg. of cortisone. Necropsy revealed a large flabby heart with verrucae on the mitral valve and left auricular wall.

Case 3.—A 13-year-old girl with a previous history of rheumatic fever and rheumatic heart disease with mitral insufficiency was admitted to a U.S. centre on the fifth day of a recurrent attack, following an upper respiratory infection with sore throat of three weeks' duration. She was moderately ill with fever, polyarthritides, elevated sedimentation rate, and probable carditis. She was treated with cortisone for six weeks with a fairly satisfactory response, although the evidence of underlying rheumatic heart disease was unchanged. Two weeks following end of treatment, she suddenly, for the first time, went into congestive failure associated with raised temperature and erythrocyte sedimentation rate. Re-treatment with cortisone was begun immediately, but she became rapidly worse and died one day later, on the 57th day after admission to the study. Necropsy revealed a greatly hypertrophied heart with obliteration of the pericardial cavity and chronic mitral disease without stenosis, bilateral pleural effusions, diffuse pulmonary oedema, and ascites. Microscopic examination showed evidence of diffuse active pancarditis.

Case 4.—A 9-year-old boy was admitted to a U.K. centre with a history of three weeks of polyarthritides with two weeks of rash. He was found to have fever, erythema marginatum, an enlarged heart, and a loud apical systolic murmur. He was admitted to the study and aspirin therapy begun. After slight improvement his temperature rose again, the heart shadow became enlarged, and a basal diastolic murmur was heard intermittently. At the end of nine weeks he was still considered to be seriously ill, and was transferred to another hospital, where he developed increasing congestive failure, which later stabilized and then gradually improved. Four months after start of treatment, while still hospitalized, he became febrile and a group A beta-haemolytic streptococcus was isolated from his throat. He was treated with penicillin but remained febrile for 12 days, after which his temperature returned to normal but signs of congestive failure progressively increased. He died one month after this relapse, five months after start of treatment. Necropsy revealed rheumatic endocarditis, myocarditis, cardiac dilatation, a bicuspid aortic valve (? congenital), and chronic venous congestion of lungs, liver, and spleen.

Case 5.—A 12-year-old boy was admitted to a U.K. centre in his second attack with pre-existing rheumatic heart disease with mitral stenosis. Rheumatic fever had continued without intermission for four months, manifesting itself by nodules, arthritis, erythema marginatum, precordial pain, and fever. Physical findings during that period were enlarged heart, apical systolic, mid-diastolic, pre-systolic, and basal diastolic murmurs, enlarged liver, pulmonary congestion, elevated sedimentation rate, and prolonged P-R interval. The patient was admitted in the aspirin group and received symptomatic benefit; relapse followed at the end of treatment. Four additional courses of aspirin were given, the patient responding in the same way each time. He was then placed on a cortisone schedule but showed no improvement, dying in the fifth week of this treatment, in congestive failure, eight months after admission to the study. Necropsy revealed rheumatic heart disease with enlarged heart, mitral stenosis, acute mitral and tricuspid endocarditis, Aschoff bodies and fibroid changes in the myocardium, congestive failure with pulmonary oedema, and cardiac cirrhosis of liver.

Case 6.—A 6-year-old boy was admitted to a U.K. centre, severely ill in the seventh week of his first (?) attack. He showed evidence of carditis with apical systolic and mid-diastolic murmurs and the signs of congestive failure. One subcutaneous nodule was noted on the right elbow. The temperature was normal and the erythrocyte sedimentation rate elevated. Because of intractable vomiting, the digitalis and aspirin were temporarily stopped late in the first week, with immediate improvement. At the beginning of the second week small doses of aspirin—20 gr. (1.3 g.) per day—were given for three days and then omitted because of lack of improvement from therapy. The patient gradually improved without treatment, but congestive failure persisted. During the fifth and sixth weeks, amidopyrine—7½ gr. (0.5 g.) per day—was given without effect on the patient's gradual improvement, which continued until the ninth week. Digitalis was then stopped and the patient discharged to a convalescent home.

The patient continued in moderate congestive failure, leading a bed-and-chair existence. Five months later he developed an upper respiratory infection, treated with sulphadiazine and penicillin. Tachycardia (145 per minute) and a pericardial friction rub developed. A six-weeks course of A.C.T.H. was given, with disappearance of acute symptoms, congestive failure continuing. The patient had a rapid increase in weight, marked moonface, and moderate hypertension, all of which gradually disappeared.

Ten months after admission to the study the patient developed another upper respiratory infection, treated with sulphonamide drugs and penicillin. He then went rapidly downhill and was transferred back to the centre, where he died in severe congestive failure after one week's treatment with A.C.T.H., digitalis, and diuretics.

Necropsy showed hypertrophy and rheumatic pneumonia, congestive failure with mitral stenosis, cardiac dilatation, acute and chronic lesions of mitral, aortic, and tricuspid valves, fibrinous pericarditis, and numerous Aschoff bodies.

In summary, there were no appreciable differences in the course of seriously ill cases, since the behaviour of congestive failure, pericarditis, or both, appeared to be similar in the treatment groups, and there were only six deaths (one on A.C.T.H., two on cortisone, and three on aspirin).

Re-treatments

Apart from the six patients who died, there were some in each treatment group who, during the one-year period, were re-treated for persisting or recurring manifestations. Thus,

re-treatment was given to 10 of the 161 A.C.T.H. patients surviving to one year. None of these re-treatments were given during the three-weeks observation period. One case was treated for chorea, and one had two courses of re-treatment. In all except the case with chorea, the symptoms demanding re-treatment were moderately severe.

Re-treatment was given to 8 of the 165 cortisone cases surviving the one year, one of which was re-treated during the observation period. All were moderately severe cases except one, having only erythema marginatum and fever. None was re-treated for chorea. One case required two re-treatments.

Re-treatment was given to 19 of 165 aspirin cases surviving to one year. Four were re-treated during the observation period, two receiving aspirin and the other two receiving cortisone. Thirteen of the 19 cases were moderately severe; of the remaining 6, 5 were re-treated for recurrent chorea and 1 for a mild illness consisting of elevated temperature and sedimentation rate.

When the cases given re-treatment are analysed according to duration of disease at start of therapy, it is seen that the differences among the three treatment groups are due entirely to the chronically ill cases. Thus in the 0-14-day group there were six A.C.T.H., four cortisone, and six aspirin cases to which re-treatment was administered. In the 15-42-day group the cases were two, one, and four, respectively; in the group of those ill 43 days or more they were two, three, and nine—a preponderance of aspirin cases in this chronically ill group.

Excluding the cases re-treated for chorea, the number of cases remains the same in the 0-14-day group, becomes one on each treatment in the 15-42-day group, and two A.C.T.H., three cortisone, and seven aspirin in the 43+-day group.

In summary, re-treatment was given to a greater proportion of cases in the aspirin than in the A.C.T.H. and cortisone groups; but this difference occurred only among the chronic cases, and was slightly affected by the larger number of cases initially admitted with chorea to the aspirin group.

Side-effects of Treatment

In both countries, practically all the A.C.T.H. and cortisone cases showed one, or a combination, of the following side-effects of therapy: moonface, hirsutism, acne, or striae. There were only 10.5% of the A.C.T.H. and 4.8% of the cortisone cases with none of these side-effects by the end of the ninth week (Table 29). These effects were recorded less frequently in the U.K. than in the U.S. cases, being absent in 15.0% of the U.K. and 6.1% of the U.S. A.C.T.H. cases, and in 10.0% of the U.K. and none of the U.S. cortisone cases.

TABLE 29.—Side-effects of Therapy in A.C.T.H. and Cortisone Cases: U.K. and U.S., all Cases

Side-effect	Percentage of Cases Showing Side-effect					
	A.C.T.H.			Cortisone		
	U.K.	U.S.	Total	U.K.	U.S.	Total
Moonface	77.5	90.2	84.0	80.0	96.6	88.6
Hirsutism	15.0	19.5	17.3	13.8	16.1	15.0
Acne	26.2	63.4	45.1	8.8	17.2	13.2
Striae	12.5	12.2	12.3	18.8	12.6	15.6
None	15.0	6.1	10.5	10.0	0.0	4.8
Total No. of cases	80	82	162	80	87	167

There were no appreciable differences between the A.C.T.H. and cortisone cases in frequency of moonface, hirsutism, or striae, but acne appeared much more often among the A.C.T.H. cases. With the exception of striae, each side-effect was recorded more frequently among the U.S. than among the U.K. cases. Although these side-effects appeared almost equally in the hormone groups, those severe enough, in the opinion of the investigator, to require stopping treatment occurred only among the A.C.T.H. cases (Table 1).

In addition to the side-effects of hormone treatment already noted, many others were reported, but, not being specifically requested, they were not uniformly recorded. These included cases of hypertension, mental symptoms, convulsions, renal haemorrhage, water and salt retention, glycosuria, infections, hepatomegaly, febrile reactions, pigmentation, increased fat deposition, and unusual increase in appetite.*

Relatively few aspirin cases developed side-effects, and these all appeared in the first week of therapy in both countries while the dosage was relatively high. In the U.K., among 80 cases there were four with tinnitus or deafness, seven with nausea, and one with hyperventilation. Comparable figures in the 88 U.S. cases were 9, 19, and 5. The few side-effects and the maintenance of the dosage schedule of aspirin without interruption, except in a rare case, suggests that these cases did not receive the maximum tolerated dosage.

In summary, very few patients in the hormone groups did not exhibit one or more side-effects. Further, there was little difference between U.S. and U.K. cases on differing schedules of A.C.T.H. or between those on A.C.T.H. and those on cortisone in either country (Table 29). In other words, the dosages of both hormones were large enough to produce a recognizable side-effect in nearly all cases.

Discussion and Conclusions

The object of the present co-operative study, set up in 1950, was to measure the relative effects of A.C.T.H., cortisone, and aspirin when given uniformly in all centres according to defined schedules. These schedules (dosages, periods of administration, and auxiliary therapy) were based mainly upon existent knowledge regarding apparent efficacy and toxicity. They had also to be practicable, not only in the length of time that patients could be kept in hospital during the trial itself, but to allow their subsequent application in medical practice if they proved to have value. It is obvious that innumerable other studies could be designed employing larger (or smaller) dosages, longer (or shorter) periods of treatment, or individualized dosage schedules which would need to be based on predetermined criteria for changes in dosage. It cannot be maintained that such other schedules are either more or less effective than those used here without adequate controlled study.

Evaluation of treatment of such a complex and not wholly understood disease as rheumatic fever poses a large number of problems. Acute rheumatic fever may be considered a specific type of generalized inflammatory reaction, but no means are available for measuring this quantitatively. Since it is impossible to correlate the observed manifestations with the severity of the pathological process, it must be accepted that the available data may represent only approximate indices of the severity of the disease. Furthermore, since many of the clinical evaluations are subjective, their interpretation must take into account observer error and acuity. For example, although there is general agreement on the importance of apical mid-diastolic murmurs as an index of carditis, inconsistencies in reporting them and difficulties in distinguishing them from a third heart sound or gallop rhythm gave this index uncertain value in this study. In general, such difficulties were reduced by the large number of patients in each treatment group and by the equal allocation of the three drugs within each study centre.

Other difficulties encountered in the evaluation of certain data were the lack of normal standards and the absence of normal values to serve as base lines at start of therapy. Moreover, variables which have been analysed separately may be interdependent. An example of these difficulties is interpretation of the changes in P-R intervals with changing pulse rates and heart size.

*With an initial average body weight of a little less than 70 lb. (32 kg.) in each treatment group, patients on A.C.T.H. and cortisone gained by the end of the ninth week an average of 11.3 and 11.8 lb. (5.13 and 5.35 kg.), whereas those on aspirin gained an average of 4.3 lb. (1.95 kg.).

In addition to grouping by duration of disease, various types of classification of patients were made. The most useful was based on the presence or absence of cardiac involvement on admission to the study. Owing, however, to the random allocation of patients to treatment and the consequent balance of characteristics, such additional groupings had roughly equal numbers in the three treatment groups. Each manifestation was analysed in several ways, and that method chosen for presentation which gave the clearest picture.

It should be noted that nowhere in this report have analyses of combinations of measurements and clinical signs been presented. Since in clinical practice the patient is assessed as a whole, attempts were made to integrate the separate manifestations in individual patients. These attempts were unsuccessful in providing new information, but, observing each case over the entire 6-9-weeks observation period, the proportion without any manifestation of rheumatic fever was found to be greater in the aspirin than in either of the hormone groups. This difference was observed whether or not a murmur at this time (6-9 weeks) was considered to be a manifestation. Thus, including a murmur as a manifestation, there were, with no manifestations at all, 11 cases on A.C.T.H., 11 on cortisone, and 25 on aspirin. This difference, however, is almost entirely due to the smaller proportion with an elevated erythrocyte sedimentation rate and/or raised pulse rate among the cases in the aspirin group. Adding the cases with only these signs to the group showing no manifestations, the numbers of the latter become 34 on A.C.T.H., 32 on cortisone, and 34 on aspirin. If the presence of a murmur at this time (6-9 weeks) is not regarded as a manifestation, the numbers with no manifestations during the whole 6-9-weeks period were 31 on A.C.T.H., 26 on cortisone, and 53 on aspirin. Adding to these the cases with only an elevated erythrocyte sedimentation rate and/or raised pulse rate, the figures become 71 on A.C.T.H., 62 on cortisone, and 72 on aspirin.

In attempting to assess the relative efficacy of A.C.T.H., cortisone, and aspirin in altering the acute disease or suppressing its manifestations, the following conclusions appear permissible.

1. During the acute illness and the first year of follow-up very few deaths occurred—one in the A.C.T.H., two in the cortisone, and three in the aspirin group. Re-treatments were given to some cases in all three groups, but apart from a slight excess in the late-treated cases on aspirin, there was no marked difference in the groups.

2. The temperature and pulse rate during sleep returned to normal during treatment in the great majority of cases in all treatment groups, but there was a greater tendency in the groups treated with the hormones for the rates to become elevated in the 6-9-weeks observation period.

3. The erythrocyte sedimentation rate decreased more rapidly during treatment in the hormone-treated groups, but was elevated more frequently in the 6-9-weeks observation period. There were no differences between the treatment groups at the 13th week.

4. The behaviour of joint involvement, chorea, and erythema marginatum was essentially the same in the three treatment groups. Nodules, however, disappeared more rapidly in the patients treated with A.C.T.H. and cortisone, although new nodules appeared in some patients during treatment in all three groups.

5. The analysis of the effects of the drugs on carditis, while undoubtedly most important, is especially difficult, and the conclusions the least clear. The following, however, seem justified:

(a) There appeared to be no relationship between the treatment given and the behaviour of congestive failure and pericarditis.

(b) There was more frequently an increase in heart size as measured by a change of 0.6 cm. or more in each of the hormone groups as compared with the aspirin group. This may be related to a possible increase in blood volume or, in some cases, to abdominal distension. It was not related consistently to weight gain, since heart size increased frequently in the 0-3-weeks period

of treatment and much less frequently in the observation period (6-9 weeks) although the average weight gain during these two periods was very similar. At the one-year follow-up examination there was no appreciable difference between the three groups.

(c) The appearance for the first time of apical systolic murmurs was infrequent in all three treatment groups and unrelated to therapy. No consistent difference in the behaviour of murmurs present at the start of treatment was noted except that the soft apical systolic murmurs disappeared more rapidly in hormone-treated groups. At the end of one year, however, no significant difference remained. The differences in the treatment groups with respect to apical mid-diastolic murmurs in the U.K. and basal diastolic murmurs at one U.K. centre have been discussed.

(d) The P-R intervals decreased more frequently and more rapidly in the hormone groups than in the aspirin group. This difference between the groups lessened during the observation period and was absent at nine weeks and one year. Since the values at these later times might be closer to normal than those recorded during acute illness, it may be questioned whether the early decrease is an effect of the hormones on the disease or merely a direct effect on atrioventricular conduction time.

(e) At one year the proportion with residual cardiac damage was similar in the three treatment groups. A final determination of cardiac status must await results of a prolonged follow-up.

It is apparent that this study presents no evidence that rheumatic fever in children can be uniformly terminated by any of the three agents. There is evidence that hormone treatment results in more prompt control of certain acute manifestations, but this more rapid disappearance is balanced by a greater tendency for them to reappear for a limited period of time at the end of treatment. Treatment with the hormones also leads to the more rapid disappearance of nodules and of soft apical systolic murmurs. At the end of one year, however, it is clear that there was no significant difference between the treatment groups in the status of the heart.

Summary

Six centres in the United Kingdom, five in the United States, and one in Canada have collaborated in a trial of the relative merits of A.C.T.H., cortisone, and aspirin in the treatment of acute rheumatic fever and the prevention of rheumatic heart disease. The present report relates to children under the age of 16 and compares the effects of the three drugs on the acute course of the disease and on the persistence and development of rheumatic heart disease through one subsequent year.

The records of 497 patients are presented (240 U.K. and 257 U.S., including the Canadian centre in the latter). Each case met specified diagnostic criteria on admission to the trial and was allocated at random to treatment with one of the three drugs. Each treatment was given for six weeks according to a defined schedule, and detailed observations were continued for a further three weeks. Follow-up examinations were made at specified times after these nine weeks, and the present report extends to the examination made one year later—that is, 61 weeks from the start of treatment.

The study was designed to ensure a balance of cases in the three treatment groups for each centre, for the duration of illness at start of treatment, and for the time of year when cases were admitted. Random allocation of cases within this balanced design was relied upon to secure a reasonably equal distribution of cases according to age, sex, and severity and frequency of manifestations of disease. This design permits many comparisons of the total groups on each treatment.

In 51% of the patients, treatment was begun within 14 days of the onset of the attack; in nearly two-thirds there was no history of a previous attack or evidence of pre-existing rheumatic heart disease. The treatments were therefore tested on patients of whom a large proportion were still in the early stages of the disease and had no established heart disease.

The three randomly constructed groups on A.C.T.H. (162 cases), cortisone (167 cases), and aspirin (168 cases) were notably alike in most respects at the start of the trial. The results of the treatments were measured in relation to separate manifestations of the disease—namely, temperature, pulse rate during sleep, erythrocyte sedimentation rate, joint involvement, chorea, erythema marginatum, nodules, and such aspects of the status of the heart as heart size, atrioventricular conduction time, murmurs, and, in particular, those indicative of serious illness, congestive failure, and pericarditis.

There was no evidence that any of the three agents resulted in uniform termination of the disease, and on all treatments some patients developed fresh manifestations during treatment. Treatment with either of the hormones resulted in more prompt control of certain acute manifestations, but this more rapid disappearance was balanced by a greater tendency for the acute manifestations to reappear for a limited period upon cessation of treatment. Treatment with the hormones also led to more rapid disappearance of nodules and soft apical systolic murmurs. At the end of one year there was no significant difference between the three treatment groups in the status of the heart. During the period of treatment, observation, and one year of follow-up there

were only six deaths among the 497 cases, under the age of 16, admitted to this study.

The National Heart Institute of the United States Public Health Service supported the study with grants to the co-ordinating centre and to the co-operating centres in the United States and by a travel grant to the Medical Research Council of Great Britain. The Medical Research Council provided support for the six centres and for a co-ordinating registrar in the United Kingdom. The centre in Toronto received a grant from the Canadian Arthritis and Rheumatism Society. In the United States, the costs of the medical care of its patients were met by each co-operating centre, and in Great Britain by the National Health Service. The American Heart Association provided office space for the American Co-ordinating Centre and a grant for statistical services.

This co-operative clinical trial was first proposed by Dr. John R. Mote, then assistant general manager of the Armour Laboratories. For the planning of the study, funds were provided by Armour Laboratories and Merck and Company, and space and services by the Helen Hay Whitney Foundation.

Grateful acknowledgment is made to the resident and technical staffs at the co-operating centres, without whose devoted efforts the collection of these data would have been impossible.

In the planning and conduct of this trial much is owed to the wise advice and guidance of the late Dr. T. Duckett Jones and the late Sir James Spence.

A-V BLOCK AND CARDIAC OUTPUT

BY

J. H. BURN, M.D., F.R.S.

E. M. VAUGHAN WILLIAMS, D.M., B.Sc.

AND

J. M. WALKER, D.M., B.Sc.

(From the Department of Pharmacology, University of Oxford)

The Starling heart-lung preparation provides a means of determining the effect of varying degrees of A-V block and of auricular fibrillation on the output of blood from the brachio-cephalic artery of the dog. We therefore describe observations we have made in which we have produced A-V block by driving the auricles electrically at increasing rates, and also observations in which we have produced auricular fibrillation by infusing acetylcholine at a uniform rate into the blood entering the superior vena cava and applying electrical stimuli in conjunction. A description of the effects of infusing acetylcholine in this way has been given in another paper (Burn, Vaughan Williams, and Walker, 1955).

Methods

The methods employed were the same as those already described. When the heart-lung preparation of the dog

was set up, leads to a Cossor electrocardiograph (model 1314) were attached to the right and left forelegs and the left hindleg. Electrodes which did not pierce the tissue were applied to the tip of the right auricle, and stimuli of 1 mA strength and of 0.9 msec. duration were applied at varying rates. In experiments on fibrillation acetylcholine was infused from a burette at known rates. The output was measured by deviating the blood before it entered the venous reservoir through a T-piece into a cylinder for a period of 15 sec.

Results

Output at Varying Rates of Stimulation

Stimuli were applied to the auricle at a rate about 20 per minute faster than the spontaneous rate. The application continued for about one minute, during which the output was measured and a record of the E.C.G. was taken. Higher rates of stimulation were then tried in succession, the range of stimuli being usually from 160 to 560 per min. During

application of the lower rates of stimulation the ventricular rate was the same as the auricular, until a rate was reached at which some of the auricular contractions were not followed by a ventricular contraction. This change is illustrated in Fig. 1, which shows that above the rate of 296

FIG. 1.—Heart-lung preparation. Abscissa: number of stimuli per minute applied to tip of right auricle. Ordinate: upper graph shows the ventricular rate; lower graph shows the output of blood in ml. per 15 seconds.

per min. further increases in the auricular rate caused a continuing fall in the ventricular rate until the latter became half the former. At this point there was a 2:1 block. As the auricular rate rose still further the ventricular rate followed at half the rate, and often the 2:1 block was unchanged up to the maximum rate of stimulation applied. In some experiments the block increased to 3:1 and in occasional experiments to 4:1; in Fig. 1 the block increased to 5:2 above the rate of 410 per min.

The changes in output are illustrated in Fig. 1. As the rate of stimulation increased the output remained stationary or fell slightly. With a further rise in rate the output fell steeply and continued to fall, sometimes even to zero, so long as the A/V relation was still 1:1. But when the rate was reached at which some auricular contractions were not followed by ventricular contractions, the output rose suddenly and returned to near its initial value. The sudden rise in output seemed to be due to the greater filling of the ventricles during the pause created by those impulses which were not transmitted to the ventricles. This explanation is supported by the relation between the ventricular rate and the output when stimulation was faster than 350 per min. (see Fig. 1). As the rate of stimulation rose to 585 per min. the ventricular rate slowly rose to 250 per min., at which point the output had gradually fallen to 175 ml per 15 sec. But when the ventricular rate reached 250 per min. before block began, the output was also 175 ml. per 15 sec.

TABLE I.—Restoration of Output by A-V Block. Figures are Output in ml./15 sec.

Experiment	Before Stimulation	At Maximum Rate for V=A	When Restored by A-V Block	Degree of Block
1	164	68	150	3:2
2	170	118	152	3:2
3	154	72	136	2:1
4	168	54	174	4:3
5	154	112	150	3:2
6	170	74	146	2:1
7	170	110	146	2:1
8	180	5	178	3:2
9	168	30	178	3:2
10	182	20	172	3:2
11	174	10	166	3:2
12	186	5	180	3:2
13	196	0	172	3:2
14	212	44	204	3:2
15	194	0	141	4:3
16	170	5	160	3:2
17	182	138	176	3:2
18	176	0	146	4:3
19	200	66	170	3:2
20	190	128	168	3:2

In Table I the output changes which were observed in 20 experiments are recorded. The second column gives the output per 15 sec. before stimulation. The third column gives the output during the highest rate of stimulation at which the ventricles followed every contraction of the auricles. In all experiments the output was much reduced at this point; in Experiment 17 the reduction was only to 75% of the initial output, but in Experiments 13, 15, and 18 the reduction was to zero. The fourth column gives the output in the presence of A-V block, when it was restored to a figure similar to the initial output and occasionally greater than this. The fifth column gives the degree of block corresponding to the restored output. When the figure for the low output in the third column was expressed as a percentage of the initial output in the second column the mean value was found to be 29%. Similarly, when the figure for the restored output in the fourth column was expressed as a percentage of the initial output the mean value was found to be 92%. These results show that the spontaneous development of A-V block enabled the output to be maintained at high rates of stimulation.

Greater Output with 3:2 Block

When the ventricular rate fell below the auricular rate the output usually reached its greatest value when the block was 3:2. As the block became 2:1 the output fell. Figures for 11 consecutive experiments are given in Table II, which

TABLE II.—Showing the Greater Output with 3:2 Block than with 2:1 Block

Experiment	Block 3:2		Block 2:1	
	Ventricular Rate	Output (ml. 15 sec.)	Ventricular Rate	Output (ml. 15 sec.)
21	187	150	177	114
22	228	170	188	170
23	216	156	190	90
24	278	166	240	116
25	205	160	162	150
26	190	170	155	170
27	210	160	167	136
28	153	144	124	90
29	192	130	150	104
30	175	124	140	80
31	198	156	155	150

demonstrates this fall in output associated with the change from 3:2 to 2:1 block in 9 out of the 11 experiments. The ventricular rate corresponding to each output is also given. The fall in output with the fall in the ventricular rate as the block increased from 3:2 to 2:1 suggested that there was an optimal ventricular rate below which, or above which, the output fell. This optimal rate seemed to be about 200, but obviously it varied. Thus in Experiment 24 the output fell with the increase in block although the ventricular rate was still as high as 240 per min., and in Experiment 26 the output did not fall with the increase in block although the increase reduced the ventricular rate to 155 per min.

Despite the fact that the 2:1 block, when first reached, reduced the output, it enabled the output to be maintained when rates of stimulation were higher. For example, in Experiment 21, when the block was 3:2 the ventricular rate of 187 produced an output of 150 ml. per 15 sec. With a block of 2:1 a ventricular rate of 187 would correspond to a stimulation rate of 375 per min., at which the output should also be 150 ml. per 15 sec. Actually the output was recorded as 148 ml. per 15 sec. when the stimulation was 392 per min.

Output and Fibrillation

In some of the experiments described in the previous paper, in which acetylcholine was infused at a constant rate, with the result that when stimulation was applied auricular fibrillation occurred, we obtained evidence that fibrillation helped to maintain output, probably because of the accompanying block. An example is given in Fig. 2. In the first part of this experiment the right auricle was stimulated at increasing rates and a relation between the ventricular rate and output

FIG. 2.—Records as in Fig. 1. (a) Stimulation during the infusion of acetylcholine at the rate of 200 µg./min. Auricular fibrillation began at the arrow, and the output rose in consequence. The ventricular rate and the output remained steady during stimulation up to 580 per minute. When the infusion of acetylcholine was stopped, normal rhythm returned. (b) Stimulation without acetylcholine infusion then led to a large fall in output, which was, however, restored when block began.

was recorded very like that seen in Fig. 1 and closely resembling that obtained later in this preparation, which is shown in Fig. 2b. In Fig. 2a acetylcholine was infused at the rate of 200 µg. per min., and when stimulation was as fast as 266 per min. the auricles began to fibrillate, and continued to fibrillate as stimulation was progressively increased to 650 per min. When stimulation was stopped the fibrillation continued, but when the acetylcholine infusion was stopped the fibrillation stopped. Before the auricle fibrillated the ventricular rate rose in step with the auricular rate up to 252 per min., and, as Fig. 2a shows, the output fell from an initial figure of 142 ml. per 15 sec. to 91 ml. With the onset of fibrillation the ventricular rate fell to 176 per min. and the output rose to 126 ml. per 15 sec. Throughout the rest of the period in which stimulation was applied at an increasing rate the ventricular rate and the output remained more or less constant. What seemed noteworthy was that when fibrillation occurred the output did not fall to zero as in the first part of the experiment. When the fibrillation stopped after discontinuing the infusion of acetylcholine the stimulation was repeated once more. The relation of ventricular rate to output is shown in Fig. 2b. It was very much the same as in the first part of the experiment, the output falling to 20 ml. per 15 sec. at a ventricular rate of 286 per min.

Discussion

The experiments which have been described have been carried out in the heart-lung preparation in which the output of blood into the systemic circulation can be measured directly. The changes in output which occurred when the tip of the right auricle was stimulated at increasing rates have been studied and the effect of A-V block in maintaining the output has been demonstrated. As the rate of stimulation rose the output fell at an increasing rate until the moment at which block began. As soon as this occurred the output promptly rose even when only 1 in 6 or more of the auricular beats was not transmitted to the ventricles. As the rate of stimulation increased, the degree of block (the proportion of non-transmitted beats) increased, and with it the output also, until the block became 3:2. When the block

increased further to 2:1 the output fell slightly. Up to rates of stimulation of 500-600 per min. the output was then well maintained.

That a too-rapid ventricular rate results in a fall in output has been recognized by all workers. The occurrence of A-V block has been much studied, but for the most part it has been spoken of as though it represented an impairment of function, and almost nowhere has it been recognized as an essential mechanism for the maintenance of output when the stimuli reaching the auricles are too numerous. Block occurs spontaneously when the auricles are driven electrically in the heart-lung preparation. Once it has begun it is proportional in its degree to the rate of stimulation up to the point at which it is 2:1. When the block has reached this point it permits the output to be maintained even when the rate of stimulation approaches 500 per min. Thus block can be regarded as a protective mechanism to maintain the output.

There is in addition a little evidence that under certain circumstances auricular fibrillation may serve to protect the organism from the fall in cardiac output which would otherwise occur. When stimulation during the infusion of acetylcholine led to auricular fibrillation, and presumably to a high degree of A-V block, a fall in the ventricular rate occurred together with a rise in output. The ventricular rate then remained independent of the rate at which stimuli were applied to the auricle. The preservation of a reasonable output in this condition would, of course, depend on the ventricular rate being neither too fast nor too slow. It is of interest to note that three effects of acetylcholine released by vagal stimulation—namely, slowing of the pacemaker, depression of A-V conduction, and an increased tendency to auricular fibrillation—are all directed towards the same end—an optimal ventricular rate.

Summary

A study has been made of the effect of increasing rates of electrical stimulation on the ventricular rate and on the output of blood in the heart-lung preparation.

As the rate of stimulation increased, the ventricular rate also increased and the output fell. In some preparations the output fell to zero.

Block then began, some auricular beats not being transmitted to the ventricles. The output then rose promptly.

With increasing rates of stimulation the block progressively increased until it became 2:1, at which point it stayed, rarely becoming more than this at rates up to 550 per min. Throughout the period after the block began the output was well maintained.

Block thus acts as a mechanism whereby the ventricular rate is controlled and the cardiac output maintained; it is not necessarily a sign of impairment of cardiac function.

In experiments in which acetylcholine was infused stimulation led to auricular fibrillation. The onset of fibrillation caused a rise in output.

Radio-isotopes are now being widely used in industry as measuring and detecting devices; for instance, a radioactive source on one outside wall of a foundry furnace and a counter on the opposite side measure accurately the height of the molten metal in the furnace. This method is also used to measure the contents of other types of containers. Again, a block in a pipe can be accurately found by moving a container holding radioactive material along one side of the pipe at the same time as a Geiger counter is moved along the opposite side.

ACQUIRED TOXOPLASMOSIS WITH A REPORT OF A CASE OF LABORATORY INFECTION

BY

J. K. A. BEVERLEY, M.B., B.Sc.

Lecturer in Bacteriology, University of Sheffield

ERIC SKIPPER, M.D., F.R.C.P.

Physician to the Sheffield Royal Infirmary

AND

S. C. MARSHALL, F.I.M.L.T.

Technician in Charge, Bacteriological Department,
University of Sheffield

One of us (S.C.M.) recently became infected with *Toxoplasma gondii* when working in the laboratory. Brief mention was made of this in a recent publication on acquired toxoplasmosis (Skipper *et al.*, 1954) in which two cases of the glandular variety of the disease and one other possible case resembling typhus fever were described. The laboratory infection is now reported because it furnishes yet another example of mild adenopathy, with little constitutional disturbance, due to the toxoplasma.

Case Report

On August 31, 1953, S.C.M., for purposes of animal passage, set out to fill a sterile syringe with mouse peritoneal exudate rich in the Rh strain of toxoplasma. As the needle became blocked he removed it, set it aside point uppermost, and fitted a fresh one. Shortly afterwards he pricked his left third finger on the upturned needle. Realizing what he had done, he tried, unsuccessfully, to make the puncture bleed and applied tincture of iodine.

Nine days later (September 9) he felt shivery and tired, suffered from headache, and discovered an enlarged painful gland in the left axilla. On September 12 his temperature was 102° F. (38.9° C.) and the following day he had a rigor. In spite of a 48-hour course of penicillin, prescribed by his family doctor, his fever continued and ranged between 100 and 103.8° F. (37.8 and 39.9° C.). When examined on September 16 he was sweating and looked ill. The skin of his finger was red where it had been pricked, and two enlarged, tender, discrete glands, each the size of a walnut, were present in the left axilla. Some smaller tender glands were felt in the posterior triangles of the neck. The edge of the liver could be felt, but it was not tender. The blood count showed: Hb, 100%; red cells, 4,900,000 per c.mm.; colour index, 1; platelets, 165,000 per c.mm.; white cells, 11,000 per c.mm. (polymorphs 50%, eosinophils 2%, lymphocytes 26%, monocytes 14%, band cells 8%). Many of the lymphocytes were abnormal, resembling Downey cells types I and II. A Paul-Bunnell test was negative, as were agglutination tests for salmonella and brucella antibodies. A blood culture remained sterile.

On September 16 he was given 2 g. of sulphadimidine, followed by 1 g. six-hourly for five days, at the end of which period his temperature was normal. By September 26 the cervical adenitis had disappeared. On September 30 the total white count was 5,000 per c.mm. (polymorphs 36%, eosinophils 5%, lymphocytes 48%, monocytes 8%, band cells 2%). A few atypical lymphocytes were still present. Further Paul-Bunnell tests (on September 28 and October 23) were negative. By October 5 he felt well and had returned to work, but the enlargement of the axillary glands persisted in a minor degree until January, 1954. On May 5 full clinical examination was negative and x-ray films of the chest and an E.C.G. were normal. A final blood count (May 7) showed: Hb, 120%; red cells, 5,700,000; colour

index, 1.05; white cells, 13,000 per c.mm. (polymorphs 78%, lymphocytes, 16%, monocytes 4%, band cells 2%). No abnormal lymphocytes were seen.

Investigations for Toxoplasmosis.—Previously, S.C.M.'s serum had repeatedly given negative results in the dye and complement-fixation tests for toxoplasmosis. Indeed, it was so free of antibody that it had been regularly used as activator in dye tests, and only four days before the accident it had been satisfactorily employed as a negative control in the rabbit skin neutralization test. Subsequent changes in titre are shown in the Table.

Changes in Titre

Date	Dye Test (Sabin and Feldman, 1948) (Beverley and Beattie, 1952)	Complement- fixation Test (Sabin, 1949)
16.9.53	1:80	Nil
27.9.53	1:200	"
9.10.53	1:600	"
21.10.53	1:1,560	1:16
27.10.53	1:3,200	1:16
16.11.53	1:4,200	1:16
8.12.53	1:2,400	1:4
8.1.54	1:1,150	1:16
5.2.54	1:1,600	1:2
12.3.54	1:2,000	1:16

On September 16 inoculation of heparinized blood into six mice, both intraperitoneally and intracerebrally, produced no illness in the animals, and two blind passages of pooled viscera, at intervals of two months, were negative. The toxoplasmin skin test (Frenkel, 1948), which was purposely postponed until February 9, 1954, was strongly positive.

Cases Already Reported

We have been able to find a total of six recorded cases of toxoplasmosis in laboratory workers (Ström, 1951; Sabin *et al.*, 1952; Sexton *et al.*, 1953; Giroud *et al.*, 1953; Franceschetti and Bamatter, 1953). It would seem that Ström's two cases were also briefly reported by Magnusson (1951).

Ström's first case was that of a woman aged 22 who, after working for only 19 days in the laboratory, developed painful adenitis of the neck with fever. She had been employed pipetting toxoplasma exudates, and it was thought infection had been by the mouth. On the third day of her illness she developed conjunctivitis, and on the fourth day a maculo-papular rash on the trunk, which disappeared in two weeks and was followed by desquamation on the hands and feet. Meanwhile the adenopathy had spread to the axillae and groins, and early in her illness the cerebrospinal fluid showed an increase in protein and in mononuclear cells (up to 12 per c.mm.) lasting for three weeks. Three weeks after the onset of the illness transient inversion of the T waves and other slighter changes in the electrocardiograph appeared and she complained of mild anginal symptoms and breathlessness. By this time her temperature was practically normal, but some weeks later severe headaches and attacks reminiscent of petit mal began, these being ascribed to meningo-encephalitis. She gradually improved but still suffered from headaches and from mild angina after six months. The duration of the lymphadenopathy was six to seven weeks. Attempts to demonstrate toxoplasms in an excised lymph node were not successful, and inoculation of mice with cerebrospinal fluid produced no illness. The dye test, at first negative, reached a titre of 1:4,000 three weeks after the onset of the illness.

Ström's second case occurred in a 22-year-old woman who pricked a finger of her left hand with a needle infected with toxoplasma material. Three days later an enlarged gland appeared in the left axilla. Her illness was very mild, and only slight enlargement of the lymph nodes in the neck, axillae, and groins was noted. A blood count was normal except for a relative lymphocytosis of 54%. The dye test was negative two weeks after infection, but gave a titre of 1:2,000 after two months.

Sexton *et al.* (1953) reported a fatal laboratory infection in a 47-year-old woman. She admitted no accident in the laboratory. After a period of four months' vague ill-health, she developed an acute febrile illness and became irrational. On the third day an extensive maculo-papular eruption, which spared the palms, soles, and scalp, appeared. There was no adenopathy. A blood count showed a leucopenia of 2,350 cells per c.mm., but later the white cells rose to 7,850 per c.mm. Moist sounds were present at the base of the right lung and there was rigidity of the limbs and to a less extent of the neck. On the seventh day of her illness convulsions began and she became deeply comatose. The cerebrospinal fluid, previously normal, was now xanthochromic (protein 55 mg. per 100 ml., sugar 48 mg. per 100 ml., culture sterile). Treatment, which included sulphonamides, antibiotics, and, because of low plasma electrolytes, deoxycortone, was unavailing, and she died on the ninth day. The dye test, which was negative before her illness, rose to a titre of 1:256 on the eighth day and the organism was recovered from mice inoculated with whole blood and cerebrospinal fluid taken before death, and with brain, spleen, and liver emulsion obtained at necropsy. Parasites were also seen in the patient's heart muscle, which showed widespread focal myocarditis. There was extensive gelatinous oedema of the lungs with cellular proliferation in the alveoli and in the interstitial tissue.

Giroud *et al.* (1953) briefly describe, in a laboratory technician, a febrile illness accompanied by conjunctivitis, headache, and, on the sixth day, by a facial maculo-papular rash. The complement-fixation test was positive to a titre of 1:32, but a complement-fixation test for Q fever was also positive (1:40).

Sabin *et al.* (1952) mentioned that one of their number was bitten by a toxoplasma-infected rabbit. No fever or other symptoms resulted, but the dye test became positive after 16 days and reached the high titre of 1:16,000 after 30 days, while complement-fixing antibodies appeared later.

Finally, Franceschetti and Bamatter (1953) quote the case of a girl (mentioned to them by Jaeger) whose eye was splashed while manipulating a suspension of toxoplasma. She was said to have developed "relapsing meningo-encephalitis."

Discussion

Skipper *et al.* (1954) point out that acquired toxoplasmosis usually occurs in latent form, no apparent illness resulting. In describing active acquired toxoplasmosis they draw attention to its two main types. In the first, the disease runs a benign course with mild fever and adenopathy, closely simulating glandular fever. In the second, the illness is acute and sometimes fatal. In addition to adenopathy, there are protean manifestations, particularly a maculo-papular rash, pneumonia, myocardial involvement, and infection of the nervous system with the production of meningo-encephalitis. The laboratory infections here described admirably illustrate the different forms the disease may take. Skipper *et al.* (1954) draw particular attention to the glandular variety of acquired toxoplasmosis and state that the disease should be suspected in cases of lymphadenopathy of uncertain aetiology when the Paul-Bunnell test is negative. More recently, Cathie (1954a) has carried out the dye test and complement-fixation test on the sera from 20 children and young adults in whom glandular fever was suspected on clinical grounds and in whom the Paul-Bunnell test was negative. In seven cases the dye test was positive, to titres varying from 1:32 to 1:512, and in six of these the complement-fixation test was positive to a titre of from 1:16 to 1:64.

It is well known that women who bear toxoplasmic infants are latently infected and very rarely show evidence of the disease. It is therefore of interest that Farquhar and Turner (1949) published the case of a woman who during the twenty-sixth week of pregnancy suffered a short influenza-like illness accompanied by enlargement of the cervical, axillary, and inguinal glands and who subsequently bore a toxoplasmic child. In the light of recent knowledge it

seems likely that the adenopathy was a clinical manifestation of active toxoplasmosis occurring during pregnancy.

The diagnostic value of the dye test and of the complement-fixation test is well shown in the case of S. C. M. Although some authorities have expressed doubt about the specificity of the dye test, so far as we are aware high titres such as we obtained in this serum have not been encountered in any other disease. Of particular importance is the rise and fall in the titre, as was emphasized by Sabin *et al.* (1952). As stated, we were unable to recover the organism from the blood by animal inoculation; we did not feel justified in excising a lymph node. Case reports show that direct demonstration of the toxoplasma in sections of affected organs and the transmission of the disease to animals by inoculation of blood, cerebrospinal fluid, or tissue emulsion is by no means always successful. Positive results are more likely to be obtained with severely ill patients. Skipper *et al.* (1954) were unsuccessful with lymph-node tissue, heparinized bone marrow, and citrated blood taken from one of their cases. Cathie (1954b), however, has reported the successful recovery of the organism by animal passage, using saliva and blood taken from a 5-year-old boy suffering from the glandular variety of the disease.

Little is yet known about the source of the infection in acquired toxoplasmosis. Although it has long been realized that the toxoplasma infests many species of animals, including domestic, direct transmission of the disease from animal to human, except, of course, in laboratory infections, has never been conclusively demonstrated. Similarly, transmission from human to human is known to occur only in the case of a woman who bears a toxoplasmic infant. Cathie (1954b) makes the interesting suggestion that one form of transmission may well be by direct contact spread through the saliva.

A large number of compounds have been tried, without success, in the treatment of experimental toxoplasmosis in animals (Eyles, 1953). So far, none of these drugs has been used in the treatment of human infections on a scale large enough to warrant drawing any conclusions. S. C. M. was treated for two days with penicillin without any effect on his pyrexia; it was not possible to ascertain whether there was a response to sulphadimidine.

Summary

A case of toxoplasmosis resulting from a finger-prick sustained in the laboratory is described. After an incubation of nine days a mild illness characterized by fever and lymphadenopathy resulted. The diagnosis was made by means of the dye test, which rose to a high titre (maximum 1:4,200), but the organism could not be recovered by animal passage.

Other published cases of laboratory toxoplasma infection collected from the literature are described. The clinical features of these cases vary, but closely resemble those of the spontaneously acquired disease. One case terminated fatally.

We are indebted to Professor C. P. Beattie for his helpful criticism and advice. This work has been assisted by a grant from the M.R.C. to one of us (J. K. A. B.).

ANTICHOLINESTERASES AND MUSCLE RELAXANTS

BY

B. G. B. LUCAS, F.F.A.R.C.S., M.R.C.S., D.A.

AND

S. MILES, M.B., M.Sc., D.T.M.&H.

(From the Chemical Defence Experimental Establishment,
Porton)

The muscle relaxants commonly used in anaesthesia achieve their action either by competing with acetylcholine at the motor end-plate—for example, gallamine and tubocurarine—or by persistently depolarizing the motor end-plate and rendering it inexcitable to acetylcholine—for example, succinylcholine and decamethonium iodide (Paton, 1953). Normal neuromuscular transmission is dependent upon the liberation of acetylcholine, which transmits the stimulus to the muscle and is thereafter immediately neutralized by the enzyme cholinesterase, which is normally present in excess. If neutralization does not take place the accumulation of acetylcholine permanently depolarizes the motor end-plate, so preventing the passage of further impulses, and produces a paralysis (Feldberg, 1951). The competitive blocking agents gallamine and tubocurarine antagonize the action of acetylcholine, whereas succinylcholine acts in the same way as an accumulation of acetylcholine, and its hydrolysis is similarly dependent upon the presence of cholinesterase, though at a slower rate (Bovet *et al.*, 1951). Decamethonium iodide, although also achieving its effect by depolarization, is not dependent upon the presence of cholinesterase for its removal (Paton and Zaimis, 1949).

The amount of cholinesterase in the body may alter the duration of action of some relaxants, and it would therefore seem that when using these drugs in cases in which the blood cholinesterase has been lowered by previous exposure to anticholinesterase substances—for example, certain insecticides—varying modifications of dosage might be needed. To determine whether in fact such modifications were necessary a comparison has been made of the periods of respiratory paralysis following intravenous injection of comparable dosages of tubocurarine, gallamine, decamethonium iodide, and succinylcholine in Rhesus monkeys before and after they received a standard dose of a known anticholinesterase. The chosen compound was sarin (*iso*-propyl-methyl-phosphono-fluoridate), which was given subcutaneously in a dose of two-thirds of the LD₅₀ (the LD₅₀ being the dose which is lethal to 50% of monkeys of the same species in a given series). This dosage was sufficient to cause marked symptoms of miosis, salivation, respiratory distress, and muscular fibrillation.

Technique

Rhesus monkeys of approximately 4 kg. were anaesthetized with thiopentone, 0.1 g. intravenously, and intratracheal intubation was performed with a close-fitting polythene cannula, through which the animal was ventilated at a rate of 18 a minute and a stroke volume of 50 ml. by means of a standard respiratory pump. A pneumograph was attached to the chest and a continuous record of respiratory movement obtained. The relaxant under investigation was then injected, after which 1 ml. of blood was withdrawn for plasma cholinesterase estimation. At five-minute intervals the respiration pump was disconnected for 30 seconds to

ascertain whether spontaneous respiration had returned. The time of respiratory paralysis in all experiments was taken as the time from the injection of the relaxant to the re-establishment of effective natural respiration—that is, a rate and an amplitude of respiration which would lead to recovery without further application of the pump. At the end of each experiment a second 1-ml. sample of blood was withdrawn for plasma cholinesterase estimation.

The relaxants were investigated in pairs—namely, tubocurarine and decamethonium iodide, gallamine and succinylcholine—on two groups of 10 monkeys as follows:

1st week	..	Gallamine	} 5 monkeys
2nd "	..	Succinylcholine	
Monkeys then	given	sarin	
3rd week	..	Gallamine	
4th "	..	Succinylcholine	} 5 monkeys
1st week	..	Succinylcholine	
2nd "	..	Gallamine	
Monkeys then	given	sarin	
3rd week	..	Succinylcholine	}
4th "	..	Gallamine	

Similarly, a further 10 monkeys were used for the remaining pair of relaxants.

The dosages of relaxants used were as follows: tubocurarine, 1 mg./kg.; gallamine, 4 mg./kg.; decamethonium iodide, 0.75 mg./kg.; succinylcholine, 60 mg./kg. These dosages were selected, after preliminary investigations, to give 30 to 90 minutes' respiratory paralysis.

Immediately after the completion of each experiment the plasma cholinesterase estimations were carried out by Ammon's modification of Warburg's manometric method (Ammon, 1933).

Results

The results showed that there was no influence of one relaxant upon another in any experiment, and the four agents could therefore be considered independently. As

Table of Results

Monkey	Period of Respiratory Paralysis before Exposure (min.)	Days after Exposure	Period of Respiratory Paralysis after Exposure (min.)	Change (min.)
<i>Tubocurarine</i>

* In this group, there being no significant changes in respiratory paralysis after sarin within 4 days of exposure, it was unnecessary to expose further animals.

can be seen from the Table, with tubocurarine and gallamine there was a significant decrease in the period of respiratory paralysis after sarin, whereas with succinylcholine there was a significant increase. This effect of sarin was temporary, the period of respiratory paralysis in general showing less change with a longer period of delay. Sarin had no appreciable effect on the respiratory paralysis following decamethonium iodide.

Cholinesterase Estimations.—The results obtained from the plasma cholinesterase estimations were so anomalous that no attempt was made to correlate them with the periods of respiratory paralysis. There was a wide variation between individual monkeys in their clinical response, as well as in the degree of blood cholinesterase reduction produced by sarin.

Discussion

The results of this investigation are in accordance with current theories of neuromuscular block (Paton, 1953). Tubocurarine and gallamine achieve their action by inhibiting acetylcholine at the neuromuscular junction, and this effect is antagonized by sarin. The duration of the block with succinylcholine is governed by the speed with which the drug is hydrolysed in the blood and at the end-plate; sarin, by preventing hydrolysis, prolongs the action. Since decamethonium iodide acts not by preventing the action of acetylcholine but by mimicking it, and is not destroyed by cholinesterase, anticholinesterases have no effect. The experiments showed that these changes were more marked when the relaxant was given soon after exposure to the anticholinesterase and diminished with the passage of time, presumably owing to the gradual regeneration of cholinesterase to effective physiological levels.

It is interesting to note the large dose of succinylcholine needed to produce respiratory paralysis in the monkey, approximately ten times the dose for man. There was much less species difference in the dosages of the other three drugs.

Conclusions

With the exception of decamethonium iodide, the duration of action of the relaxants commonly used in anaesthesia appears to be modified temporarily by the effects of anticholinesterase intoxication. With the extended use of these substances as insecticides the possibility of inadvertent poisoning must be considered (Barnes and Davies, 1951) if a relaxant has to be used. This may be of particular importance to Service medical officers and others who may be called upon, in the event of war, to anaesthetize casualties who have been exposed to sarin.

Summary

A description is given of a series of simple experiments designed to determine the effect of intoxication with sarin on the duration of muscular relaxation produced by tubocurarine, gallamine, succinylcholine, and decamethonium iodide.

The duration of the respiratory paralysis induced by tubocurarine and gallamine is decreased, that produced by succinylcholine is increased, and the effect of decamethonium iodide is unchanged following sarin.

The clinical implications of these results are discussed.

We are indebted to the Chief Scientist, Ministry of Supply, for permission to publish this article.

FAMILIAL HYDRONEPHROSIS

BY

R. B. RAFFLE, M.D., M.R.C.P.

South Shields

The coincidence of more than one case of hydronephrosis in a family is rare enough to attract attention. The incidence of non-calculous hydronephrosis in the family here reported is remarkable, and in view of its bearing on the aetiology of non-calculous hydronephrosis in general this occurrence is worthy of record.

Details of Family.—The constitution of the family is shown in the accompanying diagram. All the members of the family other than the four patients here described are apparently healthy and no other congenital abnormalities are known. There was no consanguinity.

Genealogical tree of family, showing distribution of cases. Ages at time of writing in parentheses.

Case 1

An unmarried girl of 19 was first seen in April, 1951. Her only complaint was of embarrassment occasioned by a generalized and gradually progressive abdominal swelling, which she had first noticed three years previously. The rate of enlargement had been noticeably greater in the preceding three months. She had no other complaints, and, in particular, there was no history of pain or disturbance of micturition. There had been no previous illnesses.

Examination revealed abdominal enlargement almost to the size of a full-term pregnancy, and on palpation this appeared to be due to a cystic swelling, localized mainly in the lower abdomen and extending up over the whole of the right side of the abdomen.

Straight x-ray examination showed a complete absence of gas and bowel shadows in the right half of the abdomen, and the liver, renal, and psoas outlines were not visible. All the bowel shadows were displaced to the left, apparently by a large fluid-containing cyst which was thought to be probably ovarian.

Laparotomy on May 3 revealed the tumour to be a massive right-sided hydronephrosis which contained 11 pints (6.2 litres) of fluid. Practically nothing was left of the normal renal tissue. The tumour was removed. The ureter was not dilated. No cause for the hydronephrosis was discovered. Post-operative progress was satisfactory and the patient was discharged from hospital two weeks later, since when she has remained well.

Case 2

A female infant was delivered normally at full term in February, 1953. Her birth weight was 5 lb. 2 oz. (2.3 kg.).

At birth she was noted to have a rather protuberant abdomen which contrasted markedly with the otherwise wasted appearance of the limbs, chest, and face. She was breast-fed from birth, but sucked poorly and initially vomited after her feeds, though after about three weeks this ceased. The abdominal distension increased, and appeared to be due to an ill-defined mass, dull to percussion, on the left side of the abdomen. By the end of the sixth week the infant's general condition was somewhat improved and she was feeding better, but the abdominal enlargement was still progressing. A pyelogram at this time revealed complete absence of excretion from the left kidney.

On May 1 the abdomen was explored through a left paramedian incision and the swelling was found to be due to a large left-sided hydronephrosis. The pelvis and calices were grossly dilated and the renal tissue was reduced to a mere shell. There was a well-marked uretero-pelvic junction and the ureter was not dilated. No cause for the hydronephrosis was found. Nephrectomy was performed.

The wound healed satisfactorily but the infant did not "pick up." Two weeks later she started vomiting, and gastric peristalsis was visible. This settled completely after a short course of "eumydrin," and her subsequent convalescence was uneventful, with a satisfactory weight gain. She was allowed home on June 18, since when, apart from two attacks of bronchitis, she has been well. She is, at the time of writing, a perfectly normal healthy-looking baby aged 1 year.

Case 3

This patient, a married woman of 23, was first seen in August, 1953, almost exactly a year after the delivery of a first child. She had been perfectly well during the pregnancy. Her presenting complaint was of a dull ache in the right loin which had started two weeks previously. In the preceding week she had felt generally ill, with occasional nausea and vomiting, had complained of headaches, and had sweated profusely. Micturition was frequent and somewhat painful, and she had to rise two or three times at night to pass water. There had been no previous illnesses.

Examination revealed a healthy-looking but febrile woman with herpes labialis. There was a tender cystic mass in the right flank which was thought clinically to be a hydronephrosis. The urine contained albumin and a deposit which microscopy confirmed as pus. Bacteriological examination produced a pure culture of *Bact. coli*. The infection settled quickly with alkalis and sulphonamides by mouth, and she was admitted to hospital one week later for further investigation.

At operation on September 18 the right kidney was removed through a right lumbar incision. It consisted of a thin shell of kidney tissue round a grossly distended pelvis. A large leash of blood vessels was observed at the uretero-pelvic junction. Post-operatively, recovery was uninterrupted and she has been perfectly well since.

Case 4

A married woman of 37, the mother of three children, aged 17, 15, and 3, was first seen in June, 1953. During her last pregnancy she had suffered from pre-eclampsia, but the obstetric history was otherwise normal. There had been no other illness. On June 26 she had noted a sudden onset of pain in the right loin during the afternoon. This was associated with vomiting. She felt generally unwell and had to go to bed. When first seen later that day she complained also of headache, pain on micturition, frequency, and sweats. There was marked right-sided renal tenderness but no palpable mass. The urine showed numerous pus cells in an uncentrifuged specimen. The blood pressure was 150/90. She had a course of alkalis and sulphonamides by mouth, and after a week felt perfectly well, was afebrile, and was again up and about. There was then no albumin or microscopical abnormality in the urine. She refused further investigation.

On September 11 she was again seen with a recurrence of pain in the right loin of one week's duration, less severe

but more persistent than that experienced previously. There were no febrile symptoms on this occasion and no disturbance of micturition. A cystic mass, clinically a hydronephrosis, was now palpable in the right flank. The urine showed a trace of albumin, a deposit of pus, and a growth of *Bact. coli* on culture.

Intravenous pyelography two weeks later revealed a somewhat enlarged right renal outline. Both kidneys excreted the dye. There was very well marked caliceal hydronephrosis on the right, but the pelvis and ureter contained no visible dye.

On October 16 a right lumbar nephrectomy was performed. There was gross caliceal and pelvic hydronephrosis. The ureter was of normal dimensions. The post-operative course was satisfactory and she was discharged from hospital three weeks later. Since then she has remained well.

Discussion

The occurrence of four cases of non-calculous hydronephrosis in two generations of one family would appear to rule out coincidence as an explanation. All the patients were females. In one generation three out of four sisters were affected. I have not been able to examine the other, apparently healthy, members of this family to see if any present a symptomless hydronephrosis, but obviously such a possibility exists, since the cases here reported came under observation only because of the large size of the tumour or because of the accident of infection. Thus in Case 1 the hydronephrotic sac had reached enormous proportions, containing 11 pints (6.2 litres) of fluid; in Case 2 abdominal enlargement due to the hydronephrosis was already present at birth; and Cases 3 and 4 presented with the signs and symptoms of a urinary infection.

In speaking of the aetiology of hydronephrosis Winsbury-White (1951) states: "Heredity can claim some cases." A search of the literature, however, reveals few reported cases of familial hydronephrosis. Blackwood (1896) quotes Virchow as having described the case of a woman who gave birth to three premature children, each with hydronephrosis. The cases in the family reported by Mackay (1944) differ from those here described in that they were associated with megaloureter. The history in this family was remarkable. Of seven siblings, five had congenital kidney lesions, three having megaloureters (in one bilateral) and two having congenital sarcomata of the kidney. The paternal grandfather had had a calculous pyonephrosis and may therefore have had a congenital hydronephrosis. Aaron and Robbins (1948) reported the cases of two brothers, aged 12 and 16, with hydronephrosis. In both "aberrant lower pole vessels were definitely established as the cause of hydronephrosis."

The pathogenesis of the hydronephrosis in the cases reported here is obscure. In only two is there any suggestion of a definite cause—in Case 3, which presented following pregnancy and in which aberrant vessels were reported at operation, and in Case 4, in which the patient had had three pregnancies, the last three years previously. There was no history of pyelitis of pregnancy in either of these women. Unless the remarkable familial incidence is ascribed to coincidence alone, the underlying causal factor must be presumed to have been the same in each case. Neither the aberrant vessels, present in one case only, nor pregnancy, which had occurred in only two, could therefore be of primary aetiological significance. This supports the belief of Winsbury-White (1925) that the vascular factor is of merely secondary significance in the aetiology of hydronephrosis. He contends that obstruction of the ureter by a blood vessel occurs simply as an additional factor when the renal pelvis, dilating from some other cause, reaches a sufficient degree of distension, though it may add a very severe mechanical obstruction to the primary cause of the dilatation, whatever that happens to be.

If we disregard, then, the aberrant vessels reported at operation in Case 3, we are left with the problem of the cause of the hydronephrosis in all four cases. In each the

ureter was apparently normal; the pelvis and calices alone were dilated; the uretero-pelvic junction was well marked; and yet no cause of ureteric obstruction was found.

Jewett (1940), after careful study, showed that normally there is no absolute uretero-pelvic junction, the pelvis blending into the ureter in a funnel-shaped prolongation. He believed that when such a junction exists, as it did in the cases described here, stenosis should be considered, particularly if there is pyelectasis. The fact that he considered this stenosis often congenital, since there were no acquired factors to explain it, would make such a mechanism an exceedingly attractive explanation for the present series of familial cases. However, no evidence of stenosis was found. *Faute de mieux*, we must therefore fall back on such a conception as inadequacy of the ureter as an efficient urinary duct which has been posited as a causal factor in hydronephrosis; or we must postulate a functional defect in the neuromuscular mechanism of the renal pelvis, as the familial and inherited primary aetiological factor, though there is no positive evidence for either supposition. Consideration of the familial nature of these cases does, however, serve to show that, contrary to general opinion, a pelvic and caliceal hydronephrosis of this type can occur as a congenital condition without evidence of ureteric obstruction.

Summary

Four cases of non-calculous hydronephrosis occurring in two generations of a family are described. The literature is reviewed. The aetiology of the condition is discussed.

I am indebted to Mr. R. J. Rutherford, who was responsible for the surgical care of Case 1; to Mr. M. C. Pinkerton, who was similarly responsible for Cases 2, 3, and 4; and to Dr. C. H. Kitchen, who carried out the radiological examinations.

AND

C. W. M. WHITTY, D.M., M.R.C.P.

(From the Military Hospital, Wheatley, Oxon, and the Department of Neurology, Radcliffe Infirmary, Oxford)

Juvenile general paralysis is commonly thought to manifest itself as a gradual dementing process similar to that seen in the adult disease, but with the differences in symptomatic conduct and behaviour disorder that the onset in childhood or the school years would produce. Thus intellectual deterioration may appear as a failure to ascend the normal educational ladder or as an unexpected loss of already acquired learning. Grandiose delusions, which are uncommon, may take the form of claiming ownership of vast stores of sweets or toys. Reduced social standards, such as minor dishonesty or lack of personal cleanliness and tidiness, often presenting symptoms in adults, are likely to be less readily noticed in the juvenile age group. This is the picture given in the standard textbooks of neurology and psychiatry, though Ford (1949) and others mention a maniacal reaction as an occasional presenting symptom.

The following case is worth recording because juvenile G.P.I. is now an uncommon disease and because the

method of presentation was unusual. The sudden development of a hemiplegia drew attention to the disease, and shortly thereafter the patient developed an acute mania.

Case History

A National Service man, aged 19, was admitted to Wheatley Military Hospital in July, 1953. On the previous day, while picking peas on leave at home, he had suddenly "collapsed" in a semicomatose state, from which he could be roused only by repeated shouted requests. He was able to obey simple commands, but his answers to questions were incoherent and unintelligible. On examination he proved to have a right hemiparesis with dysphasia and right homonymous hemianopsia. There were some continuous clonic movements of the right face and hand resembling epilepsy partialis continua. The pupils were large, irregular, and did not react to light. The optic fundi were normal, as were other bodily systems. The blood pressure was 140/90. The urine was free from albumin and sugar. Lumbar puncture revealed a clear fluid under normal pressure, with a protein of 70 mg. per 100 ml., and 25 white cells per c.mm. (90% lymphocytes, 10% polymorphs). His electroencephalogram showed high-voltage delta activity in both hemispheres but focusing on the left mid-parietal electrode.

During the next 48 hours his comatose condition gave place to an acute mania. He would laugh and talk continually, and as he was still dysphasic a stream of jargon, often shouted at the top of his voice, resulted. Despite his hemiparesis he made continual attempts to get out of bed, and would keep on neither bedclothes nor pyjamas. He would try to attack anyone approaching him, and when restrained in bed made continual restless movements of his non-paretic limbs. He was incontinent of urine and faeces, and had to be tube-fed. In view of a possible left frontal abscess or tumour, a carotid angiogram was done, but this showed no convincing abnormality. By this time, some five days after admission, a strongly positive W.R. in the blood and C.S.F. had been returned, and the Lange gold curve was 455555321. The diagnosis of juvenile G.P.I. was thus suggested, and he was given penicillin, and in view of a possible gummatous process this was combined with potassium iodide. During three weeks he had 22 mega units of penicillin and 30 gr. (2 g.) of potassium iodide three times a day. On the mental side the response was dramatic. Within a week his acute mania had subsided and he would remain in bed and feed himself. He was continent of faeces, though he still occasionally wet himself.

Four weeks later he was up and helping with ward duties, though still rather emotionally labile. His neurological condition had also improved. The involuntary movements lessened gradually and ceased after some seven days, the hemianopsia and hemiparesis also cleared, though pyramidal signs—increased tendon-jerks and an extensor plantar response—remained. Some dysphasia also persisted, and there was slight proprioceptive sensory loss in the right arm and leg. The pupils remained large and irregular. There were no other signs of congenital syphilis. His electroencephalogram became more normal, with an 11 c.p.s. alpha rhythm in the right hemisphere, and some low-voltage theta activity from the anterior leads on the left. He proved to be entirely right-handed. Three months after the onset of his illness he was well enough to return home and was invalided from the Army.

As his serology remained positive he was treated with two further courses of 20 mega units of penicillin at the Queen Elizabeth Hospital, Birmingham. In March, 1954, his C.S.F. showed a protein of 42 mg. per 100 ml., with 1 lymphocyte per c.mm., Lange 3211000000, and a positive W.R. He was still emotionally labile, had occasional dysphasia and also evidence of left parietal lobe dysfunction, such as visual and tactile inattention to the right half of the body and a disinclination to use these limbs. However, he was leading a normal social life at home and was hoping to restart work in his previous trade.

Subsequent inquiries revealed that the patient had been to an ordinary school, and, although considered backward, had attended a junior technical college for a year, leaving at the age of 15. He had been employed as a factory hand and later as a storeman before his national service. On entering the Army at the age of 18, he had been regarded as rather dull and mentally immature, but no physical abnormalities were found. Three months before the illness here reported he had "collapsed" during a battle course done as part of his Army training, and a weakness of the right hand had been noted in examination. This had cleared in a few days, and he had been returned to duty but excused further battle courses.

His father, mother, and only sister each proved to have a positive W.R.

Discussion

The rarity of juvenile G.P.I. was emphasized by Worster-Drought (1940). This case also showed several uncommon features. The clinical onset was abrupt, and, although some degree of dementia may have been present for a time before the acute breakdown, it was not sufficient to prevent his wage-earning employment or his acceptance for national service. The presentation with focal neurological signs is unusual. However, such a syndrome in G.P.I. was recognized by Lissauer and Storch (1901), and these cases are sometimes referred to as "Lissauer's paralysis." Lissauer himself explained them as being due to an intense localized atrophy of a group of convolutions, but of the same pathogenesis as the more diffuse cerebral atrophy of G.P.I. More recently, however, Stewart (1933), in reviewing the pathology of juvenile cases, could find little to differentiate histologically between ordinary G.P.I. and Lissauer's type, as localized atrophy with status spongiosus occurred in both. In our case the abrupt onset of hemiparesis, the focal clonic movements, the localized electroencephalographic abnormality, and the rapid improvement with potassium iodide and penicillin, with slight residual focal signs, all suggest that a meningovascular process with gumma formation may have been present in addition to the G.P.I.; and, indeed, this may be the explanation for other cases of "Lissauer's paralysis."

A predominantly manic psychiatric picture is also unusual, though recorded in this condition. This patient's initial response to penicillin was very striking. His subsequent improvement has continued, though more slowly, and it can certainly be said that already, during the course of a year since the diagnosis was made, progress has been much better than with older remedies such as malaria, arsenic, and bismuth. Worster-Drought (1951) has used a combination of penicillin and malaria in treating 10 cases of juvenile G.P.I., with improvement in all cases. However, it is still a matter of debate whether such a combination has any advantages over penicillin alone, used, as in the acquired form of G.P.I., in large and repeated doses until the serology shows a definite response. Either way, treatment should be continued until such a response does occur.

We should like to thank Professor P. C. Cloake for the follow-up notes of the case, and the Director-General, Army Medical Services, for permission to publish.

Spastic and other disabled children in hospitals and special schools are finding the use of magnetic letters both entertaining and instructive. Clinging to the surface of special blackboards, which can be held in any position, these letters are particularly helpful in the education of children who have to lie on their backs.

ANAPHYLACTIC SHOCK AS A COMPLICATION OF INSULIN COMA THERAPY

BY

CLEMENT ROSE, M.D., D.P.M.

AND

JOHN BARRON, M.B., Ch.B.

(From Saxondale Hospital, Radcliffe-on-Trent, Notts)

Changes in insulin sensitivity are fairly common during insulin coma therapy and are shown by changes in the time and depth of coma, usually in the direction of increased sensitivity, requiring reduction of the original coma-producing dose. Insulin hypersensitivity (or allergy) is far less common and actual anaphylactic shock is extremely rare.

Case Report

A 40-year-old male paranoid schizophrenic was admitted to hospital on October 15, 1953. He had been in hospital in 1950 (when he had a three-weeks course of modified insulin) and in 1952. There was no personal or family history of allergy. He was in satisfactory physical health, and routine blood investigations were normal. After preliminary electroplexy, modified by relaxants, he began deep insulin therapy on October 22. This was administered by the routine technique modified by the use of intravenous insulin. Daily injections of insulin were given for six days a week, at first intramuscularly, beginning with 10 units, then 20 units, then increasing daily by 20 units, changing to intravenous injection at 60 units. Various brands of soluble insulin of 20 units per ml. strength were used in the treatment unit, but only one batch was in use at any particular time.

November 1 was a rest day, and on the 2nd an intravenous injection of 160 units of soluble insulin was given at the usual slow speed at 7.50 a.m. This was the tenth treatment, and the dose was the same as that administered on October 31, when only sweating had resulted, with termination of the hypoglycaemia by oral glucose at 10.30 a.m. No untoward reactions had previously been noted. On this occasion, however, five minutes after injection coughing and retching occurred. The manifestation of anaphylaxis was immediately suspected, and during the preparation of an adrenaline injection severe bronchospasm occurred with startling rapidity and severity, and the patient became pallid and cold. Intravenous adrenaline tartrate, 2 ml. of 1 in 1,000 solution, was given, and general treatment for shock was begun. Bronchospasm and vasomotor collapse remained very pronounced, and consecutive intravenous injections of 60 ml. of 33% dextrose solution and 2 ml. of nikethamide were given, accompanied by continuous insufflation of oxygen (later changed to oxygen with 5% carbon dioxide). Slow intermittent intravenous injection of adrenaline was maintained, and between 8 and 8.35 a.m. 8 ml. of 1 in 1,000 solution was administered. The case proceeded as follows.

At 8.40 a.m. he was given atropine sulphate, 0.6 mg. (1/100 gr.), and aminophylline, 0.5 g., intramuscularly and 33% dextrose, 60 ml., intravenously. He was now sufficiently recovered to ingest chlorcyclizine hydrochloride tablets ("histamin"), 100 mg., crushed in a little glucose solution. 9.5 a.m.: Blood sugar, 143 mg. per 100 ml. 9.10 a.m.: I.V. 33% dextrose 60 ml., and normal saline 40 ml. 9.30 a.m.: B.P. 114/76; pulse rate, 130 a minute. 10.5 a.m.: B.P. 94/62; I.M. nikethamide 2 ml., and I.V. injection aminophylline 0.25 g.; general condition unchanged. 11 a.m.: B.P. 80/50; pulse rate, 80 a minute; blood sugar, 43 mg. per 100 ml. 11.15 a.m.: Patient suddenly became very collapsed, with dyspnoea and very weak pulse volume; I.V.

nikethamide 2 ml., I.V. 33½% dextrose 60 ml., and I.M. aminophylline 0.5 g. administered, with rapid improvement. 11.30 a.m.: B.P. 84/60; pulse rate, 90 a minute. 12 noon: Renewed collapse, with dyspnoea, weak pulse, and cold extremities; I.V. adrenaline 2 ml., I.M. methylamphetamine hydrochloride 10 mg., and I.V. 33½% dextrose 110 ml. were injected, with consequent improvement. 2 p.m.: B.P. 114/76; blood sugar, 212 mg. per 100 ml.; I.V. 33½% dextrose 60 ml., and I.M. methylamphetamine hydrochloride 10 mg. At 2.10 p.m. the urine contained 2% sugar. The patient was now taking frequent sips of fluids and was maintaining his general condition. 4 p.m.: Blood sugar, 132 mg. per 100 ml.; B.P. 88/58, but general condition fairly good. Conversation was rambling at times, probably due to methylamphetamine abreaction.

The systolic blood pressure remained consistently below 100 mm. despite the general improvement. Another intramuscular injection of methylamphetamine produced further abreaction, and this drug was then discontinued to avert possible exhaustion. Intramuscular nikethamide, 2 ml., was continued two-hourly throughout the night and then four-hourly; chlorcyclizine hydrochloride tablets, 100 mg., were also given four-hourly from the next morning (November 3), when the patient's improvement was well maintained, although his conversation was noted to be rambling.

On November 4 he was still rambling and confused, although accessible mentally. Nikethamide and chlorcyclizine were discontinued, and paraldehyde, 2 fl. dr. (7 ml.), was prescribed as a nocturnal sedative. Next day he was more rational and quite normal physically. Clinical psychological examination on November 14 showed no significant mental change resulting from the anaphylaxis.

Follow-up Allergy Studies

An intradermal technique was adopted, using 0.01 ml. of test solution injected from a tuberculin syringe with a fine needle. The batch of insulin in use at the time of the anaphylactic incident ("AB" insulin, 20 units per ml.) gave a strong positive reaction. Similarly strong positive skin reactions were given by all other types of insulin tested, both unmodified (Novo insulin 20-unit solution, and Boots insulin 20-unit solution) and modified (Wellcome P.Z.I. 40-unit solution, Boots I.Z.S. 40-unit solution, and Boots I.Z.S. (amorphous) 40-unit solution). Control solutions used were normal saline and 0.3% cresol (since this latter was the preservative added to the original insulin solution): these gave consistently negative results, as also did Bencard intradermal solutions of pig, beef, and mutton proteins.

At the beginning of December passive transfer of sensitivity was attempted, using four healthy non-allergic subjects: three gave positive reactions and one gave a slight positive reaction. Sensitized skin areas were prepared by the injection of 0.1 ml. of the patient's serum.

In January, 1954, when his intradermal response to soluble insulin was still strongly positive, experiments with antihistamines were carried out, and it was found that oral dosage (chlorcyclizine hydrochloride tablets, 100 mg., an hour before the injection) diminished the reaction considerably; but this remained positive, whereas coincident injection with the insulin solution, using 0.01 ml. of a 2.5% solution of mepyramine maleate (0.25 mg. of salt) with 0.01 ml. of soluble insulin (0.2 unit) achieved almost complete neutralization.

In April, intradermal testing revealed the continued presence of a strongly positive allergic reaction to insulin. It is proposed to keep this patient under observation, so that the expected waning of his allergic state may be detected by repeated tests for skin allergy and circulating skin-sensitizing antibodies (reagents).

Discussion

The occurrence of a true anaphylactic reaction was confirmed by the presence of an incubation period, the positive

intradermal tests, and the detection of circulating antibodies. These features are absent in the so-called anaphylactoid response to intravenous injections (Sollmann, 1942).

Earlier literature on the allergenic properties of insulin has been well summarized by Harten and Walzer (1940) and by Yasuna (1941). The above case is an unusually severe example of the generalized reaction regarded as occurring in about 1 in 1,000 insulin users, although Ulrich *et al.* (1939) suggested that insulin allergy was relatively more frequent in the non-diabetic patient. Harten and Walzer criticized the paucity of skin-test recording in these cases and pointed out that even less often was the possible presence of circulating reagins investigated, although neither of these reactions necessarily parallels the presence or severity of clinical symptoms.

Of particular interest in the described case was the presence of the "latent period" prior to the anaphylactic incident that occurred 11 days after the first injection of the insulin course—which was itself begun two and half years after a previous course. The increased frequency of allergy (particularly generalized) when insulin therapy had been interrupted and the resemblance of the "latent period" to the incubation period of serum sickness were emphasized in the reviews by Tuft (1928), Harten and Walzer, and others. A further feature was the occurrence of the episode immediately following an insulin-free "rest day"; this can be compared with the cases of Hinko *et al.* (1941) and of Sherman *et al.* (1941). Non-diabetics are far more likely to suffer interruptions of insulin administration, and this may account for their reported greater liability to allergic reactions.

Allergy studies in the above case confirmed the activity of a specific antigen. Despite the improved purification of insulin, some authorities maintain that its apparent allergenic properties are due to minute amounts of contaminating protein material, or even to an alteration of insulin in the isolation process, rendering it a "foreign protein" (Waters and Best, 1941).

Jorpes (1949) claimed that repeated recrystallization of insulin reduced the incidence of allergic reactions, and suggested that these were usually, if not always, due to impurities.

The antihistamine experiments demonstrated the efficacy of these drugs in neutralizing insulin allergic effects: this has been confirmed by therapeutic experience, sometimes combined with desensitization, spontaneous or induced (Hunter and Hill, 1947; Leavitt and Gastineau, 1947; Armstrong and Lloyd, 1954). In the treatment of the above case an oral antihistamine was used, but it may be that early administration of an injectable compound, unfortunately not available at the time, might have shortened the emergency period.

We wish to thank Dr. J. S. McGregor, medical superintendent, Saxondale Hospital, for permission to publish this paper; Mr. D. C. Hubbard, F.I.M.L.T., for technical assistance; and the nursing staff for their invaluable co-operation.

ESTIMATION OF ISONICOTINIC ACID HYDRAZIDE IN BLOOD SERUM AND CEREBROSPINAL FLUID

BY

G. HUNTER, M.A., D.Sc.

Electro-Medical Research Unit, Medical Research Council,
Stoke Mandeville Hospital, Aylesbury, Bucks

Cuthbertson and his colleagues (1954) described a method of estimating isonicotinic acid hydrazide (I.N.H., isoniazid) in blood plasma and urine that marked a considerable advance on previous methods. Their method, however, requires about 10 ml. of blood and is rather elaborate for routine purposes. Our interest in the subject has been confined to blood and cerebrospinal fluid (C.S.F.), for which it has been possible to shorten the procedure in a manner that may be of interest to others.

Method for Serum and C.S.F.

Reagents.—Acetic acid, 0.05N. Phosphate buffer pH 6.5: 3 vol. M/5 Na₂HPO₄ and 7 vol. M/5 KH₂PO₄. Picryl chloride solution: 35 mg. (B.D.H.) in 10 ml. ethanol. Acetic acid, 5N. *n*-Butanol.

Protein Precipitation (in test-tube, 16 by 125 mm.).

Serum.—To 1.25 ml. of serum add 7.5 ml. of water and 1.25 ml. of 0.05N acetic acid.

C.S.F.—To 1.25 ml. of C.S.F. add 7.75 ml. of water and 1 ml. of 0.05N acetic acid. (When other amounts of serum or C.S.F. are used the above proportions of 0.05N acetic acid are strictly adhered to, and the volume is always made to 10 ml.) The tubes are immersed in a bath of boiling water for about three minutes to coagulate the protein. They are then centrifuged.

Colour Reaction.—To a test-tube (16 by 125 mm.) add 8 ml. of the supernatant fluid (≡ 1 ml. of serum or C.S.F.), 2 ml. of buffer, and 0.25 ml. of picryl chloride solution. Heat the tube in a bath of boiling water for 20 minutes. Cool. Add 0.4 ml. of 5N acetic acid and 3 ml. of *n*-butanol, and shake vigorously for one minute. Spin, and remove the clear butanol layer into small tubes containing 2 drops of ethanol to prevent clouding. Transfer to a glass cuvette with 1-cm. light path and note the optical density at wavelength 500 mμ.

Calibration Curve.—This was constructed from a series of readings made from solutions containing 8 ml. of water, 2 ml. of buffer, and 0.25 ml. of picryl chloride solution, and containing 0, 0.5, 1, 2.5, 5, and 10 μg. of I.N.H. Such solutions were heated as described above and the optical density of the butanol extracts was measured. When no I.N.H. was present there was a reading of about 0.01 optical density. When this was subtracted from all readings a strictly linear curve in the above range was found such that the observed optical density × 34.5 = μg. I.N.H.

It may be noted here that the optical density from controls containing no I.N.H. increases rapidly with light of wavelength less than about 480 mμ, whilst at great wavelengths the optical density from the reaction product of I.N.H. and picryl chloride decreases rapidly. At 500 mμ the blank value is almost negligible and the sacrifice in sensitivity is not more than about 20%.

Serum and C.S.F.—Controls.—Under the above conditions it has been found that sera from patients who have not received I.N.H. commonly give values, expressed as I.N.H., of 1 to 2 μg. per ml., and corresponding C.S.F.s about half such values. Such blank values are somewhat reduced but not eliminated by the extraction procedure of Cuthbertson *et al.*, so that control observations are always necessary for accurate estimation. However, as the

amount of serum or C.S.F. required is now moderate, proper control determinations are practicable with sample volumes ordinarily obtainable in hospital wards.

Recovery of I.N.H. Added to Serum.—The amount of I.N.H. recoverable from serum by the present method of analysis may be seen from the observations shown in the Table. With C.S.F., recovery values are rather better.

Recovery of I.N.H. Added to Serum

I.N.H. added, μg. ml. serum	0	0.4	0.8	1.2	1.6	2.0
I.N.H. recovered, % ..	Range of blanks: 1.41–2.07 μg. as I.N.H. ml.	89	87	85	82	84
Range of recovery values, %		86–95	83–95	78–92	69–88	77–90

To seven sera, in six lots each, I.N.H. was added in the amounts noted. In each case 1.25 ml. of the serum was deproteinized as described and the equivalent of 1 ml. filtrate was treated as further described for the colour reaction. The range of blank values is inserted to indicate the necessity for control determinations.

Tungstic acid may be used, as described by Cuthbertson *et al.*, for deproteinization, but the above method gives more consistent results, is simpler, and indeed yields better filtrates with C.S.F.

Summary

A simplified method suitable for routine estimation of isonicotinic acid hydrazide in blood serum and cerebrospinal fluid is described.

I should like to express my appreciation to Dr. S. W. A. Kuper (Brompton Hospital, London) for details of the method of Cuthbertson *et al.* before publication; to Dr. F. D. Stott for designing the photoelectric colorimeter; and to Mr. G. J. Bowser for technical assistance.

Medical Memoranda

Delay in Passage of a Ryle Tube Ingested Accidentally

Many papers in the medical literature have dealt with ingested foreign bodies and complications therefrom, but, so far as can be determined, none has mentioned a Ryle stomach tube as the foreign body. Furthermore, none has described arrest occurring at the duodeno-jejunal flexure. For these two reasons the following case is worth recording.

CASE REPORT

On February 16, 1953, a youth aged 16 suffering from a left pleural effusion had a Ryle tube passed to obtain a specimen of his gastric washings for examination for tubercle bacilli. During the procedure he swallowed the tube accidentally. A strong saline emetic given immediately failed to return the tube by mouth, but it was thought that it would pass through the alimentary canal without incident.

The following day a radiograph of the abdomen showed the tube high in the abdominal cavity, probably in the stomach. Seven days later, as the tube had not passed, a second radiograph was taken and this showed that its position had not materially altered. In an attempt to locate it a barium meal was given nine days after the tube had been swallowed, and the radiograph revealed part of it emerging from the barium-filled pylorus and occupying the curve of the duodenum. Following this, regular screening demonstrated the metal weight in the end of the tube to maintain a fairly constant position on the left of the vertebral column, at the level of the third lumbar transverse process, corresponding to the position of the duodeno-jejunal flexure.

Sixteen days after the ingestion of the tube a second barium meal was given, and a lateral radiograph showed the metal weight still lying posteriorly to the stomach, at the

level of the third lumbar vertebra. On the thirty-sixth day a third barium examination revealed the metal marker in roughly the same position, and it was thought highly probable that arrest had occurred at the duodeno-jejunal junction.

On the forty-third day it was decided that, as no progress had been made, the boy should have an exploratory laparotomy with a view to removal of the tube. Shortly before the date arranged for operation, on the fifty-third day, the boy was screened again, and this time the metal weight was clearly seen lying in the pelvis. Digital examination of the rectum confirmed the presence of the tube, which was hooked by the finger and withdrawn.

COMMENT

The interesting point in this case is the unusually long time (53 days) the tube remained in the alimentary canal; yet, despite this, the patient suffered no ill effects of any kind.

It seems probable from the radiological findings that the point of arrest was the duodeno-jejunal flexure, which must surely be unusual. Furthermore, after a delay there, known to have lasted 34 days and which was probably longer, the tube became dislodged and passed without further trouble.

It is reasonable to conclude, therefore, in dealing with cases of this kind, that, provided there are no symptoms, a delay of six to eight weeks is warranted before surgical removal is considered, and that, in addition, a failure of the tube to advance in the alimentary canal for as long as three to four weeks does not preclude the possibility of a natural passage.

I thank Dr. A. J. Moon for permission to publish this case.

WILLIAM WILSON, M.D.,
Lately Registrar, Pinewood Hospital, Wokingham.

Occupational Calcium Necrosis of the Skin

Necrosis of the skin due to calcium chloride solution appears to be a rarity in that only two cases have so far been published. Oppenheim (1935) described its occurrence in an ice-cream maker who accidentally allowed the concentrated solution of calcium chloride used as a freezing bath to come into contact with his skin. Heppleston (1946) described it in an operator using a 40% solution of calcium chloride as a dust-laying spray in a South Wales coal-mine. The following case, in a maker of anti-freeze solution, serves to confirm the existence of calcium chloride necrosis and to stress the need for protecting the skin from this substance.

CASE REPORT

A 29-year-old Turkish labourer was employed in making a 40% solution of calcium chloride. This was marketed as

FIG. 1.—Necrosis of friction areas on the legs due to calcium chloride solution.

an anti-freeze agent to add to water used for mixing mortar and concrete in cold weather. The manufacturing arrangements were primitive, and one day he splashed his trousers with the solution, but did not change them or wash his legs. That night he noticed considerable pain in the parts of his legs where the tops of his gum-boots had rubbed.

The next morning he reported to the industrial clinic and his legs appeared as in Fig. 1. On each was a thick black eschar surrounded by a thin border of inflammation. The appearance was similar to that of the coagulum produced by the old tannic acid treatment of burns. The eschar was obviously necrotic skin involving the full skin thickness.

With conservative treatment the coagulum began to separate along the edges on the 19th day, and was half separated on the 30th day. Healing was not complete until the 90th day.

A biopsy (Fig. 2) showed coagulative necrosis of the epidermis and underlying dermis. The latter was crowded with nuclear fragments and there was slight proliferation of fixed tissue cells in the surviving connective tissue. Von Kossa's reaction showed obvious impregnation with calcium.

FIG. 2.—Lesion of right leg, showing necrosis and calcium impregnation. Haematoxylin and eosin, Von Kossa.

COMMENT

The microscopical appearances in Heppleston's case were similar, except that in the less severe lesions there was necrosis and calcium impregnation of the dermis only. As in this case, severe lesions were present on those parts of the legs where friction from the tops of the gum-boots had occurred. Healing was prolonged, and it is for this reason that it is so important to protect the skin from calcium chloride solutions.

The cause of the lesions is probably the alkalinity of the solution combined with its necrosing effect. In the present case the pH of the solution was 9.4, and it was found by titration to have an alkalinity equivalent to N/50 NaOH. Calcium is a well-known necrosing agent, as shown by the dire results of its accidental injection subcutaneously or intramuscularly. The alkalinity would soften the horny layer of the skin so that penetration and subsequent necrosis could occur.

I would like to thank Dr. L. E. Glynn for kindly preparing and reporting on the section in this case.

PETER H. NASH, M.D., D.P.H., D.I.H.,
Formerly Senior Clinical Assistant,
Slough Industrial Health Service.

Reviews

KWASHIORKOR

Kwashiorkor. By H. C. Trowell, O.B.E., M.D., F.R.C.P., J. N. P. Davies, M.D., and R. F. A. Dean, Ph.D., M.R.C.P. (Pp. 308+xii; illustrated. 50s.) London: Edward Arnold (Publishers) Ltd. 1954.

A great deal of research has been done on kwashiorkor since the appearance in 1931 of Cicely Williams's classic description of the disease. Introduction of the liver biopsy technique and of new biochemical methods has given impetus to this work, and Dr. Trowell and his co-authors are able to quote over 600 references to it. When a disease of hitherto unknown causation becomes the object of much interest it is to be expected that many differing opinions will emerge, and in this respect kwashiorkor has proved no exception. There is, therefore, a need for a book, not only to draw together the widely dispersed literature on the disease, but also to mediate between varying opinions concerning it. Dr. Trowell and his associates at Mulago have been in the forefront of those carrying out research on kwashiorkor; none are more qualified to write on the subject, and they have well accomplished the task of preparing this book. It is readable, and the narrative proceeds easily from the history of the disease to the clinical features, diagnosis, pathological anatomy, biochemical findings, treatment, and prevention. There follows a discussion on protein malnutrition in adults and on the pathological and physiological implications of it and of kwashiorkor in children. There are many good photographs and diagrams.

Throughout the work the authors have put forward their own findings and views with modesty, and, though seldom leaving the reader in doubt as to their opinions, they have been careful to quote opposed views. Few will, however, disagree with their conclusion that the main features of the disease are caused by defects of protein metabolism. The use of the term "kwashiorkor" may be criticized, but this has been used advisedly. In different parts of the world innumerable terms are used for the same disease, some, such as "infantile pellagra," being sources of considerable confusion. There is need for a single generally understood term, and at present this should not imply too precise a knowledge of aetiology. There is much to be said for the term "kwashiorkor" by which the disease is known to the Ga tribe of the Gold Coast, among whom Dr. Cicely Williams carried out her original researches.

The medical world is indebted to Dr. Trowell and his associates for much of what is known about kwashiorkor. The debt is now greatly increased, for in writing this book they have performed yet another valuable service.

A. W. WOODRUFF.

RADIOISOTOPES IN MEDICINE

Radioisotope Conference, 1954. Proceedings of the Second Conference, Oxford, 19-23 July. Volume I. Medical and Physiological Applications. Edited by J. E. Johnston, assisted by R. A. Faires and R. J. Millett. (Pp. 418+xi; illustrated. 65s.) London: Butterworth's Scientific Publications. 1954.

Two important conferences have been held at Oxford on the uses of radioactive isotopes, each having been organized by the Atomic Energy Research Establishment, Harwell. The first took place in 1951, and its report, published in 1953, included about 70 papers on medical and biological radioisotope techniques (*Journal*, October 3, 1953, p. 766). The second conference met in July, 1954, and the present report is perhaps of even more value, both to those working with these methods and to anyone wishing to assess their scope or progress. Fewer communications were presented than in 1951, but they are in many cases fuller and more developed than those made at the earlier conference, though they still have the refreshing character of describing work actively in progress.

This volume gives all of the 46 medical and physiological papers presented in 1954, and the discussion following each. Fully half of these papers concern human investigation or therapy with some fifteen different radioactive elements, and the report as a whole forms a most useful source of information as to progress in new methods of investigation.

The value of this book is considerably increased by the impressively short time that elapsed between the conference in July and publication of its proceedings in November, and both the publishers and those who undertook this work at Harwell are to be congratulated and thanked for this addition to the outstanding success of the conference itself.

E. ERIC POCHIN.

CHEMISTRY OF METABOLISM

Chemical Pathways of Metabolism. Edited by David M. Greenberg. Volume II. (Pp. 383+vi. \$9.50.) New York: Academic Press Inc. 1954.

This is the second volume of the work, the first volume of which was reviewed in these columns on October 30 of last year (p. 1035). The survey of existing knowledge of the metabolism of major constituents in living organisms continues with "Nitrogen Metabolism of Amino Acids" (P. P. Cohen); "Carbon Metabolism of Amino Acids" (D. M. Greenberg); "Synthetic Processes Involving Amino Acids" (D. M. Greenberg); "Metabolism of Sulphur-containing Compounds" (D. M. Greenberg); "Enzymatic Syntheses of Peptide Bonds" (H. Borsook, with an Addendum by D. M. Greenberg); "Purines and Pyrimidines" (M. P. Schulman); "Nucleotides and Nucleosides" (L. A. Heppel); and "Metabolism of Haem and Chlorophyll" (S. Granick). Thus the review proposed is completed in this volume.

The mechanism whereby protein is synthesized in living systems remains mysterious, and perusal of the relevant chapters in the volume under review leads one to no definite conclusion. The interpretation of results in which isotopically labelled amino-acids are incorporated into tissue substance is often uncertain, and the caution advisable in the assessment of the significance of results of this sort is critically discussed. One can say that the elucidation of the mechanism of protein synthesis is the most important outstanding problem in the field of intermediary metabolism; it is one that must have relevance to the nature and control of both normal and neoplastic growth.

Some overlap was unavoidable among the chapters of the present volume, but this is not such as to inflate the book unduly. The two volumes together provide an authoritative and lucid account of the present knowledge of intermediary metabolism and can be confidently recommended to those who wish to bring their knowledge of a complex field reasonably up to date.

F. G. YOUNG.

ACTINOMYCETES AND THEIR ANTIBIOTICS

Guide to the Classification and Identification of the Actinomycetes and their Antibiotics. By Selman A. Waksman and Hubert A. Lechevalier. (Pp. 246+x. 38s. 6d.) London: Baillière, Tindall and Cox. 1953.

In this useful reference volume the discoverer of streptomycin and one of his colleagues first classify the Actinomycetes and describe each species. The genus occupying most space is naturally *Streptomyces*, since it is from within this that most antibiotics since penicillin have come; 147 species are described, many of them first studied by the author himself long before the antibiotic era, and others discovered recently as antibiotic producers in the course of large-scale soil surveys. The descriptions are intended to enable workers to decide whether any newly isolated species is in fact new, and they will be helpful for this purpose, though not always conclusive.

The second part of the book is about the antibiotics formed by this class of micro-organism, which the authors divide into twelve groups. Four of these are of clinical interest on account of their antibacterial activity, and

others because of their activity against fungi, protozoa, and viruses; the remainder are of academic rather than clinical significance. It is stated that substances with anti-neoplastic properties may come to assume greater importance. There follow a key to the identification of these antibiotics and a description of each in alphabetical order, stating its source, method of extraction, chemical and physical properties, biological activity, toxicity, and uses if any. Mycologists and anyone engaged in the present search for antibiotic-forming organisms will find this book a valuable source of information.

L. P. GARROD.

CHROMATOGRAPHY

Chromatography. British Medical Bulletin, Volume 10, No. 3, (Pp. 161-252; illustrated. 15s.) London: British Council. 1954.

The distinguished contributors who have written the separate chapters to this volume make an almost unique contribution to the literature on chromatography. The introduction by Dr. A. J. P. Martin is followed by a valuable account of the general principles by Dr. R. J. P. Williams. The gas-liquid chromatography is dealt with by Drs. James and Martin, and the application to paper is covered by Dr. Consden. The remaining chapters deal with applications of the method to special problems. Those of most interest to medical readers deal with amino-acids (A. C. Chibnall), peptides (P. N. Campbell and T. S. Work), porphyrins (J. E. Falk), thyroid hormones (J. Gross), antibiotics and vitamins (T. S. G. Jones), steroids and sterols (I. E. Bush), proteins (R. R. Porter), separation of amino-acids and peptides (S. M. Partridge), and amino-acid metabolism (C. E. Dent and J. M. Walshe).

The general standard is so high that it is somewhat invidious to select any particular article. The references are well chosen and in many cases cover the literature up to the year of publication. Although most articles are confined to technical methods, some interesting new data on amino-acid metabolism are included in the last article in the book. Altogether this most useful volume has appeared at a particularly appropriate time, and all those working in the field will be grateful to the writers for their informative summaries of work on their special subjects.

N. F. MACLAGAN.

MEDICAL LIBRARIANSHIP

Proceedings of the First International Congress on Medical Librarianship. Edited by F. N. L. Poynter. *Libri*, Volume 3, 1954. (Pp. 451; illustrated. Danish kroner 50.) Copenhagen: Ejnar Munksgaard. 1954.

The professional librarian is of comparatively recent origin. "At the first national meeting of librarians in America in 1853 some 70 of the 82 gentlemen present were university professors or clergymen; while three or four were lawyers and an equal number physicians." The full-time professional medical librarian is of still more recent origin, yet their number has increased rapidly. The medical group of librarians was the first to hold an international congress, which took place in London in July, 1953. This volume contains the 61 addresses delivered at the congress and the discussions which took place upon them, well edited by Mr. F. N. L. Poynter.

Among the papers are several dealing with the function and education of the medical librarian and with systems of classification and centralization; there are also an account of medical libraries all over the world and some historical papers. Here we have a mine of information which will be constantly referred to by all interested in medical books. In the account of London medical libraries we missed any reference to that of the Medical Society of London. Among such an array of papers it is difficult to mention many, but we particularly liked the short account given by Lieutenant-Colonel Frank B. Rogers of the growth of the wonderful Armed Forces Library at Washington; the erudite article

by Mr. K. W. Humphreys on the medical books of the mediaeval friars; the description of the Trew Library at Erlangen; and Dr. Bett's witty comments on the writing of papers by medical men. We quote from the last-mentioned: "Do remember that it is possible for a medical man to be a pillar of his profession and at the same time be utterly ignorant of the meaning of so hackneyed a term as *ibidem*."

Mr. W. B. McDaniel pays a nice compliment to doctors and to medical librarians when, in commenting on the statement made by two medical historians that medical librarians as a class were very helpful and companionable, he adds: "I confess that I have often felt we were peculiarly delightful people, for librarians. If it be true that we are, the explanation is a simple one. We serve the sons and daughters of Aesculapius—a most delightful and inspiring lot." We leave it at that.

ZACHARY COPE.

MEDICAL SHORT STORIES

Medicine in its Human Setting: Being Clinical Stories for Students, Nurses, and Practitioners. By A. E. Clark-Kennedy, M.D., F.R.C.P. Illustrations by Sylvia Treadgold, M.S.I.A. (Pp. 276; illustrated. 13s. 6d.) London: Faber and Faber, Ltd. 1954.

When Dr. Conan Doyle published *Round the Red Lamp*, a collection of medical short stories, in 1894, he was criticized for describing features of medical life which were better relegated to the lecture-room, the ward round, or the textbook. The subject was painful; then why treat it at all? To this he replied that it was the province of the novelist to describe painful things as well as cheerful ones. The course of time has changed all that, and to-day a book of medical short stories needs no apology. Authors like Treves, Francis Brett Young, A. J. Cronin, and Somerset Maugham have made use of their medical knowledge in fiction, and non-medical writers have done the same. Who can forget the masterly picture of locomotor ataxia in Kipling's story "Love o' Women," or the harrowing account of cancer in Arnold Bennett's *Riceyman Steps*?

In this book Dr. Clark-Kennedy, whose writings on the history and philosophy of medicine stimulate thought and practice, has written 22 short stories on various aspects of disease. His aims are to lighten the heavy burden of medical reading; to correct the bad habit of thinking of diseases as if they had a real existence apart from the men, women, and children who suffer from them; and to impress the lesson that the real object of medicine is not the application of science to a diseased body but the relief of human suffering. The purpose is excellent; the task is a little difficult to fulfil. Sometimes the human side of the story is over-weighted by technical detail; sometimes the picture is too sombre. I liked best the story of the eccentric behaviour of Mr. Swindlethorpe, the managing director who had G.P.I. It has a happy ending, for he responded to intensive treatment with penicillin.

Medical readers will appreciate this excursion of a distinguished physician into the realms of fiction. Miss Treadgold's illustrations are apt and amusing.

ARTHUR S. MACNULTY.

Until now Canada has had no medical directory of its own, its physicians and surgeons having been listed in the unwieldy *American Medical Directory*, which last appeared five years ago. Now the first *Canadian Medical Directory* has appeared, appropriately enough a few months before the joint meeting of the British and Canadian Medical Associations, and it will be particularly useful to those concerned with that meeting. The directory has three divisions—an alphabetical listing of doctors; a geographical listing by province and town; and a section containing general information on medical societies, departments of health, universities, journals, etc. The arrangement owes something to our own *Medical Directory*, although entries are not so informative. The *Canadian Medical Directory* is issued by Current Publications Ltd., 9, Duke Street, Toronto, 2, Canada, and costs \$7.

SATURDAY MARCH 5 1955

ACUTE RHEUMATIC FEVER IN CHILDREN

Of unique historical interest, the article in our opening pages this week is a report of the first international clinical trial to be carried out. The study was sponsored by the Rheumatic Fever Working Party of the Medical Research Council of Britain and the Subcommittee of Principal Investigators of the American Council on Rheumatic Fever and Congenital Heart Disease, American Heart Association. It was designed to test the relative efficacy of A.C.T.H., cortisone, and aspirin in the treatment of acute rheumatic fever, with reference not only to the relief of acute symptoms but to the prevention of cardiac damage.

Nearly six years have passed since Hench and his colleagues¹ reported their observations on three adolescent patients, suffering with acute rheumatic fever, to whom they administered adrenal cortical hormone. Compound E (Kendall) acetate was given by intramuscular injection, the dose being 200 mg. daily for several days, and then 100 mg. daily for a few days more. The immediate results were gratifying, and the paper is well worthy of study not only for its historical interest but also as a model of careful clinical observation and scientific wisdom. Many subsequent reports, such as that of E. N. Chamberlain, J. D. Hay, and D. M. Freeman,² have borne witness to the efficacy of adrenal hormone during the acute stage of rheumatic infection. But is it a better treatment than salicylates, and does it possess the additional advantage of preventing progressive and permanent cardiac damage?

In all, 505 children aged under 16 were admitted to the study (242 in the United Kingdom and 263 in the U.S.A. and Canada); 5 were subsequently excluded. The remaining 500 were allocated by random sampling methods to the three treatment groups, subdivided according to lapse of time between onset of symptoms and beginning of treatment. The results of treating 497 patients were finally analysed. Diagnostic criteria and details of treatment should be consulted in the

report, and the reader will be impressed by the great care taken to enable reliable conclusions to be drawn. Treatment was given during a six-weeks period, and at the same time the dietary intake of sodium was restricted to less than 2 g. per day for all patients, to minimize salt retention in hormone-treated patients and to maintain comparability among the three treatment groups.

Attempts were made to prevent recurrent attacks of rheumatic fever by giving penicillin during the first two weeks of treatment, and sulphadiazine from the fourteenth day onwards. Follow-up data (with special reference to rheumatic heart disease) were obtained at intervals during the succeeding year. The investigation continues, and a final determination of each child's cardiac state will be awaited with interest. But several important conclusions emerge from the results to date. There is no evidence that rheumatic fever in childhood can invariably be terminated by any of the three treatments used; hormone therapy controls the acute manifestations more quickly than does aspirin, but there is a greater tendency for them to reappear for a short time at the end of treatment; and at the end of one year there was nothing to choose between the three groups in respect of cardiac state. This last conclusion is disappointing, though there is still the possibility that a longer survey of these patients may show some advantage to lie with the hormone-treated group. But it seems unlikely that this treatment will be shown to have any spectacular effect in protecting the heart, and the challenge of rheumatic carditis must still be met mainly by preventive measures.

In the Harveian Oration given to the Royal College of Physicians in 1945 Sir John Parkinson³ estimated that about 16,000 people were dying annually of rheumatic heart disease, and that at least 200,000 people between the ages of 18 and 41 were at that time suffering from heart disease, mostly rheumatic. It is well known that the incidence of rheumatic infection has been waning for some years, but we should not assume that this decline will necessarily continue, and some districts have recently reported a local increase. At present about 4,000 to 5,000 new cases occur annually in England and Wales in the age-group 5 to 14 years, and to this figure must be added the frequent cases of relapse—an increasing threat to the heart. Unfortunately, from the point of view of effective prophylaxis, mystery still surrounds the essential nature of rheumatic infection. Both genetic and infective factors have to be considered,⁴ and many workers, including Bruce Perry⁵ and Ryle⁶ have emphasized the significance of social conditions in the child's environment. Family income,

¹⁰ Catanzaro, F. J., et al., *ibid.*, 1954, 17, 749.

nutritional standards, overcrowding, and ventilation all seem to bear a relationship to the prevalence of rheumatic infection, and when a single factor is sought that might be common to these possible influences the most likely conclusion is that it lies in infection (especially of the nose and throat) with group A β -haemolytic streptococci.

Claims have been made that the incidence of rheumatic infection can be lessened by effective treatment of these streptococcal infections during the acute phase, both in the primary attack and in relapses, and by sterilizing the upper respiratory passages of carriers. Sulphonamides were at first used, but sometimes they caused toxic symptoms, and the micro-organism developed resistance. Penicillin was found to be free of these disadvantages and has been administered, apparently with success, by mouth and by injection. The prophylactic dose of penicillin, when given by mouth, is 200,000 units three times daily on an empty stomach.⁷ But this treatment must be given over a long period, and the patient's forgetfulness may result in intermittent dosage. Bruce Perry and W. A. Gillespie⁸ have shown that a monthly injection of benzathine penicillin gives a prophylactic blood level and eliminates group A haemolytic streptococci from the throat. G. H. Stollerman⁹ and F. J. Catanzaro *et al.*¹⁰ seem to be in general agreement, and they stress the importance of effective penicillin treatment of the primary pharyngeal infection within ten days of its onset.

Acute rheumatic infection in childhood is still a dangerous menace demanding the continued attention of paediatricians, public health officers, and laboratory workers.

OPERATIVE TREATMENT OF AORTIC ANEURYSMS

It is now agreed that surgical treatment should be considered when the diagnosis of aneurysm of the aorta is made. The prognosis is grave and medical treatment ineffective.¹ The palliative manoeuvre of wiring—to induce a clot formation within the aneurysm—by passing into the lumen a length of wire, either as a continuous coil or as a Colt's wisp,² is often effective in relieving pain and may retard the enlargement of the aneurysm and improve the prognosis: it can only be done for saccular aneurysms with a well-formed neck, where thrombosis will not involve the main aortic blood stream. Wiring has been practised for many years, but never extensively. A small number of radical operations have now been carried out both for saccular aneurysms and for fusiform aneurysms not involving the proximal aortic arch

above the origin of the left common carotid artery. Saccular aneurysms can be excised and the aorta repaired if a clamp can be placed tangentially across the neck without occluding the aortic lumen, so as to allow lateral suture. Fusiform aneurysms can usually be treated only by grafting, a preserved homograft being used to bridge the gap left after excision.

Aortic grafting was first done for cases of coarctation where the segment which had to be resected was too long to allow direct end-to-end suture.³ In coarctation an extensive collateral circulation develops in response to the congenital obstruction of the aorta: clamping the aorta during the operation has little effect on the blood flow to the lower part of the body, and ischaemic effects are very unusual. These operations showed that grafting a large artery was practicable and helped to establish the principles described in a recent leading article in this *Journal*.⁴ Thrombosis and rupture of an anastomosis or of the graft are uncommon complications after operative treatment of a coarctation, and it now appears that this will also hold good for grafts applied after excision of aneurysms which may be of a traumatic, arteriosclerotic, or syphilitic origin. For lesions of the lower abdominal aorta, beyond the origin of the renal arteries, the necessary temporary interruption of the aortic blood stream does not usually lead to circulatory disorders. Clamping the aorta above this level for more than a short time leads to irreversible ischaemic effects on various tissues. The most susceptible organ is the spinal cord and its cauda equina, and the kidneys come next. An interruption of blood flow for ten minutes may lead to permanent paraplegia. The exact danger period is not at present accurately known: it depends on age, being considerably longer in children, and on the degree of general arterial disease present. It probably usually lies between fifteen and forty-five minutes. A grafting operation entails clamping the aorta at two levels, above and below the aneurysm. After it has been excised two anastomoses must be made between aorta and the two ends of the graft, which may well take a considerably longer time than can be tolerated.

There are two ways in which the dangers of ischaemia can be avoided. First, a by-pass can be arranged so as to allow the aortic flow to continue throughout the operation. This adds considerably to the technical difficulties, but perhaps with increasing experience a satisfactory method will be devised. Alternatively the oxygen demands of the tissues

beyond the level of aortic occlusion can be reduced by lowering the body temperature. It has been shown experimentally that as the temperature falls oxygen consumption is progressively reduced, being about one-third the normal at 27° C.⁵: the cells can obtain enough oxygen for their basal needs without any arterial blood flow for at least a proportionately increased period. Hypothermia thus considerably prolongs the period for which ischaemia can be tolerated, and it allows the thoracic aorta to be clamped for long enough to carry out the necessary operation without haste.

The theoretical advantages of hypothermia in avoiding ischaemic complications after clamping the aorta have been confirmed by experiments carried out on dogs and reported by De Bakey and his colleagues⁶ from Texas. They clamped the aorta at various levels. Many of the animals died in both the control group operated on at normal temperatures and in the group of hypothermic animals. But of the control animals which survived 65% had paraplegia, whereas none of the surviving animals in the hypothermic group had this complication. De Bakey and Cooley⁷ have also recently reported a successful resection and grafting operation for a traumatic aneurysm of the distal aortic arch in a man aged 31. At a first operation a saccular aneurysm was excised and lateral suture performed. An accompanying fusiform aneurysm then increased in size and caused symptoms necessitating a second operation. This was done under hypothermia, the temperature being reduced to about 27° C. by surface cooling with a refrigerating blanket. The aorta was clamped for one hour, while a 9-cm. defect left after excision of the aneurysm was replaced by a homograft preserved in tyrode solution. The patient made an uneventful recovery, after evacuation of a haemothorax, and at no time were there any symptoms of spinal-cord damage.

SEPTIC INJURIES IN INDUSTRY

Most of the injuries requiring treatment in the factory surgery are small lacerations and puncture wounds, and the majority of them affect the hands. These common cuts usually heal uneventfully and do not cause any great inconvenience to the worker, nor do they result in loss of working time. But a few of them become septic, and these are apt to give more trouble. As a cause of losing three or more days' working time, sepsis accounts for about 7% of notifiable factory accidents,¹ though the conditions of notification make it likely that the real figure is rather more than this. Since the war there seems to have been a decline both in the total numbers of septic injuries and in the

proportion which they bear to total notifiable accidents. This decrease has been found in all types of industry, though some—particularly those concerned with metal working—continue to have a much higher incidence than the rest.

The recent study by Wilkes² gives further evidence of the continuing social cost of these septic injuries. Among 151 patients with infections of the hands, the usual amount of time lost was from two to four weeks, and the net loss of earnings for each man averaged about £3 10s. a week. The actual cost to the community must be several times this figure: apart from the further expenses of sickness and injury benefit with no productive return there are the costs of medical treatment, and there are further losses, though difficult to estimate, due to disturbance of team work.

The cases of sepsis as they come to the surgery divide themselves into two groups: those septic when first seen and those which become septic under treatment. The first group includes the majority of finger-pulp infections and paronychias, and because of the peculiarities of the local anatomy they present special problems of treatment and prevention. The causative organisms are most often penicillin-sensitive staphylococci. It might have been expected that penicillin-resistant forms would by now be common, but the findings of Harrison *et al.*³ and Robins⁴ suggest that they are not. Though more recent bacteriological studies are not available, it seems likely that such infections which arise away from hospitals and the common use of penicillin are caused by organisms which are still penicillin-sensitive. A combination of careful surgery and systemic penicillin has almost certainly contributed to the reduction of lost time due to sepsis, and complications such as tendon-sheath infections with their resulting disabilities are now increasingly rare.

If patients with these septic lesions are questioned, a history of some injury can often be elicited. Commonly mentioned are knocks against pieces of metal, splinters, or the edges of hand tools. Many of the patients frequently have such minor injuries in the course of their work, and it is difficult to attribute with certainty the septic condition to any particular one. Radiography of metal workers' fingers will often show the presence of many other splinters of "swarf" in the tissues than the one which is believed to be the cause of the sepsis. Of the patients

with septic lesions studied by Wilkes at the Newcastle Hand Clinic, 30% had no memory of any injury, and it is possible that in some cases organisms enter the tissues through minor cracks or even the normal sweat and sebaceous glands. The suggestive evidence presented in this study that a "run down" state of health commonly preceded the sepsis would fit in with this implication of reduced resistance to infection. Some of the patients have septic lesions such as boils elsewhere on the body which might be the source of heavy contamination of the skin with *Staph. aureus*, though about 20% of normal people having no such lesion carry these organisms on their skin. In these circumstances the prevention of all cases of sepsis is probably not attainable. In some factories earlier and better treatment of minor injuries would doubtless be an improvement, but in those with good facilities a stage is soon reached when it is not feasible for every minor wound to be treated. Williams and Capel⁵ found that about 7% of engineering workers injured themselves every day, and Wilkes quotes a workman: "If I reported everything I might just as well sit in the accident room all day." Two general lines of preventive action seem promising: improvement in methods of working, so that swarf and sharp edges are kept away from the workers' hands; and good washing facilities and changes of clothing should reduce the load of infection of the skin and hence the proportion of injuries becoming septic.

The second clinical type of sepsis, that occurring during treatment of an open wound, may also be due to staphylococci, but the more severe examples are streptococcal. The development of sepsis in such wounds is relatively rare, but the fact that it occurs at all means that current methods of treatment could be improved. These infections may occur at the time of dressing, and the studies reviewed by Williams and Miles⁶ give a clear lead to better techniques. A carefully planned routine of treatment incorporating a no-touch technique is necessary, and this is made easier if the lay-out of the dressing station is appropriately designed.⁷ Infection occurring between treatment times may sometimes be due to interference by the patient, but it must sometimes be attributed to the present lack of a really satisfactory surgical dressing which will stand the hazards of normal industrial work. Such a dressing needs to be bacteria-proof; it should be permeable to water vapour so as to avoid sogginess of the skin; it should be resistant to water, oil, and common industrial solvents; and it must remain in place when in contact with these materials during the patient's work. Attempts at such a dressing have already been made,^{8,9} but further development on these lines is needed.

CHILBLAINS

Damp cold is the most troublesome kind of cold weather for those who are susceptible to perniosis or erythema pernio, commonly known as chilblains. Lewis¹ found that the vascular responses of these people were normal if their limbs started by being warm, but if they were cold (as they usually are) there was evidence of abnormally high vascular tone and an increased readiness to develop arteriolar spasm. Together with this spasm of arterioles a dilatation of other blood vessels can be seen, leading eventually to histological appearance of chronic inflammation, fat necrosis, and obliterative endarteritis. Why damp but not dry cold should be to blame is not clear, but the geographical distribution of chilblains, as quoted by Mitchell Heggs,² leaves little doubt of it. Our climate must be accountable for the high incidence in Britain. Adolescents suffer most, particularly young women whose legs are poorly protected; fresh cases are rare after the age of 40. So-called erythrocyanosis crurum, dermatitis hiemalis, and nodular vasculitis are conditions which affect mainly the same group and appear to have the same aetiology: it is doubtful, therefore, if anything is gained by preserving their separate dermatological identities. R. B. Lynn³ suggests that all these manifestations of one pathological process should take the simple name "chilblains." There are many who will be less ready to agree that erythema induratum (Bazin's disease) is not, after all, of tuberculous origin but attributable like the rest to cold.

Lynn emphasizes the distinction between acute and chronic chilblains. Acute chilblains, even if they develop vesicles which rupture, usually clear up in a few days whatever treatment is applied, provided that exposure to cold is not repeated. Susceptibility to acute chilblains often seems to diminish as the patient grows older. A seasonal nuisance, they can usually be avoided if a good diet and sufficient exercise are taken, and above all if the victim consents to be sensibly clothed and shod. But neglect of these rules later in life, or prolonged and repeated exposures to cold from the first in people who are exceptionally prone to chilblains, may lead to changes which persist. Such chronic chilblains, using the term to include all the various clinical appearances, must be regarded as a further stage in the disorder—the pathological changes having become irreversible. Limbs which have been affected by neurological diseases like anterior poliomyelitis are particularly susceptible, which suggests that there may be several predisposing factors in the development of chronic chilblains. Tuberculosis does not seem to be one of these, save in so far as it may affect the general resistance. The sufferers are often young or middle-aged women with stout limbs and thick ankles. Commonly there is symmetrical involvement of the limbs, especially in the lower third of the legs, but sometimes the condition extends to the knees and thighs. Persistent blotchy, reddish-purple discolorations progress to large, swollen, raised lesions which even the coming

¹ *British Medical Journal*, 1941, 2, 837.

² Mitchell Heggs, G. B., in *Modern Practice in Dermatology*, 1950, London

³ *Surg. Gynec. Obstet.*, 1954, 99, 720.

of warm weather will not disperse. Later still the raised nodular lesions ulcerate. The ulcers may heal slowly to form permanently pigmented scars, but are liable to break down finally and coalesce to become large, indolent, open lesions.

In the treatment of chilblains calcium, vitamins, and ultraviolet light have had, and still have, their adherents as general measures. Local applications in great variety have been tried, including emollients, antipruritics, and counter-irritants; but their very number testifies to their slight effectiveness, and the main attack on chilblains should not be local. The basic disorder is arteriolar spasm, and it is rational to use nicotinic acid or tolazoline to offset it. Sympathectomy was suggested almost twenty years ago. This also is a rational form of treatment, though some may think it too drastic. Yet in their chronic form chilblains may cause pain, distress, and disfigurement severe enough to warrant drastic steps. Lynn reports that there has been no recurrence of ulceration on 40 limbs (of 25 patients) after lumbar sympathectomy. But the crux of the matter is prevention. Women may have to choose between the disfigurement of chronic chilblains and the less permanent embarrassment of wearing wool.

"SLUM SICKNESS"

An attempt has recently been made in Glasgow to discover the extent to which the removal of families from slums to new houses has had a beneficial effect on their health, and on social behaviour as measured by juvenile crime.⁴ For this purpose the circumstances of 388 families living in old slum property were studied, together with those of 718 families who had formerly lived in old slum houses but had been rehoused for periods ranging from ten to twenty-seven years. It was hoped at the outset of the survey to superimpose the pictures thus obtained of these two sets of families and study the contrasts, but it unfortunately proved impossible to do so, mainly because the families which had been rehoused were much older than those in the slums. Nevertheless, some interesting facts emerged, which deserve further consideration.

In the first place the comparative youth of the slum families is interesting, because it shows that the slum community which was investigated was the creation of the housing shortage; young people were unable, it seems, to find any accommodation other than in the slums to live in during the early stages of their married life. Poverty (except in the case of old people) could be disregarded as an influence driving them there, for more of the wage earners in the slums than formerly are hard-working, often skilled or semi-skilled operatives in regular employment. Indeed, the proportion of parents classified as in good health was higher in the slums than in the new houses, the reason no doubt being the differences in age between the two groups. In other respects few contrasts were found between the slum families and those which had been rehoused. The feeding habits of the rehoused families, for instance, showed

no improvement on those of the slum population, and deaths of children varied little between the two groups. Delinquency among the boys who were members of rehoused families, again, was "very similar" to that experienced among young people still living in slums. As previous researches had indicated, it was found to be "much in excess" of that which prevailed even among boys who had left school at the earliest permitted age. This may demonstrate that the social consequences of slum life are more harmful to young people than its physical effects.

The conclusion drawn by the authors from this argument is, they think, abundantly clear: "many slum families require a great deal of help and encouragement to make the transition from the slums to a new life," for the evidence "shows again that the eradication of slum sickness does not come with the mere erection of new houses." There is therefore obviously room for a more intensive study of the forms which this "help and encouragement" takes, in order to discover which of them is the most effective; this would require a general survey of the impact of all the social services, from health visiting to housing management, on the members of rehoused families.

One reassuring point emerges from the investigation. The work carried out by Dr. McGonigle in Stockton-on-Tees in 1933 demonstrated that the effect of moving slum dwellers to new houses might have harmful consequences, so far as their health was concerned, because increased rents might leave them with less to spend on food. In Glasgow, however, it was found that the redistribution of purchasing power has freed the rehoused families from economic pressures of this kind. On the contrary, there was an evident need "for the provision of more new houses, particularly to permit removal from the perils of a slum environment of young families at present driven to live there though they could well afford to pay a reasonable rent and would willingly do so."

FLAVOURED MILK

Milk to which various "fruity" flavours have been added is now being sold in increasing quantities. The flavours are mainly synthetic, but concentrated flavouring essences prepared from natural fruit are also being used on a small scale. Promotion of milk sales is the obvious purpose of these flavours; and "Drink More Milk" is a slogan which the medical profession can fully support provided there is no risk to the health of the consumer. As the law stands, however, flavoured milk escapes the provisions in the Food and Drugs (Milk, Dairies and Artificial Cream) Act, 1950, which limit the sale of milk "in specified areas" (mainly the large urban areas) to tuberculin-tested, pasteurized, and sterilized milk. This is a loophole in public health legislation that might well be closed. Fortunately the milk industry itself is aware of the risk, to which attention has already been drawn by the chief chemist¹ of the Milk Marketing Board and by the general secretary² of the National Dairymen's Association. Both strongly recommend that

³ O'Neill, P., *ibid.*, January, 1955, p. 41.

milk should be heat-treated after addition of the syrup which carries the concentrated flavours. This authoritative advice should certainly be heeded by dairymen, whether the law is amended or not. The nutritive value of flavoured milk should not differ appreciably from that of ordinary milk, but some mothers may see in these flavoured milks, especially if they have an orange flavour, a convenient means of giving their babies at one and the same time its proper feeds of milk and of vitamin C. Such notions should be dispelled.

CARRIER STATE IN VIRAL HEPATITIS

Experience with viral hepatitis in the second world war led to the differentiation of two closely related forms of the disease—infectious and serum hepatitis—but the lack of a practicable experimental approach has prevented the exact relationship between the two forms from being determined.¹ Reviewing the present state of knowledge on viral hepatitis, a W.H.O. committee² drew attention to some of the pressing problems needing clarification, of which the duration of the carrier state in both types was an important item. Recently three reports of preliminary findings on this aspect have appeared, based on the inoculation of human volunteers under carefully controlled conditions.³⁻⁵

In infectious hepatitis the virus (IH or virus A) is present in the blood for a short time before and during the acute phase of the disease and for longer periods in the gastro-intestinal tract.² The normal duration of faecal excretion is probably short, but the existence of faecal carriers has been considered a probable explanation of the smouldering endemic infection encountered in institutions.⁶ Investigations carried out by Stokes and his colleagues³ on two young children from an orphanage where hepatitis had been endemic for a number of years⁴ established that both had chronic active hepatitis without jaundice and both were faecal carriers of virus A, in one case for six months and in the other for fifteen months after the initial illness.

In serum hepatitis the virus (SH or virus B) has been demonstrated unequivocally only in the blood, in which it may persist for long periods. Just how long in the average case is not known, but three apparently healthy donors also investigated by Stokes and his colleagues³ were found to have virus B in their blood for at least 5½, 3, and 1½ years respectively. One donor appeared to be a true "silent carrier" for at least three years, in that she was symptomless and liver-function tests were within normal limits. This patient's newborn infant developed jaundice at the age of 2 months and succumbed to it. Virus B was recovered from the blood of mother and child by inoculation of human volunteers. Transplacental infection and the existence of silent carriers may help to explain some of the epidemiological aspects of virus B infection.

As both viruses are present in the blood, hepatitis can result from parenteral inoculation with either virus A or virus B if blood is collected during the viraemic phase, though it more often follows the longer incubation usually associated with virus B. In two further reports^{4,5} on viral hepatitis in blood donors it appears that 28–42% may have been due to virus A if the criterion of distinction is the length of the incubation period. Differentiation on this basis is clearly difficult but is of some practical significance, as there is more chance of type A viral hepatitis being controlled with gamma globulin.

None of the donors referred to in these reports gave a history of jaundice; a few admitted to vague non-specific illnesses, and more showed abnormal results in liver-function tests. These findings are worth bearing in mind in selecting blood donors⁷ and emphasize the need for a laboratory test for the detection of healthy carriers of either virus.

ANAESTHESIA AND THE COMMON COLD

Medicine is plagued by myth and mumpsimus,¹ the extent of which was only barely indicated in J. R. Forbes's stimulating and entertaining paper.² Now George Ellis³ suggests that perhaps he might have included as an example of mumpsimus the belief that anaesthesia is contraindicated in the presence of the common cold. However, even Ellis would agree it would probably be going too far to say there is no foundation whatever for the belief that anaesthesia is better avoided in these circumstances. The hundred years or so of world-wide experience of anaesthesia has shown that an anaesthetic may well exacerbate an upper respiratory infection and that more serious chest complications may follow. Nevertheless, Ellis points out, there is little worthwhile factual evidence on this matter. No one will disagree with him that if the operation is urgent then the common cold can be ignored; equally so, that an operation which is necessary for a patient's livelihood or peace of mind should not be postponed. He carefully points out, however, that "it is all too likely that the patient will acquire a nasty hacking cough and that therefore abdominal operations, including those for hernia, should be postponed." Operations on the respiratory tract itself and those inside the chest are better not performed. But Ellis does maintain that a whole host of operations of less gravity, and outside these regions, could be carried out with little increased risk in the presence of a common cold. In view of the current bed shortage and long waiting-lists, Ellis's opinions deserve the closest consideration. They may well be treated with a little reserve and should not be construed into meaning that the presence of a common cold indicates an anaesthetic. This refreshing paper is a worthy addition to the literature on mumpsimus in medicine.

EMERGENCIES IN GENERAL PRACTICE

ATTEMPTED SUICIDE

BY

I. R. C. BATCHELOR, M.B., Ch.B., F.R.C.P.Ed., D.P.M.

Deputy Physician-Superintendent, Royal Edinburgh Hospital for Mental and Nervous Disorders; Lecturer in Psychiatry, University of Edinburgh

A patient's suicidal attempt commonly takes both his relatives and his doctor by surprise. In this emergency the doctor's first duty is to conserve the patient's life, by administering whatever first aid is necessary for the injuries sustained, and by arranging without delay for the patient's further physical and psychological care and treatment. This duty takes precedence, of course, over any detailed investigation of the causes and circumstances of the attempt. Where possible, immediate admission to the mental observation ward of a general hospital is the ideal arrangement. Even if the individual has not sustained serious hurt and the situation appears less urgent to his relatives, it is usually advisable to insist that he goes into hospital. The most skilled medical and surgical care is available there for the treatment of injuries; also a breathing space is obtained, during which the situation may be calmly assessed by everyone concerned. The patient should always be kept under observation for at least a few days. He must be safeguarded from further self-injury, his relaxation and sleep must be ensured by sedatives, a detailed assessment of his mental and physical state must be made, the relatives interviewed, and both the individual and the social aspects of the situation fully considered. Usually a proper decision about his future can be taken within two weeks.

All this calls for such a specialized investigation that the help of a psychiatrist should be enlisted as soon as possible, whether or not the patient has been admitted to a general hospital. Where the practitioner is unsupported by a general hospital or psychiatric advice, he will have to rely more on his first estimation of the seriousness of the attempt (see below) in deciding whether or not to arrange prompt admission to a mental hospital. Mental hospital admission is most often required for those suffering from depressive, schizophrenic and paranoid psychoses, and more often for those past middle age than for younger individuals. It is necessary for most of those aged 60 years or over. If the individual's progress cannot be adequately watched and safeguarded at home, mental hospital or other in-patient care is essential. Admission to a mental hospital should not, however, be made the rule: of those who are admitted initially for a short period to a general hospital, about one-half may be discharged home reasonably safely. Those who go to a mental hospital will usually do so as voluntary patients. Psychiatric out-patient treatment is required for many others.

To discharge from observation an individual who has attempted suicide, just as soon as he is physically fit, is malpractice. Sometimes the patient is asked first to promise that he will not attempt suicide again. This promise, if given, is usually valueless. It may reassure the doctor but it does nothing to safeguard the patient, who can no more control his self-destructive impulses than the sufferer from an acute appendicitis his pain.

How Serious was the Attempt?

The determination behind a suicidal attempt may be very difficult to measure and cannot be judged by any one criterion. It is not profitable to draw a sharp distinction between real suicidal attempts and suicidal gestures. It is better to err on the safe side, which is to consider a gesture a real attempt and to treat it as such. After middle life suicidal gestures are uncommon; in old age they are exceptional.

If the individual has injured himself seriously, or has jumped from a height, or has attempted to hang or drown or shoot himself, there can be little doubt that he intended to take his life. The more bizarre the method used, the more likely is it that the individual is seriously mentally ill. Those who have chosen a solitary place, and those who have used more than one method, are likely to have been in earnest.

That the attempt was feeble in execution does not, however, necessarily mean that the intention was feeble. If the individual has not taken a gross overdose of drugs, or has attempted gassing with the windows open, or has made only a few superficial cuts on his wrists or throat, it is sometimes immediately concluded that he was not serious. But a psychotic patient may make a poor attempt: his agitation or retardation may cloud his judgment and render his hands impotent.

It is of great importance to find out if the individual who has made the attempt has recently appeared nervously ill. If he has not appeared to be ill, especially if he is of chronically unstable temperament, and if the act has been an obvious response to some quarrel or frustration and is described by the actor as done on the spur of the moment, then one may usually conclude that the immediate danger has passed, particularly if the actor himself has become calm again. But there are exceptions here too: the young schizophrenic, hardly recognized to be unwell, may act with great impulsiveness.

Unfortunately one cannot accept at its face value the patient's own estimation of his act, but one must correlate his statement with the rest of the evidence. Not infrequently a suicidal individual denies his suicidal intentions after the act, out of fear of police action or the reproaches of relatives, or to get another opportunity to complete the act. On the other hand, an admission of suicidal intent is usually to be believed. A farewell letter is usually of serious import, and its contents may throw light on the motives which prompted the attempt. Inquiry should always be made whether or not the individual left any communication, since such letters are often suppressed or quickly destroyed by relatives.

The most difficult cases to assess are often those in which the suicidal attempt has been made at home and the method has been barbiturate poisoning. The individual may assert that all he wanted was a long sleep. This statement should not be readily accepted. Some suicidal individuals will deny vehemently that suicide was their intention. The story may be given that the drugs were at the bedside, that the patient took two perhaps, then two more, and when drowsy more still. Such an accident, leading to prolonged and deep unconsciousness, is rare. The story, which relatives are only too glad to accept, is usually a cloak for a suicidal attempt.

⁷ Trumbull, M. L., *Amer. J. clin. Path.*, 1954, 24, 254.

Attempts made when the individual is under the influence of alcohol are also difficult to assess. While it is true that certain suicidal attempts are made under the influence of alcohol which would not have been made in a state of sobriety, alcohol may release a serious suicidal trend; it may also interfere with its consummation. It may be very difficult in these cases to know how prolonged was the oblivion sought. Perhaps two-thirds of such attempts are to be judged serious.

That the attempt was dramatic does not necessarily mean that it was not serious. A serious attempt may be dressed up for and executed publicly. The sufferer from a depressive psychosis may wish to demonstrate to others the extent of his wickedness and his self-punishment: while the aggressive psychopath, venting a murderous spite upon himself, may at the same time court a posthumous publicity by which relatives will suffer.

More men than women commit suicide, and men more often use active and violent methods. These generalizations, though true, hardly help one with the individual case.

Could it Have Been Prevented?

After such a distressing emergency has arisen, one is prompted to ask, could it have been foreseen and forestalled? While it is perhaps doubtful if the really determined individual can often be deviated from his intention, it must be admitted that preventable suicides do occur. They occur because either the doctor or the relatives or both feel sure that, knowing the patient to have been a decent and trustworthy person, a suicidal attempt was not to be expected. But suicide is no respecter of persons.

Almost any nervous or mental illness, at any age, may lead to a suicidal attempt. Suicide is thought of particularly in relation to depressive psychoses, but it is a mistake to consider it as limited to them. It may be a symptom of any psychosis where there is emotional disturbance. It cannot be ruled out in neurotic reactions. It may be the panic response to a sudden crisis of disablement or bereavement, for example, or to a threat of loss of liberty or reputation, or to the self-discovery of homosexual trends. It is the typically exaggerated response to frustration of that large group of temperamentally unstable people which includes the psychopaths and a certain number of epileptics and mental defectives.

The emphasis must be on the early diagnosis of nervous and mental instability, and on treatment and protection at the earliest possible stage. If the risk of suicide is thought of, it is much more likely to be recognized. To appreciate, even approximately, the degree of risk one must get to know the patient well, must give him time to speak freely about his problems, and must exercise great delicacy in questioning when trying to sense the dangers of his situation. At a single interview it is usually possible to give the depressed patient a feeling of confidence that he is understood; and if he has admitted to despondency he may then be asked if he has had any morbid thoughts or at any time felt discouraged or even hopeless about his future or the outcome of his illness. He must be gently assisted, never forced, to reveal further his emotional state. Any disclosure of suicidal thoughts should be taken seriously. When a patient has spoken of suicidal thoughts it is advisable always to reassure him that these are usual symptoms of a depressive illness, that they are not evidence of sinfulness, and that they will disappear as the illness lifts.

On physical examination scars on the neck and across the fronts of the wrists, which might indicate a previous suicidal attempt, should be noted. There are other features of the patient's history and symptomatology which will point to a particular need for vigilance.

Warning Signs

One still often hears it said that those who talk of suicide to other people do not commit it. This is a false and dangerous belief. At least one-third of those who attempt

suicide have threatened suicide. Such threats should therefore never be ignored but should be evaluated carefully in the setting of the type of abnormal reaction and all the individual circumstances. Suicidal threats are not only warnings often of an impending attempt, but cries for help.

If a history of a suicidal attempt in a previous illness is obtained it increases the risk in the present illness. In the case of the manic-depressive, the fact that previous depressions have not been associated with a suicidal attempt may give one a feeling of greater security about the risk in the present illness, but it does not exclude this risk. Neither does one suicidal attempt in a depressive illness eliminate the possibility of further attempts in that illness.

A family history of suicide is significant, and there may be a family mode of committing suicide. A living person may come to identify himself with someone who is dead. If he becomes depressed he may wish to rejoin that person; and if he says so, this is usually to be construed as a suicidal threat. If the individual identified with has himself committed suicide, the risk of a duplicate suicide is materially increased.

There is some evidence also that the history of a "broken home" in childhood is correlated with an increased suicidal risk.

Depression and insomnia are the usual symptomatic precursors of a suicidal attempt. All depressions carry a suicidal risk, whether they have clear precipitants—for example, bereavement, financial ruin—or come out of the blue. The risk is often greatest in the early stages of the illness, and again in convalescence. This unexpected and almost paradoxical risk in convalescence is often forgotten. Depressions associated with retardation are less dangerous than tense, agitated depressions. Any individual past middle-life, who presents a picture of persistent anxiety and who has not previously had neurotic symptoms, should be suspected of suffering from an early involutional melancholia and precautions against suicide should be taken without delay. Particularly dangerous are those who blame themselves, who express feelings of intense shame and guilt and failure, and who say that their continued existence would be burdensome for those they love. The obviously very depressed individual who denies having had thoughts of suicide should on principle be disbelieved; he may be determined to be unhindered. Those who say that they are too cowardly to carry out the act may do it successfully.

Insomnia, Fear, and Loneliness

In general the greater the concern about insomnia, the greater the suicidal risk. The patient may assert that he is certain that lack of sleep is doing irreparable damage to his brain. Though he may sleep for some hours, he may declare that he has not slept at all; if one just dismisses the statement as untrue, one will miss its significance as a danger signal. The psychotically depressed individual often awakens at an early hour of the morning, and is most ill then. A suicidal attempt is often prefaced by a sleepless night.

Severe hypochondriasis in a depressive setting is also a significant complaint, particularly if it is focused on a single organ or part of the body and is accompanied by a phobia of disabling or fatal disease—for example, tuberculosis, heart disease, cancer. The fear of insanity is very common, often associated with intense feelings of tension and head pains, so that the patient feels that something is about to snap in his head. Venerophobia also, accompanied by depression and agitation, must be viewed very seriously. The individual's feelings of great guilt and contamination may urge him to attempt suicide even before the result of a blood test becomes available. Perhaps the most potent fear of all is the dread of the unknown.

Of all the reality fears which may precipitate serious suicidal attempts, the prospect of entering a mental hospital is one of the most noteworthy. The period during which arrangements are being made for a depressed patient to

enter a mental hospital, if the patient has got to know what is planned, is a period of real danger, during which he must not be left unattended.

In a depression, fears of losing control and of hurting or killing others, and actual attacks upon others, particularly if this behaviour is foreign to the person's usual disposition, are serious warning signs. This aggression may at any time be turned by the individual against himself. If the depressed individual goes unexpectedly on a journey, or wanders away with mind clouded (a fugue), he is suicidal.

Feelings of loneliness and of being unwanted are common harbingers of suicidal attempts, particularly in older people.

While none of these several symptoms is found exclusively in the suicidal patient, the presence of any of them will indicate the need for extra caution, and their concentration is always ominous.

Refresher Course Books.—Copies of the first two volumes of collected articles from the Refresher Course for General Practitioners published in the *Journal* are still available at 25s. (postage 1s.) each. The first volume contains 55 articles and the second 60. Each article has been revised and brought up to date by its author.

These books may be obtained from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller.

MUSIC IN MEDICINE

Galen advised playing music to cure snake bite, Pythagoras thought music good for depression, and more recently a dentist claimed that he needed less gas for his anaesthesia if he played Debussy's "Clair de Lune" or "The Moonlight Sonata" on the gramophone at the same time. These were a few of the examples quoted by Mr. FRANK HOWES, music critic of *The Times*, in the third Cantor Lecture given to the Royal Society of Arts on February 21. Mr. Howes is a member of the council for music in mental hospitals, which for the past ten years has tried to make systematic provision of music for psychiatric in-patients, and has sponsored investigations, particularly by the late Dr. Mitchell at Warlingham Park Hospital, into the therapeutic value of music. In one experiment soothing music was played to disturbed patients at bedtime, instead of giving them sedatives, but the only result was a fight. In another, when the last two movements of Vaughan Williams's *F* minor symphony were played to a group of neurotic patients, the effect was to bring into the open their hostility to psychiatrists, which was freely expressed.

Dr. Cunningham Dax at Netherne Hospital had played music to patients and then made them paint their response. Their pictures showed either elation (after Mahler's adagietto) or depression—after Mendelssohn's "Midsummer Night's Dream." Thirteen out of seventeen pictures were of violence, robbery, murder, and a Chopin nocturne provoked a suicide. Bach and Mozart were probably tranquillizing. But the hope of a musical pharmacopoeia was dashed by the inconstancy of the effects. Results were so often unexpected, or varied with the individual. With some, music provoked an emotional explosion and release which was beneficial; in a few others, epilepsy; and yet others remained indifferent to it. But there are different types of listener, susceptible of classification like other personality attributes. We all listen in various ways, but predominantly in one way characteristic of us. A simple classification, went on Mr. Howes, was Vernon Lea's, into Sicilians (those susceptible to the sheer power of sound, sensuous euphony), dionysiacs (those who respond to the emotion), and apollonians (the intellectual-technical approach). Only the

second group was likely to be therapeutically approachable. Mr. Howes's own estimate of music in hospital was modest and commonsensical. An American authority, Dr. S. Licht, in his *Music in Medicine* (1946) thought the music played should be bad music, an endless succession of old-time favourites, but Mr. Howes believed that in-patients were a cross-section of the public with the same musical tastes, and needed something not too long or complicated, but not too well known either. Music for them could be a part of occupational therapy and an entertainment. It might make some temporarily less introspective, in a few it might awaken a new and lasting interest, but above all it was a communal activity, and brought solitary people into contact with their fellows. Those who played had in addition the satisfaction of exercising a skill and of creating something. Beyond that it was difficult to say. Plato in his *Republic* laid great stress on music as an element of education, because rhythm and euphony entered into the inner recesses of the soul and made a man a well-ordered person—an idea which was very foreign to us to-day. We were more accustomed to the thought that music speeded industrial production, or human performance, and Mr. Howes quoted an odd experiment from 1911, when 46 mile-long bicycle races were ridden, 23 to music and 23 in silence. The average speed of the control group was 17.9 m.p.h., and that of the musically stimulated 19.6. To sum up in a sentence, music is certainly hygienic, even if not therapeutic.

Reports of Societies

DEFECTS IN MODERN TREATMENT OF LEPROSY

The introduction of the sulphones for the treatment of leprosy a few years ago aroused world-wide interest and great hopes for the eventual eradication of the disease. But to-day opinion, if no less hopeful, is certainly becoming more critical. Speaking on March 2 before the Edinburgh Branch of the Royal Society of Tropical Medicine, the director of the newly established East African Leprosy Research Centre, Dr. JAMES ROSS INNES, roundly declared: "The modern treatment of leprosy based on the sulphone group of drugs is unsatisfactory." He realized, he said, that many would think this statement outrageous, when they recalled the few lepers who ever came within sight of cure during the chaulmoogra era; but it was high time leprologists expressed their dissatisfactions as a preparation for further advance.

Limitations of the Sulphones

Broadly speaking, the sulphones brought clinical arrest and bacterial negativity to a high percentage (70 to 80) of active cases of leprosy, the relapse rate was low, and relapses were easily reversed. Dosage was moderate, drug reactions were infrequent, and the annual cost was low. Useful adjunct drugs were also available, such as isoniazid, thiosemicarbazone, A.C.T.H. and cortisone, streptomycin, chlorpromazine, and vitamin B₁₂. Drug resistance to the sulphones proper was practically unknown. In fact the whole therapeutic picture seemed rosy. "We ought to be able to 'plug away' with the sulphones and clear leprosy from the face of the earth." But, said Dr. Innes, after experience of the sulphones on a large scale it was by no means certain that this would be so.

For one thing, it took far too long to achieve bacterial cure in lepromatous cases. A failure rate with the sulphones of 20 to 25% in various countries indicated their inadequacy. Instead of achieving bacterial negativity in six months to a year, which would be a useful period in controlling the spread of the disease and a fair one to expect, they took three to five years or more. It was true that when widely and carefully applied in an endemic country the sulphones achieved great things, but their slowness and imperfection

of action suggested that it might prove very hard to eradicate the hard core of endemic infection. "Leprosy patients soon discern that the drug has power and wait as patiently as they can for the final happy result, but few escape periods of doubt and despair as month succeeds month. In some of them, hope dies, and this reacts unfavourably on their prospect of ultimate cure." What is wanted, said Dr. Innes, is a dynamic bacteriostatic or bactericidal drug, or combination of drugs, stronger than the sulphones, both for the sake of the leper himself and for the sake of the community.

Other Weaknesses

Quite apart from the sulphones, there were other serious weaknesses in the attack. The criteria of cure were still too vague. Laboratory checks were few and limited. Clinicians could not tell how many resting bacilli, or viable granules or debris of bacilli, might lie low in the tissue planes. In the last resort, if biopsies detected nothing, they had to fall back on long periods of observing their patients. Then, there was no way of modifying the resistance of the patient with leprosy. They badly needed an agent that would stimulate direct resistance to the infection. The lepromin test did not do this; it indicated only the degree of resistance already present. Nor was there any evidence that B.C.G. inoculation raised the resistance of the leper to his disease, although some had suggested that it might be a valuable prophylactic.

Perhaps also, in the understandable enthusiasm for the sulphones, the use of hydnocarpus oil had been abandoned too readily. Local intradermal injections were still useful in resistant tuberculoid and indeterminate lesions. The trouble with hydnocarpus oil was that the dose was large and the injections took such a time.

Tuberculosis and Leprosy

Finally, Dr. Innes indicated the tardy co-operation between tuberculosis and leprosy workers in countries where both diseases were rife. There were many points of similarity between the two diseases. "In leprosy therapy the only sound policy at present is to investigate drugs which have an action in human tuberculosis or on the human tubercle bacillus." Likewise, tuberculosis workers could gain from the trial of drugs in leprosy. Closer co-operation was long overdue, and great benefit to both sides would result from it. In East Africa, for instance, with almost a quarter of a million cases of leprosy and probably an equivalent number of cases of tuberculosis, co-operation should be at all levels—in control, therapy, follow-up, and research.

LOCAL MEDICAL SOCIETIES

Manchester Medical Society

During a discussion on January 24 on "Recent Advances in Obstetrics and Gynaecology," Dr. R. NEWTON, a clinical lecturer in the subject at Manchester University, told the Section of General Practice that he questioned the usefulness of many of the investigations undertaken in cases of infertility. Nevertheless, he went on, there was a useful by-product of these investigations—the discovery of many early cases of tuberculous endometritis and salpingitis. Reports on their treatment with streptomycin and P.A.S. were more hopeful.

Basingstoke Plastic Centre Medical Society

On February 17 the Society held a symposium on "Fractures of the Long Bones with Soft Tissue Loss," the speakers being Professor J. TRUETA, Mr. J. S. ELLIS, Mr. A. J. EVANS, and Mr. E. W. PEET. In the healing of fractures, said Professor Trueta, the periosteal vessels were most important. Stripping of the soft tissues away from the periosteum reduced the blood supply at the fracture site and delayed union. His own work had convinced him of the importance of early skin repair in long-bone fractures. This view was shared by Mr. Ellis, who said that good results had been

obtained when simultaneous skin and bone replacement was carried out within a week or two of injury. Mr. Peet discussed the technique of skin repair in these cases, and Mr. Evans reviewed a series of 39 cases treated at Rooksdown House between 1940 and 1945. This series showed a strong preference for the cross-leg flap, and included nine successful examples of simultaneous skin and bone replacement.

Liverpool Medical Institution

"Tin-smelters' pneumoconiosis" was the subject of a paper read to the Institution by Dr. P. H. WHITAKER and Dr. A. JOHN ROBERTSON on February 10. During a field survey 120 cases of pneumoconiosis were found at a tin-smelting works. A film was shown illustrating the main sources of dust formation and the smelting process. Dr. Whitaker then demonstrated some typical chest radiographs from the men and Dr. Robertson presented some preliminary clinical, environmental, and experimental studies in support of the view that the condition is a benign pneumoconiosis due to tin oxide.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Adrenalectomy for Breast Cancer

SIR,—I have read with considerable interest your leading article entitled "Adrenalectomy for Breast Cancer" (*Journal*, January 1, p. 33). I should like to comment on the endocrine types of breast cancer—namely, ovary-dependent, adrenal-dependent, and hormone-independent.

My colleagues and I have discussed this subject previously,¹ classifying breast cancer into two types—namely, oestrogen-dependent and non-oestrogen-dependent. Our studies demonstrated that approximately 50% of pre-menopausal women with metastatic breast cancer have an oestrogen-dependent type of tumour, as shown by the fact that oophorectomy results in cessation of growth and regression of the tumours, subsequent administration of oestrogen to the patient produces reactivation of the tumour growth, and on withdrawal of the oestrogen the tumours again regress. In the other 50% of cases oophorectomy produces no benefit, and oestrogen fails to stimulate tumour growth.

We have also presented evidence which suggests that adrenalectomy produces its benefit by removal of another source of oestrogen. Thus pre-menopausal women who have obtained a remission from oophorectomy may obtain a second remission from adrenalectomy; whereas those who fail to benefit from castration invariably fail to benefit from adrenalectomy also. This information provides the only practical means of selecting patients for adrenalectomy. In post-menopausal women combined oophorectomy and adrenalectomy will benefit about 50% of patients and is the treatment of choice, since oophorectomy rarely produces a remission.

The leading article also raised the question as to whether human mammary cancer may be dependent upon pituitary hormones for its growth. We have presented preliminary observations which indicate that some tumours are probably growth-hormone-dependent.² Thus, hypophysectomy has produced remissions in patients whose disease had relapsed after oophorectomy and adrenalectomy. In one of these patients administration of a beef pituitary growth hormone preparation caused acceleration of the tumour growth, which subsided when the growth hormone was withdrawn.

Hypophysectomy for the treatment of metastatic mammary cancer in man is being pursued with the hope

of attaining a higher percentage of response and longer-lasting remissions.³ It is already apparent, however, that in some patients the disease is unaltered by ablation of all three endocrine organs.—I am, etc.,

New York.

Advertising by Post

SIR,—The bombardment of advertising material aimed at general practitioners by every morning's post has recently increased to a full-scale barrage. If anyone were seriously to attempt to read all this verbiage, it might take two or three hours every day to get through it, but in practice 90% of it goes unopened into the waste-paper basket. Ultimately the public has to pay for this appalling waste, and in the interests of manufacturing firms and doctors alike it seems to me very desirable to try and do something about this. However, most doctors find it necessary to use a certain number of proprietary preparations, and information about new products is necessary and often very interesting and instructive.

I have suggested to representatives of many different firms that a card should be prepared for every product with certain necessary information only recorded on it such as indications, composition, dosage, contraindications, and price, and that the size of these cards should be standardized by all firms so that they can be easily filed for reference in a simple box. At present the number of pamphlets is so excessive, and they are so different in shape and size, that filing is impracticable. This suggestion has been well received by most representatives, although many expressed the view that it was too much to expect that all firms would agree on this. But the advantages of such a scheme would seem to be so great that in my opinion it would be well worth while for the manufacturing firms to consider it. And if only a few firms started with my suggestion, the rest might soon find it advisable to follow suit.

If in addition the manufacturing firms could come to some agreement between themselves to limit the advertising pamphlets about any particular product to a certain number per year, I believe that this would also be of great benefit to all concerned, and some doctors might even read them.—I am, etc.,

Sandwich, Kent.

A. K. JONES.

Trichomonal Vaginitis

SIR,—I have been very much interested in the correspondence opened by Mr. Aleck Bourne (*Journal*, January 22, p. 226) on the problem of the resistant and relapsing case of trichomonal vaginitis. Mr. Bourne emphasized that the trichomonas may be found as an inhabitant of the healthy vagina and may be almost entirely absent in a clinically severe case of recurrence of the disease, yet other correspondents have said little about these underlying causes and predisposing factors which surely are the most important aspect of the problem.

I suggest that in addition to the frequent association of secondary bacterial infections and monilia (and possibly virus infections), which require their own appropriate treatment before the condition can be cleared, and the by no means rare allergic manifestations in sensitive individuals, one or more of the following factors may play a part: (1) An endocrine factor—indicated by the tendency to relapse in the post-menstrual phase. At this time cyclical ovarian activity is at its lowest ebb, the vaginal epithelium is inactive, leucocytes are few, and the secretion less acid, and the trichomonas is encouraged (it is my clinical impression that the woman with highly active ovarian function rarely suffers from vaginitis). (2) A neuromuscular factor: a woman with an irritating vaginal discharge tends to hold the vaginal introitus closed, which may become so much of a habit that a state of vaginal spasm is induced, and this may well retard recovery by retaining secretion and

squeezing organisms into the many available hiding-places. (3) A urinary factor: a gaping introitus and lax vaginal wall lead to constant soiling with drops of urine after micturition, and this admixture, if highly acid or alkaline, may so alter the pH of the vaginal secretion that conditions are favourable for the trichomonas to flourish. The importance of the urinary factor is seen in the vulvo-vaginitis of diabetics, which, although admittedly more often due to a monilia and secondary bacterial infection than to trichomonal vaginitis, may resist all treatment until the urine is kept more strictly sugar-free—or is it that the lowered blood sugar affects the glycogen content of the vaginal mucosa? (4) Certain contraceptives: women who have had an attack of trichomonal vaginitis are not able to use with impunity some of the contraceptives which are entirely innocuous to others.

Knowledge of the means of increasing the powers of resistance of the vaginal mucosa to the trichomonas seems a more effective method of attack than either the production of stronger or the use of larger dosage of anti-trichomonal drugs.—I am, etc.,

Hove, 3.

MARGARET NEAL-EDWARDS.

Subscapular Swellings

SIR,—On January 4, 1955, a young housewife presented with bilateral subscapular swellings. These had been insidious in onset and quite painless. The patient's attention was drawn to them by her husband, who remarked that she was becoming round shouldered.

She had been doing extra housework of recent weeks, but had also acquired a rather boisterous dog that she exercised daily on a lead. The patient had had a chronic cough over the past two to three years.

Four and a half ounces (128 ml.) of heavily blood-stained fluid was withdrawn from the right side at the first attendance and 3½ oz. (92 ml.) on January 31. A proof puncture only was made on the left side, where the quantity of fluid has gradually increased over the past four weeks. It has been suggested that (1) there was bilateral tearing of rhomboid major, (2) tearing of latissimus dorsi, (3) friction between subscapularis on the deep aspect of the scapulae, the serratus anterior, and the chest wall, and (4) that it is an inflammation of unusual bursae.

I should like to thank Professor Lockhart and Dr. Fyfe, of Aberdeen University anatomy department, for their interest, and Mr. Wilsher, of Chesterfield, for the photography.—I am, etc.,

Chesterfield.

KENNETH E. McIVER.

Cancer and Tobacco

SIR,—I enjoyed your leading article entitled "Carcinogens in Cigarettes" (*Journal*, November 20, 1954, p. 1213), but wish to suggest that perhaps there has been too much emphasis upon the need for combustion to produce carcinogenic agents from cigarettes. There is good clinical evidence from India, Ceylon, the United States, and other countries that the habitual use of chewing tobacco alone or with additives is associated with the development of tumours at the "quid-site."

The apparent association of cancer and the use of tobacco, whether burned, unburned, and with or without additives,

paper, insecticides, etc., would suggest that the carcinogenic property is an inherent one. If lung cancer is caused by heavy cigarette-smoking, it is probably the result of a quantitatively higher exposure of a susceptible tissue by the carcinogenic agent; one would expect the larynx also to have a higher incidence of tumours. Tobacco chewers, in contrast, should be expected to have a high incidence of oral cancers, hypopharynx, and oesophagus. Pipe and cigar smokers apparently swallow more tobacco products than they inhale, and therefore would be expected to fall into this group.—I am, etc.,

Buffalo, 3, N.Y.

GEORGE E. MOORE.

Cardiac Asthma

SIR,—I read with great interest Dr. J. G. M. Hamilton's article on "Cardiac Asthma" in the "Emergencies in General Practice" series (*Journal*, January 1, p. 39), and would like to make one addition to his suggestions for immediate treatment. Instead of morphine, I now use only pethidine—usually intramuscularly but if necessary intravenously—or sometimes half dose by one route and half by the other. The dose is normally 100 mg., and the results are as dramatic as one would wish, no oxygen or any other medicament—e.g., aminophylline intravenously—being required in the majority of instances.

I was introduced to this drug as a cure for asthma by Dr. A. H. Walker, the house-physician at the Lowestoft and North Suffolk Hospital, in 1952, when I sent in a small girl of 6 years with a severe attack of "adrenaline-fast" bronchial asthma, and he injected pethidine, 50 mg. (I think that was the dose), and cured the attack in 20 minutes. Following this example I have used it in a few cases of bronchial asthma where adrenaline has failed, and in all cases of cardiac asthma, which have been fairly numerous in my practice, as one patient alone suffered one attack every two or three weeks until he died about 12 months ago.

I should be interested to learn of other observations concerning pethidine in the treatment of asthma. Its use in these cases may be well known, but my belief is that it is not.—I am, etc.,

Lowestoft.

T. S. NICOL.

Changes in the Mental Health Services

SIR,—I would like to make a comment on your recent correspondence over the importance of observation wards in the mental health service.

In regard to the observation ward, I too, like one of your correspondents, Dr. I. S. Kreeger (*Journal*, January 8, p. 104), have spent a similar period in the same observation ward (that now attached to a teaching hospital) and also a period in another observation ward, between them dealing with a very large proportion of London's mentally sick. It seems to me that all three correspondents are right: Sir David Henderson (p. 104) in pointing out the Scottish method of dealing with those problems by admitting them directly to general hospital; Dr. I. B. S. Lewis (*Journal*, December 4, 1954, p. 1354) by suggesting that observation wards should be abolished; and Dr. Kreeger by pointing out how valuable and important the work of observation wards is. A recent article in the *Lancet* by Dr. J. F. Stokes *et al.*¹ has shown, on figures from the same observation ward as Dr. Kreeger and myself have worked in, the very high proportion of physically sick patients admitted to the observation ward with apparent mental disorder.

All these distinguished contributions surely point to the abolition of the observation ward as such, as Dr. Lewis suggests, and to the establishment of properly equipped psychiatric wards within the general, and particularly the teaching, hospital—as Sir David Henderson points out is now the method in Scotland. This would mean that, as Dr. Kreeger rightly asserts, the valuable and important work now done in observation wards will be carried on side by side with other medical and surgical specialties and given its rightful due—of which it is still deprived by many within

the medical profession. It would mean that social, psychiatric, medical, and medico-legal problems at present kept inside the observation wards would be properly ventilated, explored, and, very much more important, taught to students, instead of being relegated to a minor, unimportant role in a full curriculum; and taught with appropriate case material at the bedside in the most reputable clinical fashion. It would help to underline the complex interrelation between the psyche and the soma in all disease, whether mental or physical. It would also mean that the nursing of such cases could be shared by nurses fully trained in both aspects of nursing and teaching programmes integrated to this end. It might also help the enormous difficulties of attracting suitable men and women into the nursing of the mentally disturbed, instead of maintaining an increasingly unreal isolation. Within this framework more cases could be dealt with by treatment on the spot, later discharge, out-patient support, and follow-up than is now possible. The burden could be more effectively lightened on the mental hospitals, as well as establishing closer relation between the mental hospitals and the general hospitals, and the difficulties surrounding certification and mental disease more easily circumvented in the lay mind.—I am, etc.,

London, N.W.1.

M. J. ROSENTHALL.

Grants for New Hospitals

SIR,—Your leading article "Grants for New Hospitals" (*Journal*, February 15, p. 466) is timely in two respects; first, in stating that the reason for priority of some projects is not clear, and, secondly, in indicating the possible danger of attracting staff away from old hospitals to new ones.

The situation in the North-west Metropolitan Region is of some interest. Certain of the urban hospitals are unable to meet their commitments fully or efficiently. It is however stated that there is no question of adding to their beds while beds stand empty elsewhere. The hospitals in question are, however, struggling to deal with their work under most difficult conditions. Additional accommodation in such hospitals would cost but a fraction of the capital outlay on some of the proposed new hospitals. A hospital of 150 beds is planned for the Welwyn Garden City and Hatfield area (an ultimate bed total of more than 400 was mentioned by an official of the Regional Board in a press interview). At the present time the hospital work of the Welwyn Garden City and Hatfield area goes mainly to St. Albans, Hertford, and Barnet. The hospital at St. Albans consists of three separate units, with inadequate x-ray and theatre facilities, as well as many other difficulties. Despite these handicaps, this hospital and others drawing patients from the Welwyn Garden City and Hatfield area still have unused reserves. What justification can there be for planning a further hospital which may exceed in size any of those already draining this area? Much of the increase in population has already occurred, and even at its peak will result in about a 25% increase of the total population. To say this is not to deny the need for improved hospital facilities in the area concerned, but merely to question the scope and detail of the present plans.

You, Sir, press for the publication of reasons for various decisions, and I am sure this will receive wide support. One might also put in a plea for prior consultation with those who provide the service. So far as I am aware, the medical advisory committee of the group to which I have referred (representing hospital staff, general practitioners, and medical officers of health of the area) have not been consulted about details of the proposed Welwyn Garden City and Hatfield Hospital. It is hard to see how the Ministry can get a true idea of the medical requirements of such an area without consulting the professional people on the spot.

If I have referred to one particular area, it is only because of my personal knowledge of it. I have, however, no wish to imply that the conditions there are necessarily any less satisfactory than elsewhere, nor do I wish to attribute

responsibility for that state of affairs. Speaking as a doctor and a taxpayer, I am by no means satisfied that the best, or even the second best, will be done with the available resources.—I am, etc.,

Radlett, Herts.

R. S. MURLEY.

Alcohol as a Diuretic

SIR,—Dr. Lawrence Mackie's copy of *Macbeth* "shows Act II to have but two scenes" (*Journal*, February 12, p. 415), and he implies that Professor L. J. Witts must have given the wrong reference when he wrote of the dialogue between Macduff and the porter (*Journal*, January 29, p. 271). In the First Folio (1623) Act II consisted of four scenes. It was Nicholas Rowe (1709) who reduced this Act to two scenes. Evidently Dr. Mackie's *Macbeth* follows Rowe's arrangement. A modern example of this is the Shakespeare published by Collins about 30 years ago: the name of the editor is unknown, but the book can be identified from the fact that it includes an exhilarating introduction from the pen of St. John Ervine dated June, 1923. Happily, Collins's new edition, prepared by the eminent Shakespearean scholar Peter Alexander, reverts to the arrangement given in the First Folio.

"What, I wonder, did the porter at Inverness castle drink?" asks Dr. Mackie. I gather that he is not offering a prize for the correct answer. As a former citizen of Inverness, I feel entitled to suggest that "carousing until the second cock" means only one thing, no matter whether we consider it by the standards of the twentieth century or by those of King Duncan's time. Revelry amounting to "carousing" was almost certainly sustained by liberal indulgence in an alcoholic beverage of some kind. It is probable that the porter had been drinking whisky or other spirituous liquor. "Distilling was practised in England as early as the eleventh century, but was confined to the monasteries, the produce being used as a medicine. . . . In Scotland during the fourteenth century whisky had already displaced much of the imported Continental spirit. . . . By the middle of the sixteenth century a large trade was established, and house or cottage stills were found in all parts" (*Chambers's Encyclopaedia*, 1904). It is unnecessary for Dr. Mackie to insist that the porter "be shown to have ingested pure alcohol." No self-respecting Scotsman would thus abuse his stomach; nor would he waste "pure alcohol"—a preparation rarely seen, even in the laboratory of the analytical chemist. The product of the pot-still distillery contains 80% of pure alcohol when 50% over proof; the patent-still yields a spirit containing about 95% alcohol.

It has long been held that the presence of alcohol in the blood produces diuresis independently of the water and ethereal substances which are imbibed with most alcoholic beverages. As a therapeutic measure, the action is perhaps unimportant; and in any case alcoholic beverages would rank among the most expensive preparations for producing a flow of urine. On the other hand, if it does occur, the diuretic action of alcohol must be a matter of some interest to physiologists and pharmacologists. We may be sure that academic niceties about higher esters and the like had no place in the mind of the porter at Inverness castle. He had evidently been impressed by what might be called the over-all effects of alcoholic beverages taken late at night; perhaps he had evolved a crude test of diuretic potency by simply noting the number of times he had to rise during the night to empty his bladder.

Dr. Mackie is evidently not convinced that excessive drinking causes a red nose. Whatever may be the importance of alcohol in the pathogenesis of redness of the nose, it is certain that this disfigurement is by no means rare among those of temperate habits, and florid cases have been observed even among strict abstainers. Nevertheless, a flushed face is one of the early signs of an alcoholic orgy, and over a period of years the face of the inveterate drinker often becomes both congested and coarse. I do not suggest that the action of alcohol is selective in the sense that the skin of the nose is particularly liable to be affected, but

in the presence of other diseases such as acne rosacea alcohol may intensify redness of the nose to an alarming degree. It is probable that Bardolph was a victim of this distressing combination of disabilities—rosacea and alcoholism. When Fluellen was describing him to King Henry V he said: " . . . his face is all hubbuckles, and welks, and nobbs, and flames o' fire; and his lips blows at his nose, and it is like a coal of fire, sometimes plue and sometimes red; but his nose is executed and his fire's out" (*Henry V*, Act 3, Scene 6, line 101). The aetiology of this condition is suggested by a conversation that takes place before the Boar's Head tavern (Act 2, Scene 3, line 40) *à propos* some of the foibles of the late Sir John Falstaff.

Boy.—Do you not remember 'a saw a flea stick upon Bardolph's nose, and 'a said it was a black soul burning in hell?

Bardolph.—Well, the fuel is gone that maintained that fire: that's all the riches I got in his service.

Doubtless the fuel was sherris-sack—so eloquently eulogized by Falstaff in his soliloquy on wine (*Henry IV*, Part II, Act 4, Scene 3):

. . . A good sherris-sack hath a twofold operation in it. It ascends me into the brain; dries me there all the foolish and dull and crudy vapours which environ it. . . . The second property of your excellent sherris is the warming of the blood. . . . It illumineth the face, which as a beacon, gives warning to all the rest of this little kingdom, man, to arm. . . .

—I am, etc.,

Glasgow, W.2.

STANLEY ALSTEAD.

Prevalence of Dysentery

SIR,—It is satisfactory to see that you gave your leading article (*Journal*, February 12, p. 401) to this important disease, but I think you are mistaken in attributing its lessened severity amongst the young and healthy to the higher proportions of Sonne as opposed to Flexner infections. Experience over the last dozen years is that both types of dysentery have been much milder, and the diarrhoea has been as a rule of moderate intensity, with blood and mucus, prostration, and high temperature only exceptionally. The reason for this change is unknown, but perhaps the constitution of the organisms has been altered and virulence diminished as a result of widespread sulphonamide therapy.

This decrease in virulence, however, carries a new danger, for it has led the public to treat the disease with complacency. Bacteriological tests of the stools are often omitted, so that carriers abound, and, as your leader showed, the disease is assuming serious endemic proportions. Complacency is unjustified, since, although the mortality amongst healthy adults may be trivial, it is not so in the invalid aged; moreover, the disease is still severe and frequently fatal in infants.—I am, etc.,

Warwick.

E. S. STERN.

Chlorpromazine

SIR,—In your leading article on chlorpromazine (*Journal*, February 5, p. 338) you state that the main control of body temperature is due to tonic impulses passing down the voluntary nerves to skeletal muscles, and later you ascribe the hypothermic properties of chlorpromazine to a peripheral neuromuscular depression. Recent work has suggested that under normal conditions skeletal muscle activity plays a negligible part in the maintenance of body temperature, the main centres of heat production being the liver and the brain.^{1,2} The shivering mechanism comes into operation when active cooling of the body is carried to such a degree that the normal heat conservation mechanisms can no longer maintain body temperature. Neuro-muscular blocking agents may be used as adjuvants in the production of hypothermia by surface cooling, when they prevent reactive shivering, but are useless as the primary agents to induce hypothermia.

If chlorpromazine produced hypothermia by neuro-muscular block one might expect even the surface of the

limbs to be cooler than the rest of the body, whereas the mild fall in body temperature induced by clinical doses of chlorpromazine is characterized by the warm state of the extremities.³ It would appear likely that in the hypothermia induced by chlorpromazine a defect in heat conservation is more important than any derangement of heat production.—I am, etc.,

London, W.C.2.

Hair-grips as Foreign Bodies

SIR.—Mr. Ralph H. Gardiner's memorandum (*Journal*, February 12, p. 397) serves a very useful purpose in drawing attention to the special dangers of the swallowed hair-grip. It requires operative removal much more commonly than any other swallowed foreign body. I feel that Mr. Gardiner was too impatient when he operated on his patients after the hair-grips had been in the stomach for only 5 and 10 days. Foreign bodies don't usually do any harm there, and I have seen hair-grips pass the pylorus and manipulate the alimentary canal successfully after lying in the stomach for three weeks.

When a grip gets arrested in the bend of the duodenum it may erode the bowel wall, and operation is indicated. The sequelae to erosion, however, are not as dramatic as might be inferred from Mr. Gardiner's article. Of the four grips which I have removed and which were lying partially or completely outside the bowel wall, none had caused more than localized peritonitis and the clinical features were mild abdominal pain and local tenderness. One hair-grip was removed from a deep abscess in the abdominal wall. No faecal fistula developed.

I cannot agree with his treatment of bulky diet and "normacol." The most important objective of treatment is to prevent intestinal spasm. This is best achieved by giving the child the diet it is used to. For this reason it would seem wise not to admit these children to hospital, once it is ascertained that the object has entered the stomach, but to supervise them carefully as out-patients.—I am, etc.,

Manchester, 3.

H. M. GOLDBERG.

Agranulocytosis

SIR.—Drs. D. G. Wraith and F. Dudley Hart in their letter (*Journal*, February 12, p. 412) advocate the use of cortisone and A.C.T.H. in the treatment of drug-induced agranulocytosis, and cite a number of cases which recovered following the exhibition of these drugs. Cases have also been described by Kirkeby¹ and Peyman² which responded to A.C.T.H. and cortisone, although the latter considered the marrow was probably recovering before the drug was given.

There have, however, been a number of cases recently³⁻⁵ which recovered on antibiotics alone without the use of A.C.T.H. and cortisone, and one¹⁰ who probably would have recovered, as well as some cases¹¹⁻¹³ who did not respond or died after the use of these drugs. In an annotation¹⁴ you say: "In agranulocytosis the drugs [that is, A.C.T.H. and cortisone] have given far less benefit, a favourable response being a rare and unpredicted event." The use of these drugs is also not without risk especially in the presence of an established infection—a common enough event in agranulocytosis. In a further annotation¹⁵ you state: "It is now fairly well established that all the common bacterial infections are enhanced [by the use of these drugs], including those with spirochaetes and tubercle bacillus"; and Page¹⁶ states: "Little emphasis has been laid on the practical results of the well-known disseminating qualities of these drugs in occult infections."

Two cases of drug-induced agranulocytosis have been treated in this hospital in the past eighteen months. One was a woman who had had sulphonamides, chloramphenicol, and a compound of amidopyrine and a barbiturate, and who had on admission a white cell count of 600 per cubic mm.,

with no polymorphs present. She was treated by antibiotics initially, but A.C.T.H. was started on the fourth day. No polymorphs appeared in the peripheral blood until a few hours before her death on the tenth day. The second case was a woman who had had phenobarbitone for six weeks, and was admitted because she had a generalized maculopapular rash and sore throat. Her white cell count was 170 per cubic mm. with no polymorphs. She was given penicillin, and on the fourth day after admission her temperature settled and polymorphs reappeared in the peripheral blood. She is now quite normal.

Hutt and Lee¹⁷ suggest not giving A.C.T.H. and cortisone for at least seven days, because the marrow frequently recovers in this time. It is possible that our first case would have recovered without the use of A.C.T.H. and that she died of a septicaemia induced by this drug. Post-mortem examination confirmed that death was due to a generalized infection, with meningitis and bronchopneumonia.

There is therefore need for considerable caution in the use of A.C.T.H. or cortisone in treating agranulocytosis: and it would seem desirable that a properly controlled trial of these drugs in agranulocytosis should be made. The Medical Research Council trials have so far been quite inadequate, as in the first report¹⁸ no case of agranulocytosis was included and in the second¹⁹ only two. Aber and others²⁰ quote only three cases in their report, and Whitby and Britton²¹ quote only Hart's case.²² We also do not know how many cases have been treated unsuccessfully by A.C.T.H. and not reported. I suggest that the case for A.C.T.H. or cortisone in drug-induced agranulocytosis is not proven.

I am grateful to Dr. R. G. M. Longridge for permission to include the clinical notes of these patients.—I am, etc.,

Salisbury.

Silver Stool Sign

SIR.—Mr. Arnold S. Aldis in the interesting case he reported exhibiting silver stool (*Journal*, February 12, p. 414) suggests it would be interesting to hear if others had observed this phenomenon.

In south China and Hong Kong I have on several occasions observed silver stools in patients suffering from tropical sprue. All were advanced cases of this disease and all were undergoing treatment with large doses of calcium lactate by mouth and twice-daily doses of parathyroid gland, gr. 1/10 (6.5 mg.), as this was said to regulate the amount of calcium absorbed into the system. Sprue cases do not exhibit blood in the stools, unless there is some superimposed cause to account for the blood, but of course there is little or no bile and usually an excess of fat in sprue stools.

It was suggested that the action of the fat on the calcium, aided by the parathyroid gland, and with no bile pigment to obscure the reaction, gave rise to the silver stool, so aptly described by Mr. Aldis as just like aluminium paint. In these sprue cases there was no question of cancer of the ampulla of Vater or cancer at any other site, but silver stool was regarded as a serious and often fatal complication in tropical sprue.—I am, etc.,

Belfast.

J. H. MONTGOMERY.

The New Insulins

SIR.—Dr. E. B. Kraus writes (*Journal*, February 19, p. 478) about the virtues of isophane insulin (N.P.H.), produced originally by Hagedorn in Denmark and widely used in the U.S.A. since 1948. He says that it has received little publicity in Britain; but that does not mean that it has not been studied by some of us on our own patients and its effects observed on travelling Americans. My opinion was, and is, that, containing very little protamine, its action as a one-dose preparation is not much more prolonged than globin insulin. It works well, as do other slightly retarded insulins, on the milder insulin case but will not carry through for 24 hours in the average severe case needing some 40 to 60 units a day. It is therefore not lack of trial and knowledge that has led to silence in the British medical press.—I am, etc.,

London, W.1.

R. D. LAWRENCE.

Princess Louise Children's Hospital

SIR.—Dr. R. W. Smithells (*Journal*, February 19, p. 479) recalls the "Battle of Paddington Green" in writing of the threat to convert the Princess Louise Hospital for Children to adult use. It was in 1949 that the Sporborg Subcommittee recommended the Board of Governors of St. Mary's Hospital to close Paddington Green Hospital as a children's unit. And it was outraged public opinion, which was prepared to chain itself, its prams, and its babies to the railings of St. Mary's, which finally made the board abandon the proposal.

In their latest report the Sporborg Subcommittee say: "Members of the Board may well be surprised that whilst in their earlier proposals . . . the Subcommittee recommended the conversion of Paddington Green Hospital to adult use, they now put forward a similar recommendation in respect of Princess Louise Hospital." And well they may be surprised. For the same arguments against such a conversion apply now as then, and the same solution exists—namely, that if St. Mary's do not need so many cots for teaching paediatrics to their students they should allow one of their two children's hospitals to be transferred to a less favourably placed teaching hospital.—I am, etc.,

London, W.1.

MICHAEL HARMER.

Tonsillectomy

SIR.—I congratulate Mr. E. H. Miles Foxen on his protest (*Journal*, February 12, p. 413) against the extraordinary inefficiency of the present removal of tonsils and adenoids in this country as a whole. The rate of failure appears to be about 20%; and the amount of damage to patients and discredit to the profession caused by this misuse of an excellent operation is immense. He is right in emphasizing that the true principles of tonsillectomy were laid down by George Waugh,¹ since in many clinics the term "dissection" is applied to the use of a snare, after a preliminary loosening of the upper pole.

May I suggest that, in addition to applying to this operation the standards of surgery aimed at in other branches, we might also teach the true anatomy of the region concerned? Some twenty-odd years ago I put forward my views on this.² If I am wrong, they should be controverted: if I am right, a considerable number of children have quite unnecessarily bled to death in the interval from the paratonsillar vein. I may say that no surgeon or anatomist would discuss these views for many years, with the exception of George Waugh himself, who came to agree with me completely.

Some of the points I made are now getting into the anatomy books, but no anatomist has dared to recite the old description of the six arteries of supply and the venous plexus and then announce, "*Nous avons changé tout cela.*" The change is being made gradually, so as not to arouse the dawn of doubt among those who have been taught to recite the anatomy of the books as unquestionable dogma.

Of course, the trouble is that anatomists do not get specimens of the developing human body to study and demonstrate; can anyone refer me to a really good preparation showing the adenoids or the tonsils *in situ*? Such specimens of the adenoids would demonstrate that the most popular sizes of curettes are too wide to be used on many children without scarring up the openings of the Eustachian tubes, with results only too familiar to those interested in hearing.—I am, etc.,

London, W.1.

DENIS BROWNE.

- ¹ *Lancet*, 1909, 1, 1314.
- ² *J. Anat.*, 1928, 63, 82.

SIR.—The expression of any views on tonsillectomy is always followed by considerable controversy. This fact alone would suggest that consistently good results are not being achieved in all centres. Mr. E. H. Miles Foxen (*Journal*, February 12, p. 413) has no doubt started a prolonged controversy on guillotine tonsillectomy by quoting and supporting George Waugh's¹ statement that "the cause of failure lies not with the operator but with the type of operation."

May I suggest that the key to it all is anaesthesia? If an inexperienced surgeon is only allowed two minutes' operating time, during some of which time the patient is probably moving, he should be forgiven if the uvula or anything else is extracted rather than the tonsil. But if, on the other hand, as in most other surgical operations, he is allowed good operative conditions without a time limit he can remove the tonsil carefully with a guillotine and then examine the surgical field. Should there be a remnant, and this can happen to the most experienced guillotinist, it can be dissected then and there so that complete removal can be ensured in every case. This technique would appear to combine all the advantages of the old method with all the advantages of the new one. If the cases can be successfully treated at a rate of ten or more per hour I can see no reason to reduce the rate to four or less per hour. The end-result should be the same in either case.

One anaesthetic technique which allows this is N₂O→O₂→ether—relaxant if required—with intubation orally or nasally according to the surgeon's wishes. After a gag has been inserted the ether should be turned off and only N₂O and O₂ given. This ensures that the patient will be in a light plane of anaesthesia at the end of the operation regardless of time. Another technique which has been used successfully in Portsmouth on many cases has been designed for an experienced guillotinist. A single injection of thiopentone is given in the anaesthetic room; nothing else is given afterwards. This allows some two to three minutes for surgery and examination. Should tags remain the child is given a relaxant and intubated. This technique is not suitable for a slow surgeon or for one who often leaves remnants.

May I, as one who has seen much harm result from the guillotine, suggest that, properly used, it can still play a major role in good modern surgery. While anaesthetists can provide the operative conditions, this is of no avail should we have a generation of surgeons who have never seen it used and are quite determined that they never shall.—I am, etc.,

Southsea.

H. B. C. SANDIFORD.

REFERENCE

- ¹ *Lancet*, 1909, 1, 1314.

SIR.—Mr. E. H. Miles Foxen (*Journal*, February 12, p. 413) must not be disappointed in his expectation of opposition to his wish to relegate the guillotine operation to the historical section of every textbook. Alas, this wish will never be granted by calling what is indeed the truth a dangerous platitude. The guillotine operation, carried out properly, is a sound procedure.

Trained in a Scottish medical school I saw many cases post-operatively whose tonsils had been removed by the

guillotine method. Later, while a registrar in the ear, nose, and throat department of a London hospital, I saw many cases post-operatively whose tonsils had been removed by the dissection method. I can assure Mr. Miles Foxen that it is not just the guillotine method which is responsible for tonsillar remnants and damage to the faucial pillars, soft palate, etc.

Obviously, with either the guillotine or dissection method, there will be initial failures in the training period of any surgeon. If the failures proceed, then either the operator has not been taught correctly or is inept. To reverse Mr. Miles Foxen's quotation, surely "the cause of failure lies not with the operation, but with the type of operator."—I am, etc.,

Carlisle.

J. C. CAMPBELL.

A Case of Phaeochromocytoma

SIR,—In reply to Dr. A. C. Kendall's letter (*Journal*, February 19, p. 482), I would like to state that the perirenal insufflation (*Journal*, February 5, p. 331) was undertaken by the presacral route as described by Blackwood.¹ I have no personal experience of undertaking this procedure by any other route, and I would agree that the presacral route should be used for preference. It would appear that Dr. Kendall has been more fortunate than myself in the results that he has obtained.—I am, etc.,

Liverpool, 1.

Natural Childbirth

SIR,—Dr. Constance Lang Beynon (*Journal*, February 19, p. 475) entertains a series of fears about natural childbirth and expresses an urgent desire to "ventilate some of the problems before it is too late." With all due respect to an inquiring mind, her letter persuades me that she has neither read, practised, nor closely observed the subject of her anxieties. It may be that, like many of our senior colleagues, she is more occupied with obstetric abnormalities and gynaecological cases. One cannot help feeling she has not often attended natural births, for had she done so it is unlikely she would have expressed fears lest all women might be given an opportunity of similar experience.

This obstetric programme provides the most humane consideration and treatment of mothers and their babies. All of us know that the care of women and the conduct of labour, particularly in many hospitals, leaves much to be desired. This problem must be faced frankly so that we can concentrate on making childbirth a healthier and happier event. Surely we owe this to those who place their confidence in us. It cannot be overlooked that the rapid spread of this teaching across the civilized world has been due, almost entirely, to the women themselves. Had there been no justification for their enthusiasm, it would have died out long ago. If responsible medical men, who conscientiously studied and employed its procedures, had proved it to be harmful it could not have survived their denunciation.

Innovations which imply change of orthodoxy usually meet with professional prejudice or apathy, and this case has not been an exception. In spite of all, natural childbirth has survived 30 years of careful thought, discussion, and trial, and the demand for it steadily increases. Men cannot have babies, but there is no shame in sacrificing their academic "stance and circumpomp" in the cause of kindly and compassionate unselfishness for women who bear babies. Dr. Beynon must not be afraid lest mothers receive a service that can do no harm, but will bring to the majority of them happiness, health, and a fund of family affection.

I agree with Dr. Beynon that "more general and open discussion might be wise at this juncture," but I go further. The time is ripe for a full inquiry into the care of pregnant and parturient women, which should be made by medical and lay investigators who are competent and unbiased. I

urged those responsible for our obstetric standards to do this eight years ago. The suggestion had interesting repercussions, but there was no inquiry. Childbirth is a much wider subject than obstetrics, for true motherhood is the cornerstone of domestic and social stability.—I am, etc.,

Petersfield, Hants.

GRANTLY DICK READ.

Comparison of Vole and B.C.G. Vaccination

SIR,—As there has been considerable publicity in the daily press following the publication of our paper (*Journal*, January 15, p. 133) one or two explanations are called for.

B.C.G. and vole vaccination of the children in the orphan homes and those of our staff was introduced as a protective measure. Eleven cases of tuberculosis had been notified in the 10 years previous to vaccination, and these did not include any case occurring after the children had left the homes, and there has been a number of such tragic sufferers. No case has occurred since this vaccination was undertaken 3½ years ago. In our report we reviewed the state at the end of two years, and since then many of the arms showing a persistent lupoid reaction have responded well to treatment; the two most severe are now healed. In no case has any child complained of pain or discomfort, and there was no systemic upset. The general health of the children has never been better. The opportunity was taken to compare two tried and established forms of vaccination. The persistent vole reactions were unexpected and it was our duty to record this. Nevertheless, we still consider vole vaccination to have certain advantages over B.C.G.

For the most part the article was fairly and accurately reported, but it is most regrettable that a section of the Press has misrepresented facts which may cause public opinion to be unfairly influenced against a voluntary institution whose first concern has always been the health and welfare of the children. The way in which this publicity has been used brings much discredit to those responsible. They have done a great disservice to the children and those sincerely interested in their problems who give such devoted care as house mothers and fathers. It must be made quite clear that the management acted on medical advice in the best interest of the children. There was a similar outburst when diphtheria immunization was first introduced. Finally, any measure which may prove of help in the eradication of tuberculosis should surely be welcomed.—We are, etc.,

HUGH W. O. FREW.

J. ROMANES DAVIDSON.

J. T. W. REID.

Paisley.

Fluoridation of Public Water Supplies

SIR,—To fluoridate or not—that is the question. The Commission on Chronic Illness, an independent national agency founded jointly by the American Hospital Association, the American Medical Association, the American Public Health Association, and the American Public Welfare Association, considered all the available evidence regarding the "effects of fluoridation of community water supplies upon the aged and the chronically ill" in the U.S.A. (report dated Chicago, Illinois, March 17, 1954). In this report the concluding paragraph reads: "The fluoridation of water supplies involves no new experience in human welfare. Over 3,000,000 people are living in ordinary good health on water naturally containing fluorides in the amounts recommended for caries control, or more" (my italics). The Commission goes further, urging "American communities to adopt this public health measure as a positive step in the prevention of the chronic disease, dental caries."

As regards the undoubted beneficial effects in so far as the children are concerned, all the evidence points to the difference between caries resistance of children drinking controlled fluoridated waters, which has become "most marked," as compared with children drinking non-fluoridated waters.

It is indeed curious to read the beginning controversy in the British medical press timed as it is a year or so after a similar controversy here—a controversy that still continues but with abating force, in spite of all the vituperation of the antagonists of the measure, in Massachusetts as elsewhere in the country. Incidentally, there are several anti-fluoridation bills before the present session of the Massachusetts Legislature—the sponsors either very long-haired persons, or very short-haired persons, both groups with their own particular varieties of bias. Very few average individuals, whether they be "men in the street," or "professionals," dental or medical, belong to this extremely vociferous group of anti-fluoridators.—I am, etc.,

Ayer, Massachusetts.

K. I. E. MACLEOD.

Disk Lesions and Low Backache

SIR,—It is surprising that in the long discussion on low backache in your columns so little attention has been given to the relatively common occurrence of this symptom in pregnant women. Dr. E. Schleyer-Saunders (*Journal*, February 5, p. 348) has alluded to it. We found¹ that 3.7% of 3,030 women attending the antenatal clinic of the Royal Maternity Hospital in Edinburgh suffered from this symptom in such a degree as to call for special treatment. In 60% the pain commenced before, and in 40% after, the 28th week. In general the severity of the symptoms corresponded to the degree of loosening and mobility of the sacro-iliac joints. This softening at the pelvic girdle is frequently associated with an up-and-down gliding movement at the symphysis pubis, and the amplitude of this displacement as studied radiologically gives a measure of the rocking movement at the sacro-iliac joints. With the consolidation of the pelvic joints, which occurs after delivery, the symptoms tend to subside rapidly, but in a relatively large number the backache persists.

It is generally agreed, on seemingly sound evidence, that the mobilization of the pelvic joints during pregnancy is dependent upon hormonal factors, and that the change is limited to the joints. At the same time rarefaction of the adjacent bone is common, and in two instances we have been able to demonstrate that the forcible movement at the pubic joint had resulted in a tearing away of fragments of the adjacent bone. It is quite possible that similar laminar fracture may occur at the sacro-iliac joint without being revealed by x-ray.

The treatment of the backache of pregnancy is relatively straightforward. Rest in bed in the majority of cases leads to rapid relief, which persists. In the occasional case rest in bed throughout the remainder of the pregnancy and the puerperium is imperative. In the rare case, in which the pain is severe and the loosening of the joints extreme, the treatment is best given in a hammock as for fracture of the pelvis. In 15 years at the Postgraduate School of London we had only three such cases; this proves its rarity. Where in the ordinary case the backache persists after childbirth, manipulation gives relief in a high proportion.

Whilst we believe that the majority of cases of low backache in pregnancy are explained as above, there are cases, as O'Connell² and others have shown, which depend upon a disk lesion. It may be that the endocrinal factors that determine the joint lesion may predispose to disk protrusion.—I am, etc.,

Haywards Heath, Sussex.

JAMES YOUNG.

REFERENCES

¹ Young, J., *J. Obstet. Gynaec. Brit. Emp.*, 1940, 47, 493.
² O'Connell, J. E. A., *Surg. Gynec. Obstet.*, 1944, 79, 374.

SIR,—Mr. John Charnley's article on acute lumbago and sciatica in general practice (*Journal*, February 5, p. 344) is a delight to a general practitioner, perhaps most of all in the grouping of lesions and degrees of symptoms. I am particularly interested in the phenomenon that he describes as a rise of internal tension in the pulpy nucleus

due to an abnormal imbibition of water accompanied by guarding spasm of the back muscles. I have the impression that I have precipitated this condition in a number of women in the menopausal phase by giving them oestrone in small doses for even a few successive days. The backache subsides slowly after withdrawal of the oestrone, which is usually prompt since irritability and lack of well-being accompany the pain, even when flushes are relieved. The type of woman affected is a water hoarder. The pain does not resemble that accompanying pelvic congestion.

Since the publication of this article, a patient has been willing to reproduce this syndrome, which had been observed to follow treatment by oestrone on three previous occasions. This woman is post-menstrual, bothered by flushes which are relieved by oestrone, and an accepted case of chronic disk lesion following an accident.

Mr. Charnley states that reasons for this watery swelling of the pulp are unknown. If other observers can confirm any relation to oestrone intake, an endocrine approach to this aspect of the disorder may be of value. The possible antagonizing effects of ethisterone or methyl testosterone obviously need consideration. It is interesting, too, to recall Dr. Cyriax's observation that low backache in women tends to be chronic, in contrast to the more acute but briefer crises in men.—I am, etc.,

London, W.2.

ANNIS GILLIE.

SIR,—In his paper entitled "Spinal Disk Lesions" (*Journal*, January 15, p. 140), Dr. James Cyriax speaks of "patients with reducible displacement of part of a disk," who "abound in every hospital," and expresses his belief that such a "minor disk subluxation" can be "manipulated back into place," usually in one session.

A critical reader feels that such statements call for some elucidation. Can Dr. Cyriax substantiate his words with photographic or at least diagrammatic illustrations, to show exactly what structures are affected by the "subluxation" and the "reducible displacement of part of a disk"? It is difficult to visualize how a ruptured annulus fibrosus and herniating nucleus pulposus can be repaired in the brief ritual of a manipulation; in fact, it is a very severe strain upon the reader's credulity.—I am, etc.,

Halifax, Canada.

FREDERICK W. KNOWLES.

SIR,—I am sorry to see that Mr. John Charnley has come to swim with the current on the relationship between disk disorders and "fibrositis" (*Journal*, February 5, p. 344). A theory, to become established as an axiom, must be true for every case, and judged by this standard the theory that disk trouble (I use the word to cover all the gradations of pathology Mr. Charnley describes) is responsible for "fibrositis" must fall to the ground. I am tired of hearing every conceivable abnormality laid at the door of the disk, and while I am aware that, most likely, disks are responsible for hyperthyroidism, mitral stenosis, gall stones, and pregnancy, not to mention typhoid, lupus, and worms, I do not know which disks are displaced in "fibrositis" of the occipito-frontalis, temporalis, and masseter (presumably those between the basi-sphenoid and basi-occiput, or perhaps between the dens and the basi-occiput, or even between the dens and the body of C2).

I have deliberately put "fibrositis" in inverted commas because it is established beyond doubt that it is not an inflammatory lesion. But it may very well be a metabolic one which would not show under the microscope. When an unexpected demand is placed on a muscle not in training, and particularly in a reduced state of health of the patient, that muscle, as Mr. Charnley states, goes into spasm, thus restricting its own blood supply. It cannot then get rid of its metabolites and it remains in spasm until its blood supply is re-established by accurate deep friction, which traumatizes it sufficiently to produce the inflammatory response of local vasodilatation. The surrounding normal muscle-fibres must not be traumatized, of course. The same effect can often be obtained by passively stretching the muscle, hence the success, at times, of manipulation. This conception also quite easily explains the sudden onset in many cases. But I still have too great a faith in Nature's way of arranging things to believe that

the body tries to protect an internal derangement of the spine by making a few bundles of vastus lateralis go into spasm, or tensor fascia lata, or even gluteus maximus. If nature wants to protect a joint, the muscles controlling it are put into spasm, and then in no uncertain manner—not just a pencil thick (or even pencil-lead thick) fasciculus of one or two scattered areas of often unrelated muscles.

You will want proof, Sir, of my contentions, and I regret that by far the best proof I can give is to cite my own case, as I am the walking torpedo of the diskopath theory. I am still physically fit for strenuous activity of every kind (which I need not elaborate beyond saying it included Rugger till over 40), and have all my disk spaces fully maintained, in spite of having been a life-long sufferer from acute, chronic, and recurrent "fibrositis" in almost every muscle in my body, and having had both "brachial neuritis" and acute sciatica due to referred pain from trapezial and gluteal "fibrositis." The reference is proven because the massage of the areas of origin has cured the referred pain without any treatment of the spine at all. But it is a condition my 10-year-old daughter can cure for me. I look forward to the day when physiotherapists will relearn the same art, and orthopaedic surgeons and specialists in physical medicine will again come to recognize that there are more things in heaven and earth than disks.—I am, etc.,

Canterbury.

F. G. ST. CLAIR STRANGE.

SIR.—May I, as another general practitioner, support the comments of Dr. R. N. R. Grant (*Journal*, February 19, p. 480) on the "disk" controversy? We all see scores of cases of fibrositis, only a small proportion of which are sent to the hospital. Most of us would agree that the syndrome is related in some way to weather, to muscular strain, and is quite certainly epidemic. It is my impression that even the muscle groups affected vary in each epidemic, one producing "lumbago" and the next affecting the shoulder girdle. Perhaps there is a relationship to Bornholm disease, in its being a specific infection.

It is very difficult to let oneself be persuaded that what is probably second only to the common cold in causing epidemic "dis-ease" is produced by mechanical disorder.—I am, etc.,

Dundee.

RONALD A. B. RORIE.

SIR.—As a routine in general practice for more than 30 years, I have manipulated cases of low backache of sudden origin and have followed this with a firm bracing of the hips, back and front, with four or five strips of 3-in. (7.6-cm.) rigid zinc oxide plaster. Unless there was an allergy to rubber, this temporary corset gave support and comfort that was appreciated. It was removed after a fortnight, and then, but only if necessary, was physiotherapy advised.

The key word here is "sudden," for it eliminated most cases of gynaecological or urological origin. If there was a sciatica I ordered absolute bed rest for up to six weeks if needed, and have never withheld morphine. I have also used subcutaneous infiltration of oxygen into the buttocks, which, by forming a personal air ring, seemed to give comfort. One case required surgical aid; several, after one or two relapses, were helped by surgical belts; but the majority improved and appeared to be grateful.

Even allowing for fashion in diagnosis there does seem to have been a real increase in the occurrence of this disability in the last few years.

May the modern craze for comfort be the cause? The drawing-room of my youth is now the lounge, and the parental exhortation has changed from "Sit up straight" to "Oh, do relax." The old chairs had almost upright backs which kept the spinal muscles at the alert. No effort is required supinely to sit in the modern ultra-comfortable armchair, supporting as it does every part with soft pads of latex foam, but, in contrast to the old type, a big demand is made on over-slackened muscles to raise the body from its luxurious setting. Three of my cases of sudden low backache were caused in this way. Should the body have

to adapt itself to the furniture or the furniture to the body? Is the multi-spring mattress an improvement on the firmer flock or horsehair, and is it entirely blameless?

The suggestion is that our modern luxury tends to promote a laxness in the spinal tissues which renders them increasingly liable to dislocation.—I am, etc.,

London, N.W.11.

C. BERKELEY WAY.

POINTS FROM LETTERS

Experiments in Hospital

Dr. SYLVIA DICKINSON (Bristol) writes: With regard to the work done by Dr. B. Laurance at the Bristol Maternity Hospital (*Journal*, December 11, 1954, p. 1392), are any follow-up studies being made to find out whether these children subsequently react differently to infection compared with untreated children or show any other effect of the penicillin treatment in early infancy?

Trilogy

Mr. MICHAEL REILLY (Plymouth) writes: As "Fallot's tetralogy" is now so firmly ensconced in medical literature (*Journal*, January 29, p. 269), may I put forward a plea, in the interests of uniformity, that "Charcot's triad" be rechristened "Charcot's trilogy"? Triad, tetrad, pentad, and so on, have for long enough denoted mere groups of three, four, five, etc., while a cycle of four dramas, three tragic and one satiric, has for two and a half millennia been called a "tetralogy." Why not "trilogy" for Charcot's signs, which really are three tragic manifestations?

What is Health?

Dr. A. R. EATES (London, S.W.3) writes: Why do we want to know what it is? How are we to assess or measure it? . . . Health or wholeness is a harmonious development of a man's physical, mental, and moral qualities. It can only be estimated in relation to the man's environment; it must be a variable quantity. The health or fitness required of a young athlete which enables him to run 100 yards in 10 seconds is very different from that of an elderly clerk in a quiet office. Each may be equally efficient in what he sets out to do, and, so long as each can do . . . without excessive strain and with satisfaction to himself and others all the calls upon him in his day's work, each is to be classed as "healthy." Health is a relative quantity.

Medical Aspects of Professional Boxing

Dr. P. F. CASSIDY (Glasgow) writes: I have read with interest Dr. J. C. Laurie's letter on boxing (*Journal*, January 22, p. 227). I disagree that a boxer enters the ring with the object of doing damage to his opponent's cranium and its contents. He enters the ring to pit his skill and ability against an opponent, as men have done since the beginning of time. In boxing no one wishes to see unevenly matched opponents. No one who is a true lover of the sport likes to see a knock-out, because the term knock-out does not exist in true boxing parlance. Points decision is the verdict of choice. . . . In his last sentence, however, Dr. Laurie expresses the sentiments of all true lovers of the sport that "'boxing' grows on one." In this I agree, and I trust that there will always be doctors who without financial gain will give protection to those lads who, in spite of all anti-boxing advocates, continue to give pleasure to boxing lovers.

Unwrapping the "Journal"

Dr. H. LYNTHURST DUKE (Cross-in-Hand, Sussex) writes: Before you finally close this correspondence I feel you should learn of a quite unforeseen, indeed sensational, sequel, news of which I have received from a fellow member of the Association: "Re your letter 'Unwrapping the Journal,' I see you advise the Editor to have it 'loosely wrapped.' Two weeks ago the wrapping was delivered to me minus the *Journal*!"—the opposite extreme to that about which the correspondence opened and even more distracting. I can only hope the wrapper arrived in one piece and that the loss has been made good.

Mr. A. C. GOODWIN (Dawlish) writes: My experience differs completely from that of Dr. H. Lyndhurst Duke (*Journal*, February 12, p. 419) as I rarely (if ever) find the *Journal* so loosely rolled that I can carry out the methods he describes. I find the following procedure simple and efficacious in all cases. With the sharp point of the narrow blade of an ordinary pair of scissors I cut through the length of the outer layer of the wrapper (avoiding the exposed pages of the contents), then insert the point of the broad blade into the cut and run the blade along its whole length. The wrapper is then removed in one piece.

Obituary

Sir HENRY WADE, C.M.G., D.S.O., M.D.
F.R.C.S., F.R.C.S.Ed.

The death occurred at Edinburgh on February 21 of Sir Henry Wade, consulting surgeon to Edinburgh Royal Infirmary. He was 78 years of age.

The son of the Rev. George Wade, Henry Wade was born at Falkirk in 1877 and was educated at the Royal High School, Edinburgh, and at Edinburgh University, where he graduated M.B., Ch.B. with honours in 1898. For nearly two years after graduation he was on active service as a civil surgeon with the Royal Scots Fusiliers in the South African war and was awarded the Queen's

Medal with four clasps.

On his return to Edinburgh Wade became assistant to Sir William Turner in the department of anatomy in the university, and in 1903 was elected F.R.C.S.Ed. In that year he was appointed conservator of the museum of the college, and subsequently he served the college for exactly fifty years as lecturer, examiner, member of the President's council, and, from 1943 to 1953, as representative of the college on the General Medical Council. He was

[Swan Watson, Edinburgh]

awarded a gold medal for his thesis when he proceeded to the M.D. in 1907.

Wade was early appointed to the surgical staffs of Leith Hospital and Edinburgh Royal Infirmary, and was assistant surgeon there on the outbreak of the first world war in 1914, when he joined the Scottish Horse mounted brigade field ambulance and served with the unit in Gallipoli. In 1916 he was appointed consulting surgeon to the Egyptian Expeditionary Force, and for three years served in Egypt, Sinai, Palestine, and Syria. For his services with Allenby in Egypt and Palestine he was twice mentioned in dispatches, was awarded the D.S.O. in 1918, and in the following year was appointed C.M.G., receiving also the Order of the White Eagle of Serbia. On the conclusion of hostilities Wade returned to Edinburgh and resumed his appointments as conservator of the museum of the Royal College of Surgeons, lecturer in surgery in the school of medicine, and surgeon to Leith Hospital, appointments he held for 17 years. In 1924 he became surgeon-in-ordinary to Edinburgh Royal Infirmary, and remained in the active service of the hospital until he retired in 1939 as consulting surgeon. During the second world war he continued in active surgical work as consulting surgeon to Bangour E.M.S. Hospital, West Lothian. He was knighted in 1946. He was predeceased by his wife in 1929.

We are indebted to Mr. DAVID BAND for the following appreciation: Wade was a surgeon of outstanding brilliance and an enthusiastic clinical teacher. At the outset of his surgical career he devoted two years to pathology, and personally performed all post-mortem examinations on surgical cases at Edinburgh Royal Infirmary. In the post-mortem room he became interested in the changes in the upper urinary tract which accompanied prostatic obstruction, and he traced the post-operative sequelae which had

led to the fatal issue. He made serial whole sections through the pelvis and prostate in the cadaver and observed the morbid anatomy of the prostate in the various age groups and at different stages of prostatic obstruction. As a result of this investigation Wade published in 1914 in the *Annals of Surgery* a profusely illustrated monograph on the surgical anatomy and pathology of the operative treatment of prostatism. The drawings in black-and-white and in colour of the entire urinary tract in prostatism demonstrated more perfectly than had before been done the effects of backward pressure on the upper urinary tract. The whole sections clearly showed that in the operation of prostatectomy enucleation of the gland had not been complete, but that the adenomatous part alone had been enucleated through a line of cleavage between it and a false capsule produced by compression of the more peripheral gland elements. These lie within the true gland capsule and, with the latter, must remain intact if the operation of enucleation of the prostate is to be performed with success. His presentation of this work made a deep impression on Hugh Hampton Young, of Baltimore, and Wade was invited by him to attend the following year in the Buchanan-Brady Institution of the Johns Hopkins Hospital, which was to be opened as a urological department. War prevented this, but in 1920 the promised visit was made and Wade remained with Young for several months.

Between the two wars Wade published some 35 papers on urological surgery. In each, advances in surgical management were described or appraised. Throughout his career as a surgeon and clinical teacher Wade insisted on attention to anatomical detail and an adequate knowledge of surgical pathology as essential qualifications in the training of a surgeon. It was the application of these principles which brought to him such a great measure of success in the surgery of urinary tuberculosis and in the treatment of vesical tumours, including a large series of cases of total cystectomy with ureterocolic anastomosis. He was one of the first to draw attention to the invasion of the renal vein by hypernephroma, and he showed in his paper in the *Australian and New Zealand Journal of Surgery* in 1935 that in nephrectomy for tumour the renal vein could be ligated with safety between its junction with the vena cava and the limit of neoplastic invasion. His collection of serial whole sections of renal pathology was unique, and he always maintained that the radiographic appearances obtained by retrograde pyelography must be correlated with a detailed study of the pathological changes in the kidney. He held no brief for pyelographic anomalies which might be listed as due to faulty technique.

During his 15 years as chief in the Royal Infirmary Wade attracted to his operating theatre and his ward a steady stream of visiting surgeons from overseas. His Saturday morning lectures and demonstrations became an outstanding example of postgraduate instruction at its best. He travelled by invitation to America and Australia, and was awarded the honorary Fellowships of the American College of Surgeons in 1930, the Royal Australasian College of Surgeons in 1935, and the Royal College of Surgeons in Ireland in 1939. It was his forthright support of all that was genuine in surgical progress which led to his election to the most exclusive surgical societies of the English-speaking world, including membership of the International Association of Surgeons and Fellowship of the Los Angeles Surgical Society. In 1932 he delivered the Ramon Gutierrez lecture on the balanced urinary system before the American Urological Association, of which he was elected an honorary member. He was elected a Fellow of the Royal Society of Edinburgh in 1932, he was President of the Royal College of Surgeons of Edinburgh from 1935 to 1937, and he was elected an honorary Fellow of the Royal College of Surgeons of England in 1943 and of the Royal Society of Medicine in 1951.

His years of active surgical progress behind him, Wade devoted his energies to help in the formation of the National Health Service, and he became a convener of many committees in connexion with the services of the South-eastern

Regional Hospital Board in Scotland. He was a strict disciplinarian in every surgical service under his control, but there was another side to his nature. He was a student of social and natural history and was widely read in the literature of these subjects. His Harveian Oration on "Harvey in Scotland" in 1938 and his Thomas Vicary lecture before the Royal College of Surgeons of England on "The Barber Surgeons of Edinburgh" in 1949 record the diligence of his researches and his erudition. A member of the British Medical Association for over 50 years, Wade served as a vice-president of the Section of Surgery when the Association held its Annual Meeting at Edinburgh in 1927. He was a member of the Representative Committee in 1943-4, the Negotiating Committee from 1944 to 1949, and the Evidence Committee in 1947-8. He was also a member of the Medical Planning Commission.

At his country home of Pilmuir, Haddington, East Lothian, Wade had acquired and preserved an old house and garden in the Scottish baronial style. His favourite flowers were the rare primulas, and the habits of the nesting birds were observed from year to year, as many had been expertly ringed. The versatility of his interests brought to Wade a humanity and a wealth of understanding which were reflected in the lifelong friendships he made at home and abroad with all who came to know him—surgical colleagues or patients, historians or pupils.

OSWALD T. AVERY, M.D.

Dr. Oswald T. Avery, the distinguished bacteriologist, died in Nashville, Tennessee, on February 20, after a long illness.

Oswald Theodore Avery was born in Halifax, Nova Scotia, on October 21, 1877, and qualified in medicine from the College of Physicians and Surgeons, Columbia University, where he graduated M.D. in 1904. After a few years in general practice Avery was appointed associate director, department of bacteriology, Hoagland Laboratory, in 1907, a position which he left to become an assistant in the hospital department of the Rockefeller Institute for Medical Research. Here Avery began the studies on the pneumococcus with which his name will always be associated, and was one of the founders of immunochemistry. He discovered and identified the capsular polysaccharides of type III pneumococcus and demonstrated their function. He also separated the polysaccharide antigens. Avery remained at the Rockefeller Institute until his retirement in 1943, when he became a member emeritus. His writings chiefly concerned the biological activities, immunological characteristics, and pathogenic properties of the pneumococcus. This work was recognized in the award of the Kober Medal by Georgetown University Medical School in 1946, and in a Lasker Award by the American Public Health Association in 1947. Elected a foreign member of the Royal Society in 1944, Avery received its Copley Medal in 1945. He also received the Paul Ehrlich Gold Medal (1933) and the New York Academy of Medicine Medal (1944). He was Mickle Fellow, University of Toronto, in 1946. McCall University awarded him an honorary LL.D. degree in 1935, and he was an honorary member of the Pathological Society of Great Britain and Ireland.

Dr. S. D. ELLIOTT writes: Many have commented upon the similarities between Dr. O. T. Avery and Sir Frederick Gowland Hopkins. To some extent they were alike in appearance as well as in personality; both through their classical researches had a profound influence upon biological science; and both left an indelible impression on the minds of the young people who were privileged to work in association with them. Dr. Avery always disclaimed any ability to assess from a single interview the potentialities

of applicants for the coveted honour of a place in his laboratory. Yet it is remarkable how many of those who worked with him at the hospital of the Rockefeller Institute achieved distinction. The explanation, in part at least, lay in his capacity to transmit to others his own way of thinking; this, in the recipient, yielded its own ultimate harvest. Few of those who knew Dr. Avery will hear of his passing without deep emotion. His gay charm, great wisdom, and lovable character combined to make in him a unique personality. He was indeed a prince among scientists. "Good night, sweet prince."

Sir CHARLES J. MARTIN, C.M.G., D.Sc., LL.D.
D.C.L., M.B., F.R.C.P., F.R.S.

The obituary of Sir Charles Martin was printed in last week's *Journal* at p. 543. We are indebted to Dr. W. R. AYKROYD, director of the nutrition division of the Food and Agriculture Organization of the United Nations, for the following appreciation:

Many will feel a sense of loss on learning of the death of Sir Charles Martin. I had personally the privilege of working under him in the Lister Institute during the last years of his directorship in the late 'twenties. He was unfailingly kind to young research workers, and was always ready to help in clearing up their problems. He would turn from whatever he was doing—and he was always engaged in some research activity of his own—his eyes would glitter behind his spectacles, the keen incisive mind would come into operation like a smooth-running machine—and one had one's answer. No one who worked with him will ever forget his quick, illuminating comments on detailed technical questions or on the broader aspects of science. His own scientific papers were always beautifully written, and he would go to endless trouble in showing beginners how to present their scientific results and in editing their efforts. At the same time he distrusted words divorced from solid fact. I shall never forget one incisive remark, "You write too easily. That's a dangerous gift." I think that his old pupils, when undertaking some task in later years, often asked themselves, "What would Sir Charles think of this?" His influence is hard to define; it stemmed perhaps from a rare combination of unpretentiousness, honesty, and remarkable intellectual gifts. But such words somehow fail to convey what "Sir Charles" meant to those who were privileged to know him and the respect and affection which we felt for him.

The untimely death on January 10 of Dr. DONALD P. DOW has removed an outstanding personality and reduced the number of medical men whose work has left its mark on India. He was 49 years of age. Donald Peter Dow was born at Ardrossan, Ayrshire, and was educated at Airdrie Academy and at St. Mungo's and Anderson Colleges, Glasgow, qualifying by taking the Scottish triple qualification in 1930. After qualification he held the appointments of house-physician and house-surgeon at Dumfries and Galloway Royal Infirmary, and he then practised for short periods in various parts of the United Kingdom before going to India to pursue his studies at the School of Tropical Medicine, Calcutta. Dr. Dow was brought up a Baptist and always had a leaning towards the mission fields. He applied to several churches for this kind of work, but his state of health caused them to reject his applications. In 1934—when he married Miss Esther Wells at Bombay—he persuaded the Methodist Missionary Society to appoint him medical superintendent of the Victoria Leprosy Hospital at Dichpali, Hyderabad, and from then until he returned to Scotland in 1944 he devoted much time to the improvement of the facilities of the institution, particularly in connexion with the sanitary arrangements and the electricity supply, eventually building up a modern leprosarium. While at the hospital he saw the accommodation for inmates increase from 400 to 850. He also became lecturer in leprosy in Osmania University, conducting clinical courses for students

and postgraduates at Dichpali. Dr. Dow was the first missionary to become a member of the Hyderabad State Medical Council, and a final recognition of his work and worth came with the award of the Nizam's jubilee medal. During his stay in India Dr. Dow wrote extensively, his publications including lecture notes on leprosy and articles on leprosy research—he came to be regarded as an authority on leprosy—and on occupational therapy, the psychological approach, pellagra, and on other subjects. In 1944 ill-health compelled him to return to Scotland, and in the following year he established himself in practice at Newtyle, Angus, where he became widely known as a "beloved physician." A devout Christian, Dr. Dow could hold his own in theological circles, and his services as a preacher and speaker were much in demand at Strathmore and beyond. Many people derived encouragement from his logic, enthusiasm, and example. Fees he received as a preacher went to help the work of the Mission to Lepers or to augment the church funds—acts of generosity and remembrance which endeared him to a still wider circle. At the time of his death he was a member of the Angus Executive Council, a lecturer to the local branch of the Red Cross and examiner in first aid, president of the Dundee Auxiliary of the Mission to Lepers, and he attended patients at the Church of Scotland Eventide Home at Belmont Castle and the Newtyle Home for the Blind. He was a founder member of the College of General Practitioners and president-elect of the Dundee Branch of the British Medical Association. He is survived by a widow and two adopted children.

Dr. A. P. NUTTALL died on February 19 at his home at Rickmansworth, Hertfordshire, to which he had retired for family reasons 25 years ago. He was 85 years of age. Arthur Peel Nuttall was born on May 20, 1869, and was educated at the Bury Grammar School, at Rossall, and at Owens College, Manchester, from which he went to University College Hospital to complete his medical course. He graduated M.B.(London) in 1893, proceeding to the M.D. in the following year. After holding house appointments at University College Hospital (including the post of house-physician to his fellow Lancastrian Sir Thomas Barlow), he returned to his birthplace, Bury, where he joined his father in practice. When his father retired in 1905 Dr. Nuttall took over the practice until his own retirement. He became one of Bury's most respected and most successful practitioners. He was honorary surgeon to the Bury Infirmary from 1909 to 1926, when he was made honorary consulting surgeon. In his younger days Dr. Nuttall was a keen Volunteer. He was always proud of the fact that he had held the office of surgeon-major to the 5th battalion of the Lancashire Fusiliers (T.) in the days before the R.A.M.C. was constituted. He was also very proud of the honorary membership of the British Medical Association which was conferred upon him in his old age. While in retirement he was always ready to help his colleagues in Rickmansworth during periods of pressure, and he led, in fact, a very active life. His wife, formerly Miss Dorothy May Stead, died in 1953. He leaves two daughters.

Dr. G. M. ADDISON died suddenly at his home at Westgate-on-Sea on January 30 at the age of 52. George Montagu Addison was born on November 13, 1902, and was educated at Haileybury College, where he gained a science scholarship to Pembroke College, Cambridge. He went on to St. Thomas's Hospital for his clinical training and qualified M.R.C.S., L.R.C.P. in 1927, taking the degrees of M.B., B.Chir. in the following year. In 1929 he obtained the D.P.H. of the English Royal Colleges. After qualification he completed a number of hospital appointments, and then his interests turned to general practice. After practising for a time in London and Staines he went to Westgate-on-Sea in 1934. During the second world war he served in the R.A.M.C. from 1940 to 1945, through the Alamein campaign of 1941-3, and then in Europe from 1944 to 1945, attaining the rank of major. For most of his service he was employed as a hygiene officer, and in the spring of

1945 he was appointed a deputy assistant director of hygiene. After the war he returned to Westgate, where, in addition to the work of his practice, he was medical officer to St. Cecilia's Musicians Convalescent Home, the Salvation Army Eventide Home, St. Michael's Convalescent Home, and to various schools. He was also divisional surgeon to the St. John Ambulance Brigade and on the panel of the Ministry of Pensions and National Insurance. A former secretary of the Margate Medical Society, he was also secretary of the East Kent Division of the British Medical Association from 1936 to 1939. He was chairman of the standing committee of the chamber of commerce in Westgate at the time of his death.

Dr. W. G. SUTCLIFFE writes: Anyone who knew George Addison could not have failed to be impressed by his high moral integrity and his devotion to his profession. He had a keen sense of humour, and many will remember his happy way of cheering a dull meeting with his wit. He was not concerned with popular favour and never feared to express what he felt to be right. He showed great courage during the past year when, knowing his precarious state of health, he cheerfully continued to work and to support his family. He will be greatly missed in Thanet. Every sympathy is extended to his widow and to his two sons and eight daughters.

By the tragic death of Dr. LAWRENCE HENSHAW in an aeroplane accident on February 5 Nigeria has lost a particularly well loved citizen. Lawrence Michael Eken Richard Henshaw, who was born at Calabar in 1898, was educated at the Sacred Heart School there and at King's College, Lagos. He then acted as a dispenser for a time, work which helped him later when he went to Edinburgh University as a medical student. At Edinburgh he was one of a group of fellow Nigerians, many of whom have since made notable contributions to medical work in Nigeria. He graduated M.B., Ch.B. in 1927, and in the following year obtained the additional qualifications of L.M. and D.T.M.&H. before returning to Nigeria in 1928. He was employed as a member of the Nigerian Medical Service from the time he returned to his home country until 1952. Two years after he joined the Service he was granted the title of medical officer, a status which to-day would be given on entry, and in 1948 he was promoted to senior medical officer. Four years later he retired from Government service and became medical officer to the Palmol estate, near Calabar. He was appointed an honorary O.B.E. in the Birthday Honours of 1948.

We are indebted to Dr. CARMICHAEL WILSON for the following appreciation: It would be impossible to find anyone who was more popular with and more respected by all who knew him than Lawrence Henshaw, and he was known to many. As a colleague he was staunch and helpful and kind to all, no matter who they were. As a friend he could not be bettered, while his quiet joviality was a tonic to everyone, whether in hospital, at meetings, or in the home. His sterling worth and sound sense were well recognized, and he had been appointed to the governing body of the new University College Hospital at Ibadan. He was returning home from a meeting of the governing council of the Nigerian College of Arts, Science, and Technology, of which he was also a member, when he met his death. Nigeria and the Commonwealth have lost a very fine citizen who will be deeply mourned by his many friends, and not least by me.

McK. McC. writes: Colonel GEORGE A. MOORE, whose obituary was published in the *Journal* of February 19 (p. 485), was a keen and capable soldier. I first met him as D.D.M.S. of the divisions west and south of Armentières. We of the 40th division had come up from south of Arras after the great German attack of March, 1918, and were put into the front at Fleurbaix next to the Portuguese division. He knew we were to be attacked and probably driven back, and wisely prepared us all for this eventuality. The attack was not long in coming, but, thanks to Colonel Moore's

admirable administration, our losses were not heavy, though our right flank was in the air with the enemy between the ambulances and our own front line. After his retirement from the Service in 1921 he opened his house in Redcliffe Square, S.W.10, as a surgery and took up general practice. His paternal outlook on everyone endeared him to his patients, who worshipped him. During the air raids the sirens were a call to him to open his surgery and prepare tea for all of his patients who cared to come. The fearful moments were less fearful to them because of his bravery, generosity, and real Christian affection. One of his great loyalties was to all Irish graduates in and around London. He had been president of the Irish Medical Schools and Graduates Association in 1934 and continued to serve on the council, the meetings of which he rarely failed to attend. His last attendance was two days before he died. He will be missed by many of his former patients in the Redcliffe Square area, where his tall and erect soldier-like figure was so well known. He will never be forgotten by those who knew him, because of his constant charitable benevolence to his fellow men and women.

The obituary of Mr. PHILIP TURNER was printed in last week's *Journal* at p. 545. A.E.S. writes: Mr. Philip Turner was a great gentleman: quiet, somewhat shy, and always courteous. I learned from him as a dresser at Guy's. His surgery was anatomical and with minimum trauma. In later years I often saw him at the Hornsey Central Hospital. Once I met him unexpectedly in the Grand Hotel, Sheffield. He was held in respect and affection by all.

Mr. R. AFFLECK GREEVES writes: Having been privileged to diagnose and treat Lieutenant-Colonel G. E. Malcomson's eye trouble, to which Lieutenant-General Sir Ernest Bradfield refers in his appreciation (*Journal*, February 19, p. 483), I should like to correct a misapprehension on Sir Ernest's part. What Colonel Malcomson suffered from was not a retinal detachment but a bilateral paracentral choroiditis, which cleared up after the elimination of oral sepsis, leaving him with perfect central vision in one eye and slightly reduced visual acuity in the other.

Medico-Legal

MEDICAL REPORTS IN LITIGATION

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On October 1, 1954, sweeping amendments in the procedure of the High Court were brought into force in order to make a start in implementing the recommendations of the Evershed Committee. These are aimed at reducing the cost of litigation. Broadly speaking, Masters of the Supreme Court were given much wider powers than they had hitherto enjoyed to ensure the exclusion before an action reaches the stage of trial of all unnecessary expense in properly defining what is at issue between the parties, and in preparing the evidence on both sides which will be necessary for the decision of that issue at the trial.

In cases in which medical evidence is required, Masters were empowered to order at the hearing of the summons for directions that a medical report should be agreed if possible, and, if not, that the number of medical witnesses to be called by each party should be restricted. It has of course been and will remain a common practice for joint medical examinations to be made and joint medical reports to be used in litigation if there is no real difference of opinion between the doctors advising both sides, and the joint report can by agreement then be used in evidence without either side's doctor being called.

The scope of the Master's new powers in this respect was recently discussed in the Court of Appeal in the case of

Worrall v. Reich.¹ That was an action for damages for personal injuries, and on the summons for directions the Master ordered: "Exchange medical reports; if not agreed, the medical evidence be limited to two witnesses for each party." This order was upheld by Mr. Justice Glyn Jones in chambers.

On appeal to the Court of Appeal it was decided that the order, in so far as it directed the exchange of medical reports, was invalid in that they were documents made on behalf of either party on the advice of their legal advisers in preparation for the trial and therefore privileged from disclosure. Although in some circumstances it might be desirable from the practical point of view that medical reports should be exchanged, and although it might be highly expedient that the parties should adopt that course by agreement in many cases, it could not properly be made the subject of an order.

DEATH FROM PINK DISEASE

A verdict of accidental death from pink disease was recorded on February 22 at Stoke-on-Trent on an 11-months-old baby boy. The coroner, Mr. G. W. Huntbach, said that the disease was due, not as at first thought to teething powders, but to legally prescribed grey tablets (hydrarg. cum cret.).

The baby had been healthy until about November, 1954, when he was said to have had teething trouble. The father bought some teething powders. These were Steedman's new type of powder and were shown to contain no mercury. On January 13, 1955, Dr. A. G. Mowat, the family doctor, prescribed 12 tablets of hydrarg. cum cret. because the child had a slight digestive disorder, irritability, and pains in the head, and from January 14 for the next six days the mother administered 2 tablets a day to the baby in accordance with instructions. The baby got no better, and on January 26 was admitted to hospital suffering from pink disease. After improving somewhat, the baby became restless and pyrexial on February 2 and died on February 3.

At necropsy the liver was found to show slight fatty degeneration, the kidneys on both sides contained granular casts, and both lower lungs were congested. Chemical analysis carried out by Mr. F. L. Cann, of the West Midland Forensic Science Laboratory, showed that a specimen of kidney contained 500 µg. of mercury, a liver specimen 130 µg., and a brain specimen 40 µg. Dr. C. Giles, consultant pathologist at the City General Hospital, confirmed the necropsy findings and agreed that death was from pink disease due to the ingestion of mercury.

DEATH FROM SENSITIVITY TO AMETHOCAINE

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On January 17, 1955, Thomas Traynor, a ship's cook aged 62, was admitted to Broadgreen Hospital, Liverpool, for chest investigations for suspected bronchial carcinoma. He was also suffering from a peptic ulcer. On February 10 he was to have had a bronchogram carried out. He was given an amethocaine lozenge to suck, to indicate whether or not he was allergic to amethocaine. As he showed no reaction, half an hour later as a preliminary to undertaking the bronchogram his throat was sprayed with $\frac{1}{4}$ to 1 ml. of amethocaine solution. During this procedure he suddenly collapsed, had a convulsive fit, and died within three minutes.

At the inquest held by the Liverpool City Coroner on February 12 the pathologist at Broadgreen Hospital, Dr. Francis Whitwell, gave evidence that in his opinion death was caused by convulsions due to sensitivity to amethocaine, and that there was no satisfactory test for hypersensitivity. Sections of the deceased's lungs showed that bronchial carcinoma was in fact present.

Medical Notes in Parliament

PEACEFUL USES OF ATOMIC ENERGY

A motion introduced by Mr. RONALD BELL (South Buckinghamshire, Con.) on February 25 gave M.P.s an opportunity to express their hopes of the benefits to be gained from the peaceful application of atomic energy, and the use of radioactive isotopes in research, medicine, industry, and agriculture. All those who spoke shared Mr. Bell's purpose, to turn public attention to beneficial developments which had been going on unnoticed in the shadow of the great bomb explosions.

The first anxiety that was expressed was about the shortage of scientific man-power; it was said that the existing atomic programme could absorb the total output of physics graduates from British universities for several years. And the first satisfaction was that there would be no sulphurous fumes from the atomic fission generators of electric power. There was also general agreement on safety: the new atomic power stations to be built were inherently safe; the reactors could not run away and turn into junior atomic bombs, as some people seemed to fear.

Mr. BERNARD BRAINE (Billerica, Con.) questioned whether sufficient money was being spent on research, particularly in comparison with what the United States was doing. He suggested that there was a strong case for examining the finance provided for medical research in such matters as radiation sickness. The budgets of the Medical Research Council and the Ministry of Health were stretched to the uttermost. He urged that financial help should be given directly to this very special and expensive research.

Disposal Problems Solved

Mr. NIGEL BIRCH, Minister of Works, had to devote much of his reply to questions that had been asked about the £300m. capital investment programme for nuclear power stations. But on safety matters he was able to say that the most stringent precautions were taken—some people thought them too stringent—and the record had been extraordinarily good. Great advances were being made in the disposal of radioactive waste. The method depended on the degree of radioactivity; some went into the air, some was piped out to sea, some was taken in steel or concrete containers and dumped 1,000 miles out at a depth of 2,000 fathoms, and some of the very dangerous stuff had to be stored. There were some waste products, such as strontium⁹⁰ and caesium¹³⁷, that were particularly dangerous, but techniques were being evolved to put them to useful work. Caesium, for example, could be used for medical purposes. The point was that this was a manageable problem. If all electricity in the country was produced from nuclear power the dangerous products would amount to only one or two tons a year. There really was no danger, and the natural fears of the unknown that had been aroused were unnecessary.

"HORROR COMICS" BILL

The Children and Young Persons (Harmful Publications) Bill got its second reading on February 22, after some severe buffeting in debate. It is one of those measures of which all approve the end but many have serious doubts about the means chosen to ensure them, and substantial alterations will be proposed during the committee stage. No one disputed the basis on which the Home Secretary presented the Bill, to make special provision for the protection of children and young persons against the depraving effects of "horror comics." But there was vigorous criticism of the failure to deal with the whole law of obscenity in literature, on the lines suggested by the Society of Authors, instead of introducing this piecemeal measure, and serious doubts were expressed that even so its language was so wide as to endanger publishers and printers. It was apparent from the debate that in the subsequent stages efforts will be made to limit the duration of the Bill, so that its effects shall not continue and be liable to misuse after the reasons for its

introduction had disappeared; to secure that all prosecutions taken under it should be with the assent of the Director of Public Prosecutions, in order to avoid the confusion caused by different benches of magistrates taking widely different views on the extent to which pictures might tend to corrupt children; and to define more explicitly the element of intent.

Cadmium Poisoning Report

Mr. HAROLD WILSON (Huyton, Lab.) asked the Minister of Labour on February 24 what machinery existed for ensuring that the deaths through cadmium poisoning of workers employed at copper refineries were reported to the department, and whether he was satisfied that the machinery resulted in the notification of all such deaths. Mr. HAROLD WATKINSON, Parliamentary Secretary, said that any death resulting from acute cadmium poisoning at premises under the Factories Acts would be notifiable as an accident in accordance with those Acts, and satisfactory machinery existed for such notification. The question of ill effects from long-continued exposure to small amounts of cadmium was being carefully studied in the light of the recent report prepared by a member of the staff of the Medical Research Council and other available evidence both positive and negative. Mr. WILSON said the reason some of the deaths were not reported was that the disease was not generally known about. He had obtained no fewer than six certificates from registrars showing cadmium poisoning to be the cause of death, and these had not been notified to the Ministry. Mr. WATKINSON said that if Mr. Wilson would let him have the evidence it would be considered in conjunction with Dr. Bonnell's report, which was being given the most urgent attention.

Lead Poisoning Among Children

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) questioned the Minister of Health about lead poisoning occurring among children, and whether the public appreciated the danger of using paint containing lead on woodwork that children might handle. He also sought information about the deaths of two children in Manchester Children's Hospital. Miss PAT HORNSBY-SMITH, Parliamentary Secretary, replying on February 21, said that such cases were not notifiable. There were 11 deaths among children ascribed to lead poisoning in the five years ending September, 1954. Of the seven deaths from 1952 to 1954 none was reported as showing signs of lead encephalopathy; information was not available for the other deaths. Serious danger arose only when in rare cases a child developed a peculiar appetite for chewing articles containing lead which resulted in cumulative poisoning. Lead paint had been the most frequent reported cause, apart from one recent outbreak due to the use of old battery cases as fuel on domestic fires. One of the two children who died in the Manchester Hospital was stated to have chewed furniture and toys and the source of poisoning was paint; information on the second case could not be obtained. The Department had issued notes to a number of widely read journals suggesting that their readers should be warned of the danger, particularly when repainting furniture or walls, and the Minister was glad of this further opportunity of making known this occasional hazard.

Tuberculosis in Immigrants

Mr. SOMERVILLE HASTINGS (Barking, Lab.) asked the Minister of Health on February 21 what precautions were taken to ensure that immigrants from Ireland and elsewhere were not carriers of infectious pulmonary tuberculosis, and what inquiries were made to ascertain whether such immigrants had or had not been inoculated against this disease. Mr. IAIN MACLEOD stated that every person, British or alien, coming to this country was subject to the ordinary health control at the port of entry. An alien immigrant was in addition examined by a medical inspector of aliens; if tuberculosis was discovered or suspected, the medical inspector would issue a certificate to that effect and permission

to land would normally be refused. Citizens of the Republic of Ireland were not aliens. The answer to the second part of the question was "None."

Radiation Hazards in Industry

Mr. HAROLD DAVIES (Leek, Lab.) asked the Minister of Labour on February 24 what steps he was taking to study and limit radiation hazards in the health of workers exposed to ionizing radiations, and whether he would consult the Minister of Fuel and Power about the occupational health problems that might arise as a result of the programme of nuclear power development. Mr. HAROLD WATKINSON, the Parliamentary Secretary, stated that the precautions taken at factories to protect workers from ionizing radiations were carefully watched by the Inspectorate of Factories, which was notified by the Atomic Energy Authority of all consignments of radioisotopes supplied by them to factories. The Chief Inspector had also issued an advisory booklet on *Precautions in the Use of Ionizing Radiations in Industry*. He was considering, in consultation with the Chief Inspector, whether, in addition to the general requirements of the Factories Acts, more detailed special regulations would be desirable for factories using ionizing radiations. In all such matters he had the benefit of the expert advice of a radiological advisory panel, of the statutory advisory committee appointed under the Radioactive Substances Act, 1948, and of the Atomic Energy Authority itself. He was in consultation with the Minister of Fuel and Power regarding the measures that would be necessary for the protection of the health of the workers in the projected atomic power stations.

Civil Estimates

The Vote on Account for 1955-6 presented to Parliament on February 21 shows that expenditure on the National Health Service is estimated at £463,370,000, an increase of £24m. over the previous year.

Harley Street Cable.—The POSTMASTER-GENERAL said that he very much regretted the inconvenience caused to telephone subscribers in the Harley Street and Wimpole Street area. The Post Office had had to replace a section of a large cable which was in a very bad condition. By working day and night the job was finished in three weeks. They did all they could to minimize interruptions, but were seeing if it was possible in such cases to give subscribers a better system of warning.

Chiropody.—Mr. MACLEOD said that he would like to see a chiropody service available for all who would benefit from it, but financial considerations at present rule out any extension of the existing limited facilities.

Thames Pollution.—The very extensive technical investigations into the causes of pollution of the River Thames of the Water Pollution Research Laboratory have been completed. The results are being analysed; and it is hoped that in the next few months they will be ready for consideration by the departmental committee of the Ministry of Housing and Local Government.

Silicosis Claims.—In 1953 the Silicosis Medical Board dealt with 465 applications under the Workmen's Compensation Acts for certificates of death in respect of coal-miners; in 330 of these cases it was certified that death was due to silicosis or pneumoconiosis and in 135 cases it was certified that death was not due to the disease.

Universities and Colleges

UNIVERSITY OF ST. ANDREWS

The following candidates have been approved at the examinations indicated:

M.B.—Mrs. D. Avril J. Oatway (with commendation), B. O. Igwebe, M.B. Ch.B.—Sheila E. Cheong, J. S. Cook, J. L. Cribb, Rene Datner, P. A. E. Edmundson, J. G. McDonald, Anne M. MacGillivray, A. J. Mackenzie, J. A. C. Macmillan, Yvonne D. Symon, A. R. Taylor, Anne M. Thomson, Mrs. Sheila K. Tod, T. H. E. Woods.

UNIVERSITY OF LONDON

The following have been nominated for appointment as representatives of the University on the governing bodies indicated in parentheses: Professor C. G. Rob (St. Mary's Hospital); Mr.

J. D. S. Flew (University College Hospital); Mr. D. K. Mulvany (Laycock Secondary School); Professor J. M. Mackintosh (London School of Economics and Political Science); Dr. E. R. Boland (General Medical Council).

Professor W. J. Hamilton has been appointed a representative of the Board of Preclinical Studies on the Board of Advanced Medical Studies, in place of Professor J. Whillis.

Professor J. A. C. Knox has been appointed a member of the Special Advisory Board in Dietetics, Nutrition, and Household Science.

The following have been recognized as teachers of the University in the subjects indicated in parentheses: *Institute of Obstetrics and Gynaecology*, Dr. A. E. Claireaux (Pathology), Dr. J. C. Houston (Medicine), *London Hospital Medical College*, Dr. J. R. Ellis (Medicine), *St. George's Hospital Medical School*, Dr. C. W. Kesson (Children's Diseases), *King's College*, Dr. J. L. Mackinnon (Anatomy), *Middlesex Hospital Medical School*, Dr. J. D. N. Nabarro (Medicine), Dr. Margaret D. Snelling (Radiology), *Royal Dental Hospital of London School of Dental Surgery*, H. M. Pickard, F.D.S., M.R.C.S., L.R.C.P. (Dental Surgery), *St. Mary's Hospital Medical School*, Dr. P. H. Sanderson (Medicine).

UNIVERSITY OF WALES

The following degrees were conferred in Congregation on January 22:

M.B., B.Ch.—Inez Davies, W. J. Evans, R. Griffith, Margaret D. James, I. R. Lewis, H. K. Lloyd, O. McCann, V. J. Nash, B. L. P. Nelson, Jeanine Olsen, H. V. Price, I. P. Vaughan, R. N. Wade, C. G. Young.

UNIVERSITY OF BIRMINGHAM

Dr. K. H. Ginzal has been appointed Senior Research Fellow in Neuropharmacology in the Department of Experimental Psychiatry from April 1, 1955, and Dr. J. Williams Lecturer in Anatomy from July 1, 1955.

Mr. D. M. Morrissey resigned his appointment as Lecturer in Surgery on December 31, 1954.

The first line of the seventh paragraph under the heading "University of Birmingham" in the *Journal* of December 11, 1954 (p. 1428), should read "The title of University Clinical Tutor has been conferred," instead of University Clinical Lecturer.

The following degrees were conferred in Congregation on December 17, 1954:

Ph.D. in the Faculty of Medicine.—Deirdre M. Edward, M.B., Ch.B.—Yaw Asififi, P. H. Asififi, Joyce E. Bailey, Patricia A. Bramley, J. Bullock, E. P. C. Hadley, Olga R. Harbron, Eli E. L. Holt, J. W. P. Jarrams, D. Learmont, A. P. Mayne, E. T. Melley, W. K. Merfield, K. Middleton, J. D. Nicholas, P. A. North, L. J. T. Pearson, A. Sutherland, Elizabeth M. Tilsen, D. Wright, R. A. Yeomans.

SOCIETY OF APOTHECARIES OF LONDON

The following candidates, having completed the final examination, have been granted the diploma of L.M.S.S.A.:

R. N. Wade, P. M. Gurrin, P. Jago, F. R. F. Dibb, T. Freilich, A. P. Brown, E. A. Capell, D. A. Bennett, J. E. Todd, J. A. Bradford.

The following candidates have been awarded the Diploma of Master of Midwifery:

A. P. Camilleri, S. Miller.

The following candidates have been awarded the Diploma in Industrial Health:

Z. Khan, W. H. Suffield.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At a meeting of the Council of the College held on January 29, with the President, Sir Arthur Gemmell, in the chair, Professor B. P. Watson was appointed William Meredith Fletcher Shaw Memorial Lecturer for 1955.

The following were elected to the Membership of the College:

R. H. O. Bannerman, D. Barron, H. R. C. Benny, D. B. Brown, T. I. Cope, A. C. Coulthard, K. D. Drayton, W. A. W. Dutton, B. A. Gavourin, H. S. Gavourin, T. S. Ghosh, A. P. B. Harston, B. O. Howie, Beryl M. Joles, M. Konar, Wendy E. Lewington, J. D. Llewellyn-Jones, Philippa M. Ludlam, C. F. Macdonald, J. G. Mathie, A. M. Mendis, D. Methuen, Catherine H. Mitchell, N. G. Mukherjee, R. N. Nag, Chiew Seng Oon, S. Proshan, R. T. Scars, H. B. Sinha, D. H. K. Soltan, O. S. Treisman, Yin-Kai Tsao, J. K. Tully, J. A. M. Van Belkum.

The following have been awarded the Diploma in Obstetrics: L. C. Steindel, D. C. Wilkins.

FACULTY OF RADIOLOGISTS

At the examination for the Fellowship of the Faculty held in November, 1954, the following satisfied the examiners:

Radiodiagnosis—R. G. Britt, S. Davis, J. G. Duncan, R. G. Grainger, J. B. Heaz, J. W. Laws, H. F. March, L. L. Ralph, W. Stachurko. *Radiotherapy*—E. W. Emery, H. G. Frank, R. W. Gunderson, P. B. Kunkler, K. A. Newton, T. M. Prosser.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending February 12 (No. 6) and corresponding week 1954.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Vital Statistics

Influenza

In the great towns of England and Wales 82 deaths from influenza were recorded in the week ending February 19. This total was 2 fewer than the previous week's. 42 deaths were recorded in Greater London, compared with 29 in the previous week, making the highest weekly total this winter.

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in January was 109, compared with 120 in the previous month and 132 in January, 1954.

The number of cases of industrial diseases in the United Kingdom reported during January, 1955, were as follows: lead-poisoning 2, compressed air illness 2, epitheliomatous ulceration 18, chrome ulceration 20; total 42.

There was one death from epitheliomatous ulceration, due to mineral oil.—*Ministry of Labour Gazette*, February, 1955.

Week Ending February 19

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 682, whooping-cough 1,910, diphtheria 16, measles 19,976, acute pneumonia 1,020, acute poliomyelitis 21, dysentery 1,145, paratyphoid fever 3, and typhoid fever 4.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the nine years 1946-54 (influenza 1952-4) are shown thus -----, the figures for 1955 thus ———. Except for the curves showing notifications in 1955, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest variations in the notifications of infectious diseases in England and Wales during the week ending February 12 were increases of 5,634 for measles, from 12,729 to 18,363, and 131 for dysentery, from 979 to 1,110, and decreases of 148 for whooping-cough, from 2,213 to 2,065, and 45 for scarlet fever, from 791 to 746.

The largest rises in the incidence of measles were 1,018 in Yorkshire West Riding, from 1,853 to 2,871, 824 in Lancashire, from 2,453 to 3,277, 650 in London, from 1,295 to 1,945, 308 in Nottinghamshire, from 667 to 975, 299 in Northumberland, from 291 to 590, 268 in Essex, from 560 to 828, 250 in Cheshire, from 646 to 896, 247 in Derbyshire, from 531 to 778, 239 in Warwickshire, from 576 to 815, 216 in Durham, from 565 to 781, 212 in Middlesex, from 241 to 453. The largest falls in the local trends of whooping-cough were 36 in Warwickshire, from 133 to 97, 35 in Kent, from 137 to 102, and 30 in Essex, from 95 to 65. The only large decline in scarlet fever was 20 in Lancashire, from 126 to 106. 16 cases of diphtheria were notified, being 2 fewer than in the preceding week. 5 of the 14 cases of diphtheria were notified in Kingston-upon-Hull C.B. 16 cases of acute poliomyelitis were notified, and these were 3 more for non-paralytic and the same for paralytic cases as in the preceding week. The largest returns were London 3 and Middlesex 3 (Willesden M.B. 2).

The largest increases in the local outbreaks of dysentery during the week were Lancashire 93, Northampton 43, and Durham 34. The largest returns were Lancashire 461 (Oldham C.B. 128, Blackpool C.B. 94, Blackburn C.B. 73, Manchester C.B. 66, Stretford M.B. 20, Blackburn R.D. 10), Yorkshire West Riding 79 (Sheffield C.B. 29, Leeds C.B. 28), Durham 76 (Ryton U.D. 20, Durham R.D. 11), London 53 (Shoreditch 11), Northamptonshire 52 (Northampton C.B. 31, Kettering M.B. 17), Norfolk 48 (Norwich C.B. 29), Suffolk 40 (Woodbridge U.D. 33), Northumberland 37 (Newcastle-upon-Tyne C.B. 20), Glamorganshire 35 (Cardiff C.B. 14), Leicestershire 34 (Leicester C.B. 32), Lincolnshire 27

(Scunthorpe M.B. 15), Cheshire 26 (Stockport C.B. 14), Nottinghamshire 24 (East Retford M.B. 15), and Yorkshire North Riding 20 (Middlesbrough C.B. 19).

Medical News

World Population.—Since 1930 the population of the world has risen by 30%, according to estimates in the 1954 *United Nations' Statistical Yearbook*. In mid-1953 it stood at between 2,459 and 2,634 million, with a density of about 49 to the square mile (19 per sq. km.). These figures include an allowance of a little over 200 million, apparently, for the population of the U.S.S.R. The estimates of the populations of the individual continents (excluding figures for the U.S.S.R.) also include the densities. In persons per square mile (figures per sq. km. in parentheses), these were: Europe, 212 (82); Asia, 132 (51); North and South America, 20 (8); Africa, 17 (7); Oceania, 5 (2). The estimates of the continental populations (again excluding the U.S.S.R.) in descending order of magnitude are given as: Asia, 1,288-1,439 million; Europe, 400-404 million; North and South America, 347-355 million; Africa, 199-216 million; Oceania, 13.8-14.2 million.

Medical Man-power.—The news of the appointment of the committee under Mr. HENRY WILLINK, Q.C., to investigate Britain's medical man-power (*British Medical Journal*, February 26, p. 548) has provoked some immediate, anxious comment. Mr. ARTHUR BLENKINSOP, M.P., Parliamentary Secretary to the Ministry of Health in the last Labour Government, in a letter to *The Times*, is concerned that the committee should keep before it "the great need for a further reduction in the size of general-practitioner lists." He expresses surprise that the Government should even be "contemplating any form of restriction of entry into a profession," and notes the absence on the committee of "any representation of the public interest." The *Irish Times*, on the other hand, has been quick to see a possible threat to Irish doctors. "If a decision is taken in Britain to limit entry to the medical faculty," says the paper in an article on February 23, "a big problem will arise in the placing of Irish doctors, many of whom find openings in Britain."

Princess Louise Children's Hospital.—On February 24 the board of governors of St. Mary's Hospital decided to adopt the recommendations of their co-ordinating subcommittee on the conversion of the Princess Louise (Kensington) Hospital for Children to adult use (see *Journal*, January 29, p. 299). Two days earlier at a meeting held by the Kensington and Hammersmith Division of the B.M.A. and open to all members of the profession in these areas the following resolution had been passed unanimously by the 30 doctors present:

"Being satisfied as to the continuing needs of the sick children in the area, the medical practitioners of the Kensington and Hammersmith boroughs ask the Minister of Health to give serious consideration to the necessity for the Princess Louise Hospital to continue as a children's hospital serving the needs of the local population. We would further like to impress on the Minister that these needs should take priority over the teaching requirements of the St. Mary's Hospital Group."

This resolution was sent to the Minister of Health. It was also unanimously adopted by a meeting of the medical staff of the Princess Louise Hospital, which drew attention to similar resolutions passed by the council of the Royal Borough of Kensington and the Hammersmith Borough Council. The medical staff further deplored the proposed disbandment of the training school for children's nurses, "of which there are few in the country." In a statement the board of governors of St. Mary's say that they decided to inform the Minister of Health of their resolution only after giving careful consideration to the observations of

their standing committees and the Academic Board of St. Mary's Hospital Medical School, and to the representations of the borough councils of Kensington and Hammersmith.

Linstead Report.—The full text of the "Linstead Report"—in other words the report of a subcommittee of the Ministry of Health's Standing Pharmaceutical Advisory Committee of which Sir HUGH LINSTAD, F.P.S., M.P., was chairman—was published on March 3 (H.M.S.O., price 2s. net). The report deals with the Hospital Pharmaceutical Service. The terms of reference were to review the Service and advise on its most efficient and economical organization. The committee's recommendations were summarized in the report of the Central Health Services Council for 1953, published last July (see *British Medical Journal*, July 17, 1954, p. 146), but the present report, besides rehearsing the arguments which led to the recommendations, includes the comments on it of both the Central Health Services Council itself and the Standing Pharmaceutical Advisory Committee. The report has been adopted by both these bodies (subject to some reservations by individual members of the Standing Advisory Committee), and its recommendations on the place of the pharmaceutical department in the individual hospital, group organization, staffing and accommodation, and research have been accepted by the Minister; the remaining recommendations are stated to be "under consideration." The only medical member of the Linstead committee was Dr. JANET AITKEN.

Sheffield University.—The title of reader in forensic medicine has been conferred on Dr. GILBERT FORBES, senior lecturer in charge of the Department of Forensic Medicine. Dr. O. G. DODGE has been appointed lecturer in pathology. At the Jubilee Degree Congregation on June 29, the honorary D.Sc. of the University will be conferred on Lord ADRIAN, P.R.S.

Medical Research Council.—By an Order of the Committee of Privy Council for Medical Research, Mr. RICHARD FORT, M.P., has been appointed a member of the Medical Research Council in the vacancy created by the retirement of Mr. RICHARD WOOD, M.P.

Professor J. B. Duguid, professor of pathology at Durham University, who since January has been in Jamaica lecturing at the University College of the West Indies under the Commonwealth University Interchange Scheme, has now gone on to Colombia for a fortnight on behalf of the British Council.

Dr. Albert Schweitzer has been appointed by the QUEEN an honorary member of the Order of Merit. The only other living honorary foreign member is President Eisenhower.

News in Brief.—On February 24 the DUKE OF NORTHUMBERLAND opened a 4-million-volt linear accelerator unit at the Newcastle General Hospital costing a total of £65,000. The North of England Council of the British Empire Campaign contributed the cost of the building, which amounted to nearly £27,000.

At the Glasgow Royal Maternity and Women's Hospital on February 25 the COUNTESS OF ELGIN AND KINCARDINE opened a new £100,000 Out-patient Department.

The March issue of *Family Doctor* is now available.

COMING EVENTS

Institute of Dermatology, London.—Exhibition on benign tumours of the skin, March 4-25.

Harveian Lecture of the Harveian Society of London.—On March 7, at 8.15 pm., at the Royal College of Surgeons, Professor CLARENCE CRAFOORD will lecture on "The Diagnosis and Treatment of Intra-auricular Septal Defects." Open to all interested.

Faculty of Radiologists.—Postgraduate week-end course at the Royal College of Surgeons, Lincoln's Inn Fields,

March 19 and 20. Applications for enrolment (12s. 6d.) before March 12 from the Secretary of the Faculty, 45, Lincoln's Inn Fields, London, W.C.2.

Watson-Williams Memorial Lecture.—Mr. R. SCOTT STEVENSON will lecture on "The New Outlook in Otolaryngology" at Bristol University on March 8 at 8.30 p.m.

Oxford University Medical Society.—Annual Ball at Oxford Town Hall on March 11, 9 p.m. to 3 a.m. Double tickets (two guineas) from Mr. ALAN LOWER, New College, Oxford.

William Sheen Memorial Lecture.—Sir GLOFREY JEFFERSON will lecture on "The Aneurysms of the Cavernous Sinus" at the Reardon Smith Lecture Theatre, Cardiff, on March 16 at 8 p.m.

Oliver-Sharpey Lectures.—Professor W. MEVILL ARNOTT will lecture on "Order and Disorder in Pulmonary Function" at the Royal College of Physicians of London at 5 p.m. on March 17 and 22.

C.M.F./M.E.F. Army Physicians' Reunion.—Tenth annual dinner at Simpson's-in-the-Strand on April 2. Information from the honorary secretary, Dr. A. WHITCOX, 59, Harley Street, London, W.1.

British Occupational Hygiene Society.—Conference on "The Assessment of Health and Disease in Industry" at the London School of Hygiene and Tropical Medicine on April 4 at 11 a.m. Details from Dr. D. G. HARVEY, M.R.C. Laboratories, Holly Hill, Hampstead, London, N.W.3.

NEW ISSUES

Archives of Disease in Childhood.—The new issue (Vol. 30, No. 149) is now available. The contents include:

CONGENITAL DEFECTS IN THE PELVIC PARASYMPATHETIC SYSTEM. Orvar Swenson.
HIRSCHSPRUNG'S DISEASE IN THE NEONATAL PERIOD. Th. Ehrenpreis.
INTESTINAL OBSTRUCTION IN THE NEWBORN. H. H. Nixon.
PERITONITIS IN THE NEONATAL PERIOD. P. P. Rickham.
ACUTE INTUSSUSCEPTION IN CHILDHOOD. R. B. Zachary.
CONGENITAL DEFORMITIES OF MECHANICAL ORIGIN. Denis Browne.
CONGENITAL DEFORMITIES OF THE ANUS AND THE RECTUM. Denis Browne.
THE CARDIO-ESOPHAGEAL SYNDROME IN CHILDHOOD. Isabella Forshall.
TWO CASES OF ESOPHAGEAL STRICTURE IN CHILDHOOD. R. B. Zachary.
ACUTE DISTENSION OF THE GALL BLADDER IN CHILDREN. William Rankin.
A SURGICAL AND BIOCHEMICAL STUDY OF A CASE OF BILATERAL HYDRO-NEPHROSIS AND HORSESHOE KIDNEY. John Black and Joan Wagner.
SACRO-COCCYGEAL TERATOMA. James Lister.
CONGENITAL PYLORIC STENOSIS IN OLDER BABIES. John Rendle-Short and R. B. Zachary.

Issued six times a year; annual subscription £3 3s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, March 7

HARVEIAN SOCIETY OF LONDON.—At Royal College of Surgeons of England, 8.15 p.m., Harveian Lecture by Professor C. Crafoord (Stockholm): "Diagnosis and Treatment of Intra-auricular Septal Defects."
INSTITUTE OF PSYCHIATRY.—5.30 p.m., Dr. E. Stengel: Lecture-demonstration.
OXFORD UNIVERSITY MEDICAL SOCIETY.—At Radcliffe Infirmary, 8.15 p.m., Dr. F. E. Camps: The Notting Hill Murders.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Professor M. Arnot: Fever in Disease.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.—At Physiology Theatre, 4.45 p.m., Dr. Joseph Needham, F.R.S.: New Light on Physico-Chemical Aspects of Morphogenesis.

Tuesday, March 8

●**BRISTOL UNIVERSITY.**—8.30 p.m., Patrick Watson-Williams, Memorial Lecture by Mr. R. Scott Stevenson: "New Outlook in Otolaryngology."
●**CHELSEA CLINICAL SOCIETY.**—At Rembrandt Hotel, S.W., 8.30 p.m., discussion to be opened by Dr. Neville Gorton, D.D., Rt. Rev. the Lord Bishop of Coventry, and Dr. E. E. Claxton, Assistant Secretary, B.M.A.: "Divine Healing and the Medical Profession."
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. Phyllis Wade: Radiotherapy of Skin Cancers, Part I.
LONDON UNIVERSITY.—At Meyerstein Lecture Theatre, Westminster Medical School, 5.30 p.m., Special university lecture in biochemistry by Academician W. A. Engelhardt (Moscow): "Mechano-Chemistry of Muscle."
MEDICAL SOCIETY OF LONDON.—At Claridge's, 7.30 for 8 p.m., annual dinner.
MEDICAL WOMEN'S FEDERATION: SCOTTISH EASTERN ASSOCIATION.—At Pharmacology Lecture Theatre, Teviot Place, Edinburgh, 8.30 p.m., film by Professor Jan Aird: "Separation of Conjoined Twins."
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Dr. James Walker: "Postmaturity and Fetal Anoxia."
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Mr. J. Minton: "Ocular Manifestations in Clinical Neurology (Part I)."

Wednesday, March 9

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Mycotic Infections of Subcutaneous Tissues.
INSTITUTE OF LARYNGOLOGY AND OTITIS.—5.30 p.m., Dr. I. Friedmann: Pathology of Otitis Media: Experimental and Human (1).
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. F. R. Kilpatrick: Tuberculosis of the Renal Tract.
LONDON UNIVERSITY.—At Physiology Theatre, University College, 5.30 p.m., special university lecture in physiology by Dr. C. R. Skoglund (Stockholm): Functional Organization of Spinal Interneurons.
NOTTINGHAM MEDICO-CHIRURGICAL SOCIETY.—8.30 p.m., Mr. J. H. Daggart: Ocular Manifestations of Systemic Disease.
OXFORD UNIVERSITY.—At Radcliffe Infirmary, 5 p.m., Litchfield Lecture by Professor C. A. Wells: Experimental Approach to Surgical Problems.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. Dorothy Makepeace: Some Medical Aspects of Child Care.
ROYAL SANITARY INSTITUTE.—2.30 p.m., Dr. W. G. Patterson and Dr. S. L. Wright: Co-operation Between Local Health Authorities and the Hospital Service—Possibilities and Actualities.
ST. MARYLEBONE HOSPITAL FOR PSYCHIATRY AND CHILD GUIDANCE.—5.30 p.m., Dr. E. A. Bennet: Selection of Patients for Psychotherapy.

Thursday, March 10

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. Phyllis Wade: Radiotherapy of Skin Cancer, Part II.
LIVERPOOL MEDICAL INSTITUTION.—8 p.m., Mr. D. H. Young: Surgical Aspects of Male Infertility; Mr. F. C. Dwyer: Suppurative Arthritis of the Hip-joint in Childhood.
LONDON UNIVERSITY.—At Senate House, 5.30 p.m., special university lecture in pharmacy by Professor P. Karrer (Zurich): Curare—Alkaloids.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor G. C. Foster-Smith: Place of the Vascular Supply in Fatigue and Regeneration of Peripheral Nerve.
ROYAL EYE HOSPITAL.—5.30 p.m., Dr. T. H. Whittingham: Some Aspects of Refraction Work: (3) Refraction Work: Our Tools and Apparatus.
ST. ANDREWS UNIVERSITY.—At Physiology Department, Medical School, Small's Wynd, Dundee, 5 p.m., Dr. W. C. Swanson: Review of Carcinoma of the Breast in the Eastern Region.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. D. J. Williams: neurology demonstration.
WHITTINGHAM HOSPITAL.—At Archway Wing, 8.15 p.m., Dr. L. F. Hewitt: Bacterial Viruses and Heredity.

Friday, March 11

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. B. F. Russell: Benign Tumours of the Skin.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., clinical demonstration by Dr. J. Smart: Bronchitis.
INSTITUTE OF LARYNGOLOGY AND OTITIS.—3.30 p.m., Dr. I. Friedmann: Basis of Chemotherapy in E.N.T. Disease.
LONDON UNIVERSITY.—(1) At Physiology Theatre, University College, 5.30 p.m., special university lecture in physiology by Dr. C. R. Skoglund (Stockholm): Functional Organization of Spinal Interneurons. (2) At Senate House, 5.30 p.m., special university lecture in pharmacy by Professor P. Karrer (Zurich): Curare—Alkaloids.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. W. G. Oakley: Periphrastic Vascular Disease.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Urology Lecture by Mr. D. S. Poole-Wilson: Treatment of Tumours of the Bladder.
ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Dr. Thomas Anderson: Antibiotics.
ROYAL MEDICAL SOCIETY, Edinburgh.—8 p.m., Valedictory Address by the Senior President.
SOCIETY OF MEDICAL OFFICERS OF HEALTH: WELSH BRANCH.—At Park Hotel, Cardiff, 7 for 7.30 p.m., annual dinner.

Saturday, March 12

KENT PAEDIATRIC AND CHILD HEALTH SOCIETY.—At Queen's Head Hotel, Maidstone, 3 p.m., Presidential Address by Dr. P. R. Evans: Baby Farming.

APPOINTMENTS

BROWN, R. J. K., M.B., B.Chir., M.R.C.P., D.C.H., Senior Lecturer, Department of Child Health, Welsh National School of Medicine, Cardiff.
EAST ANGLIAN REGIONAL HOSPITAL BOARD.—J. R. Thompson, M.Chir., F.R.C.S., Consultant Surgeon, Peterborough and Stamford Hospital Group; R. E. B. Taggart, M.Chir., F.R.C.S., Consultant Surgeon, Newmarket General Hospital; G. C. Foster-Smith, M.R.C.S., L.R.C.P., D.A., Assistant Anaesthetist, Norfolk and Norwich Hospital Group; J. Littlejohn, L.R.C.P.&S.Ed., and Dorothea M. Norman-Jones, M.B., B.Chir., D.P.H., D.P.M., Registrars in Psychiatry, Fulbourn and Addenbrooke's Hospitals; Joan McConnell, M.B., B.Chir., Registrar in Psychiatry, St. Andrew's Hospital, Norwich; R. H. V. Ollendorff, M.R.C.S., L.R.C.P., Registrar in Psychiatry, Ipswich Mental Hospital Group; A. K. Miura, F.R.C.S., Orthopaedic Registrar, East Suffolk and Ipswich Hospital and Ipswich Borough General Hospital; Elizabeth L. Brown, M.B., Ch.B., Medical Registrar, Nayland Sanatorium; W. S. Grove, M.B., B.Chir., Medical Registrar, Foxhall Hospital, Ipswich; J. C. S. Ainley-Walker, B.M., B.Ch., D.A., Anaesthetic Registrar, United Norwich Hospitals; Kathleen M. McNamara, L.R.C.P.&S.J., Anaesthetic Registrar, Peterborough Memorial Hospital and Annexes; J. A. Scanlon, M.B., B.S., Anaesthetic Registrar, West Suffolk General Hospital.
FRANKLIN, J. A. C., M.B., B.S., D.P.H., Deputy County Medical Officer of Health and Deputy Principal School Medical Officer, Essex County Council.
GREGG, THOMAS JAMES MYLES, O.B.E., M.B., B.Ch., Regional Medical Officer, with the Welsh Board of Health for duty in South-west Wales Area.
HILL, EILEEN E., M.B., Ch.B., M.R.C.P., Paediatric Registrar at Churchill Hospital, Headington, Oxford.
KINGSTON-UPON-HULL HEALTH DEPARTMENT.—R. G. Davies, M.D., D.P.H., Deputy Medical Officer of Health and Deputy Principal School Medical Officer for the City and County of Kingston-upon-Hull, Deputy Medical Officer of Health (at Hull) to the Hull and Goole Port Health Authority and Medical Inspector of Aliens under that Authority; Margaret I. Hendrie, M.D., D.P.H., D.C.H., D.Obst.R.C.O.G., Senior Medical Officer for Maternity and Child Welfare for the City and County of Kingston-upon-Hull.
LIVERPOOL REGIONAL HOSPITAL BOARD.—Jane I. Gibson, M.B., Ch.B., Consultant Pathologist to Birkenhead and North Wirral Groups; B. H. McGuirk, M.R.C.S., L.R.C.P., F.F.A.R.C.S., D.A., Part-time Consultant

Anaesthetist for Chester and Wirral Areas; C. H. de Boer, M.B., B.Chir., F.R.C.S., M.R.C.O.G., Part-time Consultant Obstetrician and Gynaecologist to Liverpool Maternity Hospital, the Women's Hospital, and Warrington General Hospital (appointed jointly with United Liverpool Hospitals).
MACKENZIE, A. C., M.D., D.P.H., Medical Officer of Health for Borough of Shrewsbury and member of staff of Salop County Medical Officer of Health.

NORTH-WEST METROPOLITAN REGIONAL HOSPITAL BOARD.—A. P. H. Randle, M.R.C.P., D.Phys.Med., Consultant in Physical Medicine, Garston Manor and Mid-Herts and Luton and Hitchin Groups; J. A. Robertson, M.B., M.R.C.P., Consultant General Physician, Brentford Hospital and Teddington, Hampton Wick, and District Hospitals; S. Davis, M.B., M.R.C.P., D.M.R.D., Consultant Radiologist, Royal Northern Hospital, Wood Green and Southgate Hospital, and Highlands Hospital; Barbara E. Woodhead, M.B., M.R.C.P., D.P.H., D.P.M., Consultant Psychiatrist, Tavistock Clinic; H. H. G. Eastcott, M.S., F.R.C.S., Consultant in General Surgery, St. Mary's Hospital and the North-west Metropolitan Regional Hospital Board (Paddington General Hospital) (joint appointment); Cecil F. Statham, M.B., B.S., D.R.C.O.G., D.A., Assistant Anaesthetist (S.H.M.O.), Royal Northern Hospital; R. R. Wilson, M.D., Consultant in Morbid Anatomy, North-western Group Laboratory; M. J. Gilkes, M.B., F.R.C.S., Consultant Ophthalmologist, Royal London Homoeopathic Hospital; J. F. K. Muir, M.B., F.R.C.S., Consultant in Plastic Surgery, West Middlesex Hospital and the Regional Centre for Plastic Surgery and Jaw Injuries, Mount Vernon Hospital; O. Garrad, M.D., M.R.C.P., Consultant Physician, Barnet General Hospital; E. E. Bullock, L.M.S.S.A., D.Phys.Med., Assistant Physician in Physical Medicine (S.H.M.O.), Edgware General Hospital; H. F. Lunn, M.B., F.R.C.S., Senior Casualty Officer (S.H.M.O.), Watford Peace Memorial Hospital; M. F. Hart, M.D., M.R.C.P., Assistant Physician in Physical Medicine (S.H.M.O.), Mount Vernon Hospital and Northwood, Pinner and District Hospital.
ROADS, P. G., M.D., D.P.H., Deputy Medical Officer of Health, County Borough of Sheffield.

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—A. F. Barnett, M.D., M.R.C.P., Senior Medical Registrar to Plymouth Clinical Area; A. Gordon, M.B., Ch.B., Registrar to Department of Pathology at Frenchay Hospital, Bristol; D. de G. Villet, M.B., Ch.B., F.R.C.S., Surgical Registrar at Gloucestershire Royal Hospital, Gloucester; G. A. Cutler, M.B., B.S., Registrar in Obstetrics and Gynaecology to Bath Group of Hospitals; G. R. Fearley, M.D., M.R.C.P., Consultant Physician to North Gloucestershire Clinical Area; E. R. Jones, M.R.C.S., L.R.C.P., D.P.M., Assistant Psychiatrist at Mendip Hospital, Wells.
UNITED LEEDS HOSPITALS BOARD.—A. E. Wall, M.Sc.Physiol., M.B., Ch.B., F.R.C.S., Consultant Assistant Surgeon in Department of Neurosurgery, United Leeds Hospitals, and Consultant Neurosurgeon in hospitals under control of Leeds Regional Hospital Board; J. A. Aylwin, M.B., Ch.B., F.R.C.S., Consultant Assistant Surgeon in Department of Thoracic Surgery, United Leeds Hospitals, and Consultant Thoracic Surgeon in hospitals under control of Leeds Regional Hospital Board. Both part-time appointments.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

DAVIDSON.—On February 21, 1955, to Dorothy (formerly Harpur), wife of Arthur S. Davidson, M.B., F.R.C.S.Ed., D.L.O., of Cranleigh Road, Kettering, Northants, a son.
DIXON.—On February 23, 1955, in Cardiff, to Megan, wife of Dr. J. M. S. Dixon, a son.
GEE.—On February 8, 1955, at Stoke-on-Trent, to Doreen, wife of Dr. C. Gee, a brother for Michael.
LECUTIER.—On February 22, 1955, at the Duke of York Home, Bradford, Yorks, to Angila, wife of E. R. Lecutier, F.R.C.S., a son—Philip Edmond.

DEATHS

BLACKMAN.—On February 19, 1955, at Malvern, Worcs, Geoffrey Gordon Barham Blackman, M.B., B.Chir.
BOWES.—On February 11, 1955, at St. Catherine's Nursing Home, Bath, Richard Frederick Bullin Bowes, M.R.C.S., L.R.C.P., of Fiveway House, Bathaston, Bath, Somerset.
BROWN.—On February 26, 1955, at Green Garth, Yealand Conyers, near Carnforth, Lancs, Edward Vipont Brown, M.D., formerly of Manchester, aged 92. Memorial service at Friends Meeting House, Mount Street, Manchester, March 8, 1.20 p.m.
BRUCE.—On February 14, 1955, at Budleigh Salterton, Devon, Oliver Bruce, M.R.C.S., L.R.C.P., aged 74.
EDWARDS.—On February 5, 1955, at his home, The Antlers, Rathdown, Co. Wicklow, Geoffrey Dixon Edwards, M.B., B.Ch., aged 62.
GILBERT-SMITH.—On February 3, 1955, in a nursing home, Thomas Bewley Gilbert-Smith, M.R.C.S., L.R.C.P., of Fountain House, Crowborough, Sussex, aged 79.
HATCHER.—On December 19, 1954, at Greenbank Hospital, Plymouth, Devon, Georgina Roberts Hatcher, M.B., Ch.B.
HAY.—On January 29, 1955, at 25, Aglionby Street, Carlisle, James William Hay, M.B., Ch.B., aged 56.
HUMBY.—On February 2, 1955, at Lynton, Hants, Daniel Morgan Humby, M.R.C.S., L.R.C.P., L.D.S.
LEWIS.—On February 4, 1955, at 5 Hamboro Gardens, Leigh-on-Sea, Essex, Arthur Daniel Lewis, M.R.C.S., L.R.C.P., formerly of Stoke Newington, London, N., aged 81.
MACGIBBON.—On February 5, 1955, in hospital, Stranraer, Wigtownshire, George MacGibbon, M.B., C.M., of 1, Windsor Terrace, Academy Street, Stranraer.
MACKENZIE.—On February 2, 1955, Donald William Morison Mackenzie, M.B., Ch.B., Lieutenant-Colonel, R.A.M.C., retired, of Plidown, Sussex.
MACKINNON.—On February 3, 1955, at 2, Herriet Street, Pollokshields, Glasgow, Mary Jessie Mackinnon (formerly Macdonald), M.B., Ch.B., of Portree, Isle of Skye.
MACRAE.—On February 4, 1955, in Devizes Hospital, Donald Mackenzie MacRae, C.B.E., M.D., of Southbrook Cottage, Devizes, Wilts.
ROBINSON.—On February 11, 1955, at 1, Coombe Rise, Kingston-upon-Thames, Surrey, Richard Deane Robinson, D.S.C., M.B., B.S., aged 48.
SEMPE.—On February 1, 1955, at the home of his son, Kintailon, Kilmacolin, Renfrewshire, Henry Frederick Sempe, M.R.C.S., L.R.C.P., of Sandown, Exmouth, and Budleigh Salterton, Devon.
SHAW.—On February 11, 1955, at Morchard Cottage, Hardington, Northampton, Emily Helen Shaw, M.D., wife of Dr. Eric H. Shaw.

Any Questions ?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Export of Drugs

Q.—Are there any restrictions on the drugs that (a) a doctor or (b) a patient may take with him out of this country for use abroad?

A.—No export duty is chargeable on goods leaving the United Kingdom. Information about the duties and restrictions on goods taken or imported into other countries may be obtained from the Board of Trade, Export Services Branch, Lacon House, Theobalds Road, London, W.C.1 (Tel. CHAncery 4411). The exportation from the United Kingdom of drugs restricted by the Dangerous Drugs Acts and Regulations made thereunder is prohibited unless authorized by a licence issued by the Home Office Drugs Branch, Whitehall, London, S.W.1, from which department full information concerning licences and the regulations can be obtained.

Certain other drugs—that is, those specified in Group 13 of the Export of Goods (Control) (Consolidated) Order, 1954 (S.I. 1954 No. 118), as amended—may not be exported without licence from the Board of Trade, Export Licensing Branch, Atlantic House, Holborn Viaduct, London, E.C.1. Notwithstanding the provisions of this Order, however, licences are not required for reasonable quantities of such drugs which a passenger proceeding overseas might be expected to carry with him or include in his unaccompanied luggage for his own regular and private use. Additionally, a doctor proceeding overseas will be permitted to take with him or include in his unaccompanied baggage without licence reasonable quantities of such drugs as are intended for his professional use abroad. It is to be noted, however, that special regulations apply to the exportation of drugs to China, Hong Kong, Macao, Tibet, and North Korea, and the concession does not apply in respect of these destinations.

Rorschach Testing

Q.—What is the Rorschach test? How is it performed, what does it measure, and how reliable is it?

A.—If a large irregularly shaped blot of ink is made on a piece of paper, which is then folded so that the blot is pressed between two sides of paper, and the paper is then opened out again, a complexly shaped pattern with bilateral symmetry is seen. The Rorschach test forms provide a series of such shapes, photographically reproduced from originals made many years ago. The subject is asked to look at them and to imagine meaningful figures in them if he can. His responses are recorded, and are subsequently interpreted by the aid of fixed rules.

Three classifications of the responses are made, by: (1) location—that is, responses to the whole or to a part of the pattern, to the dark part of the pattern or to the white part between; (2) content of what is visualized—that is, human or animal, or man-made objects, or landscapes or maps; (3) determinant—that is, responses to shading, texture, colour (three of the patterns are coloured), responses involving the feeling of movement, etc. The results of the whole of scores based on these classifications are then recorded in a profile, which is used, together with other observations, for diagnosis. Thus numerical ratios between responses of two kinds are considered of diagnostic value for some purposes. The skilled interpreter believes he is able to provide conclusions, both of a general and a particular kind, about (1) normal balance, (2) general personality structure, (3) intel-

lectual aspects, (4) emotional aspects, (5) clinical aspects. Under the latter heading the Rorschachist claims to be able to diagnose organic disease of the brain, neurosis, depression, mania, schizophrenia. As an example, organic disease is indicated by a low number of responses of poor quality, schizophrenia by many poor "whole" responses.

There can be no doubt that such a test procedure must elicit a large amount of information, and that the skilled interpreter, especially if he is using the test as part of a guided interview, can derive valuable insight into a number of aspects of the personality. The fixed forms by which interpretation is supposed to proceed have, however, never been validated; and properly conducted controlled experiments are scanty, unreliable, and incapable of bearing the huge theoretical superstructure which has now been built up.

Implantation Dermoids

Q.—A woman of 40 has had three implantation dermoids removed from her thumb in the past few months, and it appears that there may be more developing. Do some people show a tendency to develop this condition as other people do sebaceous cysts?

A.—There is scarcely enough information given to answer this question fully, although there is certainly no known inherent tendency to the development of these lesions. Is it certain that the swellings were indeed implantation dermoids and that on each occasion there was unequivocal evidence of complete removal? Is the patient's occupation such that penetrating or punctured injuries are likely?

To distinguish them from true dermoids these cysts are now usually called "epidermoid." They may be congenital or traumatic in origin, and in the latter instance the interval between the trauma and the development of the cyst may be considerable. Congenital ones are unlikely in the hand, and so it is probable that the present case is post-traumatic. The injury is commonly, but not of necessity, a puncture, but in some cases there is no history of penetration and the cyst is thought to arise from the migration of epithelial cells from the sweat glands into a damaged area containing exudate or haematoma. If completely removed they do not recur, but as they may occasionally be multilocular the possibility of small islets of epithelium remaining must be considered as a cause of recurrence. Epidermoid cysts have rarely been reported in the bony phalanges, and, as the removal of the subcutaneous extensions of such a lesion would not be permanently curative, it would be as well to settle this question by radiography.

Modern Haemoglobinometry

Q.—What are the more modern methods of carrying out a Hb estimation in the blood? What advantages have these over the Sahli method, and how accurate is the Sahli method compared with them?

A.—The report of the Medical Research Council Subcommittee on analytical methods for the estimation of haemoglobin was recorded in a series of eight papers printed in the *Lancet*, of which three are pertinent.¹ In the first of these it was shown that the Haldane, Gowers, Sahli, Tallqvist, Tintometer, and Dare instruments were about equally inaccurate, one estimate out of twenty differing from the mean by 17% or more (coefficient of variation 8.5 to 10.9%). There was little to choose between these, but the Tallqvist was appreciably better than the Sahli. A series of wedge colorimeters were compared and these were markedly better, the coefficient of variation falling as low as 4.3% for oxyhaemoglobin. This led to the development of the M.R.C. photometer, and with this the coefficient of variation is much less, about 4%.

All these are subjective methods depending finally on a colour matching or the matching of intensities of light. The M.R.C. photometer is quicker and easier to use than the Sahli method in addition to being much more accurate, but it is, of course, much more expensive. On the other hand,

it is sent out standardized by the National Physical Laboratory and requires no further standardization, so that results obtained with it by different observers can be directly compared. The M.R.C. photometer is unquestionably the best instrument for general use.

In large hospitals objective methods using photoelectric cells and galvanometers are more commonly used. Each of these instruments costs two or three times as much as the M.R.C. instrument and has to be calibrated. Standard analysed solutions of haemoglobin are now available, and most hospitals calibrate their instruments with such samples every few months. With a good photoelectric instrument and properly calibrated glassware the coefficient of variation is very small. With National Physical Laboratory grade A glassware my own instrument gives too small a variation to express in figures. With ordinary British Standard Specification 797 pipettes and a series of half a dozen different observers the coefficient of variation is about 2%. The photoelectric method has the great advantage of being much quicker to operate than any of the others, and, since it is not a subjective method, there can be no argument over the end-point. It is for these reasons that it remains so popular in hospitals.

REFERENCE

Lancet, 1948, 1, 282; 2, 563, 971.

Ingrowing Eyelash

Q.—A man of 40 has for two years had an ingrowing eyelash on the left lower lid which impinges on the eyeball and has to be plucked out. He does not wear glasses. Is there any way of preventing this eyelash from growing?

A.—A single lash is best treated by electrolysis. This is likely to produce permanent epilation. A fine electrolysis needle attached to the negative pole is entered towards the root of the lash. The current used is 1 to 3 mA for 20 to 30 seconds. A bubble of white foam forms at the point of electrolysis. The procedure is best carried out after preliminary infiltration analgesia by 1 ml. of 4% procaine hydrochloride; it is, however, possible to dispense with this.

****** This answer is taken from the third book of *Any Questions?* Copies of the second and third books of *Any Questions?*, each containing some 200 expert answers, are available from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller, price 7s. 6d. a copy (postage 6d.). The third book contains a cumulative index.

Compatibility of Salts of the Same Drug

Q.—Is there any pharmacological incompatibility between different salts of the same drug, such as streptomycin calcium chloride and streptomycin sulphate, either when given together or on succeeding occasions to the same patient?

A.—In general there is no incompatibility between different salts of the same drug. But, if streptomycin calcium chloride were actually mixed together with streptomycin sulphate, there would be a precipitate of calcium sulphate. This would be undesirable for intrathecal injection, but would probably cause no trouble for intramuscular injection. No precipitation would occur if the two forms were given in successive doses, unless the time between the doses was very short and they were given at the same site.

Treatment of Dystrophia Myotonica

Q.—What is the best treatment for securing muscular relaxation in a case of dystrophia myotonica?

A.—Quinine hydrochloride by mouth in divided daily dose of 10–15 g. (0.65–1 g.) remains the treatment of choice for securing relaxation in dystrophia myotonica. At the present time procaine amide is under investigation in this connexion, but until further information is available its general use

cannot be advocated. In any case, the main disability in dystrophia myotonica results from muscular weakness rather than myotonia.

Risk of Having a Second Mongol

Q.—I should be grateful for your help with this problem. I have a patient, 32 years of age, who gave birth to a mongol six years ago. There is no mental abnormality on either side of the family. What are the chances of this woman having a normal child? There have never been any miscarriages or abortions, and this was her first and only child.

A.—Familial incidence in mongolism is very low. There is probably a slightly increased chance that a woman who has had one affected child will have another. The risk also increases with age in any mother. This woman is relatively young and it is probable that the chance that another child would be affected is not greater than, say, one in a hundred.

NOTES AND COMMENTS

Aphthous Ulcers.—Dr. FREDERICK SUTTON (Bristol) writes: In "Any Questions?" (January 22, p. 242) your expert states that "the painting of [aphthous] ulcers with caustic cannot be recommended, since this usually prolongs the healing process and does not prevent the formation of further ulcers." If, however, the time-honoured measure be adopted—namely, that of touching the ulcers twice daily with 2% silver nitrate in spirit of nitrous ether—not only will the ulcers immediately become less painful but in the vast majority of cases they will quickly disappear. Only a very few patients require a 4% solution, and with either of these strengths argyria never occurs. Neither from the point of view of prophylaxis, nor from the point of view of treatment, have antibiotics or antihistamines proved to be of any real value. It should be pointed out, however, that, though the real cause is unknown, it is nevertheless true that such patients have a very sensitive mucosa, and even the trauma occasioned by a toothbrush may bring about a crop of ulcers. Therefore a very soft toothbrush should be used, or even none at all, the gums being gently swabbed with a pledget of wool on the finger dipped in a liquid dentifrice. "T.C.P." or some similar preparation, 2 dr. (7 ml.) in half a tumblerful of warm water as a gargle twice daily, may have a useful prophylactic influence, and if applied undiluted to the ulcers it may bring about healing, but not so rapidly as the silver preparations above mentioned.

OUR EXPERT writes: I do not think that I can usefully add much to my original reply, in which I made it clear that unfortunately the aetiology of the condition is still obscure and any local treatment is purely symptomatic. I agree with Dr. Sutton that painting the ulcers with silver nitrate, or touching with carbolic, may desensitize them slightly, but there is, I think, general agreement among people who see many of these cases that the further destruction of tissue and possible deepening of the ulcer may in fact delay healing. I agree entirely that antibiotics, administered either generally or locally, have no beneficial effect. But it is difficult to agree or disagree with the statement that patients have a very sensitive mucosa, since this is difficult to determine. I have never noticed any association of a hard toothbrush or trauma with the condition. Most frequently the ulcers occur in crops, and they are particularly prone to occur in females. It has been said that there is some connexion with monthly periods, but I have noticed myself over the years that this does not in fact appear to be the case, but, as women have periods, they form a sort of datum line although the crops of ulcers do not really fall into any definite pattern.

BAD NEWS

for
the cocci

*No more delayed action
from enteric coating*

NEW *Filmtab* ERYTHROCIN Stearate tablets provide faster absorption, earlier blood levels. The *Filmtab* (marketed only by Abbott) disintegrates far faster than enteric coatings—permits almost immediate drug absorption. Tests show ERYTHROCIN is adequately protected.

Result? Your patient has high blood concentrations of ERYTHROCIN within 2 hours, instead of 4-6 hours as before. Peak level at 4 hours and significant concentrations for 8 hours.

ERYTHROCIN Stearate is highly effective—almost every gram-positive coccus is sensitive to its action. Especially recommended against staphylococci, because of the high incidence of staphylococcal resistance to penicillin and other oral antibiotics.

ERYTHROCIN Stearate (compared with most other antibiotics) is less toxic—less likely to alter the normal intestinal flora. Gastro-intestinal disturbances are rare. No serious side effects reported.

Average adult dose is 200 mg. every 4-6 hours. ERYTHROCIN Stearate *Filmtabs* (100 and 200 mg.) are supplied in bottles of 25 and 100. For children ERYTHROCIN Stearate Oral Suspension (100 mg. per 5 c.c.) is available in 60 c.c. (2 fl. oz.) bottles.

Consider ERYTHROCIN Abbott
(Erythromycin Stearate, Abbott) REGD.

MEDICINE IN RELATION TO SOCIETY*

BY

A. E. CLARK-KENNEDY, M.D., F.R.C.P.

Physician to the London Hospital and Fellow of Corpus Christi College, Cambridge

On a famous occasion in the House of Commons in the reign of King George III a certain member, Mr. Dunning, moved that "the power of the Crown has increased, is increasing, and is likely to increase still further." To-day, at the opening of the 218th Session of the Royal Medical Society, I would remind you that "the power of medicine has increased, is increasing, and is likely to increase still further." For what is the position? We can now prevent birth, terminate pregnancy, relieve pain, keep unconscious for long periods, prevent and treat many infections, suppress and increase instinct, modify the reactions of the mind with drugs, and influence personality with the knife. We can certainly prolong life. One day we may discover a chemotherapy for cancer and how to slow down the degenerative processes of age.

Mr. Dunning went on to move that the power of the Crown "should be reduced." I do not suggest that the power of medicine should, but, while the general public are acutely aware of the problems recently raised by the discovery of intra-atomic energy, they and many members of our profession remain largely unaware of the more personal ones which are being rapidly precipitated by our increasing power over the physico-chemical machinery of the human body, the basis of the individual life and mind. How, when, and to what extent should this increasing power be used? I am therefore asking you to consider, not medicine as a science (about which I sometimes think we hear too much), not even medicine as an art (about which I think we now hear too little), but the growing problem of the right use of the power of medicine in relation to Society. And how is that to be solved to the best advantage of humanity? Surely by establishing and maintaining satisfactory relationships between the three chief interested parties: the patient (you are all potential patients); the doctor (you will all soon become doctors); and the State, in which in this democratic country we are all incorporated by virtue of our votes.

The Patient

Let me begin with the patient, or rather with the potential patient, who at any moment may develop his disease, the average man who often knows or thinks he knows a little about medicine. What is his outlook to-day? Naturally he still expects his doctor to keep him and his family in health, but, as a result of increasing medical knowledge and specialization, his

attitude to his doctor has changed considerably of recent years. Further, it has changed at a time when the influence of the Churches has declined (although religion still sometimes complicates a medical problem), most people live in a structureless urban or dormitory society, the State has become responsible for health, and legal aid is available to all. He is aware that his doctor now knows relatively much less about medicine as a whole than he did a few years ago. (Hence his growing faith in specialists and his doctor's declining opportunity to become, as he so often became in the past, his patient's guide, philosopher, and friend.) On the other hand, does he, the average patient, understand that the most responsible and often most difficult diagnosis is still that between the early symptoms of organic disease and those of functional or psychoneurotic origin? (Whether to investigate or treat symptomatically may be a decision entailing life or death.) Does he realize that health is a relative term in relation to the constitution with which he is endowed; that avoiding the disease to which he is predisposed may depend on deliberate effort on his own part; that in seeking the aid of the growing power of medicine to live longer he may merely add to the total suffering which he must endure? Further, he still expects his doctor to maintain the principle of professional secrecy and protect him from exploitation at the expense of his health by his employer or the State, which, in these days of nationalized industry, is often his employer. And yet it is to the State that he looks to provide him with living conditions compatible with health and to protect him from the risks to which he is exposed in an industrial society. In addition, he now relies mainly on the State, and no longer on Church, charity, or some voluntary organization to which he subscribed, to restore his health when he is ill and look after him in his old age. But does he realize that elimination of risk demands some sacrifice of personal freedom and that State intervention in medicine tends inevitably to cut across the principle of professional secrecy?

The Doctor

Now for ourselves. On the one hand, we have a much clearer idea of the nature of disease than in the recent past, although we are faced with a much more difficult concept. For we no longer think of diseases as entities with characteristic symptoms and signs and definite dividing-lines between them. Rather the phenomenon has become to appear as a continuum like a mountain range in which the textbook diseases stand out like major peaks. (The outlook of the recently qualified doctor is very different from that of one of the older generation.) On the other hand, we

*The inaugural address delivered at the opening meeting of the 218th Session of the Royal Medical Society of Edinburgh

are all painfully conscious (even more so than our patients) that, as medical knowledge marches on relentlessly, we individually know relatively less and less about medicine as a whole. And what are the consequences of that? Some loss of confidence in ourselves and being forced into specialization or, if we attempt to remain general, greater reliance on specialists. (In some countries the general practitioner, as we know him, has almost disappeared.) Further, the growing power of medicine has not simplified practice, as the layman naturally supposes. Rather it has rendered it much more difficult and created many more opportunities for us to make mistakes.

When I first started, there were few diseases for which any radical treatment existed. Early diagnosis was often unimportant. All we could do in so many cases then was to treat symptoms and let the underlying pathological process run its natural course. Now something can be done for so many that early diagnosis is becoming increasingly necessary. For example, until chemotherapy for tuberculosis was discovered, all cases of meningitis of that variety died in a few weeks: the later the diagnosis in many ways the better; the shorter the period of agony for relatives. Now, if the disease is diagnosed early, modern treatment will effect a complete cure: if late, the patient dies or, worse still, is left a derelict for life.

Further, in spite of all our new methods of investigation, "front-line" diagnosis remains clinical. Laboratory tests and x-rays have not replaced history-taking and physical examination except perhaps in hospital, where the decision whether to investigate or not and what to start investigating has already been made by a general practitioner or in the out-patient department. And clinical diagnosis is still that which is most probable on the evidence immediately available, although there is often a less probable but more serious condition which, if sufficiently probable, must be actively excluded, provided that it is likely to be amenable to treatment. (There is no sense in causing discomfort and wasting public money in excluding some disease which is bound to be incurable.) So the general practitioner and the out-patient physician, unless they are to submit every patient to a whole gamut of expensive investigations, are compelled to take risks. Indeed, they take them every day, clinical diagnosis (although we may be loath to admit it) exemplifying the economic law of diminishing returns.

Let me give you an example. Carcinoma of the stomach and colon are symptomless diseases at first and the patient does not consult a doctor until the compensatory reactions of his body start to fail. Then in 75% of cases, I suppose, symptoms are sufficiently definite to permit a highly probable clinical diagnosis. Further, by exercising extreme care (mainly in history-taking) we can probably "get" the next 20% without investigating too many "functional colons" and "nervous dyspeptics." The remaining 5% are however, I believe, likely to defeat us and must be written off on the balance sheet of human suffering like a bad debt. Indeed, unless we are courageous in diagnosis within reason, we shall cause so much unnecessary anxiety that we shall undo much of the good which we otherwise succeed in doing, quite apart from wasting public money. True that an x-ray film of the chest every quarter, for example, might one day become an economic proposition, but routine investigations of the kind which would eliminate diseases such as carcinoma of the stomach and colon must, so far as one can see at present, remain outside the realm of practicability.

Some Moral Problems

In addition, as the power of medicine increases, we are all confronted, and confronted particularly often in hospital practice, by problems of a moral nature. Under what circumstances should birth control be advocated? When should pregnancy be terminated? To what extent should pain be relieved? When is it right to use drugs to suppress or increase instinct? To what extent is it justifiable to alter the reactions of the mind to experience such as the advent of death by means of drugs? When should leucotomy be

performed to render a patient socially more manageable and a lesser burden on society at an expense in terms of mind which it is impossible to estimate? When should life be prolonged at the cost of increased suffering by some palliative operation? For example, when should gastrostomy be performed in inoperable carcinoma of the oesophagus or colostomy in inoperable carcinoma of the colon?

And again and again I am confronted with this sort of problem. An elderly man is admitted with hemiplegia and aphasia, lies there semi-conscious, and after a few weeks shows little sign of recovery. Then his temperature and pulse start to rise and signs appear at the bases of his lungs. Clearly he is heading for pneumonia, Osler's one-time "master of the men of death." Do I put him on penicillin and prolong his misery, or on morphine and let him depart in peace? "His nearest relative should decide": it is easy to say that, but in situations of this kind can they really be told enough to understand the position sufficiently clearly to arrive at a decision? And how many relatives are capable, under the emotional stress of circumstances such as these, of decisions of this magnitude? In my experience most patients and relatives want decisions taken for them rather than to be left to take them for themselves. Further, if they are forced to take the decision themselves, does not the one which they take depend on the way the situation is explained to them? In practice the doctor is almost always faced with taking the decision himself.

Now, it is always easier to perform a palliative operation or put the patient on deep x-ray treatment or chemotherapy: easier, in fact, to do something than to do nothing. Some course of action will probably relieve his immediate symptoms, and often it prolongs his life. It will raise hopes and sometimes clear the bed for the admission of another case for whom more might be done. But what happens to the patient in the end? Looking back, would not analgesics and narcotics often have been better treatment, although the bed might have been blocked for weeks? (The use of drugs to relieve pain, even to the extent of keeping a patient unconscious for a long period, in my experience does not shorten life and is not euthanasia.) The Roman Catholic doctor in dealing with his Roman Catholic patients has firm guidance from his Church in these matters, and some may hold the view that it is always our duty to prolong life so far as is possible, but my experience teaches me that most of the non-Catholic laity would, if they knew the truth, wish doctors to exercise more moral courage than in point of fact is, I think, their practice in these situations. If the patient or his relatives really could be told the facts, they would have their doctor withhold treatment when "the game is up," and let nature take its course. But so often they cannot understand or be brought to face the decision, so that again and again in practice most of us are forced to act on our own sense of what is right in the circumstances of each case. But to that statement I hasten to add this rider. In general we should base our action on what appears to be (and we must always take the trouble to find out) our patient's philosophy of life rather than inflict ours on him when he is ill or dying. (The outlook of a man of 40, be he doctor or patient, may be very different from that of a man of 60.) It is written "Thou shalt not kill." But letting nature take its course when nature cannot be stopped is not killing. Nor in my judgment is a patient committing suicide when he refuses palliative or problematical, as opposed to a reasonably certainly curative, medical or surgical treatment. Never before in the history of medicine has it been so important to remember Clough's oft-quoted rider to the sixth commandment: "But needst not strive officiously to keep alive."

More difficult still is the decision whether to adopt a procedure which may arrest a lethal pathological process possibly only at the cost of leaving the patient a mutilated relic of his former self: for example, deciding whether to operate for a tumour of the brain. It may be that in a particular case there is a one-in-four chance (so far as

chances can be estimated) of a spectacular success and a one-in-four chance of the patient dying. If the choice lay between those two alternatives alone, there would never be any doubt of what to do. But there may be even chances of leaving him derelict for life. If the patient realized that, would he consent to operation? Yet it is seldom possible, and it is doubtful if it would be right if it was possible, to explain the position to him. So these decisions remain for us to take, and are most difficult. Further, they must remain individual. It is impossible to generalize. It is no platitude that the doctor should treat his patient and not his disease. Rather that is the first principle of medical practice. The disease, that complicated reaction between the psychosomatic constitution of the individual man and the risks to which he has succumbed, is the abstract concept. The patient is the concrete reality. There can be no disease without a man, woman, or child to suffer from it, any more than there can be a human mind, as we know it, without the physico-chemical machinery of a human body to maintain it. If I really thought that I was either under a moral obligation to keep all my patients alive as long as possible, or under a legal obligation always to apply the textbook treatment for the textbook disease, I would give up medicine to-morrow!

Responsibility for Major Decisions

Now, in actual fact by whom are these major medical decisions usually taken? Almost always, I think, by the physician or surgeon under whom the patient has been admitted to hospital, and who, although he is often a specialist in some particular branch of medicine or surgery, seldom knows much (because in his position he cannot) about the background of the patient's life. Further, they are usually taken without reference to his general practitioner. Indeed, to-day he seldom "comes into the picture," except in so far as the medical fate of a patient may depend on the specialist (Dr. X or Y or Mr. A or B) to whom he is referred in the first instance. A duty of every general practitioner is to "know" his specialists and choose that one most suitable to advise his individual patient. But the gulf of loss of contact between specialist and general practitioner has grown wider and wider of recent years, and, as things stand at present, the responsibility of the latter for any major decision ends completely in most cases as soon as his patient is admitted to hospital. Nor am I altogether happy about responsibility in a large hospital. For a patient may be attending several departments simultaneously. His G.P. has been "cut out" and no one doctor is now primarily responsible for him. Further, we seem to be developing a race of laboratory middle-men who now sometimes dominate the investigation of a patient, and therefore come to influence his treatment, and yet must know less than anyone else of the background of his life. As I see it, all major decisions in respect of a hospital patient, whether to investigate, how to treat, and above all the vital decision whether to treat, should be taken by one physician or surgeon who should be responsible for ascertaining the background of his life by getting in touch with his general practitioner.

Divided Loyalties

The problem of divided loyalties also bothers me. By the tradition in which our profession has developed, and we ourselves have grown up, our allegiance is still primarily to our patients. I say primarily deliberately, because we have two other allegiances. On the one hand, we have an inclination always to get as near the truth as possible, the scientific approach determining the pattern of medical education to-day. On the other, we have a feeling of duty to the State. True that the latter is not very strong in our minds, anyhow as yet, but duty sometimes calls awkwardly in that direction. For practically all doctors are now full- or part-time servants of the State, or, if you prefer it, of the public embodied in this democratic country in the State. Further, we are now entrusted, both in domiciliary and in hospital practice, with the expenditure of public money.

Now, at one time there were no expensive methods of diagnosis (sometimes to be proved or disproved on the post-mortem table), so that these three loyalties seldom came into collision, and, when modern methods of investigation started, we spent the patient's money, or money subscribed by the charitable or contributed voluntarily by him to a society. To-day, not only are investigations far more numerous and expensive, but they can be used to paint a much more complete picture of a disease. Sometimes this must be painted in all its details. But how often do we order investigations (apart from planned research) merely to paint more completely the picture of a disease for which nothing can be done; or, to state it crudely, how often do we spend public money merely to satisfy our own intellectual curiosity? Nevertheless, curiosity is necessary if medicine is to feel its way and each of us individually is to continue learning. The conflict of interests exists, and it is better to realize it. The only solution lies in compromise.

The State

Now for the State, the latest comer on the scene. Indeed, it is a very recent comer. It is less than 200 years since the importance of environment in the pathogenesis of disease began to be understood, and only in the memory of living man did the cost of treatment become so great that Church, charity, and voluntary organizations could no longer cope. Lloyd George's National Insurance Act was introduced just before the first world war, and Mr. Bevan's National Health Service Act just after the second. Further, in the modern world, every State has begun to take a positive interest in health for two reasons. In peace the labour force must be maintained. In war the Services must be kept up to strength. The State can no longer sit back and look on. It must intervene, and intervene with the maximum economy compatible with efficiency. So medical administrators, with financial considerations always "treading on their tails," would gain complete control of medical certification and expenditure if they could. Further, State medicine is impersonal. It thinks in terms of numbers and percentages, not in terms of individuals, dislikes professional secrecy, and would have all the information about the incidence of disease which it can get.

The State has three main functions in relation to health. First it must reduce to a minimum those risks which are prejudicial to human existence. It must therefore take responsibility for housing, water, and sanitation and enforce regulations to minimize the traumatic and chemical risks to which people are exposed in an industrial society. As to these functions of government there can be no controversy.

The control of infection is a more difficult problem. Vaccination against smallpox and inoculation against diphtheria are not compulsory, because some people have conscientious scruples against them. The State accepts these scruples (in the same way as it accepts conscientious objection in time of war), although both are actively discouraged. If, however, a patient develops smallpox or diphtheria he has no choice in the matter. He is bundled off to a fever hospital. Tuberculosis we handle differently. The patient must be notified, and is then kept under observation and encouraged to undergo treatment, but he cannot be compelled to enter a hospital or sanatorium. Public opinion would not stand for treating people with chronic tuberculosis as lepers were treated in the Middle Ages, although patients with open lesions must be almost as dangerous. Venereal disease is not even notifiable, but the State sees that facilities for treatment are easily available. Thus we compromise between eliminating risk and sacrificing freedom.

The third function of the Government is now the organization of the medical services, and as the result of the National Health Service Act doctors are becoming distributed more equitably in relation to population, the standard of medical care has been raised in many areas, and special centres are growing up where previously they did not exist.

The best medicine has not become available to everybody (there is never enough of the best to go the whole way round), but the National Health Service has brought good medicine within the reach of all. It is a great advance in social legislation, but there are difficulties and dangers inherent in the new system which it would be folly to ignore.

The State looks to the doctor not to spend public money unnecessarily. It does not expect him to waste it either in the satisfaction of his own intellectual curiosity or in acquiescing to his patients' unreasonable requests. In most cases expenditure is justified, but there are difficult cases. For example, when is an x-ray examination justified merely to convince a patient who doubts a purely clinical opinion? When is the more expensive drug justified which might do the patient just a little more good? When is physiotherapy really worth the cost of repeated visits to a hospital? But I am not suggesting that problems of this kind are new, still less that they are the result of the National Health Service. (That started at a time of economic stress and rapid progress in methods of diagnosis and treatment. Medicine was becoming so complex that the State was compelled to take over.) Rather, they have assumed larger proportions and become more difficult because, now that they are servants of the public, it is not as easy for doctors to be firm as when they gave their services to hospitals in an honorary capacity and were paid fees which they could refuse or remit. The man in the street, whatever his politics, held charity and, whatever his religion, the Church, and naturally the society to which he voluntarily subscribed, in some respect. But the State is often fair game, and he may claim the right to be investigated or treated in a certain way or given a certificate to get him this or protect him from that. The unpalatable truth is that the hospital doctor who did his work unpaid, and the consultant or general practitioner who worked for fees, have both to some extent lost the throne of freedom of action on which they used to sit.

Further, there is this added danger. If a doctor makes a mistake (we must all make mistakes sometimes), a patient is much more likely to sue him or his hospital now than in the recent past. As paid servants of the public, we are a tempting target for that dangerous few who have a "down" on the profession and enjoy publicity. Nevertheless, I am not suggesting that the recent spate of litigation against hospitals and doctors is due to the National Health Service, or that in general our patients are any less grateful than they were before it started. Rather, it is the consequence of the general public thinking that they now know so much more about medicine (when in reality they know much less), our much greater opportunity to make mistakes, and legal aid becoming (if a reasonable case for it exists) accessible to people with small incomes. True that we are probably passing through a transient spate of it, but there has been enough to tend to make doctors play for safety to a greater extent than safety should be played for. And what are the likely consequences of that? To the patient, unnecessary discomfort and loss of working time. To the State, loss of output and additional cost to the Health Service.

A further danger to the happiness of the doctor-patient relationship (on which successful medicine so much depends) is the inevitable tendency of the National Health Service to undermine the traditional principle of professional secrecy. For these are the days of reports to employers (often the State) and copious records. Hospital notes are banded about from hospital to hospital by lay secretaries and must be produced in court if demanded. The patient's record card changes hands through a central office whenever he changes his doctor. Can that too be demanded in court? Has the patient the right to insist that it or his hospital notes be destroyed? I do not know the answer to these questions.

The cost of the Health Service is, as everyone knows, steadily increasing (it is doubtful if there can be any natural limit to expenditure on health), but this is in no way due

to the Service itself. Rather, as I have already emphasized, it is due to present-day economic conditions and recent advances in expensive methods of diagnosis and treatment (which together rendered the Service necessary), and, I should add, the increasing age of the population (one of the results of modern medicine) and the higher cost of keeping old people alive (as the power of medicine increases). Economy is clearly necessary. There are already directives intended to reduce the cost of prescribing in domiciliary practice, and we are repeatedly implored to cut down x rays, expensive investigations, and the use of costly drugs in hospital. Further, it would certainly be more economical to run hospitals with a smaller number of full-time consultants than on the present half-time system. Indeed, if we let medicine get too expensive—and that rests to some extent with doctors—the National Health Service, which retains at present most that was best and has eliminated most that was worst in the old system, might be forced into the pattern of a full-time salaried medical service. And what could that be like? The allegiance of the doctor might become primarily to the State. Promotion might become based mainly on service to it rather than to the patient for which the service was intended. In the interests of economy some forms of treatment might become standardized and the progress of medicine thereby hindered.

Further, a State medical service might lead to an orthodox State medicine. But even under the National Health Service as at present organized I sometimes think that we are nearer to it than is generally realized. There is a movement to limit prescribing and reduce expensive investigations already. True that there have been no directives regarding treatment as yet, but no patient can get free homoeopathy, osteopathy, or faith healing under the Act except from a legally qualified practitioner. True, also, that at present we are free to act as we believe to be right in the circumstances of the individual life, and that Common Law holds that a doctor cannot be found negligent if he has exercised all reasonable care in diagnosis and treatment. But suppose a doctor takes the view that it is right in certain circumstances to withhold treatment and let a patient die, and is then sued by his relatives. What then? I do not think that a case of this kind has been taken to court, but, unless inaction of this kind in certain circumstances is upheld, if a case does come to court, doctors will be afraid to let nature take its course in certain circumstances, adding vastly to the sum of human misery. The rising expense of the Health Service and the growth of Common Law might between them force the orthodox medicine which we have at present into a dangerously rigid system.

Basic Principles

Three principles stand out to keep us straight.

1. The patient must remain free to choose his doctor and change him when he feels inclined. That principle has long been conceded, and is an integral part of the Act of Parliament on which the National Health Service is founded. It is Statute Law.

2. The doctor must be free to treat his patient as he thinks right, and feel confident that he will be upheld in court if, after all due consideration, he decides to withhold the textbook treatment for the textbook disease, thinking that under the circumstances it would serve no useful purpose or merely prolong suffering. This principle has not yet been established.

3. The nature of medical practice is such that the State must continue to control medical education indirectly through the General Medical Council and the medical schools of the universities, but they must not have direct power over methods of medical treatment. It must achieve economy by suasion rather than directives. It must continue to organize the medical services, but it must never command individual doctors. Under no circumstances must the growing power of medicine be handed over to committees or vested unfettered in the State.

Conclusion

After thirty-five years in medical practice I have attempted (I am afraid in a very muddled way) to paint a picture of a peculiarly difficult problem in human relationships—namely, the triangular one between the patient, the doctor, and the State. A perfect solution depends upon an agreed philosophy of life, but unfortunately that does not exist. Compromise is therefore essential. Now I must have said much with which you will not agree. I may have made statements which you positively dislike. You may think that I have painted the darker corners of medical practice in too sombre colours. But I have raised questions which must be faced. True that I have given you no answers to any of them, but I venture to hope that I have helped you toward a better understanding of the problems being raised by the power of medicine which, to adapt again Mr. Dunning's famous motion in the Commons, "has increased, is increasing and is likely to increase still further."

THE CANCER PATIENT: DELAY IN SEEKING ADVICE

BY

JEAN AITKEN-SWAN, A.M.I.A., A.H.A.

AND

RALSTON PATERSON, C.B.E., M.C., M.D.
F.R.C.S., F.F.R.

Christie Hospital and Holt Radium Institute, Manchester

Cancer of the breast, cervix uteri, skin, or mouth usually presents symptoms which a patient can recognize and for which early successful treatment is a practical possibility. Yet of 2,700 patients attending this hospital with cancer in these sites 45% had delayed consulting their doctor for three months or more, and 17% for a year or more, after the onset of symptoms. This article describes a study of factors which influence people with these cancers to delay seeking advice. The study is based on the interviewing of a series of 75 men and 239 women patients and their relatives, resident in Manchester, Salford, and Stockport, and attending this hospital. All the interviewing was carried out by one person (J.A.-S.).

Interpretation of facts obtained by these means is inevitably subjective. Sometimes more can be learned in a few minutes from a relative than from several interviews with the patient. Conclusions are not based, therefore, on the patient's statement alone, but on all the evidence available. In addition, 63 patients were tested by the Wechsler-Bellevue method of intelligence testing to ascertain the relationship between individual I.Q. and delay.

Early in the study it appeared evident that there were two clear-cut groups of patients: (1) those who "knew" they might have cancer, and (2) those who were genuinely ignorant of the possible significance of their symptoms. The mental processes of these two groups are entirely distinct. Nevertheless, it was sometimes far from easy to place individuals into the correct category, especially as those in the first group often tried to hide the truth. The degree of awareness of a symptom, and the extent to which people will consciously accept what they suspect to be the truth, are dependent on personal factors. Shands *et al.* (1951), describing three levels of knowing, say: "(1) A person may be in

the possession of a number of facts that are not related to each other; he may know, for instance, that 'a lump may be a cancer,' and 'I have a lump,' without arriving at the conclusion, 'I may have a cancer.' (2) He may have taken the initial step of the relationship but stops short of translating the insight into action. . . . (3) A third level of knowing is that characterized by the integration of the pertinent information into the behavioural patterns of the individual."

In the present study a patient is considered to have known if there is evidence that at any level she thought of cancer in relation to her symptoms before consulting a doctor. Patients who "knew" can be subdivided according to a characteristic positive or negative response—those in whom fear is the dominating factor, and those who fatalistically accept the situation and mean to do nothing. The former group may offer a series of superficial reasons for their delay, and some of these are discussed later. Basically, these patients are motivated by fear, and their actions, wise or unwise, represent response to fear. As will be seen, fear may result in immediate action, as it ought to, but more often it leads to an only half-conscious policy of concealment and appropriate rationalization. The latter group, usually older people, are well adjusted to the situation which they do not deny.

Where there is genuine ignorance clearly no such factors operate, and delay, if it occurs, represents a normal response to the problems of health and illness which would take place regardless of the type of disease. At this point it may be noted that if education masters ignorance it may only result in a transfer to the other category.

It appeared later that the fraction falling into the two categories of "knowing" and "not knowing" varied greatly with the type of cancer, category 1 being dominant for breast cancer and category 2 for cancer of the cervix, skin, and mouth. This is, of course, an important finding in regard to the placing of emphasis in any educational campaign.

The average length of delay and numbers delaying three months or more are significantly higher among patients who knew than among those who did not know. This is not to say that they necessarily all delayed because they knew. Naturally, delay is also influenced by the degree of inconvenience suffered. The figures may therefore also reflect the fact that, generally, cancer of the cervix and mouth present troublesome symptoms earlier than cancer of the breast or skin.

Table I sets out an analysis of the whole material divided with as great accuracy as possible on these lines for the four diseases under review. In 19 cases it was impossible to determine on the evidence available whether the patient "knew" or not.

Action Related to Ignorance

Where the first symptom was not a lump in the breast women with breast cancer were apt to mistake the possible significance of their symptoms. Enlargement or swelling of the breast, a lump in the axilla, or retraction of the nipple was genuinely attributed to old lactation difficulties, menopausal disturbances, or recurrence of previous complaints. Even where the first symptom was a lump, in some cases the history was long and the lump unchanging. In addition, some put off through apparent indifference about their symptoms. They did not think the condition important, and allowed it to drag on owing to pressure of other events, and possibly low health standards and a low level of intelligence.

TABLE I.—*Delay of Patients who Knew they had Cancer and those who did not, by Site of Disease*

Site	Total	Knew	Did Not Know	Indeterminate	Delay

* Squamous-cell carcinoma and malignant melanoma only.

One case typifies this group.

A young woman did not bother about the lump in her breast until it began to "fester." Her husband agreed that they were not people to go to the doctor unless they had to. She complained of trouble with her eyes, he said, but she had not had new glasses for 20 years—she did not bother. She suffered from bad headaches, her husband suffered from stomach ulcers, and their little girl was delicate, with asthma and "nerves." Having been treated, this patient characteristically failed to respond to follow-up appointments.

Altogether one-quarter of the women with breast cancer did not realize the possible significance of their symptoms.

Almost two-thirds of the women with symptoms of cancer of the cervix were similarly ignorant. Naturally enough, younger women predominated in this group. Nineteen out of 20 pre-menopausal patients did not suspect cancer. Women of all ages from 35 to 65 attributed their symptoms to "the change," other reasons given being emotional upsets, strains, after-effects of confinement, and recurrence of previous gynaecological complaints.

Well over three-quarters of patients with skin and mouth cancer were ignorant of the nature of their symptoms. The patient with these symptoms had usually gone to his doctor (or dentist) before anxiety was aroused about the condition. Delay in these patients reflected their attitude to "doctoring," there being a general reluctance to seek advice for what seemed an exceptionally trivial matter.

Not all the 169 patients who were ignorant delayed—in fact, 46 had consulted their doctor within a month of the onset of symptoms. Further analysis showed that in over half these cases the reason for this prompt action was that the symptoms were too troublesome to neglect (flooding, painful mouth, etc.), relatives had insisted, the patient was under the doctor already or had gone about something else. Only 19 had gone within a month on their own initiative about symptoms which were not yet severe, and which they did not suspect to be cancer.

Action Determined by Fear

In essence the breast story exemplifies the fact that women do know as a matter of public knowledge that a lump in the breast is dangerous. Why the minority with cancer of the cervix, skin, and mouth suspected cancer while the great majority were ignorant can be broadly classified (Table II).

TABLE II

Other	34

The reaction of seeking immediate advice appears to be related to age rather than to "knowing" or "not knowing," or to intelligence. Younger people predominated in this group. Of all those who acted immediately, 18 were psychologically tested, and in this group are to be found the highest and lowest scores obtained in the test. About the

same proportion of patients who suspected cancer as of those who were ignorant sought advice immediately, or within one month of noticing symptoms—32 out of 126. These were mostly patients who had found a lump in the breast, and all but three went on their own initiative about symptoms which were not yet severe. Although these 32 had admitted to themselves the possibility of cancer it must be noted that not all sought advice with any sense of urgency. Two comments were: "It did occur to me afterwards that I wished I'd put it off a bit longer." "I thought people with cancer were wasted and ill. I wasn't ill and I wouldn't have bothered, but my daughter said if anything happens to you everything is going to come on me, so I went."

Only 15 more patients acted before the end of the third month.

The group which constitutes the main challenge to any public education project are the 79 who, though suspecting cancer, incurred substantial delay before seeking advice (three months and over). Four types of psychological reaction can be clearly seen in 68 of these patients (in 11 instances the data are inadequate). Almost half (36) had adjusted themselves psychologically in various ways to the threat of cancer. Thirty-two others delayed through a fear which inhibited action, and were in a state of conflict and anxiety. Usually some circumstance outside their own control had finally got them under medical care.

One patient in this later group, aged 59, delayed for a year after finding a lump in her breast. She "didn't tell a soul," for she knew her husband would insist on fetching the doctor. She fomented the discharging lesion and dressed it without looking at it—"I was terrified of it being something serious." Her husband, eventually noticing what was going on, fetched the doctor in spite of her insistence that the condition was improving. This patient had been an elder daughter and had nursed an ailing mother for 30 years. This experience of invalidism which had shadowed her life, and uncomprehending fear of the concept of cancer, were factors influencing her initial delay. Having delayed, feelings of guilt at "deceiving her husband" and wilfully neglecting herself made it increasingly difficult, as time passed, for her to take action.

Another patient, aged 40, found a lump in her breast and "didn't know what to do." She was "worried sick" and she readily admitted: "I concealed it from everyone." Faced with this calamity, for she never doubted it was cancer, she reacted on an emotional level and with no intellectual insight and therefore with no ability to work out the problem realistically. The emotional shock was too great and her personality a little too vague and ineffectual to integrate this new factor, and she was quite literally "ill with the worry of it." She was admitted to hospital for treatment for her stomach ulcer, and the breast condition was discovered then.

The following three common defensive reactions were noted.

Denial.—Seven patients denied to the interviewer and apparently to themselves that the condition could be serious, and they denied the implications of the disease, which were that it would not get better by itself, and that if left untreated it would kill them. They had ignored advice to see a doctor; their minds were already made up. Yet the very emphasis of their denial and the advanced stage of their disease belied their statements.

A single woman aged 43, pleasant and reserved, gave an impression of speaking with sincerity. She appeared to be on good

terms with the relatives with whom she lived. After being very fit for 12 years she developed a lump "like an abscess" in her breast. "I never thought it was anything I could not cure myself with lint and ointment, and I honestly never dreamed of worrying about it." The medical history described a huge, fixed cancer with wide skin involvement and ulceration. The smell from this lesion had become so noticeable that her relatives, to whom she had said nothing, insisted on fetching the doctor. Now here, she asked no questions, she was feeling better, and she presented an equable and completely blank front against any disturbing implications.

Suppression.—Eighteen patients did not deny that the condition was serious, but they rationalized it and did nothing. Two expressed this mechanism forthrightly. "I did think it might be cancer, but I shook it off." "I just put it right out of my mind. I didn't think of it and I didn't intend to until it hurt."

A retired ladies' companion delayed a year, when, instead of returning to her doctor as instructed, she delayed a further two years. She had always tended to put anything unpleasant away from her, she said. She felt that "cancer was a disease that people got who were dirty or who had done something wrong." The whole subject was distasteful to her and she did not wish to think of it. She had dismissed it from her mind while the lump in the breast caused no trouble, and she had two good reasons for doing so: First, she could not afford private care, and "objected to being put on show"; then, "and I don't tell this to everyone, there was no one but myself to look after my little dog."

Acceptance.—These 11 patients were mostly elderly. The severity of their symptoms alone finally induced them to seek advice. They were not looking for cures.

A patient aged 78 said: "I didn't want to be upset about it. I'm not expecting to be cured, you know."

Another old lady, living alone, said: "At my age, what was the use of bothering?" She felt that to give in to illness meant dependence on others, and she said with great feeling: "I couldn't have people coming in and running about for me."

A patient aged 76, with five years' delay, summed up the views of this group: "It didn't hurt and I'd turned 70 and had my span of life."

Some had a hard attitude to illness, regarding it as a weakness and making a virtue of "not giving in." It was something to put up with and not to complain about. In most of the stories of these older patients, however, was anxiety about dependency, about "being sent away" and losing their rooms or houses. So much depended on their keeping going, and they saw no hopeful outcome if they let themselves get into the hands of the hospitals.

Whatever the defensive reaction, fear is probably at the bottom of all delay that is not due to genuine ignorance. It sometimes derives from something concrete, childhood experiences, cancer in relatives, etc., but more often it is the reflection of a kind of cultural fear—a herd instinct rooted in prejudice and ignorance. Patients naturally have not thought it out in terms of "fear of what?" The fear of cancer is vague and is therefore usually expressed in some more concrete, secondary (or rationalized) basis. "Reasons" for delay include fear of "doctoring" and hospitals, operations, dependency, leaving home, "being sent away," losing a job, leaving a young family or a sick husband. These are more immediate and tangible and more easily expressed. They are an important part of the total situation, but it is difficult to know, had there not been fear of cancer in the background, if the patient who "knew" would have delayed for these "reasons." They are mentioned briefly in the section that follows.

Other Factors Influencing Action

Fear of Doctors and Hospitals.—Practically all the patients spoke appreciatively of their general practitioner. Yet this did not prevent expression of strong prejudices against "doctoring" in general; this attitude, and a "dread" or "horror" of hospitals, played a considerable part in delay, especially among older patients. Sometimes

this feeling derived from childhood or adult experiences, and the reasoning was simple: they were hurt or frightened in hospital and they would not go again. Those who were most afraid were often those who had never been in hospital but were full of alarming hearsay. Sometimes a patient's fears were not so much of going into hospital as of leaving home. Some housewives had become home-bound, seldom going out on their own. They may have feared that their condition was cancer, but if it did not trouble them a much greater fear was of "being sent away." Another aspect of the dislike of "doctoring" was the patient's feeling that she would be found to be making a fuss about nothing. "They think you're mithering if you keep going," expressed a common attitude.

Fear of Operation and Treatment.—Mixed up with fear of hospitals was the fear of operations and treatment, allied with doubt about the value of such procedures. Patients would say that they knew that cancer is sometimes cured, but this theoretical knowledge did not affect their tendency to delay. Over a quarter of all the patients spoke of fear of operations in connexion with their delay. Most were speaking of operations in general; others were referring specifically to radical mastectomy. Some said this was no worse than any other operation, but to some the mutilation aspect was deeply disturbing. Age was not always a factor in this. Fear of operation "because it makes it spread" was frequently met with.

A patient aged 72 said: "I don't believe in cutting, and I was expecting this if I went to the doctor." She had had a slow-growing lump in the breast for six years, and thought it would not be much bigger by the time she was 80.

Another patient said: "I always feel that if you're cut there it just goes on and you have to have more done—the beginning of a long process leading to the end." She had known two women who had died following radical mastectomy. "People seem to think it best to leave anything that doesn't hurt, and not stir it up," said another. "People believe that even if they have this operation it is just the beginning of a lot of trouble."

Friends and Relatives with Cancer.—It is difficult to say what influence looking after or having relatives with cancer will have on the patient's own subsequent behaviour when symptoms occur. Most of the relatives and friends mentioned had died, but even when some had done well this fact does not seem to have helped. The fear of cancer is such that while a bad outcome may have an adverse effect a good outcome seems to give little encouragement.

A patient had accompanied to hospital a friend who had found a lump in her breast. She had thought at the time how sensible her friend was to see to it at once. The lump was removed and the friend had no further trouble. A few years later our patient found a lump in her own breast, which she concealed from everyone until it ulcerated.

Another patient, whose mother and sister had both died of cancer of the breast, claimed complete ignorance of the significance of a lump she had found in her breast. Later, she gave away unintentionally the fact that she had known. Her sister had lived for ten years after treatment, but our patient considered it a failure. She was not prepared "to go through such painful treatment for nothing."

Domestic Difficulties.—In many cases where the reason for delay was said to have been domestic difficulties other factors were clearly involved, but in some this did appear to be an overriding consideration. Apart from domestic crises causing delay there were the housewives who had never before left their families. They felt that the accustomed pattern of life could not be upset.

"It is easy to tell other people, but it's so difficult when it comes to yourself. If it had just been myself to think of, or if it had been painful, I'd have seen to it sooner, because I did know it was dangerous to leave lumps. But I've been thinking too much of the family. I just couldn't go off and leave them to manage on their own."

Not Realizing the Need for Early Treatment.—Many patients knew in theory that they should not delay with a "lump," but there was much ignorance about whether it

was safe to delay so long as it did not hurt. Other patients, thinking the condition ultimately incurable, saw no reason to hurry.

A brisk, talkative patient of 40 had heard cancer education talks, which she thought most useful. Her father had been successfully treated for cancer of the mouth, and was now "wonderful." This patient developed a lump in her breast. "Of course, naturally your thoughts fly right away to cancer, don't they?" She delayed nine months. "I kept it to myself because I didn't want to worry my mother. I've had to tell her now, of course, but I was attending classes and I'm an active club worker—you know how you keep putting off. I definitely knew I mustn't leave it too long, for then perhaps nothing could be done. I just became conscious of the lump and made up my mind one night that it was time to see the doctor."

"I believe something can be done if things are taken in time" (delay of three months). "I knew I must get it seen to, as otherwise it might spread" (delay of one year).

Ending of Delay

Delay here is arbitrarily defined as three months or more, and this analysis concerns the 79 delayers who suspected cancer and the 72 who did not. One point stands out. Patients who "knew" tended to seek advice only when forced to do so by the severity of their symptoms. Most of those who did not know had sought advice before that stage was reached. Nevertheless, a quarter of the latter came under medical care only when their symptoms were severe. It was not, therefore, through fear of cancer that they delayed. Other factors were present—fear of "doctoring" and hospitals, waiting to see, shyness, "elderly neglect," etc., which contribute to delay whatever the disease. In a considerable number of cases the action of others ended the delay, the patient being unwilling to seek advice. The main circumstances in which delay was ended are given in Table III.

TABLE III

	Knew	Did Not Know
Patient's initiative, symptoms too painful or troublesome to ignore longer	39	18
Patient's initiative, symptoms not severe	11	21
Action of relatives or friends	19	18
Condition found by doctor, patient intending to conceal it or not bothering	6	5
Other	4	10
	79	72

Shands *et al.* (1951) mention the element of chance in the circumstances which finally decide the patient to seek advice—the "magic" intervention for which he waits. This is a very real thing. A number of patients in this series mentioned such chance happenings. From the point of view of cancer education it is an important aspect of the delay problem, for it would appear that a patient may have heard talks about the danger of "lumps" and do nothing about her own, yet months later she may go to her doctor suddenly because of a chance remark by a stranger in a queue, or because "I happened to be passing a gate with a doctor's name on it, and I just thought I would go in and ask him if he would tell me what it was." Chance stimuli are effective when the patient is already predisposed to act but is procrastinating. Education may help in the process of predisposing without necessarily providing the stimulus—this may come on a more personal level.

Relation Between Delay and Intelligence

To see if there was any relationship between delay and intelligence as measured by an accepted test an additional investigation was carried out among 63 women with breast and cervix cancer, aged under 60, who were up and about. Out of 68 asked there were five refusals (Table IV).

The Wechsler-Bellevue intelligence scale has been very much used in England for testing adults and has been standardized separately for people of different ages. This means that a 50-year-old patient is being compared with a wide variety of other people of 50, and not directly with younger or older people. The construction of the test does

TABLE IV

	Group Tested	Total Group Under 60
No delay or under 1 month	23	44
Some delay, 1-3 months	15	26
Delay of 3 months or more	25	59

not draw too heavily on educational achievement or the ability to use words.

There is no evidence that the patients with the highest scores did not delay while those with the lowest scores delayed the longest. Scores obtained by patients who had delayed a year or more are spread over the middle of the range, with perhaps a slight tendency to have higher than average scores. Results expressed in terms of the product-moment coefficient by Pearson's method give a figure of 0.18, which is not significant. It is concluded, therefore, that there is probably no significant relationship between delay and intellectual level as measured by this test.

Discussion

It has been shown that over half the patients with cancer of the breast, cervix uteri, skin, and mouth did not suspect cancer when they first sought advice. Some of these sought advice only when the symptoms were severe or troublesome. Action, therefore, depended on individual standards of fitness and the level of ill-health they were prepared to put up with. They delayed through ignorance, and we do not know what they would have done had they suspected cancer.

We do know, however, what a group of patients who suspected cancer from the beginning actually did. Nearly two-thirds delayed three months or more, while one-third delayed a year or more. This delay is greater than that found among those who did not suspect cancer. More patients who suspected cancer sought advice only when the symptoms were severe.

Prima facie, it might be argued from this that people are better left in ignorance. This might be so if they were in the habit of going to their doctor promptly with symptoms which are not troublesome and which they do not take seriously. However, it has been shown that this is not a sufficient stimulus in a large enough number of cases.

Harms *et al.* (1943), discussing causes for delay of cancer patients attending an American hospital, say that it is noteworthy that fear of cancer played a minor part. "The major cause for the patient delay is primarily lack of proper information on the cancer problem. . . . Thus the failure of the educational programme to furnish the patient with sufficient information may be held responsible for delay in at least 85% of the cases." Earlier they say: "The median delay for patients who thought they had breast cancer was 3.25 months, while the median delay for all breast cancer was 6.5 months. This suggests that the delay could be halved if all patients were aware of the significance of their symptoms." If this is so education in America has succeeded in reducing the fear of cancer which is so largely responsible for the delay of patients who "knew" in the present series. Our study has shown no ground for assuming that, given adequate information on the significance of symptoms, people in this area—particularly women with cancer of the breast—would as yet react "rationally." Cancer education here, in addition to its purely informative role concerning significant symptoms, still has the more fundamental task of convincing those who suspect cancer that ultimately they will be better off if they seek treatment soon. It has also to influence the deeper and more primitive level of thinking, with its "magical," moral, and retributive elements.

Lack of confidence in what can now be done for them is clearly an important factor in the delay of patients who suspect cancer. Two things which appear to contribute to this lack of confidence are the fate of the advanced patient and the policy of medical silence about cancer.

From the point of view of influencing people to come earlier for treatment the fate of the advanced patient has an adverse effect. As Donaldson (1952) points out, an enormous number of people are brought into direct contact with cancer every year through nursing relatives dying at home. Their attitude and that of the group around them are influenced by these experiences. At the time of increasing anxiety when the patient begins to go downhill the hospital may give him a longer appointment, and his own doctor, it is sometimes alleged, "doesn't seem to take the same interest now." Perhaps he cannot get a bed in hospital, and living conditions may be unsuitable or squalid. He may be inadequately sedated. Worst of all is the feeling that nothing is now being done for him. This is cancer as the general population knows it—unpleasant, incurable, and rejected. These are not entirely welfare considerations; they have a direct bearing on the public's lack of confidence in what can be done for the cancer patient.

A policy of silence regarding a diagnosis of cancer is maintained in general in this country in the supposed interests of the patient. Is this done at the cost of diminishing public confidence in the value of treatment? The fact of palliative treatment is not understood, and hospitals appear to be trying to cure all their patients and failing in a high proportion of cases. If the patient does well the condition "cannot have been cancer." The known cured cancer case is a rarity. This is not the place to discuss what should be done about it, but the fact is entirely relevant to the findings of this study. It is clear that one of the causes of delay is lack of confidence in the efficacy of any treatment. In some way or other it must be brought home to people that some types of cancer are not only curable but are being cured in early cases.

Summary

A study, based on detailed interviewing of 314 patients with cancer of the breast, cervix uteri, skin, or mouth showed that approximately one-half delayed seeking advice for three months or more, and a quarter for a year or more, after first noticing symptoms. Most of the patients with breast cancer suspected they had cancer; patients with the other three types of cancer were, in the main, ignorant of the significance of their symptoms. There was greater delay among those who suspected cancer than among those who did not. Two quite distinct processes operate to cause delay.

1. *Ignorance.*—Here, delay in seeking advice clearly reflects the patient's general attitude towards "doctoring" and has no special relationship to cancer as such.

2. *Fear (of cancer).*—This is clearly indicative that, in some degree at least, the patient really "knows" the probable nature of the disease. Such fear may trigger a reasonable response and make for "immediate" action. Much more often, in the group analysed, it inhibited rational action and was the underlying factor causing delay, although this was camouflaged behind a variety of more superficial ostensible reasons. Testing by the Wechsler-Bellevue intelligence scale indicated that there was no significant relationship between delay and intellectual level as measured by this test.

These distinct and mutually exclusive attitudes to the different diseases must be recognized in any schemes for public education in this field.

We are indebted to Mr. J. C. Kenna, lecturer in clinical psychology, University of Manchester, for advice on psychological testing, and to Miss E. F. May and Mrs. P. F. R. Venables for carrying it out.

EARLY CANCER DETECTION AND EDUCATION: A PILOT TRIAL

BY

J. WALTER, B.M., F.F.R., M.R.C.P., D.M.R.E.

Deputy Medical Director, Sheffield National Centre for Radiotherapy

AND

E. C. ATKINSON, M.B., B.S., D.L.O.

General Practitioner

Every clinician in the field of cancer finds that a large proportion of patients coming for treatment at present must be classed as "late" cases, in which radical cure cannot be expected. Our thesis is that many of these cases could and should have been diagnosed and treated at a much earlier stage. Efforts to reduce the delay have been on two main lines: (1) education of the public by suitable propaganda, and (2) medical examination.

Present Investigation

The Ministry of Health, in a recent circular, considers public propaganda inadvisable at present but favours local exploratory schemes to enlarge our knowledge of the possibilities.

We have sought to combine some of the advantages of both the above methods—education and examination. We feel that cancer education is desirable, but should be conducted as personally as possible between physician and patient. Education and medical examination can and should be carried out together.

It was decided to offer all the patients between the ages of 40 and 70 on the National Health Service list of one of us a brief examination conducted specifically to detect early accessible cancer and to combine this with an effort at education in the cardinal symptoms of malignant disease. The women were invited first.

Circular letters were sent out in batches, offering free medical examination: stamped envelopes and reply forms were enclosed. The word "cancer" was avoided at all times, if possible, as being in itself a potent agent of distress.

Female Patients

Invitations were sent to 766, and 422 (55%) accepted. This, we felt, was a very satisfactory response. The examinations were carried out in batches of about 20 at one session a week, lasting about 2½ hours. The patients' National Health Service cards were available to assist rapid visualization of their histories.

After taking a careful menstrual history, with special reference to heavy or irregular bleeding and discharge, leading questions were asked concerning the following: regularity of bowels, unusual constipation or diarrhoea, blood in motions, piles, abdominal pain, sore places in mouth or throat, dysphagia, dysuria, haematuria, cough, hoarseness, moles or warts, lumps or swellings, usual weight, smoking habits.

If the answers appeared unsatisfactory, further inquiry was made and all the facts were noted. The mouth, tongue, pharynx, and larynx were then examined, including indirect laryngoscopy, and the neck was inspected and palpated. The patient then passed into the undressing-room, where she was instructed to take off all her clothes and to put on a dressing-gown provided. She then passed on into the examination room, where the body was inspected, the

breasts were examined, the abdomen was palpated, and a manual and speculum vaginal examination and a digital rectal examination were made. While the doctor conducted the breast, etc., examination he took the opportunity of telling each patient that she should feel the breasts every month and at once report any swelling, and that she should always report any irregular bleeding or discharge, etc.

No attempt was made to examine the heart, lungs, or central nervous system. If any feature of the history brought out the need for such an examination it was arranged for at another time in the ordinary consulting hours. No pathological investigations were undertaken; it was considered that if any indication for special examination was present the patient should be referred to an appropriate consultant in the same way as if she had attended as an ordinary surgery patient. All examinations were purposely confined to the scope of ordinary general practice, and no attempt was made to set up a hospital-type diagnostic centre. At the conclusion of the examination each patient was given a pamphlet, listing the chief warning signs (lumps, bleeding, hoarseness, dysphagia, etc.) to be reported without delay, and emphasizing the importance of *not waiting till pain was felt*.

Recall Examinations.—Inevitably, a number of conditions were met which, while being obviously abnormal, were insufficiently well defined to merit any immediate action. These were cases for recall in three to six months—for example, some erosions, vague swellings in the pouch of Douglas, and unsatisfactory menstrual histories. The actual process of recall set a major problem, how to proceed without causing alarm and anxiety. At first, patients were told quite briefly that they would be sent for again in three months for re-examination. But experience quickly showed that they worried in the meantime and thought all sorts of things had been discovered. After trying various alternatives, we eventually decided to send each a personal note near the time of recall, offering another appointment in view of the previous findings; this had the desired effect. The recall problem is certainly one of the major difficulties of a scheme such as ours.

Results.—The principal findings are listed in Table I. Only one new major cancer was discovered (of breast). Eight patients were referred to gynaecologists for opinion

TABLE I.—Principal Results of Survey in Females

Invitations issued	766
Acceptances	422 (55%)
New cancer discovered	1 Breast (radical mastectomy performed; histologically confined to breast, no axillary secondaries)
Referred to hospital, excised, and proved benign	8 { 1 Recurrent lipoma of arm 3 Uterine fibroids 1 Ovarian cyst 1 Cervix papilloma 1 Palate 1 Thyroid adenoma
Follow-up examination for doubtful findings	32 { 21 Pelvis (uterus, ovary) 5 Breast (including 1 case of bleeding nipple, under regular observation) 4 Rectum (polyp) 2 Larynx (papilloma)
Miscellaneous	3 { 1 Dyspareunia—operation performed 1 Procidencia— 1 Larynx chondroma (asymptomatic)

on masses in the pouch of Douglas. Three have had hysterectomies for fibroids, one was discovered at laparotomy to have secondaries from a previous carcinoma of the colon, two proved to have benign ovarian cysts, and the other two refused operation. Abnormal pelvic tumours are not rare, and must always arouse suspicion. Ovarian cysts, benign or malignant, are usually symptomless for a long time, but can be felt on pelvic examination at an early stage. They represent a fertile field for prophylaxis, for benign cysts can probably become malignant, and the present-day poor results in ovarian carcinoma cannot be improved without early removal of enlarging pelvic

tumours. *This can be achieved, not by education of the patient in early symptoms, but only by periodic pelvic examination.*

Male Patients

Invitations were sent to 716 patients, and 415 (58%) accepted. The same type of history was taken and the same leading questions (where appropriate) were put. A similar examination was conducted, including mouth, pharynx, larynx, abdomen, genitalia, and rectum.

As a concession to an almost universal anxiety among men of this age group it was decided to take the blood pressure in every case. In only one instance was it found necessary to refer a young hypertensive to a physician. Practically the entire remainder were told that the reading was satisfactory and the expressions of relief and appreciation were constant.

Results.—These are summarized in Table II. No new major cancer was discovered primarily, but the pre-malignant and potentially malignant lesions discovered and

TABLE II.—Principal Results of Survey in Males

Invitations issued	716
Acceptances	415 (58%)
Minor new cancer discovered	1 Rodent ulcer of face (treated by x-rays, healed)
Pre-malignant or doubtful lesions, under observation	9 { 1 Larynx—chronic hypertrophic laryngitis. Biopsy taken, showed suspicious areas without definite invasion 3 Larynx—papillomata 1 Penis—erythroplasia 2 ? Early rodent ulcers of face 1 Testis—nodule 1 Enlarged bilateral axillary lymph nodes
Benign lesions referred to hospital	4 { 1 Cyst of hand 1 Advanced osteoarthritis of hip (on waiting-list for arthroplasty) 1 Dyspnoea (fully investigated—final diagnosis of "chronic bronchitis") 1 Molluscum sebaceum of nose (treated by curettage, healed)

kept under observation are noteworthy. Slow-growing tumours such as these carry generally a good prognosis with early removal when appearances justify active treatment.

Benign Lesions Discovered

In any series of medical examinations, however superficial, a number of benign lesions, inflammatory, neoplastic, degenerative, etc., will inevitably be discovered. Although it was not our intention to search for such common things, note was made of the obvious benign lesions as they appeared in the systems examined. Vaginal examination, for example, revealed 43 cases of cervical erosion and 10 cases of urethral caruncle. In none of these was treatment thought to be indicated. Other benign lesions found included cervical polyp, uterine fibroid, Bartholin cyst, "chronic mastitis," goitre (common in this region, on the edge of Derbyshire), and laryngeal chondroma.

An enlarging thyroid adenoma (a potentially malignant lesion) was treated by excision. One case of dyspareunia and one of procidencia were also sent to hospital and treated surgically.

Repeat Survey of Female Patients

Following the initial survey of both sexes, it seemed desirable to attempt to repeat the examination, at least in the women. Of the 422 initially examined, second acceptances were obtained in 170 (or 40%). Some drop, of course, was inevitable, and a similar experience was found by Siddall (1952).

This time we were able (by the kind help of Dr. G. R. Osborn, of the Derby Royal Infirmary) to extend the investigation by including a routine vaginal smear, by the method of Papanicolaou (Papanicolaou and Traut, 1943; Osborn, 1953).

The chief results are summarized in Table III.

TABLE III.—Principal Results in Second Female Survey

Invitations issued	422 That is, the "acceptances" of Table I
Acceptances	170 (40%)
Vaginal smear examinations	170 { 2 showed trichomonas infection 1 showed doubtful neoplastic cells
Minor operations	2 { Enlarging pigmented papilloma on abdomen; excision—histologically benign Cervical polyp removed—histologically benign
Miscellaneous	6 Referred to hospital for benign conditions (cervicitis, etc.)

Undetected Cancers

It is clearly of major importance to determine the number of cancers "missed" by our survey, as shown by the subsequent history of the patients. To this end Table IV has been compiled, with details of all the cancer cases that have been diagnosed in patients examined, beginning from the date of the first examination (July, 1951) to the present—

TABLE IV.—Malignant Cases Appearing Subsequent to Examination

No.	Site of Cancer	Sex and Age	Alive or Dead	Length of History of Symptoms	Interval from Examination to Diagnosis	? Cancer Present at Time of Examination	Value of Examination or Education
1	Colon	M 54	Alive	2 weeks	3 weeks	Yes	Prompt attendance definitely due to pamphlet
2	Bladder	M 50	..	"Cystitis" 3 months; haematuria 2 days	1½ years	No	No definite effect
3	Stomach	M 64	Dead	1 month	1½ ..	..	No effect. (Old gastric history. Neurotic subject)
4	Colon	M 52	Alive	2 weeks	1 year	..	No definite effect. (Early attendance because of primary symptom of pain)
5	Stomach	F 44	Dead	Indefinite	1 ..	..	No value. (Symptoms from secondaries only)
6	Brain	F 42	..	1 week	2 months	Yes	No value
7	Breast	F 47	Alive	1 day	1 year	No	Early self-detection through pamphlet
8	Bladder	F 57	Dead	1 week	6 months	Yes	No definite value

a period of 2 years 9 months. Column 6 gives the time interval from our examination up to the appearance of symptoms relative to the cancer, and the next column attempts to estimate whether the growth was present at the time of our examination. This estimate is necessarily personal and subjective, and apt to be very wide of the mark: it is well known that microscopically recognizable cancer can be present many years before giving signs; our "Yes" or "No" is often rather an answer to the question, Could the cancer probably have been detected by more detailed and thorough investigation at the time?—and even the answer to this more limited question is subject to a very considerable margin of error. The last column attempts to assess the actual value of the examination or propaganda as judged by the patient's subsequent history; here again considerable uncertainty enters, but we felt it important to make some attempt of the kind, if only as a basis for argument.

From column 7 it will be seen that we consider cancer to have been present but undetected by us at the time of our examination in three cases (Nos. 1, 6, and 8). In Case 6, of cerebral glioma, although symptoms of "rheumatism" appeared only two months after our examination, it is highly improbable that more thorough clinical examination by ourselves at the time would have detected anything abnormal or altered the prognosis. Case 8 was examined in January, 1952, and at the time was on the waiting-list at hospital for treatment of urethral caruncle; in March dysuria and frequency set in, and she was sent to hospital again, but the symptoms were attributed to the caruncle and she had to wait till June before being admitted as an emergency with acute retention; cancer was quite unsuspected, being discovered only on cystoscopy; it is difficult to blame anyone for this sequence of events, and nothing short of routine cystoscopy—clearly quite impracticable—could have revealed the growth sooner.

Case 2 was examined in June, 1952, and there was then some history of mild dysuria: no physical signs were found, but a note was made on the patient's card advising

reference to a urologist if symptoms persisted. His next attendance was in December, 1953, with symptoms of cystitis for the past three months; treatment for cystitis was begun, but he did not reappear till February, 1954, with two days' haematuria; cystoscopy showed multiple papillomata, one of them infiltrating and malignant. With retrospective wisdom, we might blame ourselves for not following up his original dysuria in June, 1952; the symptoms apparently improved spontaneously and an ordinary bout of cystitis gives the same clinical picture. It he had been examined cystoscopically, papillomata would presumably have been discovered, and active treatment of these might possibly have prevented the later malignant degeneration. This case, as well as No. 8 above described, underlines the value of early cystoscopy; clearly, it is an impracticable counsel of perfection to submit all cases of cystitis to this inconvenience, and a line must be drawn somewhere—just where, is the problem before us.

Cases 1 and 7 represent undoubted triumphs for the educational campaign. In Case 1 the patient stated that it

was certainly the pamphlet that was responsible for his reporting so soon; since his symptoms began only one week after his examination, the warnings would be fresh in his memory. In Case 7 the nodule in the breast was reported at once—it was less than 1 cm. in size, one of the smallest we have ever seen. Radical mastectomy was carried out, but microscopically invasion of lymphatics was evident, with secondaries in axillary nodes. In spite of post-operative radiotherapy, recurrence on the chest wall followed and the prognosis is virtually hopeless. This is an example of the biologically virulent type of growth which metastasizes from the start.

Additional evidence of the potential value of education comes from the fact that some half-dozen patients have reported since the start of the examinations, for rectal bleeding—all of them mentioning the pamphlet with its warning. All of these cases proved to be due to haemorrhoids.

Financial Cost

The chief items of expenditure were for the services of the secretary-chaperon, duplication of circulars, envelopes, and postages (including stamp enclosed for reply).

Fifty-five sessions were held and about 1,000 examinations carried out. The total cost was approximately £150.

The medical man-hours totalled about 140, but in this experimental survey the question of payment for medical services did not arise.

Discussion

Detectable Cancers

With the type of examinations we have used, "detectable" will necessarily approximate to "accessible." What proportion of total cancer will this include? Using the figures of Tod (1949) for estimated incidence in different organs for England and Wales, we may attempt an answer as follows: Out of a total incidence of 2,112 cases per million of population we may place in the "accessible" group the sites listed in Table V, giving 977—that is,

TABLE V.—List of "Accessible" Cancers, and Incidence
(Abstracted from Tod, 1949)

Site	Incidence per Million
Skin	200
Lip	16
Tongue	27
Mouth	10
Jaw (including antrum)	12
Palate	4
Pharynx (including tonsil)	18
Larynx	29
Breast	225
Parotid	5
Thyroid	8
Rectum and anus	156
Male genitals	10
Prostate	56
Uterus	132
Ovary	56
Vulva and vagina	13
	977

approaching one-half. The largest groups among the "inaccessible" types are: lung and mediastinum (171), oesophagus (54), stomach (322), other intestine (including liver and pancreas) (389), bladder (48), Hodgkin's disease and leukaemia (51)—all these together total 1,035.

From Table V it is clear that the cancers most likely to be "picked up" are: skin, breast, rectum, and uterus. Of these, the skin is the least important from the present standpoint, as the mortality is relatively low. The most dangerous of skin cancers is the malignant melanoma; there is a useful field for prophylaxis here in the removal of doubtful moles and pigmented patches, especially from sites exposed to friction and trauma.

The factor of expense has ruled out even the simpler supplementary tests such as urine analysis, Wassermann reaction, and blood counts. Since we had no intention of providing a general medical examination, we felt no compunctions about omitting these tests, as their contribution to cancer detection could not be considerable. Blood counts might have picked out, for example, a case of leukaemia, especially of the chronic lymphatic type in the elderly, where it may be almost symptomless. But leukaemias, like the reticuloses generally, are not such urgent candidates for early detection as the common carcinomas, as their ultimate prognosis is scarcely influenced by earliness or lateness of detection.

There are at least two ancillary investigations, however, that are reasonably practical policies and of real value in "large-scale" cancer detection—the chest x-ray film and the vaginal smear.

Chest X-ray Film.—Some recent results of the largest mass chest x-ray survey so far made are given by Guiss (1952); in 1,867,201 people, 3,500 "suspects" were found, and after investigation 144 carcinomas were confirmed; the operability rate (57%) and resection rate (47%) were relatively very high. Boucot and Sokoloff (1954), however, are much less optimistic about its possibilities. To be of real value the surveys would need to be repeated at intervals of, at most, six months.

Vaginal Smears.—The experienced pathologist can pick out cancer cells, even in isolation, that have been exfoliated from a malignant growth. The method has been used extensively in the U.S.A., especially as a screening test for large groups, and there is no question about its ability to pick out cancers, both of the cervix and of the body of the uterus, at a stage long before they are clinically apparent. The method has, in fact, led to increasing interest in, and detection of, the "carcinoma in situ"—that is, in the pre-invasive stage, when malignant changes are still confined to the epithelium. A recent example of its value is given by Erickson (1953): in 20,000 women of the general population screened there were 1.8% of "positive and suspicious" findings; subsequent biopsies showed about half of them to have carcinoma of the cervix, intra-epithelial or invasive. Siddall (1952), in an investigation comparable with the present one, found three early cancers of the cervix by this method in 563 apparently well women. The drawback of the technique is the relatively great length

of time required for examination of the smears, as well as the scarcity of experienced workers. This has so far confined its use in this country mainly to the gynaecological departments of a few large hospitals—that is, to patients with some complaint; here it has been found of undoubted value (Discussion, 1951).

Other Diagnostic Aids.—Investigations such as smears of gastric aspirations, routine sigmoidoscopy, etc., have been used in the U.S.A. but are practicable only in hospital, and can hardly be used on a large scale. Serological tests for cancer have also proved very disappointing so far.

Is Early Treatment Essential?

The orthodox assumption that early treatment, before spread takes place, should in general be curative has been under heavy recent criticism. On the basis of breast cancer statistics, McKinnon (1952a, 1952b) and Park and Lees (1951) conclude that the survival rate is not appreciably influenced by treatment; delay is therefore not of prime importance, and "curability" is explicable wholly by intrinsic variations in growth rate. Foulds (1951) emphasizes the complex characters of growths—rate of growth, invasiveness, aptitude for dissemination, etc., are not necessarily in step in a particular growth. Considerations of this nature help to explain the paradoxical findings that a short history of symptoms is not necessarily a good prognostic index and may even be the reverse (Walters, Gray, and Priestley, 1941; Harnett, 1953; Swynnerton and Truelove, 1952). But this does not imply that there is no difference in survival rates of patients treated in the early or later stages of the disease (Russ, 1953): all Stage 2, 3, and 4 cases will at one time have been Stage 1 cases, and if treated during Stage 1 would presumably give some at least of the superior results of Stage 1 cases.

The concept of an "early" case is clearly not as simple as was once thought, and clinical "early" cases may be pathologically late (compare Case 7 above). But, as pointed out by Kreyberg (1953) and Kreyberg and Christiansen (1953), who found that 50% of clinically very early breast cancers eventually succumbed to secondaries, early diagnosis and treatment are still of great importance, as we cannot know beforehand who will benefit. Even if the benefit is statistically modest, early treatment of the primary usually gives improved palliative effects, which are normally neglected in cancer statistics.

With the exception of the two extremes of biological virulence, earlier detection and treatment of the large intermediate group seem to hold out the best present-day hope of improvement.

Some Results in Cancer-Detection Work

The American Cancer Society (1949) quoted 0.8% cancers and 10% pre-cancerous lesions in a mixed group of 51,728 symptomatic and asymptomatic patients seen in detection centres throughout the country. Jones and Cameron (1950), from their data, estimate a potential case-finding rate of 1%. Clifton and Rush (1951) report 1.2%, while 2.6% of known cancer subjects were found to have a second malignant tumour.

Siddall (1951, 1952) reports a survey in general practice, more nearly comparable to ours, confined to women. During eight years 1,131 patients were seen; 14 cancers were found in the asymptomatic group and 22 in those with symptoms.

Psychological Aspects

This side of the problem demands the most careful consideration. Indiscriminate publicity can do a great deal of harm. Cancerphobia is common, and medical examination and reassurance can do much to combat it. Its victims, however, may promptly transfer their anxiety to some other field—for example, cardiac. The problem is not that of cancerphobia specifically, but the vastly greater one of neurosis generally.

Our own experience parallels that of Siddall (1952), who found that his patients with cancerphobia could all be

considerably or completely relieved, and that the psychological benefits outweighed the disadvantages.

As an example of the confusion and ignorance in the public mind, as the basis of so much fear and worry, it is worth noting the results of a recent questionnaire to the general public reported by Raven (1953)—17% thought cancer was infectious, 27% that it was incurable, and 20% that it was of doubtful curability.

Other Aspects

In the U.S.A. the average cost per case of cancer discovered has been estimated at anything from 1,000 to 8,000 dollars—clearly prohibitive here. On this score alone, the general practitioner's consulting-room is preferable. Moreover, it is work of a type that enhances the scope of general practice (unlike so many proposals). Conclusions about the value of periodic examinations can be reached only on the basis of large-scale surveys, with adequate follow-up. A suitable agency would appear to be the health centre, of the type recently built, and the financial cost would be relatively low.

Summary

This paper describes a survey in a general practice, in which clinical medical examination was offered to patients between the ages of 40 and 70 combined with instructional propaganda in early cancer symptoms. Four hundred and twenty-two women and 415 men responded, making acceptance rates of 55% and 58%. A follow-up examination on the women was also carried out, including a vaginal cytological smear, bringing the total of examinations to about 1,000.

The findings are reported, with details of malignant and non-malignant lesions discovered.

Some of the arguments for and against such examinations and their possible value in cancer morbidity and mortality are discussed. The psychological and financial aspects are also touched on.

It is concluded that further experimental trials on similar lines would be justified, and are necessary before any appraisal of their long-term value can be made.

Our grateful thanks for the initial grant towards expenses are due to the Sheffield Regional Hospital Management Committee No. 4 (chairman, Sir Ronald Matthews) and its secretary, Captain T. W. Barnard, who gave invaluable help at all stages. Also to the Sheffield Regional Hospital Board for a continuation grant. We would also thank Sir Ernest Finch and Professor Sidney Russ for their interest, encouragement, and help. On the medical side, we are indebted to the kindness of Dr. G. R. Osborn for enabling us to include the vaginal smear examinations; all the material was examined by him. For laboratory assistance we are grateful to Mr. L. R. Reeves, F.I.M.L.T., of the Sheffield National Centre for Radiotherapy, and for secretarial help to Miss B. Wheatley and Mrs. R. Martin.

RECENT DEVELOPMENTS IN THE MANAGEMENT OF BRAIN ABSCESS*

BY

WALPOLE LEWIN, M.S., F.R.C.S.

Assistant Neurological Surgeon, Radcliffe Infirmary, Oxford

During the last ten years there have been considerable advances in the diagnosis and treatment of brain abscess. Of overriding importance has been the introduction of the antibiotics, but superior methods of location, and experience in the methods of treatment available, have all contributed to the improved results. Thus in the Department of Neurological Surgery, Oxford, the mortality has fallen steadily (Table I). The earlier series

TABLE I.—Brain Abscess, 1938-54

Years	No. of Cases	Deaths
1938-43 (before penicillin)	48	22 (46%)
1944-48	62	18 (29%)
1950-54	36	7 (19.4%)

have been described previously (Pennybacker, 1951), and in the present paper the results over the last four years (1950-4) are recorded. During this period there were 36 cases with 7 deaths, a mortality of 19.4%. Concerning these seven deaths it should be noted that three of the patients had been admitted at a late stage, when the abscess had already burst into the ventricle and ventriculitis was established, and one other patient had had multiple abscesses.

In trying to assess these results, the bare figures do not perhaps tell the whole story, since in later years there have been an increasing number of acute cases (including metastatic abscesses, particularly from the chest) reaching neurosurgical clinics for treatment, which may weight the results adversely. The modern trend is perhaps best reflected in the treatment of abscesses resulting from paranasal sinus and otogenic infection: of 20 consecutive patients with abscesses from these sources in the last four years, 19 recovered and 1 died. However, a brain abscess is still a serious matter, and in looking to the future one should not only be seeking for further improvement in diagnosis and treatment but be attempting to reduce the incidence of brain abscess by attention to the sources of infection and also criticizing the quality of the result obtained.

Sources and Prevention

There is a general impression that brain abscess is less common than used to be the case, and this may well be so. No dramatic change is yet shown, however, in the incidence from neurosurgical clinics, but this may be due to the fact that diagnosis is much better than formerly and more cases are now recognized and sent for treatment.

TABLE II.—Source of Infection in 36 Cases, 1950-4

	No. of Cases	Deaths
Frontal sinusitis	5	1
Mastoiditis (Temporal lobe)	14	0
Mastoiditis (Cerebellum)	1	0
Chest infections	4	2
Metastatic from other sources	4	2
Direct implantation (penetrating wounds, etc.)	4	0
Infection of face, scalp, and facial bones	4	0
	36	7

The sources of infection in this series are shown in Table II. The common cause of abscess is paranasal sinus and ear infection, and it would indeed be surprising if the better social conditions of recent years and the greater

*Read in the Section of Neurology at the Annual Meeting of the British Medical Association, Glasgow, 1954.

attention given to otitis media and the chronic running ear did not lower the incidence of brain abscess. Effective treatment of ear, nose, and throat infections is the most important preventive measure in this field.

Of the 36 cases, 4 resulted from *direct wounds* of the scalp or skull. The insistence on proper surgical management of all scalp lacerations and compound fractures has yielded rich dividends, and first-intention healing is now so much a routine that there is even a danger of under-rating the relatively narrow margin of safety that exists. In a recent patient from Korea, for example, brain abscess followed a small compound depressed fracture of the skull in which definitive surgical treatment was delayed owing to the prior claims of associated severe limb injuries. It was the only case of brain abscess seen among these patients returning to Oxford.[†] Particular attention is also necessary for fractures of the skull which implicate the paranasal air sinuses and mastoid regions, since they carry an additional risk of intracranial infection (Lewin, 1954).

Before the days of penicillin, metastatic brain abscesses from *chest infection* such as bronchiectasis and empyema carried a mortality of wellnigh 100%. It is still the most lethal of all the abscesses, but many cases have now been carried through successfully, and indeed the stage has been reached where—for example, after treatment of a brain abscess secondary to bronchiectasis—removal of the affected lung may be undertaken to lessen the chance of a recurrent abscess. A recent series of successful cases so treated has been reported (Pennybacker and Sellors, 1948).

Brain abscess may complicate congenital heart disease even in the absence of bacterial endocarditis, owing to infected venous blood being recirculated through the systemic circulation without first passing through the lungs. Gates *et al.* (1947) have shown that about 5% of deaths from congenital anomalies of the heart and great vessels are due to this cause. In the cases recorded, the brain abscess has usually been solitary, so that with the recent developments in cardiac surgery the possibilities of treating the abscess and also the causal lesion are apparent. The risk of precipitating brain abscess by cardiac catheterization in the investigation of congenital anomalies has also been pointed out, and it has been suggested that penicillin and heparin should be given prophylactically.

All these factors, therefore, may combine to lower the incidence of brain abscess in the future. Indeed, in few other instances of serious complications in surgery are the opportunities for preventive measures higher than with brain abscess.

Early Diagnosis

The clinical picture of the early invasive stage of intracerebral infection with severe headache, vomiting, slowing pulse, and drowsiness passing on to coma is well known, and there is little difficulty in concluding in these circumstances that an intracranial complication has supervened. These gross symptoms and signs due to cerebral oedema and encephalitis still occur, but in many cases nowadays the early use of penicillin so controls this active and very dangerous invasive stage that the first signs of a brain abscess may be attended by only relatively mild changes in the patient's condition. Indeed, the risk is that a diagnosis of cerebral abscess may be excluded on the premise that the patient is not ill enough.

During a sinus or mastoid infection, the very fact that the patient is not as well as he ought to be should be enough to raise the suspicion of an intracranial complication, and this probability is increased if headache is present. It is at this stage that a careful neurological examination may yield unequivocal evidence. Obvious papilloedema, a hemiparesis, dysphasia, or frank ataxia may be present, but again in other patients such gross signs are absent. Frontal lobe abscesses, for example, may declare themselves by only a

mild reflex change down one side of the body, or possibly a little facial weakness or an isolated fit, or nocturnal incontinence in a patient otherwise alert. In the temporal lobe, an abscess will very commonly produce a visual-field defect in the opposite upper homonymous field, which may be missed unless confrontation tests and careful perimetry are done as a routine; and if it is in the dominant hemisphere a dysphasia may be present, but may be mild and detected only if formal examination such as the meaning of objects, etc., is carried out. A cerebellar abscess usually gives rise to nystagmus. These relatively mild signs, when looked for, are present much more often than is thought to be the case.

Lumbar Puncture.—A lumbar puncture may be invaluable, since the fluid is rarely normal in the presence of an acute or subacute abscess. The protein content is usually raised to 100 mg. per 100 ml. or more (normal 40 mg.) and there is often an increase of white cells in the C.S.F. from 10 to 200 per c.mm. Nevertheless this test should be used with caution in the presence of marked papilloedema, a slow pulse, or rapidly increasing drowsiness, since there is a risk of tentorial impaction, and in these circumstances it is wise to have facilities for dealing with the abscess at hand.

Electroencephalography and angiography are two other ancillary methods of diagnosis that have been developed in recent years and are proving helpful in the more accurate location of an abscess.

Electroencephalography.—This test may help in locating an abscess and also in differential diagnosis from such conditions as thrombophlebitis. In addition, serial recordings during the management of an abscess may give a clue should a further abscess be developing elsewhere, particularly in cases of metastatic origin. The focal disturbance seen is that common to any rapidly expanding intracranial lesion, and consists essentially of a high-voltage delta activity in the vicinity of the lesion, together with a local phase reversal. Tutton and Whittaker (1953, personal communication) have commented favourably on the use of the E.E.G. in the management of brain abscess. It has the merit of being easy to perform and not disturbing to the patient.

Angiography.—Another recent development in the diagnosis of brain abscess has been the use of angiography. For supratentorial lesions, particularly of the frontal and temporal lobes, which are the common sites for abscess, it may be invaluable and will locate the lesion accurately without the considerable upset that may attend the use of ventriculography in such cases. It affords, of course, no evidence of the true nature of the lesion, and in abscess cases the appearance is one of vessel displacement by an avascular space-occupying lesion.

Ventriculography is still used for the diagnosis of the difficult deeply seated hemisphere and infratentorial abscess, but the tendency nowadays is to employ air studies less in the acute stage, although, as referred to below, to rely on them, if anything, more in the later stages as a test of cure.

Treatment

Now that the antibiotics, usually penicillin, do so much to control the invasive stage of encephalitis and cerebral oedema, it is possible to simplify the surgery of the acute abscess, and most surgeons are agreed to-day that the first treatment of choice, and one which is applicable to the majority of abscesses, is simple needle aspiration of the abscess through a suitably placed burr-hole, repeated as required, with local injection into the abscess cavity of the appropriate antibiotic—in most cases penicillin (Tutton, 1953). Taylor (1950) favours in addition the routine use of intraventricular penicillin during this stage, and makes the point that it lessens the risks of dissemination of the infection into the cerebrospinal fluid spaces of the brain around the abscess, one of the main complications in the management of brain abscess.

Part of the success of aspiration is due to the accurate location of the abscess, and the advantages of the recent developments already referred to are apparent. The operation is conducted through a clean incision, and we have long since abandoned attempts to drain an abscess along the entry track, as, for example, through a mastoid wound, which may lead to cerebral fungus. Similarly, open drainage is rarely effective after the first escape of pus, and the insertion of tubes and subsequent manipulations may cause further brain destruction and risk of rupture of the abscess; in addition it may leave undrained a loculus of the abscess.

In a few cases aspiration with local and systemic antibiotics is inadequate to control the raised intracranial pressure during the acute stage and a decompression may also be required. In addition there are other abscesses, especially those resulting from penetrating wounds or metastatic from the thorax, in which a honeycomb of small abscesses or a complicated abscess cavity may result, for which aspiration or tube drainage proves inadequate, and in this instance excision of the phlegmon in the acute stage may be indicated. Indeed, Le Beau (1946) has advocated its wider adoption, but we would restrict this operation to those few cases in which there is no other effective alternative, since it must mean sacrifice of recoverable cerebral tissue and an increased risk of resultant disability.

Thus, although one can see a general plan of treatment emerging, there is no one operation which is applicable to all acute abscesses. To improve the results of this stage therefore requires that the surgeon should have all these methods at his disposal and consider each case on its merits. Even so, the risks of rupture of the abscess into the ventricle, as shown from the deaths in this series, and the problem of multiple abscesses remain major problems. Thus in one of two recent fatal cases the patient had a left metastatic parietal abscess treated by aspiration, supplemented later by a decompression when it was clear that more was required, but at necropsy a second abscess with gross surrounding oedema was found further forward, deep in the post-frontal region, and a third on the opposite side. In the other case (not in this series) small quantities of pus were aspirated from both frontal lobes of a patient who developed signs of cerebral infection with no obvious primary focus other than an upper respiratory infection which had resolved. At necropsy it was possible to count at least 130 small abscesses scattered through the hemispheres. These two examples may be uncommon, but they serve as a salutary reminder that the treatment of the acute abscess is unlikely to become a matter of routine.

The management of the later stages is still debatable. Most abscesses can be treated by aspiration alone in the acute stage, and some surgeons believe that if further aspirations yield no pus, and provided the patient is well, no more need be done, although the majority agree that, as a final test of cure, air studies should be carried out in the quiescent stage to ensure that no loculus remains and that the lumbar C.S.F. protein and cell content have returned to normal. This policy is attractive in its simplicity and treats the abscess with the least possible damage to the surrounding brain, and, presumably, therefore lessens the risks of ultimate scarring.

There are difficulties, however. If this method alone is to be used then the tests of cure have to be rigid; most surgeons have had the experience of the well patient with only a doubtful abnormality in the ventricular air studies and yet shown subsequently to have a large abscess. Indeed, the gross displacements seen in ventriculograms and angiograms during the acute stage are due as much to the oedema around an abscess as to the amount of pus (Schurr, 1951); and subsequently a sizable collection may remain in the frontal pole or the inferior part of the temporal lobe or the cerebellum, with the production of only minimal radiographic changes. Moreover, a negative aspiration does not exclude the presence of pus: in some instances the pus becomes so thick as not to flow through the needle;

or a loculus, which occurs in over 40% of abscesses, may be present and remain untapped; or the abscess may be missed altogether. Further, we have seen several examples where sudden and dangerous enlargement of an abscess has occurred in a patient previously doing well.

For these reasons, therefore, other surgeons have injected radio-opaque substances into the abscess cavity at the time of aspiration so that its subsequent fate may be followed. Detection of an unsuspected loculus or enlargement of the abscess may then allow a timely aspiration before dangerous complications supervene. For many years now this has been our policy, and we have used thorotrast. Oliver and Leese (1949), to overcome the objection of introducing a substance which is retained in the abscess wall, have suggested the use of diodone, which is absorbed; but this method does not confer the real advantage of using a radio-opaque substance—namely, to watch the progress of the abscess and be able to anticipate developments.

Thorotrast is of course a foreign material, and Taylor (1950) thinks that it may promote chronicity. It has also been suggested that it may increase the fibrous reaction around the abscess. The substance is also radioactive. We have not seen any obvious differences in the brain around an abscess at the time of excision whether it has previously been injected with thorotrast or not, nor, in the amounts used, have we so far seen any adverse effects from possible radioactivity. The substance has now been used for this purpose for about 14 years, so that presumably the risk is a small one. It is possible that in the future early diagnosis and effective antibiotics will make loculation of abscesses and other complications of management less common and that in some cases at least it will be possible to dispense with this additional guide. If so, it would be welcome, but at present one would feel that, as further improvement in results is likely to come from attention to individual details, the surgeon needs all the help he can get in a condition so dangerous and treacherous as brain abscess.

Excision

Apart from those particular abscesses which may require excision in the acute stage, there are others in which pus continues to reaccumulate despite repeated aspiration. In some instances this is related to the sensitivity of the causal organism to antibiotics, and careful bacteriology is, of course, an essential part of the aspiration-antibiotic regime. Nevertheless some of the most troublesome abscesses to deal with are those in which all cultures are persistently sterile, yet the behaviour of the abscess is evidence that the infection is anything but quiescent, and for these cases excision may be required.

How safe is the patient from recurrent infection when treated by aspiration alone and when it is realized that 40% of abscesses are multilocular? In a recent review of 295 abscess cases from Edinburgh, Manchester, and Oxford, Jooma *et al.* (1951) found that, of 88 survivors treated by aspiration or drainage alone, 7 developed recurrent infection (8%) at intervals of from 3 months to 13 years later, and they all died; among 96 patients who survived excision there were no recurrences. These figures should not be overemphasized, since much of the material was in the pre-penicillin era, and one would anticipate that, with recent developments and the more rigid standards of cure in the future, this incidence would fall. Nevertheless, it is clear that only by excision of the whole area can one be certain of ultimate cure. Provided, therefore, that it can be done without increasing the patient's disability, or materially increasing the mortality, excision requires consideration. We have followed this policy in the past. An added hope was that by removal of the abscess scar the incidence of epilepsy later on would be significantly lowered. As referred to below, this has only been partly realized. It is certainly true that, with the more successful management of the acute abscess by aspiration and antibiotics, fewer abscesses will need excision in the future, but there are still cogent reasons for advising excision of frontal,

[†]The patients from Korea were admitted to the Military Hospital (Head Injuries), Wheatley, Oxon, and their management will be described elsewhere.

temporal, and cerebellar abscesses when there is the slightest doubt that the infection has not resolved. In the last four years we have excised 18 abscesses (62% of the survivors from the acute stage) with no deaths.

The Primary Focus

The primary focus of infection needs to be considered in every case, although in some it has resolved before the brain abscess is evident and in others it responds to the antibiotics given during treatment. When surgery is required it is generally agreed that the brain abscess should first be brought under control. In cases of sinus infection or mastoiditis which require drainage this can then be carried out shortly afterwards with greater safety or, in other cases, deferred into the convalescent stage. More elective treatment, such as lobectomy for bronchiectasis, is usually carried out when treatment for the brain abscess is finished.

Sequelae

The late effects of cerebral abscess are three: recurrent infection, which has already been discussed, permanent neurological disability, and epilepsy. It is not proposed to discuss the permanent effects in detail except to say that grave disabilities are happily uncommon. Of the 29 survivors of the last four years, only two are permanently disabled. In one disablement was due to a decerebrate state which resulted from brain-stem compression, the patient being admitted in coma with fixed dilated pupils; in the other patient a progressive hydrocephalus developed secondary to meningitis, which accompanied the abscess. Indeed, it is remarkable how ill and handicapped these patients can be in the acute stage and yet ultimately make good functional recoveries.

Epilepsy, however, remains the major problem in patients with abscesses of the cerebral hemispheres: it develops in over 45% of the survivors. Indeed, with recovery from brain abscess becoming more the rule, this complication is likely to be more apparent to the surgeon in the future. Nevertheless, one should hasten to add that in most cases the attacks are infrequent, and in only a few are they of such an order as to render the patient unemployable. Its incidence is highest with multiple abscesses and with frontal abscesses, being well over 50%, and is least with temporal abscesses, 34%. Fortunately with the wide range of anticonvulsant drugs now available, the majority of patients are able to lead a normal life with perhaps an occasional attack, the tendency being for the attacks to diminish as time goes on. Nevertheless our aim should be to reduce its incidence if possible, and in this connexion there are at least two possibilities.

If one believes that it is the scar left after the abscess has healed, rather than the very fact of having had an acute infection of the brain, that is responsible for the epilepsy, then the smaller the scar the better, and it may be that, in the future, early diagnosis and antibiotics will lower its incidence. Again, if it is the scar that is responsible, would not excision lower the incidence of subsequent fits? Joorna *et al.* (1951) showed that the incidence of epilepsy was significantly lower after excision of a frontal abscess (44%) than after treatment by aspiration or drainage alone (72%). The fits after a frontal abscess are particularly important, since they are the more dangerous as they may occur without warning, and in this site also status epilepticus is likely. Indeed, in the review by Joorna *et al.* (1951) there were five fatal cases in the late results from status epilepticus, and all were frontal abscesses. On these results, therefore, there would appear to be a good case for excision of a frontal abscess on the grounds of epilepsy alone.

Temporal lobe abscesses also show a lower incidence of epilepsy after excision (27%) compared with aspiration alone (40%), but the practical results are not so striking, since disabling epilepsy from this site is uncommon. The explanation for this improvement with excision may lie in the fact that in excising a frontal abscess one is usually

able to take a more generous excision into the surrounding white matter and the track is usually excised as well as the abscess cavity, so that in effect a scar excision, as in operating for traumatic epilepsy, is not infrequently performed. To some extent this may also be true of some temporal lobe abscesses, particularly in the non-dominant hemisphere. It may therefore be that in suitable cases electrocorticography and removal, where practicable, of active foci in addition to excision of the abscess should receive further consideration. Certainly surgery directed to the epilepsy as in post-traumatic cases should yield results, either in the phase of active treatment or later on if epilepsy is declared and is proving a major handicap, which are at least comparable.

Summary and Conclusions

The advent of antibiotics, the wider recognition of the early signs of intracranial infection, and the use of ancillary methods of investigation such as angiography and electroencephalography have all contributed to the improved results in the treatment of brain abscess. In the series of 36 cases reported here over the last four years there were seven deaths, a mortality of 19.4%. Prevention, however, is better than cure, and the several ways by which this may be partly achieved are outlined.

Intermittent aspiration of the abscess combined with local and systemic antibiotics, usually penicillin, is recommended as the treatment of choice in the acute stage, but formal decompression may be required in certain cases. The indications for excision of the abscess both in the acute and in the later stages are also discussed.

The various ancillary methods of investigation are valuable both in differential diagnosis and in the management of a brain abscess, but it is wise to remember that in some instances the results they yield are at the best equivocal and that in dealing with intracranial infection a sound clinical appreciation of the case remains the first essential.

There are at least two major problems which call for further study. One is the management of the metastatic abscess, especially that from the chest. Frequently multiple, often multilocular, neither easy to diagnose or locate nor necessarily occurring in sites readily accessible to surgery, it remains a challenge to the surgeon. The other problem is the high incidence of epilepsy (45%) among the survivors from brain abscess. It may be that its incidence in the future will fall with improved methods of treatment in the acute stage, but the possibilities of surgical excision with the help of electrocorticography, particularly in the frontal region, merit further attention.

The recent advances in the management of brain abscess should be a stimulus to lower the mortality further and to improve the quality of the result.

My thanks are due to Mr. Joe Pennybacker for his helpful criticism in the preparation of this paper.

CHRONIC LEG ULCERS IN NON-THROMBOCYTOPENIC PURPURA

BY

A. R. HORLER, M.B., M.R.C.P.

Graduate Assistant

AND

S. C. TRUELOVE, M.D., M.R.C.P.

Assistant Physician

Nuffield Department of Clinical Medicine, Radcliffe Infirmary, Oxford

Apart from a probable case reported by Osler in 1914, we have been unable to find in the literature any account of leg ulcers occurring in non-thrombocytopenic purpura. As we have seen three such cases in the last two years we think it worth while to report them.

Case 1

A married butcher aged 57 first came to the out-patient department in December, 1953, with a complaint of swollen joints for 10 days. He had a history of developing painful swollen joints 30 years previously while serving in the Army in Egypt. They became normal in six months with no residual disability (he was later a racing cyclist). In 1943 he was treated for a prolapsed intervertebral disk by laminectomy, and post-operatively developed a thrombosis of the left small saphenous vein. Following this episode he was subject to mild ankle oedema after standing for prolonged periods, but no other disability. His present illness began suddenly with swelling of the right knee and a blotchy rash on the skin surrounding that joint. In the course of the next few days, the left knee, right ankle, both elbows, and right wrist also became swollen and painful. At the same time the rash spread over both legs, and, to a less extent, over the trunk. It came as a series of crops, and the patient noticed that the spots were raised above the skin and did not itch. There was no past history of any allergic disorder and he had never taken any drugs.

On examination he was well nourished, with a purpuric rash in which there was an urticarial component, richly distributed over the legs, buttocks, and extensor surfaces of the arms, and more sparsely over the trunk. Several joints were swollen and painful on movement—namely, both knees, both ankles, both elbows, both wrists, and the left shoulder. The spleen was not palpable. Small, discrete, painless lymph nodes were felt in the occipital, the cervical, and both axillary regions. The left small saphenous vein was represented by a firm cord-like structure, which was evidently the sequel of his post-operative venous thrombosis ten years earlier. The left long saphenous vein was prominent, but there was no evidence of varicosity; and the skin was healthy apart from the purpura. In other respects, physical examination was negative. A diagnosis of Schönlein-Henoch purpura was made, and he was admitted to hospital for further investigation and treatment.

While in hospital he was found to have a persistent albuminuria with occasional red blood cells. Apart from a moderately raised E.S.R. (17 mm. in one hour by the Wintrobe method) his blood picture was in all respects normal—namely, platelets, 557,000 per c.mm.; red cells, 4,840,000 per c.mm.; haemoglobin, 14.4 g. per 100 ml.; white cells, 3,900 per c.mm. on one occasion and 8,600 on another, with a normal differential distribution. The bleeding-time (Duke) was

one minute and the clotting-time (Lee and White) 6 minutes. The one-stage prothrombin time was normal. The report on a bone-marrow examination by Dr. S. T. E. Callender was as follows: "The marrow is moderately cellular. Eosinophils are fairly frequent. Apart from this, there is no definite abnormality." The tourniquet test caused increase in size of the existing purpuric lesions, but no fresh petechiae occurred.

During his stay in hospital he developed cramp-like abdominal pain and was found to have large amounts of occult blood in the stools. Thus the classical picture of anaphylactoid purpura was complete.

He was in hospital for two months following this admission. During this time he received treatment with cortisone by mouth in a total dose of 4.2 g. over a period of three weeks. The disease was unaffected. The purpura persisted, fresh crops of lesions occurring intermittently, and there was no notable improvement in his joints. He later showed gradual improvement, with his joints returning slowly to normal and the petechial rash diminishing. As already mentioned, gross albuminuria persisted, but he remained normotensive and his blood urea was normal. The tourniquet test became strongly positive during the latter part of his stay in hospital. He was discharged from hospital on February 16, 1954, with no joint symptoms or bowel symptoms, but with a scanty petechial eruption.

He was then regularly seen in the out-patient department. He continued to have recurrent crops of purpura, mainly over the legs, with both ankles particularly affected. In March, 1954, he developed an ulcer of the left ankle at the site of a patch of profuse purpura. The ulcer persisted and became more extensive, and he was readmitted to hospital in June. At that time there were two shallow ulcers, each about 2.5 cm. in diameter, in the region of the left medial malleolus and one shallow ulcer about 7 by 1 cm. in the region of the left lateral malleolus. There was a fading purpuric eruption on the legs. Investigations at this time gave the following results: haemoglobin, 13.6 g. per 100 ml.; white cells, 6,000 per c.mm.; platelets, 248,000 per c.mm. The urine contained albumin, red blood cells, and occasional granular casts. The blood urea was 35 mg. per 100 ml.; plasma proteins, 5.4 g. per 100 ml., with albumin 3.2 g. The tourniquet test was strongly positive on admission and later became negative. With rest in bed the ulcers healed and he was discharged in 24 days, having had no fresh purpuric eruption.

Shortly after leaving hospital fresh purpuric crops occurred and he had occasional abdominal pain and painful joints. By September the purpura had become more severe and ulceration of the left ankle had recurred (see Fig.). He was readmitted to hospital, where rest in bed and eusol

Photographs of Case 1, showing large areas of ulceration and surrounding purpuric lesions.

dressings brought improvement of the ulcers. His purpura became less severe, but albuminuria persisted. When last seen, in October, the ulcers were covered by scabs and appeared to be healing well. The purpura was then absent.

Comment.—The history, physical signs, and results of investigation leave no doubt that this patient suffers from Schönlein-Henoch purpura. The only doubt that exists is whether the venous thrombosis he sustained ten years previously played any large part in the genesis of his leg ulceration. We do not think this likely, for the following reasons. He had been working for those ten years as a butcher, standing a great deal, with negligible symptoms. The ulceration occurred when he was living the life of a semi-invalid involving less need for a perfect venous return. Secondly, the ulcers were not surrounded by the eczematous changes in the skin which almost invariably accompany varicose ulceration. Finally, the ulceration occurred at a site where the purpura was so dense as to be confluent.

Case 2

A clergyman aged 62 was under our care for severe rheumatoid arthritis, which began in 1934, and later made him dependent upon an electric chair for mobility. From April, 1952, until March, 1953, we treated him with large doses of sodium salicylate with relief of his joint symptoms, but only at the expense of troublesome deafness. In March, 1953, salicylate therapy was stopped and he was put on to treatment with phenylbutazone by mouth in a dose of 200 mg. four times a day. He continued on this therapy, and on August 13 he noticed purple spots on his legs. The eruption became more profuse and he was admitted to hospital ten days later.

On examination at that time he had a profuse purpuric eruption covering both legs, buttocks, and the extensor surfaces of both arms. His joints showed evidence of long-standing rheumatoid arthritis. The spleen was not felt. All other systems were normal. Investigations gave the following: platelets, 745,000 per c.mm.; red blood cells, 4,380,000 per c.mm.; haemoglobin, 14.4 g. per 100 ml.; white cells, 8,000 per c.mm., with a normal differential distribution; bleeding time (Duke), 3½ minutes; E.S.R., 32 mm. in one hour. The tourniquet test was negative. The phenylbutazone had been discontinued before admission on the assumption that it was the agent responsible for the purpura and he was treated with calcium aspirin. The purpura appeared to be subsiding and he left hospital after one week, being anxious to return to his parish.

When seen in the out-patient department a week later several of the purpuric patches on his legs appeared to be about to slough and arrangements were made for his readmission. By the time he was admitted to hospital, a week later, painful ulcers had developed on his legs, three on the right and two on the left. On the anterior surface of the shins there were two ulcers on the right side and one on the left. Both medial malleoli were the site of ulceration. The symmetrical distribution of the lesions was notable. The surrounding skin was inflamed. At this time the purpuric eruption was confined to the legs below the knees. The results of investigations were similar to those on his previous admission, except that the tourniquet test had become positive.

The ulcers were treated with eusol dressings, and after three weeks complete healing had occurred and he was discharged from hospital on October 5.

A week later, when seen as an out-patient, the ulcers of the legs had recurred. He was unwilling to be admitted to hospital, but was seen frequently as an out-patient. From October, 1953, until February, 1954, he had several severe exacerbations of the purpura, with occasional ecchymoses. Throughout this period the ulcers repeatedly healed and broke down; they were extremely painful. Complete bed rest at home assisted the ulcers to heal, but made the stiff-

ness of his joints much worse, so that a satisfactory regime was difficult to achieve.

In April he overcame his reluctance to desert his parish and was readmitted to hospital, where it was hoped to combine treatment in bed with active physiotherapy for his joints. On examination there were fresh petechiae of the legs superimposed on areas of fading purpura. There were several ulcers of both legs, about 2.5 cm. in diameter, from which came a purulent discharge. They were treated with eusol dressings and later with tulle gras, and healed well in the course of the next few weeks. The results of investigations on this admission were: platelets, 343,000 per c.mm.; red cells, 4,290,000 per c.mm.; haemoglobin, 12.8 g.; white cells, 6,000 per c.mm., with a normal differential distribution; bleeding-time (Duke), two minutes; clotting-time (Lee and White), eight minutes; one-stage prothrombin time, normal; E.S.R. (Westergren), 52 mm. in one hour. A patch test with phenylbutazone was negative.

He was discharged from hospital in June. He has been seen since and the ulcers have not returned.

Comment.—There is no doubt that in this patient the purpura was responsible for the ulceration of the legs. The cause of the purpura is uncertain, but it is highly probable that it was a toxic effect of phenylbutazone. Non-thrombocytopenic purpura is a rare complication of phenylbutazone therapy, occurring in 4 out of 800 patients studied by Kuzell *et al.* (1953).

Case 3

A housewife aged 66 attended the skin department, Radcliffe Infirmary, in August, 1952, complaining of a painful localized swelling on the inner side of the right lower leg which had been present for three months. Three weeks later a purpuric rash developed on both arms, and later became generalized. She was referred to us and was found to have the following signs. There was a generalized purpuric rash, which was most pronounced on the extensor surfaces of the arms and on the trunk. The petechiae were discrete and raised above the surface. There was an indurated erythematous area, about 7.5 cm. in diameter, on the front of each lower leg. The distribution was symmetrical. Each area contained several ulcers which were covered with hard scabs. Apart from a palpable liver, there was no other abnormality on clinical examination.

She was later admitted to hospital, when investigations were essentially negative—namely, platelets varied from 193,000 up to 667,000 per c.mm.; haemoglobin, 11.7 g. per 100 ml.; red cells, 4,200,000 per c.mm.; white cells, 7,200 per c.mm., with a normal differential distribution; bleeding-time (Duke), 2½ minutes; clotting-time (Lee and White), 6½ minutes; one-stage prothrombin time, normal; clot retraction (Marfarlane), 50% (normal); plasma proteins, normal. Liver function tests: plasma bilirubin, 0.4 mg. per 100 ml.; flocculation tests, normal. Coombs test, the Wassermann and Kahn reactions and the tourniquet test were negative.

She was discharged after one week at her own request to care for her invalid husband, with no change in her clinical state. In December, when she was seen as an out-patient, the purpura was still present but less intense. The ulcerated area on her left leg had healed, but that on the right was still active. Blood investigations were negative, with the exception of the E.S.R., which was 102 mm. in one hour (Westergren). She refused to enter hospital for cortisone therapy and failed to attend the out-patient department until five months later (May, 1953). Her purpuric rash had by then completely disappeared, and the ulcers of the legs were healed. She refused to have a blood examination, so that we do not know whether the E.S.R. had become normal.

According to her family doctor, she remained well and free of purpura until August, 1953, when he was called in because she had died suddenly in her bed at night. The cause of death was certified as coronary thrombosis.

Comment.—It is probable that this patient's non-thrombocytopenic purpura was an example of so-called anaphylactoid purpura. It is noteworthy that she developed indurated areas of both legs before the onset of the purpura and that these subsequently ulcerated. The most reasonable conjecture would appear to be that both the indurated areas and the purpura were independent manifestations of the same underlying allergic state.

Discussion

We have no doubt that leg ulcers which persist for several months are decidedly rare in non-thrombocytopenic purpura. Davis (1948) reported 44 cases of Schönlein-Henoch purpura without mentioning ulceration among the skin lesions. Gendel (1948), in a review of the reported cases of chronic leg ulcer in diseases of the blood, likewise does not mention this association. Chronic leg ulcers have been observed in a number of blood dyscrasias, such as congenital haemolytic anaemia, sickle-cell anaemia, polycythaemia, splenic anaemia, thrombocytopenic purpura, and Gaucher's disease, in all of which splenomegaly is a frequent finding, and it has been usual to attribute the liability to leg ulceration to some abnormal action of the spleen.

In thrombocytopenic purpura the occurrence of leg ulcers is also rare, being reported for the first time by Witts (1942). It is worth mentioning that the two cases which he reported did not show splenomegaly and that splenectomy carried out on one of them had no effect upon the ulcers.

The only reference to the occurrence of leg ulcers in non-thrombocytopenic purpura appears to be the one made by Osler (1914), who states that necrotic areas may occur in purpuric states. "When a localized infiltration of blood and serum is very intense in a patch [of purpura] of considerable size, bullae form and the superficial layers of skin necrose, leaving an open ulcer." In describing a number of cases, he includes that of a girl aged 14 years who was treated in the Radcliffe Infirmary for Henoch's purpura. Although no platelet count is recorded, there seems to be little doubt from the clinical description that the diagnosis was correct. She suffered from pains in the legs, purpura, haematuria, and albuminuria. There were extensive haemorrhagic lesions on the legs, many of which broke down, leaving ulcers which took a long time to heal.

Osler's description of the genesis of skin ulceration in purpura is an apt account of how ulceration developed in Cases 1 and 2 of the present series. In Case 1 there was the possibility that a previous venous thrombosis may have been an additional cause, but we have given reasons for concluding that this was not a major element. Case 3 is totally different in that ulceration developed in indurated erythematous areas which appeared on the legs some months before the onset of purpura.

Summary

Three cases of leg ulceration in non-thrombocytopenic purpura are described.

The aetiology of the purpura was different in the three cases, one being a classical example of Schönlein-Henoch purpura, one a toxic purpura, presumably due to phenylbutazone, and one possibly a manifestation of an obscure allergic state.

We are grateful to Professor L. J. Witts, Nuffield Professor of Clinical Medicine, Oxford, for permission to publish these cases.

POST-PUERPERAL RECURRENT DEPRESSION

BY

A. B. HEGARTY, M.B., M.R.C.P.Ed., D.P.M.
Deputy Medical Superintendent, Winson Green Hospital, Birmingham; Psychiatrist, All Saints' Clinic, Birmingham

The purpose of this paper is to draw the attention of practitioners to a form of illness which is not uncommon and which is important, not only because of the distress and incapacity which it inflicts upon the patient, but also because of the repercussions which it produces within the family group.

There are few references in the literature to the sequelae of puerperal depression. Hemphill (1952) mentions "a periodic affective illness . . . after childbirth, with subsequent attacks related to menstruation." There is little doubt that he had in mind patients such as those I am about to describe. Linford Rees (1953) has observed that "in some patients with children it was found that premenstrual tension had developed or had become worse after childbirth." These, however, are merely the passing remarks of writers who were dealing with a different theme.

Summaries of seven cases are here presented of women with a history of puerperal depressive illness some years previously, following which full health has never been regained and recurrent sharp phases of depression, tension, and irritability have occurred, with short interludes of comparative well-being. The resemblances which these patients bear to one another in their history and symptomatology appear to class them as a distinct group, to which it is proposed to attach the name "post-puerperal recurrent depression."

These patients tend to take a moral rather than a medical standpoint towards the alteration in their feelings and behaviour. While they are not rare as visitors to psychiatric clinics (5 in the last 300 new patients seen), it is probable that many of them do not seek medical advice, or, if they do, are not sent for psychiatric examination.

Typical History.—A woman of pyknic build and cyclothymic temperament suffers from a relatively mild puerperal depressive illness in her thirties or late twenties. Emotional stress or an infective illness may have coincided with the puerperium. She appears to make a good recovery from her depression, but within a short time becomes unwell again. Thenceforward, for years, she suffers from recurrent phases of depression, irritability, and tension, with phobias, obsessive fears, or hypochondriasis. The severity of her symptoms is related to the menstrual cycle, usually the premenstrual phase. Irregularity of the menses is a concomitant feature. Her moodiness, unpredictability, and loss of temper are reacted to by the children and the husband, the family atmosphere becomes clouded and unstable, and the family ceases to function as a unified group.

Case 1

Observation period, All Saints' Clinic, seven years; personal observation, two years. Large-framed woman of pyknic build, aged 38. Facial pallor. Expression morose. Para-3.

Her present illness began in 1943: after birth of her second child lacked confidence to go out and about. Within a few days of birth of third child in October, 1945, became depressed and agitated. Had a mild febrile illness attributed to throat infection at this time. Three attacks of

quinsy in subsequent eight weeks. Remained acutely disturbed for three months. Something in her head seemed to say, "Put the baby on the fire." Impulses to strangle the child or to throw her out of the window or to jump out of the window herself. "Not real voices, but thoughts in her mind."

Admitted to Midland Nerve Hospital in tenth month of puerperium. In hospital nine weeks. Treated by sedation. Acute symptoms subsided. Attended as out-patient at Midland Nerve Hospital subsequently for two months, but developed pneumonia. Stopped going.

Referred to All Saints' Clinic in August, 1946. Still plagued by impulses to strangle child. Received E.C.T., six shocks, October, 1946. No lasting improvement. Termination of pregnancy and sterilization, 1948. Attended until August, 1950, receiving analytical psychotherapy. Appreciated the opportunity to express her fears but did not lose strangling ideas, and continued to have depressed moods.

Returned to all Saints' Clinic April 18, 1952. Complained of intermittent feelings of hopelessness; lack of inclination to do things; marked irritability; depression, lasting for a few days at a time, accompanied by impulses to strangle children or throw them out of the window, to commit suicide, to smash crockery, to smack people in the face, etc. Symptoms most marked nine or ten days after start of menstrual period. Severity fluctuates at other times, and she has freedom from symptoms for two to three days at a time.

Response to Treatment.—Acetylcholine shock, 1953: no appreciable effect. Dextro-amphetamine, 10 mg., and amylobarbitone, 1 gr. (65 mg.) b.d., and supportive therapy. Moderate symptomatic benefit. Decrease in irritability and depression, and in intensity and frequency of obsessional impulses, together with some all-round improvement in the family atmosphere. Withdrawal of medication leads to immediate worsening of symptoms. Weight remains fairly constant at 10 st. 1 lb. (64 kg.).

Comment.—Severe case. Good spells infrequent and last only a day or two. Anxieties and febrile illnesses during puerperium. Symptoms related to menstrual cycle. Patient's illness had led to serious repercussions within the family.

Case 2

Personal observation, one year. Stoutish woman of pyknic build, aged 39, para-1: florid complexion; anxious expression.

Present Illness.—Seven years ago, when eight months pregnant, she developed right-sided Bell's palsy. Much worry about this. Prolonged labour—forceps delivery. Urinary infection with high fever for first week of puerperium. For next three to six months had to fight against feelings of depression and lack of energy. Got a bad fright when baby was 8 weeks old, when she found a cat lying on his face in pram. Feared he was smothered. Depression gradually diminished, but she has never felt quite well. Feelings of weakness; "no life" in her legs; avoids company; giddiness and fears of falling; lacks confidence to do things; sensitive about residual facial weakness; irritability and intolerance of noise. Symptoms vary in severity from day to day. Much worse before and during menstrual period. Gradual improvement in past one to two years, but still much handicapped before start of treatment.

Environmental Factors.—Strict mother, but no family strife. Husband's untidiness annoys her, but on the whole the relationship is good.

Previous Health and Personality.—Very active, energetic, and sociable. Very particular and fastidious regarding house and personal appearance. No previous breakdown. No severe physical illnesses. Mild chronic bronchitis.

Response to Treatment.—Excellent symptomatic response to dextro-amphetamine, 5 mg. b.d., amylobarbitone, 1 gr. (65 mg.) b.d. Feels well. Has taken a part-time job.

Actively seeks company. Symptoms return if tablets are withdrawn temporarily.

Comment.—Moderately severe case. Good spells last only a day or two. Anxiety over facial palsy and acute infection during puerperium. Symptoms related to menstrual cycle. Tendency to spontaneous improvement in recent years. Dramatic response to dextro-amphetamine.

Case 3

Observation period, All Saints' Clinic, 10 years; personal observation, two years+. Large florid-complexioned woman of pyknic build: para-1, aged 47.

Present Illness.—Began 11 years ago when her baby was about 7 weeks old. Depressed for six months; then improved but has never been quite well since. Feelings of depression accompanied by "dislike" of her husband and child; general irritability; fears of becoming insane, committing suicide, or attacking others; fatigability; discomfort, sometimes amounting to pain, in left side of head and face. Symptoms begin abruptly, last for one to three weeks and disappear rapidly. They tend to begin premenstrually and to lift soon after period ends. In past 12 months increased tendency to flushing and weeping (? menopausal).

Environmental Factors.—Much difficulty with interfering mother-in-law, who lived with patient and family. This relative's removal following a cerebral thrombosis had no appreciable effect on patient's symptoms.

Family History.—Nothing relevant.

Previous Health.—Hard-working, capable, sociable woman. Always inclined to be over-emotional and to take things too much to heart. Depressive breakdown of two to three months' duration following father's desertion of mother. No other history of psychiatric symptoms.

Physical Health.—M.P.s regular 4/28 until past six months, during which there have been floodings and amenorrhoea of up to three months. No serious illnesses. **Present physical status:** Moderate obesity; B.P. 120/85; no signs of disease found.

Response to Treatment.—No appreciable response to hexoestrol. Moderate symptomatic response to dextro-amphetamine. Time incidence of symptoms as before, but severity much decreased.

Comment.—Moderately severe case. Good spells of up to six weeks' duration. Symptoms related to menstrual cycle. Liability rather marked: probably related to menopause. Aggravating factors in environment, but modification of these has not led to change in patient's state.

Case 4

Personal observation, eight months. Large woman of pyknic build, aged 43; para-2 (children 7½, 3½).

Present Illness.—Marked irritability, with temper loss and fears of harming children. Feelings of acute despondence: "life not worth living." Tendency to avoid people. Much worse for seven days premenstrually. Good spells in which symptoms are practically absent for two to three days. Blames "selfishness" on her own part and failure to accept move to a city which she dislikes. Did not realize that she was unwell or that there was any possibility of medical treatment. Husband responsible for her seeing psychiatrist in first instance.

Onset.—Became depressed within two weeks of birth of first child seven and a half years ago. Improved after three to four months, but has never been quite herself since. Symptoms as above in comparatively mild form. Considerably worse since birth of second child.

Environmental Factors.—None other than ordinary family responsibilities. Husband extremely forbearing and considerate. Excellent home conditions.

Previous Health.—Excellent. Highly capable, sociable woman of more than ordinary intellect. Good-humoured and philosophical. No neurotic traits of any kind before

onset of present illness. **Physical Health.**—M.P.s regular, 3-4/28; no illnesses. **Present physical status:** excellent.

Response to Treatment.—Complete alleviation of symptoms on dextro-amphetamine, 10 mg. in morning, 5 mg. at noon. Retrospectively realizes the degree of her disorder. Husband (specialist physician) describes effect of dextro-amphetamine as "most dramatic" and compares it with the effect of insulin in diabetics. Continuous medication is not now necessary. Since initial week's treatment, attacks of depression have been less frequent and have yielded to renewed medication. Very great improvement in family relationships since patient has been receiving treatment, particularly in behaviour of youngest child, who previously was tending to become capricious and unruly.

Comment.—Moderately severe case. Good spells last only a few days. Environment very good. A further childbirth after symptoms had begun in mild form had a pronounced aggravating effect. Symptoms related to menstrual cycle. Patient's state tended to disorganize family and create new difficulties. Dramatic response to dextro-amphetamine. Improvement maintained after drug was withdrawn.

Case 5

Observation period, All Saints' Clinic, four years; personal observation, one year. Aged 26; para-2. Average build; good colour; mildly anxious expression.

Present Illness.—Became depressed while in hospital after birth of second child four years ago. Had fears that the nurse would drop him. Became agitated on return home, wept frequently, could not sleep. Eventually told husband that she had fears of murdering the children, or would commit suicide to prevent herself harming them. Also fears that a man would break into the house and kill her. Depression decreased gradually and obsessive fears waned in severity in subsequent three months. Since then she has had frequent attacks of depression and irritability with return of obsessive fears of variable intensity. Periods of freedom from symptoms for up to three months. Menses irregular, 6/20-30. During ill phases feels worse before and during M.P. and a little better after menstruation.

Environmental Factors.—Difficulties with husband's family at time of onset but not recently. Husband loyal to her. Elder child very active and mischievous at time of onset. Patient has turned to religion for comfort, with some success recently.

Previous Health and Personality.—Happy person, easy-going; good mixer. Menses regular until last childbirth. No serious physical illnesses. Mild depression, lasting for three to four months after birth of first child. Recovered spontaneously and completely. **Present physical status:** Healthy; B.P., 128/80.

Response to Treatment.—E.C.T. June, 1953 (six shocks). No appreciable effect. Dextro-amphetamine, 5-10 mg. b.d. Regular medication since July, 1953. Good symptomatic response. Took a part-time job in November, 1953, on own initiative, but had to stop after six weeks because it interfered too much with household management. Symptoms occur as before, but are very much milder and do not constitute a serious handicap.

Comment.—Relatively mild case. Periods of freedom up to three months. Symptoms related to menstrual cycle. Domestic worry during puerperium. Age of onset (22) younger than the majority in present series.

Case 6

Observation period, three months. Aged 37; para-1. Pyknic build; moderate obesity; fresh complexion.

Present Illness.—Began nine years ago, when baby was 7 weeks old. Husband was badly wounded in France at that time and patient had to make "an awful journey" to Portsmouth with baby on the breast. She became depressed and indecisive, and remained so for several months. Since then she has had recurrent episodes of depression and irritability lasting for two to four months, interspersed with

periods of one to two months, during which she feels comparatively well. During the spells finds everything too much trouble. Housework gets her down. She has a lump in the throat, poor appetite, and broken sleep. She sweats a lot; her legs feel like jelly, and she has palpitation and beatings in her head and ears. Annoyed with herself for being as she is. Periods irregular in duration and amount. Husband thinks that before and just after periods she is worse.

Environmental Factors.—Husband irritable and changeable since the war, but has improved a great deal in the past two years. Patient's symptoms are apparently unaffected, however.

Previous Health and Personality.—Always rather sensitive and easily hurt, but fond of sport as a girl and liked parties and dances. Fastidious; likes to do things well; inclined to be house-proud. Symptomless mitral valvular lesion, of which she is aware. **Present physical status:** moderate obesity; rough systolic murmur in mitral area; well compensated circulation.

Response to Treatment.—Symptom-free since receiving dextro-amphetamine, 5 mg. b.d., and amylobarbitone, 1 gr. (65 mg.), over past two months, but may be in spontaneous remission.

Comment.—Relatively mild case. Good spells of one to two months' duration. Severe emotional stress during puerperium. Symptoms related to menstrual cycle.

Case 7

Personal observation, three months. Aged 42; para-7. Pyknic build; moderate obesity; looks rather older than her years.

Present Illness.—Two miscarriages at three months when aged 31. Periods scanty since then. No further pregnancies. "Like this ever since." Feels depressed and cries readily; but had bright spells of a few days at a time. Irritable, restless, wants to keep changing all the time. Headaches off and on—"a pressing-down and thumping on top of the head." Gets excited easily and has palpitation at such times. Occasional attacks of diarrhoea, flatulence, and indigestion. Sleeps fairly well, but feels tired in the morning. Face puffy below the eyes in the morning. In recent years: thinness about the chest, fatter about abdomen and hips.

Environmental Factors.—Heavy family responsibilities and financial hardship.

Family History.—One brother has had a depressive attack.

Previous Health and Personality.—Nervous as a child. Intelligent at school. Active, sociable, hard-working as an adult. Depressive illness of moderate severity, starting in fourth puerperium at age 23. Treated in hospital. Spontaneous recovery in six months. **Present physical status:** Moderate obesity; no signs of disease found; B.P., 140/88; menses brief and scanty (1/28).

Response to Treatment.—Dextro-amphetamine, 5 mg. b.d., amylobarbitone, 1 gr. (65 mg.) b.d. Marked and immediate improvement. "Before, I had no interest in anything. I can keep on at anything now. I don't seem to get that irritable feeling or that depression so much. I wish I'd had these tablets before. I've had this trouble for years."

Comment.—Moderately severe case. Good spells of a few days' duration. History of depression (? puerperal) preceding onset of present illness by eight years. Present illness followed miscarriages, but course and clinical picture essentially similar to puerperal cases. Symptoms not clearly related to menstrual cycle, but menses scanty since onset.

Points in Clinical Findings

A digest of the above clinical data brings out some interesting points.

The average age of onset in these seven patients is 30. If one excludes the youngest patient (22 at onset) the average age for the others is 32.

There is a history of stress during the puerperium in six patients; emotional stress in all of these, plus an infective

illness in two. In one patient there was a history of a previous non-puerperal depressive attack. In two patients symptoms had begun in mild form during one puerperium and a further childbirth had had an aggravating effect. In one case the starting-point had been an abortion at three months.

Patients with milder symptoms enjoyed well-being for periods up to three months. Those with more severe symptoms had only occasional "good days."

There was a relation of symptoms to the menstrual cycle in six patients; in five of these there was worsening during the premenstrual phase, in one worsening at ovulation time.

Irregularity of menstruation or oligomenorrhoea of the same duration as the psychiatric symptoms occurred in five patients.

There was clinical evidence of disturbed water balance in two patients.

In the majority the pre-morbid personality showed some cyclothymic traits, but on the whole these women were well-integrated people who had reached a good all-round level before they fell ill.

Discussion

Diagnosis.—The history of puerperal depression as the starting-point of the illness could be established without leading questions in all these patients, but, largely on account of their preoccupation with current problems, some persistence was necessary to get them to give a satisfactory account of the onset. This history is the main pointer to the diagnosis, since the symptoms themselves are not of a specific kind.

Differential Diagnosis.—The majority of these patients had been regarded by their family doctors as psychoneurotic, one or two as "ordinary" depressives. The personality, history, and symptomatology are, however, quite different from what is characteristic of the neurotic: "ordinary" recurrent depressives usually enjoy much longer symptom-free periods than do these post-puerperal patients. Depression in psychopaths and epileptics may have some resemblance in frequency and brief duration of attacks to what is found in the post-puerperal group, but the history of fits or of lifelong personality disorder suffices to distinguish them.

Aetiology.—In the absence of knowledge of the nature of the depressive state and of the neuro-endocrine effects of the puerperal involutonal processes one cannot go far towards a physiological understanding of this disorder, or, for that matter, of those puerperal depressions which run a self-limiting course. The condition may, on clinical grounds, be regarded as a variant of manic-depressive disorder combined with features of the premenstrual tension syndrome. Pre-menstrual tension and its relation to disturbed water metabolism has been adequately discussed by Stieglitz and Kimble (1949), Bickers and Woods (1951), and Linford Rees (1953). Hemphill (1953) has referred to "the acute alteration in the physiological state associated with childbirth operating on a susceptible personality" . . . appearing "to activate . . . puerperal depression." Rees's (1953) remark about the precipitation of premenstrual tension by the puerperium has already been quoted. On the basis of the material under consideration it would appear that two alternative interpretations might be made: either that a relatively irreversible reinforcement of the manic-depressive diathesis may occur, or that some other alteration in the constitution—for example, tendency to premenstrual water intoxication—may supervene which increases susceptibility to depressive attacks.

Course and Prognosis.—No women of post-menopausal age have been seen suffering from this illness, and the possibility exists that the menopause may lead to an improvement in these patients. Two patients had shown slow spontaneous improvement over the years but were still far from recovery. In the others there had been little or no change, even when the environment had improved.

Response to Treatment.—Dextro-amphetamine produces a dramatic symptomatic relief in some patients and a useful improvement in others. Acetylcholine shock therapy had no effect on the one patient on whom it was tried. Electric convulsion therapy produced no lasting benefit on two patients who received it. Its known effect in alleviating a depressive attack without touching the diathesis may explain its failure here. Hormone therapy and measures to control water-retention have not been adequately explored.

Summary

A syndrome is described in which recurrent depression, irritability, and tension dating from an attack of mild but typical puerperal depression are the leading features.

The symptoms tend to be worse in the premenstrual phase.

A pyknic body build appears to be typical.

The condition follows a chronic course, and treatment is problematical.

Serious disturbance of the life of the family is a secondary effect of the illness.

The condition appears to be related to the premenstrual tension syndrome.

It is a common and important condition and is at present insufficiently recognized.

I am grateful to Dr. J. J. O'Reilly, medical superintendent of Winson Green Hospital and medical director of All Saints' Clinic, for permission to publish this paper.

ALPHA-PROTHROMBOPLASTIN DEFICIENCIES (HAEMOPHILIA) OF DIFFERING DEGREES IN A MOTHER AND SON

BY

P. FANTL, D.Sc., F.R.A.C.I.

Associate Director, Baker Medical Research Institute,
Alfred Hospital, Melbourne, Australia

AND

J. MARGOLIS, M.B., B.S.

Acting Bacteriologist, Royal Alexandra Hospital for
Children, Camperdown, Sydney, Australia

(From the Pathology Department, Royal Alexandra Hospital for Children, Camperdown, Sydney, Australia, and the Baker Medical Research Institute, Alfred Hospital, Melbourne, Australia)

There are a number of reports in which female bleeders are described as haemophiliacs. However, it has been realized that, despite clinical similarity, the "haemophilic" syndrome can be caused either by a deficiency of any one of several essential clotting factors, or it can be due to the presence of an inhibitor of blood-clotting. Although haemophilia has been connected by most workers with a derangement of the blood thromboplastin complex, in the last few years it has been found that it consists of several components. Clinical manifestations are therefore insufficient to establish the diagnosis of haemophilia. As the various components of the clotting system have been separated from plasma,

it seems logical to apply biochemical nomenclature to haemorrhagic disorders. Since it is customary to refer to hypoprothrombinaemia or to fibrinogenopenia it has been suggested (Fantl and Sawers, 1954a, 1954b) that haemophilia be called alpha-prothromboplastin deficiency, and the related condition, known as P.T.C. deficiency (Aggeler *et al.*, 1952) or Christmas disease (Biggs *et al.*, 1952), be called beta-prothromboplastin deficiency.

Laboratory investigations are necessary to find the particular deficiency. Blood from alpha-prothromboplastin-deficient patients shows several characteristic features. There is a slightly to grossly delayed whole-blood clotting time, which can be corrected *in vitro* by the addition of blood or plasma from a beta-prothromboplastin-deficient patient. If this is not available, such plasma can be prepared from normal human oxalated plasma by adsorbing the beta factor with alumina gel or barium sulphate (Ba plasma). Further, the patient's deficiency should not be corrected by the addition of stored plasma or serum which are devoid of the alpha factor. Another indication of the clotting defect is the prothrombin content remaining in serum after clotting has taken place. In the serum of normal persons this is very low, whereas thromboplastin-deficient blood examined 60–150 minutes after clotting contains more than 12% of the plasma prothrombin. In addition to the tests which are necessary to establish the diagnosis it is desirable to estimate the degree of the deficiency. This can be carried out by the determination of the rate of thrombin formation in diluted blood in the presence of pyrocatechol, which acts as a thrombin stabilizer. The theoretical basis and the experimental details for this technique have been given by Fantl (1954b).

The Investigation

The clinical examination and laboratory investigation of a mother and her son, which we record here, show that both are suffering from alpha-prothromboplastin deficiency, although of differing degree. The mother is in fact a true haemophiliac.

Mrs. M., aged 30, stated that she bruised much more easily and extensively than the other members of her family. She suffered heavy menstrual loss, the bleeding often lasting eight days. She bled consistently after teeth extractions, the oozing often beginning one week after extraction and continuing for another week. After the birth of each of her two children she had severe post-partum haemorrhage, which on the first occasion lasted one week and was associated with a cervical tear. She submitted to radium sterilization,

following which she again bled severely and required a blood transfusion. Apart from the haemorrhagic tendency no other pathological lesions have been found. So far as it was possible to trace her family history, no abnormal haemorrhages were noted except for a vague story of excessive bleeding after teeth extractions in her maternal great-uncle, who died at the age of 80 (see Fig. 1).

Mrs. M.'s daughter, born in 1951, does not show any bleeding tendency. Her son was born in 1952. He was first admitted to the Royal Alexandra Hospital for Children, Sydney, at the age of 14 months with severe bruising of head and buttocks. The parents stated that after circumcision at the age of 10 days the child bled for one week, and could only be controlled with difficulty with several blood transfusions. Repeated attacks of extensive bruising had been observed since the age of 6 months. Primary dentition was accompanied by oozing from the gums. The child was admitted to the above hospital six times with bleeding episodes, and received several blood transfusions. The clinical symptoms of the mother are much less severe than those of her son. Table I gives the results of laboratory investigations.

TABLE I.—Laboratory Data of the Haemorrhagic Defect of Mother and Son

	Mother	Son	Normal
Whole-blood clotting time of 2 ml. at 37° C. in minutes . . .	14–30	40–>100	9–19
Skin bleeding-time in minutes. Technique (Copley and Lalich, 1942) . . .	3	3	1.5–3
Plasma prothrombin. Technique (Quick, 1951), in seconds . . .	10	10	10–12
Prothrombin assay. Technique, Fantl (1954a) in units per ml. oxalated plasma . . .	530	420	440–600
Serum prothrombin: 1 hour after clotting . . .	10	9.5	14–∞
2 hours . . .	14	9.5	20–∞
Technique, modified Quick in seconds . . .			
Serum prothrombin: 1 hour after clotting . . .	31–43	—	0–12
2 hours . . .	17–31	—	
Technique, Fantl, in units per ml. serum as % of plasma prothrombin . . .			
Thrombocytes indirect. Technique, Fonio per cubic mm. blood . . .	450,000	450,000	>100,000
Clot retraction . . .	Complete	Complete	Complete

The type and degree of the deficiency were determined in the blood of mother and son by the rate of thrombin formation. These results are given in Fig. 2.

Rate of Formation and Yield of Thrombin in Diluted Blood of Mother and Son

The laboratory data show a coagulation defect in Mrs. M.'s blood in degree consistent with the clinical findings. The whole-blood coagulation time is moderately prolonged; the residual serum prothrombin is well above the upper normal limit (Table I). The thrombin formation in Mrs. M.'s diluted blood is delayed although the yield is normal (Fig. 2, curve A). The addition to Mrs. M.'s blood of 10% normal Ba plasma, as a source of alpha-prothromboplastin, converts the rate of thrombin formation to normal (Fig. 2, curve B).

These findings are characteristic of a partial alpha-prothromboplastin deficiency. No evidence of abnormality of other clotting factors or the presence of clotting inhibitors or fibrinolysis was detectable.

There is no doubt that the son is suffering from the same type of deficiency as his mother, but, in contrast to her, his blood is completely devoid of alpha-prothromboplastin (Fig. 2, curve C), the abnormality being again corrected *in vitro* by 10% Ba plasma (curve D), but not significantly by stored plasma (beta-prothromboplastin) (curve E). In the child's case these results corroborate the evidence obtained from plasma clotting times of mixtures of the patient's plasma with that of authentic alpha- and beta-prothromboplastin-deficient patients respectively, as can be seen from Table II.

FIG. 1.—Family tree. ● Refers to Mrs. M. ■ Refers to her son. □ Refers to the maternal great-uncle of Mrs. M., who is believed to have had abnormal haemorrhages. All the other relatives gave no indication of abnormal bleeding.

TABLE II.—Recalcification Time of Oxalated Plasma Mixtures (0.2 ml. 0.01 M CaCl_2 was added at 37° C.)

	Plasma in ml. of			Normal Serum (ml.)	Clotting Time (Seconds)
	Authentic Alpha-prothromboplastin Deficiency	Authentic Beta-prothromboplastin Deficiency	Normal Albumin Plasma		
Mother, 0.1 ..	—	—	—	—	130
Son, 0.1 ..	—	—	—	—	>400

FIG. 2.—A 20% dilution of venous oxalated blood with 0.15 M sodium chloride was made immediately after collection. Mixture 1 consisted of 0.2 ml. 20% diluted blood added to 1.5 ml. of a solution containing 0.6 ml. 0.025 M CaCl_2 , 0.6 ml. 0.15 M NaCl , 0.3 ml. 0.18 M pyrocatechol in veronal buffer pH 7.4. Temperature 28° C. Thrombin was measured according to the technique of Fantl (1954a). Curves, full line (A, B), were obtained from Mrs. M's blood. Curve A + — — — — —, o — — — — — indicates mixture 1 plus 0.1 ml. 0.15 M NaCl . Curve B + — — — — —, o — — — — — indicates mixture 1 plus 10% Ba plasma. Dotted line curves C, D, and E were obtained from son's blood. Curve C — — — — —, o — — — — — indicates mixture 1 plus 0.1 ml. 0.15 M NaCl . Curve D — — — — —, o — — — — — indicates mixture 1 plus 10% Ba plasma. Curve E — — — — —, o — — — — — indicates mixture 1 plus 10% stored plasma. The shaded area presents the normal range.

Discussion

A critical review of the literature dealing with female bleeders, believed to be haemophiliacs, has been made by Merskey (1951) and by Israëls *et al.* (1951). Both groups of workers produce good evidence for the existence of congenital haemophilia in females, although the possibility that some of the cases may have suffered from beta-prothromboplastin deficiency must be considered. In both instances the homozygous state in the affected women has been established.

Additional reports of female haemophiliacs have been published (Koller *et al.*, 1950; Graham *et al.*, 1953; Quick and Hussey, 1953). With the exception of the latter, who described a sporadic case in a girl in whom the hereditary nature of the condition could not be established, the other females showed both clinically and on laboratory evidence the same degree of deficiency as their affected male relatives. Graham *et al.* (1953) have postulated the existence of a series of allelic genes which decide the plasma level of the anti-haemophilic factor in individual families. This is usually constant within an affected family, and breeds true according to the degree of the defect. Generally the inherited pro-

thromboplastin-deficiency diseases show the recessive sex link type of inheritance, but there is some evidence that the trait may not be completely recessive in female members of a pedigree.

Most of the haemophilic carrier women have not given any laboratory evidence of a clotting defect (Merskey and Macfarlane, 1951).

There is little doubt that Mrs. M and her son suffer from a well-defined congenital defect. Unfortunately the genetic features remain puzzling and unsolved. They are unique in that the mother suffers from a relatively mild haemorrhagic disorder. She is a true haemophiliac, her plasma exhibits a partial alpha-prothromboplastin deficiency, whereas her son is a very severe haemophiliac, whose blood is completely devoid of alpha-prothromboplastin. So far as can be ascertained there is no likelihood of consanguineous marriages in Mrs. M's family. Her husband and his family are free of bleeding tendencies. If the doubtful story of bleeding in the maternal great-uncle is accepted as a manifestation of mild haemophilia, it does not explain the severity of the condition in the child. It appears most probable that Mrs. M is heterozygous in respect of the gene responsible for her son's condition, but in her own case the trait is incompletely recessive. Although other possibilities could be considered, no useful deductions could be made, and it is therefore best to refrain from further speculations concerning the genetic features of the presented cases.

Summary

A congenital haemorrhagic tendency of moderate severity in a mother was shown to be due to a partial alpha-prothromboplastin deficiency (haemophilia) in her blood. Her daughter has no bleeding tendency. The son is a very severe bleeder. His blood is completely devoid of alpha-prothromboplastin. Puzzling genetic features in the presented cases are pointed out.

It is desired to acknowledge the co-operation of Dr. J. M. Alexander, under whose care the patient was. The laboratory investigations were carried out in the pathology department of the Royal Alexandra Hospital for Children, Camperdown, Sydney (director, Dr. R. D. K. Reye). One of us (P. F.) as guest worker enjoyed the hospitality and generous co-operation of Dr. Reye and his staff.

Prostitution is the subject of a pamphlet published by the British Social Biology Council (*Occasional Paper*, No. 8, price 1s. 6d.), with the object of providing the general reader with some reliable information on the subject. The author, Eleanor French, points out that the young prostitute and the "spiv" are figures of at least equal importance in their anti-social potentialities, and yet study of the former is neglected: "The 'Teddy Boy' is accepted as a respectable subject for interest, and receives far more help and study than does the prostitute." After presenting briefly what little is known about the prostitute and her clients—"the prostitutes who have been studied by research workers have in practically all cases been the failures"—the author discusses what could be done in the way of rehabilitation and prevention. There is also a note on the legal position.

NON-TUBERCULOUS AND TUBERCULOUS EPIDIDYMITIS

BY

DAVID MESSENT, M.B., F.R.C.S.

AND

RALPH SHACKMAN, M.B., F.R.C.S.

From the Department of Surgery, Postgraduate Medical School of London, W.12

Non-tuberculous (non-specific) and tuberculous epididymitis have been separately well documented in the surgical literature (Morson, 1933; Robinson, 1943; *Army Medical Department Bulletin*, 1943; Handley, 1946; Borthwick, 1947). Direct comparisons of parallel series of the two conditions are, however, rare (Stevens, 1923; Campbell, 1928; Järvinen, 1944). In this paper, based on a study of 80 cases of non-tuberculous and 28 cases of tuberculous epididymitis seen at Hammersmith Hospital between the years 1938 and 1952, an attempt is made to compare and contrast the two conditions; the differential diagnosis still sometimes remains a difficult problem. The diagnosis of tuberculous epididymitis was based on histological findings in 9 cases and on the presence of tubercle bacilli in the urine in 12; in the remaining 7 cases the diagnosis was based on persistent epididymal swelling in the presence of renal tuberculosis (5 cases) or pulmonary tuberculosis (2 cases).

The average age of the patients in both groups was 42 years; the age ranges were virtually identical—15 to 69 in the non-tuberculous cases and 13 to 72 in the tuberculous. The right and left sides were equally involved in both conditions, but the incidence of bilateral involvement in the non-tuberculous cases (9%) was considerably lower than it was in the tuberculous cases (32%).

Symptoms

Scrotal Swelling and Pain.—Scrotal swelling and pain were the commonest symptoms in both groups, and their incidence is indicated in Table I. The duration of the swelling, deduced from the statements made by the patients, is shown in Table II. Previous attacks of epididymitis, with subsequent resolution, affecting either the same or the other side, occurred in 15% of the non-tuberculous cases.

Urinary Symptoms.—Increased urinary frequency, dysuria, and macroscopic haematuria occurred in both groups (Table III), and these symptoms at times preceded the development of the scrotal symptoms. One or more of these symptoms of increased frequency, dysuria, and haematuria occurred in 47 (59%) of the non-tuberculous and in 18 (64%) of the tuberculous cases. Urinary symptoms preceded the scrotal symptoms in 26 (32%) of the non-tuberculous and 12 (43%) of the tuberculous. In the 26 non-tuberculous cases in which the urinary symptoms preceded the scrotal symptoms there was generally a short interval between the onset of the urinary symptoms and the development of the scrotal symptoms—less than 7 days in 6 cases, from 7 to 14 days in 5 cases, and 15 to 90 days in 10 cases. In the tuberculous cases the interval was always longer than 90 days.

Sinus Formation.—This was rare in the non-tuberculous cases, occurring in only 5%. In the tuberculous cases, however, it was much more common, occurring in 35%.

Tuberculosis Elsewhere in the Body.—Of the 80 patients with non-tuberculous epididymitis none had known tuberculosis anywhere in the body either before or at the time of presentation: it must be pointed out, however, that persistent epididymal swelling in the presence of tuberculous

disease elsewhere has been accepted by us as tuberculous epididymitis. Nevertheless, allowing for the possible error in such a presumption, there was a striking difference in the cases of tuberculous epididymitis, and if only those patients in whom the diagnosis was made by histology or by the occurrence of tubercle bacilli in the urine are considered (21 cases), 76% were known to have had tuberculosis elsewhere: 11 patients had pulmonary tuberculosis, 2 renal tuberculosis, 1 spinal tuberculosis, 1 "tuberculous rib peritonitis," and 1 tuberculous cervical lymphadenitis.

Prostatic and Vesicular Involvement.—Prostatic and/or vesicular involvement, judged by the presence of nodularity on rectal examination, occurred in the cases of non-tuberculous and tuberculous epididymitis (Table IV).

Urinalysis

Records of urinalysis were available in 68 cases of non-tuberculous and 21 cases of tuberculous epididymitis. The results are shown in Table V.

TABLE V.—Urinalysis

	Non-tuberculous Epididymitis	Tuberculous Epididymitis

The incidence of tubercle bacilli in the urine in the cases of tuberculous epididymitis was as follows:

Tubercle bacilli found on direct examination ..	8
" " " " guinea-pig inoculation ..	4
" " " " not found ..	10
No record	6
Total	28

The high incidence (at least 66%) of urinary infection in the cases of non-tuberculous epididymitis is to be noted, while the relatively high incidence (at least 26%) of secondary urinary infection in the cases of tuberculous epididymitis is of interest. Of interest, too, are the observations that 5 of the patients with non-tuberculous epididymitis and urinary infection did not admit to any urinary symptoms and 19 of those with coliform pyuria had haematuria.

Treatment

No records of treatment are available in seven cases of non-tuberculous epididymitis: conservative treatment was generally employed, but surgical measures were required in 20% of the cases. Orchidectomy was carried out in 6 cases, incision and drainage of an abscess in 5, epididymectomy in 2, and vasectomy in 2.

The majority of the tuberculous cases were treated before the introduction of streptomycin and adjuvant drugs, and surgical treatment was commonly employed. Orchidectomy was carried out in 9 cases, epididymectomy in 5, and drainage of an abscess in 1.

After-history

Postal inquiry was made in 71 (89%) of the non-tuberculous and 14 (50%) of the tuberculous cases, and replies were received on behalf of 37 non-tuberculous and 7 tuberculous cases; 4 other non-tuberculous and 13 other tuberculous cases were seen personally.

There was a striking difference in the after-histories of the two conditions. Only four of the non-tuberculous cases had further symptoms: one reported haematuria, one dysuria, one scrotal swelling on the opposite side, and one thought there was some residual scrotal swelling. In contrast, 36% of the cases of tuberculous epididymitis were known to have died.

Discussion

It would be unwise to compute the relative incidence of the two conditions from the present series of cases. It is almost certain that more cases of non-tuberculous epididymitis were seen and treated only as out-patients, and the records of such patients are not readily available to us: nevertheless, it would appear that there is at least a 3 to 1 preponderance of non-tuberculous over tuberculous cases among patients attending the out-patient department of a general hospital.

The average age incidence (42 years) in our own series of non-tuberculous cases is higher than that reported by Campbell (1928), McGavin (1943), Robinson (1943), and Handley (1946): the last two authors, however, based their observations on Service personnel, who, not unnaturally, were made up of younger age groups.

Bilateral epididymal involvement occurred in 32% of our tuberculous cases, and this high incidence confirms the reports of Stevens (1923) and Robinson (1943). Our observations do not support the statement (McGavin, 1943) that non-tuberculous epididymitis is often bilateral and simultaneous.

Although a short history of scrotal swelling favours a diagnosis of non-tuberculous disease, an acute onset can occur in tuberculosis: three of our patients with tuberculous epididymitis had histories of less than seven days. Conversely, patients with non-tuberculous epididymitis may have a scrotal swelling which has been present for as long as three years (Stevens, 1923). While it is common for a patient with non-tuberculous epididymitis to complain of a painful scrotal swelling, it is to be noted that 25% of our tuberculous cases presented in a similar way. Recurrent epididymal swelling is said to occur in 30% of non-tuberculous cases (Campbell, 1928): the incidence in the present series was 15%. Tuberculous epididymitis is persistent.

Urinary symptoms are commonly present in both non-tuberculous and tuberculous cases, but a long history of urinary symptoms preceding the onset of scrotal swelling

favours the diagnosis of tuberculosis. Macroscopic haematuria, no doubt the result of an associated *Bact. coli* cystitis, may be commoner in the non-tuberculous cases than is usually recognized: it occurred in only two of Robinson's cases (1943) and one of Handley's (1946), but in 30% of the present series. Haematuria occurred in only 10% of our cases of tuberculous epididymitis: this incidence is lower than that reported by others (Ross, 1953), but in four of our cases a previous nephrectomy had been carried out and it is possible that haematuria had preceded this operation.

Sterile pyuria, in the presence of an epididymitis, is suggestive of tuberculosis; nevertheless it occurred in 10% of the non-tuberculous cases in the present series. Conversely, although coliform and/or coccal pyuria, in the presence of an epididymitis, is suggestive of non-tuberculous disease, secondary infection of the urine was found in 26% of our cases of tuberculous epididymitis. The presence of tubercle bacilli in the urine of patients with epididymitis is practically conclusive, but it must be admitted that exceptions to this general rule could occur.

A scrotal sinus usually reflects the degree of chronicity of underlying epididymal disease; it was rare in the non-tuberculous cases, but occurred in 35% of the tuberculous cases, an incidence which is virtually the same as that reported by Stevens (1923).

Prostatic and vesicular involvement is a common finding in cases of tuberculous epididymitis: Borthwick (1947) recorded an incidence of 89%, and the incidence was 70% in the present series. Nevertheless, prostatic and vesicular nodularity occurred in 36% of our cases of non-tuberculous epididymitis. Stevens (1923) has stated that the presence of prostatic and vesicular involvement is not as significant as progression of the lesion while the patient is under observation: if a prostatic or vesicular nodule has been present for less than one month there is an equal chance that it is either tuberculous or non-tuberculous, but if it persists for several months it is likely to be tuberculous.

Judged by the benign after-history of our cases of non-tuberculous epididymitis treated expectantly, there seems to be little indication for carrying out epididymectomy in all cases of non-tuberculous disease as recommended by Järvinen (1944); there is, no doubt, a place for epididymectomy as the definitive treatment for the tuberculous patients, even with streptomycin and adjuvant therapy, but it is irrational to carry out an early excision of a non-tuberculous epididymis simply because its function has been destroyed and because it may prove to be tuberculous on histological examination. There is little doubt that the differential diagnosis between the two conditions is sometimes difficult when the patient is first seen, but it is our opinion that the diagnosis eventually declares itself either as a result of full urological investigation or after the lapse of time.

Summary

Parallel series of 80 cases of non-tuberculous epididymitis and 28 cases of tuberculous epididymitis seen at a civilian general hospital during a fifteen-year period have been compared and contrasted.

The average age of the patients in both series was 42 years and the age ranges were virtually identical.

The right side was involved as frequently as the left in both series: bilateral involvement was relatively less common in the non-tuberculous cases.

A short history of scrotal swelling occurred in 80% of the non-tuberculous cases and in 33% of the tuberculous. Pain occurred in both the non-tuberculous and the tuberculous cases; it was more common in the former. Recurrent swelling occurred in 15% of the cases of non-tuberculous epididymitis; the swelling persisted in the tuberculous cases.

Urinary symptoms were commonly present in both the non-tuberculous and the tuberculous cases, but a long

precedent history of urinary symptoms favoured the diagnosis of tuberculous epididymal disease. Macroscopic haematuria occurred in 30% of the cases of non-tuberculous epididymitis and was probably due to cystitis. Sterile pyuria was noted in 10% of the cases of non-tuberculous epididymitis: it was considerably more common in the tuberculous cases. Coliform and/or coccal infection of the urine was commonly present in the non-tuberculous cases but occurred also in 26% of the tuberculous. Tubercle bacilli were isolated from the urine in 12 of 22 cases so examined.

A scrotal sinus was rare in the cases of non-tuberculous epididymitis but developed in 35% of the tuberculous cases. Prostatic and vesicular nodularity was noted in 36% of the non-tuberculous cases and in 70% of the cases of tuberculous epididymitis. Clinical tuberculosis elsewhere in the body, either concurrent or precedent, was found in 76% of the tuberculous cases. The majority of the cases of non-tuberculous epididymitis were treated expectantly and ran a benign course. The tuberculous cases were treated by surgical excision—before streptomycin and the adjuvant drugs were available. 36% of the patients were dead within a few years.

The differential diagnosis between the two conditions is sometimes difficult and is apparent only after the lapse of time: full urological investigation is advisable.

A PURPURIC DRUG ERUPTION CAUSED BY CARBROMAL

BY

PETER BORRIE, M.D., M.R.C.P.

Assistant Physician in the Skin Department,
St. Bartholomew's Hospital, London

Carbromal (α -bromo- α -ethylbutyrylcarbamide) is a hypnotic, belonging to the class of open-chain ureides and closely related chemically to chloral, bromvaletone, and "sedormid." It was introduced in 1910 and popularized by Bayer Products Ltd. under the name of "adalin." The first report that the substance caused a drug eruption did not appear until 1921 (Loeb, 1921), and the purpuric nature of the eruption was well emphasized in the same paper. Since then, further cases have been described by Continental authors. The nearest approach to a description of the condition in the English language, however, is in a paper by Sneddon (1952), where it is cited as a differential diagnosis to purpuric textile eruptions. Usually it is merely alluded to by including carbromal in a list of drugs capable of causing purpura—for example, Brain (1950); while it has even been stated that carbromal does not cause purpura at all (Ackroyd, 1949; Beckman, 1952). However, it is generally agreed that carbromal has no effect on the blood platelets, as has sedormid, which is a well-recognized cause of thrombocytopenic purpura.

Carbromal is becoming increasingly popular in this country as a nocturnal sedative. It can be purchased

by the general public without a doctor's prescription, and seems to be the first choice of the chemist when asked for "something to make me sleep." Besides being sold as 5-gr. (320-mg.) tablets, carbromal is sold under a variety of trade names, such as "persomnia," containing, *inter alia*, 3 gr. (200 mg.) of carbromal, "dormiprin," containing 2 gr. (130 mg.), and "sornotil," containing 1 gr. (65 mg.). Finally, it is also being fairly widely advertised to the public.

In view of these facts, it was thought that a full description of the drug eruption caused by carbromal might be of value, and this paper deals with six such cases seen in the skin department of St. Bartholomew's Hospital in the first half of 1954.

Case Reports

Case 1.—A spinster aged 40 complained of a very irritating rash that had been present for four weeks. It had begun on the thighs and was still spreading. On examination well-defined patches, irregular in shape and size, were found on the thighs, buttocks, and lower trunk, consisting of petechiae and linear purpuric streaks, erythema, pigmentation, and branny scaling. Over the hips the eruption had become confluent and thickened. Increased capillary fragility was present. Five weeks previously she had begun taking persomnia, two tablets nightly. A patch test with 1% carbromal in propylene glycol was negative, but the eruption cleared in two weeks after stopping the drug. Slightly increased capillary fragility was still present a fortnight later.

Case 2.—A man aged 53 complained of a very irritating rash, present for six weeks, which had begun around the ankles, the inside of the knees, and over the hips, and which had spread steadily ever since. On examination the whole skin, with the exception of the soles, hands, and face, was affected by an eruption consisting of petechiae and linear purpuric streaks, erythema, pigmentation, and branny scaling. On the trunk, thighs, and upper arms these elements were aggregated into well-defined, irregularly shaped patches of varying size. On the forearms and lower legs the eruption was mainly petechial, in some areas diffuse and in the others confluent. Over the inner aspect of the knee-joints, the hips, and shoulders the eruption formed a slightly thickened sheet. Marked increased capillary fragility was present. He had been taking persomnia, one or two tablets nightly, for nine weeks. A patch test to 1% carbromal in propylene glycol was negative, but the eruption cleared completely in four weeks on stopping the drug.

Case 3.—A married woman aged 52 complained of an irritating eruption, present for three months, which began round the right ankle in the region of her varicose veins. On examination an eruption was seen on the legs, trunk, and upper arms, consisting of petechiae and purpuric streaks, erythema, pigmentation, and branny desquamation. On the thighs, trunk, and upper arms the eruption was patchy; over the shoulders, hips, and knees it was confluent and thickened; and on the lower legs it was profuse and mainly petechial. Slight increased capillary fragility was present. She had begun taking persomnia, two or three tablets nightly, six months previously. On stopping this drug the eruption cleared completely in two weeks.

Case 4.—A single woman aged 27 complained of an irritating eruption, which had been present for three months. On examination a grossly excoriated eczematous reaction was seen affecting the legs, thighs, and upper arms. The eruption had coincided with extreme domestic difficulties and cleared completely in four weeks as a result of bland local applications, mild sedation, and sick-leave. She was referred again, one week after returning to work, with a relapse of the eczema. This time, however, the eruption was mainly petechial, together with some erythema, pigmentation, and branny scaling, patchy on the thighs, trunk, and upper arms, and diffusely purpuric on the lower legs and forearm. It had begun on the feet, had spread suddenly in a few days,

and was extremely irritating. Increased capillary fragility was present, and persisted for a month after the eruption had cleared. She had started to take carbromal three or four tablets nightly, three months previously—that is to say, two months after the onset of the original eczematous rash. Patch tests to a saturated solution of carbromal in propylene glycol were negative, but the eruption cleared a month after stopping the drug.

Case 5.—A married woman aged 50 complained of a non-irritant rash, present for four months, which had begun on the thighs and which had steadily spread. On examination well-defined, irregularly shaped patches of varying size, consisting of petechiae, erythema, pigmentation, and branny scaling, were seen on the limbs and trunk. Some petechiae were seen between the patches and they were particularly marked and profuse on the lower part of the legs. Increased capillary fragility was present. She had been taking carbromal, one tablet nightly, for a year. The eruption cleared two weeks after stopping this drug, at which time the capillary fragility had also disappeared.

Case 6.—A man aged 42 complained of an eruption which had been present for three months and which had been irritating for one month. It had appeared first on the feet

The eruption in a typical case.

and had spread steadily to affect the limbs and trunk. On examination the eruption was found to consist of petechiae, purpuric streaks, erythema, pigmentation, and branny scaling, diffuse and mainly purpuric on the forearms and lower legs, but aggregated into irregular patches on the trunk and upper limbs. A similar eruption had appeared one year ago on the feet and had spread suddenly to the limbs and trunk within a week. It had been irritable for the first week only and had persisted for three months. Three weeks before the eruption he had begun taking carbromal, two tablets nightly, but reduced the dose to one tablet a night about three months later—that is, a few weeks before the eruption cleared. He increased the dose to two tablets a night just before the eruption appeared for the second time. The carbromal was stopped when he was first seen and the eruption cleared in three weeks, at which time increased capillary fragility, which had been present at first, could no longer be demonstrated. A patch test to a saturated solution of carbromal in propylene glycol was negative.

Discussion

The eruption was remarkably constant in all six cases and warrants no further description. Severe irritation was complained of by five of the patients, but was completely absent in the sixth. The dose of carbromal varied between 3 and 20 g. (0.2 and 1.3 g.) nightly, but in all cases was within the therapeutic range (Martindale, 1952) and bore no relationship to the severity of the eruption. Increased capillary fragility was constantly present, and in two of the cases persisted for some weeks after the eruption had cleared, but in no case was any haematological abnormality found. Patch tests were uniformly negative. Only one of the patients obtained the drug on a doctor's prescription.

Unless the purpuric element in the eruption is recognized the condition may be mistaken for pityriasis rosea, seborrhoeic dermatitis, or eczema. Two other eruptions, morpho-

logically identical with that produced by carbromal and in which irritation is usually present, must be considered in the differential diagnosis. The first of these is the purpuric textile dermatitis, first described by Hodgson and Hellier (1946), occurring among British troops in north-west Europe. Subsequent cases have been reported among civilians (Peterkin, 1948; Sneddon, 1952). Invariably the cause has been a new article of clothing, but many garments have been incriminated, such as a vest, shirt, bathing-dress, pair of riding-breeches, and a suit. The causative factor, which is not a dye, appears to be some chemical used in processing the clothing, which can, while the clothing is still new, cause capillary damage in certain individuals. In the second condition the eruption appears for no discernible reason, persists for anything from two months to a year, and resolves spontaneously. Treatment has no effect. Sneddon (1954) has suggested that these three varieties of purpuric dermatosis, due to external contact causes, to ingested allergens, and of purely endogenous origin, may be a change comparable to the eczema reaction. To regard the eruption as a particular variety of skin change which may have a number of causes appears to be the most rational approach.

The final diagnosis of a carbromal drug eruption must rest on the effect of stopping the drug. Patch tests are misleading, since a positive result is difficult to obtain, and a test dose is out of the question in an eruption which may persist for up to a month after the responsible drug has been withdrawn. Nevertheless, improvement in the intensity of both the eruption and the irritation is obvious within a few days to a week of stopping the drug, and the condition clears completely in, at the most, a month.

Summary

Six cases of purpuric eruption caused by the ingestion of carbromal in therapeutic doses are described, and the differential diagnosis is discussed.

It is emphasized that the use of this drug as a nocturnal sedative is increasing in this country, and that it may be purchased without a doctor's prescription.

According to the U.S. Army Surgeon General, radiographs of wounded soldiers on the battlefield with a newly designed portable x-ray unit powered by radioactive thulium will soon be possible. The new device can produce an x-ray picture without electricity, water, or darkroom. The complete unit weighs only 48 lb. (21.8 kg.) and may be carried on the back. A 1-in. (6-mm.) lead plate contains the radioactive thulium and protects the user from accidental radiation exposure. The piece of thulium is expected to be effective for about one year, when it will be returned to an atomic pile for rejuvenation. The developer is a cassette or filmholder in which all pictures are made with radiosensitive paper and pads instead of film. The paper and pad are saturated with developer and stabilizer and are separated by leak-proof dividers. The cassette is wrapped with a light-proof and waterproof covering. As the cassette is exposed, the dividers are removed and the radiosensitive paper records the picture. These radiographs lack the fine detail of standard x-ray films, but are suitable for field and emergency use. A person can be trained to use the machine in a few hours, and can set it up, take a picture, and develop it within five to ten minutes. Timing of the exposure is done with a wrist watch. Each unit will cost about \$200, but additional tests must be made before it can be standardized for commercial manufacture.

Medical Memoranda

Paradoxical Haematemesis in Oesophageal Atresia

An essential prerequisite for the diagnosis of oesophageal atresia is to have the condition in mind. From the variations in its reported incidence it seems probable that in some areas the diagnosis is less frequently considered than in others. However, it may happen that because of the co-existence of an additional condition the diagnosis may be delayed or even missed altogether. As the subsequent case report shows, the occurrence of haematemesis in a case of oesophageal atresia might well obscure the diagnosis, and so lead to undesirable delay in operative treatment.

CASE REPORT

A primipara aged 35 was delivered of an apparently normal male child in her own home on the evening of October 9, 1953. The birth weight was 8½ lb. (3.7 kg.). The baby was not put to the breast. Next morning the midwife noticed that the baby's colour was poor, that the respirations sounded moist, and that there was some white frothy mucus in the mouth. The patient's own doctor was called; he examined the chest and found no abnormality. The foot of the cot was raised to drain the chest. No feeds were given that day. On the second day the baby was put to the breast, and he sucked well. The colour was good and meconium was passed. Later he brought up some thick mucus from the nose and mouth. In the evening he would not suck the breast.

Early the following morning (third day) the baby brought up some red blood. His colour was poor and he appeared to be shocked. The doctor was called again, and he immediately sent the patient to the Bradford Children's Hospital. Here a diagnosis of haemorrhagic disease of the newborn was made and 10 mg. of vitamin K was given intramuscularly. Feeds of glucose water were returned together with some bright-red blood and, on one occasion, clots. Later he passed a melaena stool. On the fourth day there was no change and no feeds were retained; it was at this time that the diagnosis was made. An attempt was made to pass a catheter into the stomach, but without success. A little lipiodol was therefore instilled into the catheter in the back of the throat and a radiograph taken. This showed the typical upper blind pouch of oesophageal atresia together with gas in the stomach, indicating the presence of an oesophago-tracheal fistula.

Soon after this the child was transferred to the Bradford Royal Infirmary, where an operation was performed a few hours later. Through an intrapleural approach the fistula between the lower stump of the oesophagus and trachea was divided, and continuity of the oesophagus was effected by an end-to-end anastomosis, using interrupted catgut sutures. For the next seven days no feeds were given, and fluid requirements were supplied by the subcutaneous route. On the eighth day a glucose-water feed was taken well. On the ninth day, however, he vomited after feeding. A lipiodol swallow was given; the radiograph showed lipiodol to be present in the stomach and was not suggestive of a leakage from the anastomosis. The child, however, did not look well, and as a precautionary measure a gastrostomy was performed under local analgesia. The gastrostomy feeds, however, made him vomit just as much as feeds by mouth, so after twenty-four hours feeding by mouth was restarted, and this time no further vomiting occurred. He made a gradual but uninterrupted recovery.

COMMENT

The occurrence of haematemesis in the presence of oesophageal atresia is, of course, rare, but the route from the stomach up the lower segment of the oesophagus through the oesophago-tracheal fistula, up the trachea, and into the

mouth has been known for a long time as an explanation for the occurrence of acid saliva in these cases. The term "paradoxical haematemesis" would seem to be a reasonable one, and serves as a reminder that vomiting can occur in oesophageal atresia with a fistula from the lower segment if there is anything in the stomach to vomit.

The delay in diagnosis in the case described was about twenty-four hours, and, as subsequent events show, was of no importance; but it takes little imagination to realize that the symptom of haematemesis might appear to exclude the diagnosis of atresia of the oesophagus in the mind of a person unfamiliar with the anatomy of the condition.

My thanks are due to Mr. J. S. Davidson, who performed the operation, for permission to publish this case, and to Dr. Elizabeth Rosenblum, of the Bradford Children's Hospital, who made the diagnosis.

E. R. LECUTIER, M.B., F.R.C.S.,
Senior Thoracic Registrar, Bradford Royal Infirmary.

A Case of Malignant Melanoma and Pregnancy

The association of malignant melanoma and pregnancy is not commonly reported. Cases have been described of malignant melanoma giving rise to secondary deposits in the placenta or foetus, but no reference is found to the effect of pregnancy on the growth of a melanoma. The following case illustrates this relationship.

CASE HISTORY

A woman aged 39 was first seen in July, 1949. She was expecting her first child, and was eight weeks pregnant. In August she noticed that a deeply pigmented mole on her left calf was enlarging and weeping a little. There were no signs of any secondaries and she was referred to hospital for surgical opinion. A biopsy of the tumour was performed and the histological report was of a "non-malignant cellular naevus." In February, 1950, the baby was delivered, but it died six weeks later of bronchopneumonia. In May the tumour was excised and a histological report confirmed that it was a "simple non-malignant cellular naevus."

In June she was once again eight weeks pregnant. The antenatal period and delivery in January, 1951, was normal, but three weeks later she noticed a rapidly enlarging lump developing in the left groin. This was clinically a mass of glands and she was referred for further surgical opinion. A biopsy of a gland was taken and fresh sections were cut off the original naevus. The histological report stated that "the naevus is almost certainly malignant and the glands in the groin are secondaries." The glands were excised in May, 1951, and a course of x-ray therapy to the groin was given.

All was well for the next two years, and mother and baby flourished. In September, 1953, she was once again 20 weeks pregnant. The antenatal period and delivery in January, 1954, were again quite normal, but after delivery a large tender mass was felt in the left iliac fossa displacing the involuting uterus to the right. She was referred to hospital and the diagnosis of further metastases made. A further course of x-ray therapy was given and the mass of glands disappeared. The patient is at the time of writing quite well, showing no other secondaries. Unfortunately the baby is a mongol.

COMMENT

The case appears to show that pregnancy has stimulated the growth of a melanoma. It is difficult to think such an appearance could be mere coincidence, since it happened on three different occasions. Presumably the stimulus is hormonal in character, and the query arises whether pregnancy should be terminated in such cases. Since this is but a solitary case the query must remain unanswered.

H. STEWART, M.B., B.S.,
General Practitioner, Watford, Herts.

Hypoglycaemia in Chronic Alcoholism

The following case is unusual and presented certain difficulties in diagnosis.

CASE REPORT

The patient, a man aged 54, was known to be a chronic alcoholic. The doctor was sent for one morning because of difficulty in rousing him. Initially it appeared that he had been mentally very confused; about an hour later he was found by his daughter to be completely unconscious. He had spent the previous day normally and retired to bed about 9.30 p.m., apparently sober. There was no admission of any immediate alcoholic excess.

When he was examined there was a strong smell of ketones in the small airless room. He was deeply comatose, lying flat on his back, with open eyes and giving an occasional twist of his head. The skin was distinctly moist, but unfortunately the significance of this was not realized until later. The pupils reacted to light; all tendon reflexes were present and equal; abdominal reflexes were present, and no plantar responses were obtained. A catheter specimen of urine showed Rothera's test quickly and strongly positive, and Gerhard's and Benedict's tests negative. Other systems were all normal. By this time he had been in coma for about three hours.

Treatment was based on a provisional diagnosis of diabetic—that is, hyperglycaemic—coma without glycosuria. In view of some uncertainty, however, it was decided to administer dextrose intravenously before giving the insulin. At the conclusion of an injection of 25 ml. of 25% dextrose the patient at once regained immediate consciousness, in the dramatic manner associated only with recovery from hypoglycaemia.

The differential diagnoses considered at this stage were (1) ketosis and hypoglycaemia due to liver insufficiency, and possibly aggravated by inadequate food intake; (2) spontaneous hypoglycaemia; (3) diabetes mellitus.

He was admitted for investigation. One hour later his blood urea was 31 mg. per 100 ml., and blood sugar 253 mg. per 100 ml. (in view of recent glucose administration, this was not of much value). Twenty-four hours later his fasting blood sugar was 94 mg. per 100 ml. The latter was taken to exclude diabetes mellitus, of which there really was no positive evidence. The urine was tested on frequent occasions during the next few days, and no glycosuria was found. The ketosis resolved after about 36 hours without specific treatment, although he was encouraged to eat.

Liver-function tests at this stage showed: Serum alkaline phosphatase, 3 units; serum thymol turbidity, 4 units; icterus index, 3 units; serum proteins, 9.8 g.% (albumin 5.8 g., globulin 4 g.); A/G ratio, 1.45:1.

The glucose-tolerance test gave the following results:

	Fasting blood sugar	Urine Sugar	Urine Acetone
1 hour after 50 g. glucose	91 mg./100 ml.	—	—
1 1/2 hours	101	—	—
2 hours	121	—	—
2 1/2 hours	171	—	—
3 hours	100	—	—
4 hours	88	—	—

The change in the serum proteins suggests some degree of liver damage. The delay in storage of glucose supports this. The glucose-tolerance test also suggests a lowered renal threshold.

Three days after admission he had a classical episode of delirium tremens, which was treated in the usual way, and from which he recovered quite normally.

Five months later a similar incident of hypoglycaemia occurred in which he became mentally confused and disorientated. He did not go into coma and the blood sugar was 62 mg. per 100 ml. Frank ketosis was again present. Treatment and subsequent progress were as recorded in the first instance.

DISCUSSION

The recognition of hypoglycaemia dates from 1849, when Claude Bernard found that the mobilization of liver glycogen was the source of blood sugar. Between this discovery and the isolation of insulin, which does not concern us here, attention was mainly directed to the liver. Hepatic poisons were used experimentally—for example, phosphorus (Frank and Isaac, 1911)—to induce the condition.

Le Count and Singer (1926) have pointed out that alcoholics with huge fatty livers may die suddenly and unexpectedly. The large globules of fat take up most of the room in the liver cell, leaving no space for glycogen. The probable cause of death is hypoglycaemia. In this patient a similar condition probably was present, although there was no clinical evidence of hepatic enlargement.

Failure of endogenous sugar may also occur from wasting muscles and failure to replenish the stores, as in starvation. There was no evidence of either of these conditions in this case.

Ketosis has been established as due to carbohydrate lack, but many conflicting views have been put forward regarding how exactly this is brought about. One of the most recent theories is that propounded by Macallum (1930) by which ketone bodies are regarded as normal products of metabolism having an energy value of which most tissues, except the liver, could make use. In 1926 Raper and Smith suggested that the factor responsible for mobilizing fat in excessive amounts was a reduction of the liver glycogen below a certain level. MacKay (1943) has summarized the position as follows. The body is supplied with two types of fuel: "slow fuel" which represents the fat used directly by the tissues without any liver intervention, and "quick fuel"—namely, glucose and ketone bodies. He suggested that the production of ketone bodies, in times of need, was a device to conserve glucose for the central nervous system, which is unable to metabolize them. Mirsky (1942) asked, If ketone bodies are normal oxidation products why does excess ever occur? He answered this by saying that there was a maximal rate at which muscles could use ketone bodies, just as there was a maximal rate at which they could use glucose.

It is therefore postulated that hypoglycaemia and ketosis could both be explained by diffuse hepatic lesions. What evidence is there for this in the present case? The patient is a known addict to an established hepatic poison. The liver-function tests and the glucose-tolerance test show changes consistent with this argument.

This hypothesis seems to account for most of the features. However, it does not explain why such an episode should suddenly occur in a long-standing condition which showed no other immediate change for the worse. Further, if the liver involvement was severe enough to produce this picture, it might reasonably be anticipated that the liver-function tests would be more upset; but these are well known to be not unduly reliable. Also, it might be thought that the combination of hypoglycaemia and ketosis would be more common in other more obviously gross diseases of the liver than it is.

It is concluded that this is a case of fatty change in the liver due to alcohol poisoning, producing the clinical picture of hypoglycaemia and ketosis—a series of events which may be summarized thus: "Alcoholic hepatitis"→Depletion of hepatic glycogen→hypoglycaemia→production of ketone bodies by the liver.

My thanks are due to Dr. Serge Keys, who carried out the laboratory investigations.

Reviews

CLINICAL PSYCHIATRY

Clinical Psychiatry. By W. Mayer-Gross, M.D., F.R.C.P., Eliot Slater, M.A., M.D., F.R.C.P., D.P.M., and Martin Roth, M.D., M.R.C.P. (Pp. 652+xx; illustrated. 50s.) London: Cassell and Co., Ltd. 1954.

The need for an entirely new systematic textbook of psychiatry in the English language has been realized for some time. None of those that have appeared in the last ten years have been fully satisfying from the point of view of the postgraduate who wishes to specialize in the subject. They have been either too short or insufficiently comprehensive, have been written from the point of view of one system of psychopathology, have been uncritical, or have lacked cohesion through multiple authorship. For the descriptive textbook based on long clinical experience and a discriminating knowledge of the literature it has been necessary to refer to the larger German works. Now that it has been accomplished, it seems very natural that a compromise in form should have been sought between the factual completeness of the German *Lehrbuch* and the more readable British medical text. For the first time there is now available a textbook that contains about as much theoretical information as a trainee psychiatrist needs, together with clear indications of how to supplement this from specialized and original sources. Furthermore, the field covered is a large one—that of clinical psychiatry as applied at all ages in hospital and clinic, but restricted to those aspects which are not functional disorders of mind alone. The emphasis on constitutional factors is in fact such that the psychoneuroses and psychosomatic disorders themselves receive relatively little attention except in so far as they are an expression of maladjustment due to constitutional vulnerability.

This book is based on the experience of three psychiatrists of wide clinical knowledge who have inherited much of the unwritten teaching passed from one generation to the next both at Heidelberg and at the Maudsley Hospital in London, where all three have worked. In the tradition of Mott and Mapother they have taken an active part in extending the scientific and medical approach to problems of mental illness which has been a feature of British psychiatry in the last quarter of a century. The book abounds with evidences of a rich clinical experience. Some of the asides show a unique clinical wisdom, and in reading them one is grateful that much of the personal teaching of the authors and of the Maudsley school has now found its way safely into print.

It is doubtful if any attempt to achieve a full synthesis of the two contemporary approaches to problems of mental health, psychodynamic and constitutional, could be achieved in the present state of knowledge without a good deal of fence-sitting, and the authors have made it abundantly clear that, whatever faults may be found in their presentation, this will not be one of them. The result is a somewhat downright introduction in which collectively the three authors achieve a degree of aggressiveness which exceeds that found in the individual work of each, and within a few pages they earn for themselves an honoured place on the index *expurgatorius* of the psychoanalytic faith. While by quoting the work of some of its less-balanced adherents they are able to present the excesses of the psychodynamic outlook in all their absurdity, the authors are more than reluctant to admit that any good has come out of this movement at all. It is surprising, too, that in accepting a multi-dimensional approach they show relatively little sympathy for the reaction of Myerian psychobiology, with its melioristic attitude of considering important any factor which can help the patient, to the descriptive and deterministic heritage of Kraepelin. If, however, this results in a rather spectacular attitude to mental misfortune, they are spectators who do not miss much of the game. Further, their cohesion is such

that the book, which contains many descriptions of high literary merit, might well have come from a single pen.

The chapter on schizophrenia does a great deal to clear away the air of mystery with which this group of disorders is often approached, and to make the process of diagnosis and the choice of treatment less one of intuition and fancy than it often is at present. In particular the authors' authoritative and balanced views on the place of leucotomy operations will be welcome. The sections on mental deficiency and child psychiatry together satisfy the urgent need at the moment of presenting the notable advances made in these subjects, especially in the fields of genetics and organic determinants, and as a guide to the literature of an aspect of child life that is apt to get forgotten in the much more voluminous writings based on the work of child-guidance clinics.

A fully satisfactory eclectic postgraduate textbook of psychopathology and psychotherapy, written from the point of view of therapy within the social and economic framework and incorporating the results of the experiments of the last 20 years, has still to be written, and, until it is, the psychiatric trainee will have to muddle through, as he does at present. His load has, however, been immensely lightened in the field of general psychiatry by the publication of this book. Much forethought has been shown in its design and in its selective bibliography, and the co-operation between authors and publishers has been notably successful.

ALEXANDER KENNEDY.

FLUID THERAPY

Fluid Therapy. By James D. Hardy, M.S.(Chem.), M.D., F.A.C.S. (Pp. 255; illustrated. 42s.) London: Henry Kimpton, 1954.

In its comparatively limited compass of some 250 pages this book very largely fulfils its professed aim of providing "a concise discussion of total fluid therapy." It is written by a surgeon with experience of electrolyte problems in the laboratory as well as in the wards. The opening chapter, on the physiology of body fluid, is well arranged and well illustrated; only two of its 22 diagrams are taken from the Gamble mine of electrolyte illustrations, so that in this respect it has a refreshing "new look." There is a sketchy chapter on methods, in which more than half the space is taken up by photographs of technicians operating machines. In the next seven chapters the recognized syndromes of electrolyte distortion are summarized, and a number of appropriate case reports give reality to the discussion. The last 100 pages are devoted to the clinical situations in which electrolyte problems are likely to arise, and this section includes short chapters on fluid therapy in the elderly patient, and in urology, neurosurgery, and orthopaedics.

The book is well produced, and a detailed table of contents and index make its information accessible. The references at the end of each chapter are representative of the literature without being so numerous as to discourage looking them up. The clinical emphasis is largely, but not entirely, on surgical problems, and the book seems to me fitted to arouse, maintain, or increase a surgeon's interest in rational fluid therapy.

D. A. K. BLACK.

SURGERY OF THE CAECUM AND COLON

Surgery of the Caecum and Colon. By Stanley Avlett, M.B.E., M.B., B.S., B.Sc., F.R.C.S. (Pp. 295; illustrated 45s.) Edinburgh and London: E. and S. Livingstone Ltd. 1954.

This is a new and beautifully illustrated work dealing essentially with the surgical lesions of the caecum and colon and their treatment. The preliminary 50 pages cover the surgical anatomy, symptomatology, and diagnosis, with special reference to carcinoma of the colon. Chapter II, on pathology of tumours of the colon, is contributed by Dr. James Earle. The rest of the work describes very clearly the details of surgical technique in non-obstructed and obstructed

lesions of the colon, and the management of such controversial subjects as benign tumours of the colon, polyposis, and diverticulitis. The author describes the surgical treatment of chronic ulcerative colitis by colectomy, and discusses very fairly the possibility of preserving rectal function by ileo-rectal anastomosis, which he states has been done at the Gordon Hospital in 30 cases without operative mortality and so far without need for an ileostomy. The final chapters deal with regional or segmental colitis, tuberculosis of the colon, volvulus, megacolon, and gunshot or other wounds of the colon. The importance of early diagnosis in blast injuries of the large intestine is stressed, since a mortality of 100% occurs if surgery is delayed for more than 10 hours.

Throughout this work there is a wealth of detail regarding operative techniques as well as pre- and post-operative management. The illustrations, whether diagrams, radiographs, or illustrations of surgical technique, are uniformly excellent. The book will prove of great value to surgeons who have to deal with some of these difficult and debatable subjects, and will help them in the choice of the best treatment; the details which the author has taken the trouble to recount are very important and will greatly assist in bringing cases to a successful conclusion. The production of the book is first-class, and the only misprints noticed are in the spelling of Connell, and Paul-Mikulicz should have been printed thus, otherwise Paul might be taken for a Christian name.

W. B. GABRIEL.

PROGRESS IN ENDOCRINOLOGY

Glandular Physiology and Therapy. Prepared under the auspices of the Council on Pharmacy and Chemistry of the American Medical Association. Fifth edition. (Pp. 611+xx, 80s.) London, Philadelphia, Montreal: J. B. Lippincott Company, 1954.

This book has been produced under the auspices of the Council on Pharmacy and Chemistry of the American Medical Association. The contributors are highly distinguished, among them being such well-known names as Astwood, Barter, Forsham, Eager Howard, Palmer Howard, Jailer, McCullagh, Reifenshtein, Sayers, Segaloff, Selye, and Venning. The work was first published in 1924, when the only hormones available to the therapist were insulin, adrenaline, and extracts of the thyroid and posterior lobe of the pituitary. Twelve years have passed since the last edition, and the contributors have reviewed authoritatively the new work which has been done in their own fields. The result is a book on clinical endocrinology of great value. The secretary to the Committee on Publications of the A.M.A. forecasts that this may be its last edition, as the need for this work has largely disappeared with the production of many excellent books occupied with the same subjects. This book has a special approach, however, which allows the editors to include monographs not to be found in any other work and permits them to exclude complete accounts of many conditions which require comprehensive treatment in the textbooks. There are, for example, chapters on the endocrine management of neoplastic diseases, abnormalities of sexual behaviour and intelligence in relation to endocrine disease, and common misconceptions in endocrine therapy. This last subject is discussed by John Eager Howard with the same wisdom and experience as were shown by Fuller Albright in his famous pages in *Cecil's Medicine*. The text of Howard's exhortation is that most endocrinopathies can be diagnosed from a thorough history and physical examination without extravagant laboratory investigation "performed at great expense to the patient."

The editors have rightly allowed the individual contributors to express opinions which they themselves do not necessarily share, and this may be the reason that we find Werner maintaining that the anterior pituitary has nothing to do with thyrotoxicosis because the TSH blood values are not increased, and Segaloff advising against thymectomy in myasthenia gravis without mention of Keynes's results showing 65% of patients with complete remission or considerable improvement after this operation.

This book is a valuable work of reference, and this edition should not prove to be the last.

D. V. HUBBLE.

DIAGNOSTIC ERRORS

Klinische Fehldiagnosen. By Professor Dr. M. Bürger. (Pp. 550+xx; illustrated. D.M. 59.40.) Stuttgart: Georg Thieme, 1954.

Perusal of this book on clinical mistakes in diagnosis puts one in mind of the old saying that the churchyard covered the doctor's mistakes. Here is a selection, some two hundred of them, all resurrected for the benefit of posterity. This is rather a remarkable book. The mistakes in diagnosis are carefully arranged under the various topics to which they belong, and this makes in all some 21 sections; these comprise the nervous system, metabolism, pancreas, blood diseases, and so on. Each section begins with a discussion on how mistakes in that particular subject may arise, and ends with a summary. The book starts off with a very interesting essay on diagnosis in general. The author distinguishes between "illness" and "sickness"—an interesting point. Diagnosis, we learn, can depend on "harm done" or "good done," on "intuition," and can be confused by the effects of age; it is discussed from the anatomical and topographical angles, with their associated mistakes. Under laboratory diagnosis comes the wise heading, "Omnia sunt dubitanda."

All this sounds rather elaborately German, but there is a lot of common sense in it. Unfortunately the case histories are in very small print and not particularly readable. The wrong diagnosis is given on one side and the correct diagnosis on the other, and the necropsy findings are described where pertinent. Collected over many years, some errors are now quite out of date because newer knowledge and understanding make them unlikely nowadays. These are mistakes of "agnosis," as the author would say. The skiagrams are all first-class, but the cardiograms are old-fashioned. There are a good index and many references.

Altogether this is a most unusual and interesting book, but one to be taken in small doses. One feels that one learns less from one's mistakes than one should; but, alas, however often is it never known that one has been made? Osler once quoted a famous German surgeon as saying, after a wrong diagnosis, "We didn't think right." Nowadays, with so much diagnostic information available, that is probably the main source of error, rather than ignorance or carelessness or lack of skill.

TERENCE EAST.

PRACTICAL BIOCHEMISTRY

Practical Biochemistry: An Elementary Course for Students of Medicine and Science. By G. T. Mills, H. N. Munro, and G. Leaf. Foreword by J. N. Davidson. Second edition. (Pp. 156+x; illustrated. 20s.) Glasgow: John Smith and Son Ltd. 1954.

The appearance of a second edition of this book indicates that it is filling a valuable place in the instruction of medical and science students in practical biochemistry. It is based on the teaching at Glasgow University and is supported by a foreword from Professor J. N. Davidson. It is well written, and the first part covers the list of subjects usually taught in elementary biochemical classes, such as the composition of living matter, enzymes, digestive juices, blood, cerebrospinal fluid, and urine. The second part is more quantitative and starts with an introductory account of colorimeters and polarimeters. Here the rather scanty reference to photoelectric colorimeters is to be regretted, and a little more detail in the section on tissue-function tests would have been an advantage. On the other hand, the inclusion of a section on the paper electrophoresis of serum proteins was noted as a welcome addition.

The book is well produced and moderately priced, and will undoubtedly be useful to all students attending practical classes in elementary biochemistry and to those engaged in their instruction.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MARCH 12 1955

WINTER COUGHS

As any theatre-goer knows all too well, this is the season of persistent coughs. Usually they are the result of the common cold which has "gone to the chest" and produced a chronic tracheitis or tracheo-bronchitis. Although many people recover quickly, in some the cough may persist. This is especially true of those who have an inherited asthmatic tendency or are liable to bronchospasm. In children the common cold is often accompanied by a sinusitis which persists after the nasal discharge has ceased, and this is the commonest cause of chronic cough in the child of school age. Influenza epidemics usually reach their peak in the first few months of the year, and the early, dry, irritating cough of this disease is nearly always followed by a more productive tracheobronchitis. In some patients the cough persists for several weeks after recovery from the febrile stage of the illness. If radiographs were taken of the chest of every sufferer from a persistent upper respiratory-tract infection with cough, some would be found to have mottled opacities indicating absorption collapse, a condition which is called benign or localized aspiration pneumonia.

It is clearly desirable to examine carefully all patients who seek advice about a cough which has persisted for more than a short time after an acute respiratory illness. The great majority will be found to have no eradicable cause, and treatment must perforce be symptomatic. For the child with sinusitis, ephedrine nasal drops (½% in saline) may diminish the severity of the cough. But in general the problem is to decide what sort of cough medicine to administer. Drugs given for the relief of cough fall into three main groups: those intended to liquefy the sputum and help its removal by stimulating the cough centre; those intended to depress the cough reflex; and the antispasmodic drugs which are used when bronchospasm is present as well. In view of the large quantities of cough mixtures which are dispensed—Dunlop *et al.*¹ in a pilot survey found that they constituted

8% of all prescriptions issued—it is remarkable that so few attempts have been made to assess their clinical value. The claim that emetic drugs given in sub-emetic doses will reflexly increase the bronchial secretion has never been verified in the human subject, and yet this is the basis for the use of ipecacuanha, ammonium chloride and carbonate, squill, and senega. However, Alstead² was unable to find an increase in the volume or fluidity of the sputum in patients suffering from chronic bronchitis after treatment with ordinary doses of ipecacuanha or potassium iodide.

While the value of expectorant mixtures is doubtful, we are on more certain pharmacological ground when we attempt to depress the cough reflex. Morphine, diamorphine, and methadone ("amidone," "physeptone") are all effective. This was confirmed by Hillis,³ whose method of provoking cough in normal subjects was to spray the larynx with irritant solutions. Codeine, given orally in doses of 3 gr. (200 mg.) or subcutaneously in doses of 1 gr. (65 mg.), was no more effective than saline injections. It is of special interest that in some subjects saline injections, acting through suggestion, significantly diminished the liability to cough. These observations, interesting though they are, cannot be immediately applied to the cough of respiratory disease, and most clinicians will continue to use codeine phosphate in the treatment of unwanted cough. If morphine is prescribed for this purpose it should be given in doses of at least 1/30 gr. (2 mg.). The usual morphine-containing preparation which is added to cough medicines is the camphorated tincture of opium, and the usual amount of morphine present in so-called sedative cough mixtures is of the order of 1/150 gr. (0.4 mg.) for adults and 1/900 gr. (0.06 mg.) for children. The minuteness of these doses suggests that the term depressant or sedative cough mixture is usually a misnomer. Mixtures such as the ipecacuanha and morphine mixture of the *National Formulary*, which contains chlorodyne, are more likely to be effective, though it seems illogical to combine a sedative and a stimulant expectorant in the same preparation. Methadone in doses of 2 mg. (1/32 gr.) is an effective sedative for a useless cough and is available as a linctus; it may be administered instead of diamorphine, which will no longer be imported or manufactured in Britain.

There is no doubt that the vehicle is important in cough medicines. Syrups have a soothing effect on inflamed upper respiratory passages, and the simple linctus or the squill opiate linctus of the *National Formulary* may give relief without the danger of side-effects. Sudden changes of temperature and hot stuffy

¹ *British Medical Journal*, 1952, 1, 292.

² *Lancet*, 1939, 2, 932.

³ *Ibid.*, 1952, 1, 1230.

atmospheres which may accentuate coughing should be avoided. The tickle in the throat which is so embarrassing in the theatre will usually disappear if a flow of saliva can be induced. Liquorice lozenges or almost any lozenge or sweet may be useful for this purpose. When bronchospasm accompanies a cough, greater relief is usually given by mixtures containing stramonium or belladonna or by ephedrine elixir.

It is highly desirable that more information should be obtained about the relative merits of the many preparations available for the treatment of cough. It would, for example, be fairly easy in general practice to carry out a clinical trial of linctuses. The simple linctus could be used as a control preparation and could be compared with codeine linctus and methadone linctus. This is the sort of investigation which the College of General Practitioners might well sponsor.

CANCER PREVENTION

The rising death rate from cancer in Britain cannot fail to impress our profession with the urgent need for an all-out effort to control this great killing disease. It remains one of the biggest health problems awaiting solution, though the achievements in the control of other diseases since the turn of the century give hope of progress soon in the elucidation of cancer problems, many of which are concerned with those of life itself. Meanwhile the prevention and early detection of cancer are of outstanding importance. In his recent survey R. W. Raven¹ dwelt on this at some length, since certain varieties of cancer are preventable provided the attempt is made, and he referred to the necessity for a vigorous search for possible exogenous carcinogens to whose action the population may be subjected. The prevention of certain forms of cancer in industry shows what can be achieved when the carcinogens are known, and the contemplation of the evidence linking cancer of the lung with smoking tobacco stirs the imagination with what might be done by vigorous action in an enlightened community.

Apart from some controversial data, it is generally agreed that the best chance for a patient with cancer lies in early diagnosis and efficient treatment. Discussing cancer of the cervix uteri, S. Russ² contended that if the leading facts were presented to, and understood by, the population it is a fair inference that the death rate from cancer of the cervix would fall. Knowledge is increasing about what lesions are pre-

malignant, and it is important that they should be detected in patients and treated. Hence the need for some cancer education of the public. Moreover, members of all branches of the medical profession need information of advances in this field—doctors in the public health service, for instance, may play an increasingly important part in the future. In addition, more instruction might well be given to medical students, nurses, and some ancillary workers. In this issue of the *Journal* two complementary papers on the subject appear. Drs. J. Walter and E. C. Atkinson (p. 627) call attention to the value of cancer education conducted personally between physician and patient and to the use of medical examination. Assessment of the results of an educational programme may be difficult, and it is interesting to find they detected a cancer of the colon and a cancer of the breast. The scheme's value was indicated also by the number of patients who reported with rectal haemorrhage. As to the detection of premalignant or doubtful lesions, nine male patients with various conditions required attention. Among the female patients were 32 with lesions requiring follow-up examination, and another eight were referred to hospital with lesions requiring excision but proved benign. Pelvic tumours in women are fairly common and symptomless, but can be detected on examination; early diagnosis and treatment of them, whether they are benign or malignant, are necessary, and the premalignant nature of some must not be overlooked. Over a 15-year period C. Macfarlane *et al.*³ have tried to determine the value of periodic examination in the control of cancer of the female pelvic organs and breast. They discovered seventeen patients with pelvic cancers; of these nine are still alive, with one recurrence. In addition they found 986 benign lesions of the pelvic organs in the entire group of 1,319 volunteers throughout the period; these included 547 inflammatory lesions of the cervix believed to predispose to the development of cancer. A total of 11,203 breast examinations were made on a group of 537 volunteers; 11 breast cancers were found and all had been discovered first by the patients themselves. Six of these patients are alive without recurrence from three to twelve years after treatment; two others died of coronary occlusion without recurrence, three and thirteen years later. This research shows the value of periodic examination of the pelvic organs and breasts in women who are presumably well.

Another aspect of the subject is considered in the *Journal* this week by Miss J. Aitken-Swan and Dr. Ralston Paterson; they discuss delay in seeking advice. The factors responsible for this time lag are analysed after interviewing 75 men and 239 women

patients and their relatives. It is recognized that ignorance and fear are important causes of delay, and these workers found that one-quarter of the women with breast cancer were unaware of the possible significance of their symptoms and almost two-thirds of the women with symptoms of cancer of the cervix uteri were similarly ignorant. Another fact brought out in this paper is that probably no significant relationship exists between delay and the standard of intelligence. These authors report too that a lack of confidence in what can now be done for cancer patients causes delay, a lack engendered by seeing the fate of friends with advanced disease and the silence of doctors on the subject of cancer. It is not enough to tell people of the early symptoms of cancer; they should know what action to take in certain circumstances and what can be done to help them. They should be told of patients with many varieties of the disease who are well and living normal lives many years after treatment. With this knowledge the public will be better able to play its part in the prevention and early diagnosis of the disease. The mistaken opinions that many people hold on cancer have been well brought out by R. W. Raven and J. Gough-Thomas⁴; they showed that 17% of the people they studied believed cancer is infectious, 27% believed it is incurable, and another 20% were doubtful. Two main criticisms were levelled at cancer education—that surgeries would be crowded with worried people and that cancerphobia would be created. An experiment in cancer education by Ralston Paterson and co-workers⁵ showed that these fears are groundless.

Further efforts in cancer education seem to be desirable, but how best to proceed? The Ministry of Health favours local exploratory work, and this is going on in various places. The ignorance of the public on health matters—including cancer prevention—can be gradually dispelled, and people can also be advised to consult their doctor on the appearance of symptoms or signs. Patients should quickly notice signs of cancer in the mouth, pharynx, larynx, breast, skin, salivary glands, thyroid, rectum, and cervix uteri, yet Mr. Reginald Vick's analysis at page 660 indicates that they often fail to do so. Many women discover accidentally a cancer in the breast; would it not be advisable to teach them breast palpation at definite intervals to identify a single lump? The general practitioner might well consider a periodic health examination for some of his patients, though perhaps further exploratory work such as is described in the *Journal* this week is necessary before its practicability can be finally decided.

NIGHT CRAMPS

Most of us have suffered at some time and in some degree from attacks of cramp in the legs of the type which usually affect the muscles of the calf and which always occur when the subject is at rest. Sir Arthur Hall¹ obtained a history of such nocturnal cramps from 112 of 200 normal persons between the ages of 15 and 80. That the incidence increases with age is suggested by the fact that of the people in his group who were 50 years of age or over, 70% had had cramp. Six of his subjects had had only one fulminant attack, usually following violent exertion; in 15 it was a frequent and troublesome symptom; but in most it was no more than a minor nuisance.

Many people find that cramp may be induced by certain movements of the foot or toes in bed, and they soon learn to avoid making them. Others have noted the tendency for it to occur after unaccustomed exercise, as indicated by Hall. Nicholson and Falk,² for example, reported the occurrence of severe nocturnal cramps in twenty-three young soldiers during their period of primary training, which included a good deal of marching and drill. In this group the commonest associated abnormality was some minor defect in the feet, such as pes planus. Nocturnal cramps are also a frequent complaint during the later stages of pregnancy. It has been suggested, too, that venous thrombosis in the legs may be a predisposing factor, though there appears to be no association with arterial insufficiency.

The cause of this curious malady is not known, though there is no lack of unproved hypotheses. Abnormal irritability of skeletal muscle fibres or the neuro-muscular junction, calcium deficiency, alkalosis, and "disequilibrium" of muscle electrolytes are suggestions that all have their advocates. The most popular treatment in recent years has been the administration of quinine. Harvey³ showed that quinine diminishes the ability of skeletal muscle to respond to tetanic stimulation because of an increase in the refractory period of the muscle fibres, an action comparable to the effect of quinidine on heart muscle. Moss and Herrmann⁴ gave quinine 3 gr. (200 mg.) twice daily to twenty patients whose night cramps were severe enough to disturb sleep and often lasted for months at a time. Relief was obtained within twenty-four hours, and the cramps returned when a placebo was substituted. After treatment for up to ten weeks it was often possible to stop the quinine without the cramps returning. Gootnick⁵ also reported good results from the administration of quinine to thirty patients.

In a recent study of the problem, Lippmann and Perchuk⁶ have confirmed the value of quinine salts in reducing the incidence and severity of the cramps. They also found, however, that a number of other forms of treatment were effective: these included oral dihydro-

tachysterol, dilute hydrochloric acid or diphenhydramine, intravenous calcium gluconate, and supportive bandaging. Of all the remedies tried the most consistently efficacious, the least toxic, and the cheapest was calcium lactate, given in doses of 10 gr. (650 mg.) three times daily. The theory that there may be a deficiency of ionized calcium in these subjects has also been supported by Page and Page,⁷ who found that in two groups of obstetric patients the incidence of cramps was much higher in the group drinking larger quantities of milk. They suggest that the high content of phosphorus-containing proteins in milk leads in these patients to a rise in the inorganic phosphorus and a fall in the diffusible calcium in the blood, and they found that relief from the cramps could be obtained either by reducing the intake of milk or by administering a calcium salt free from phosphorus, such as the lactate.

IMMUNIZATION BY THE KELL ANTIGEN

The discovery of the anti-human-globulin test, or Coombs test,¹ enabled certain blood group antibodies hitherto undetectable to be recognized in many human sera. One consequence was the discovery of three new blood group systems known by the names Kell,² Duffy,³ and Kidd.⁴ The first of these to be discovered, and the most important clinically, was the Kell system.

Of the English population some 8% carry the Kell (K) antigen on their red cells. The corresponding antibody has been found in the serum of a number, now considerable, of Kell-negative persons. In every case it has been attributable to immunization either by pregnancy with a Kell-positive foetus or by transfusion with Kell-positive blood. Examples are now known of Kell antibodies active in albumin or even in saline, but it remains true that the only proved reliable method of detecting the presence of anti-Kell antibodies is the indirect Coombs test, and that with most of the available testing sera the same test must be used for detecting the Kell antigen. However, Grove-Rasmussen *et al.*⁵ claim to have devised a sensitive technique using human AB serum as a suspending medium.

Family investigations⁶ have shown that Kell reactions are controlled by a pair of allelic genes K and k. Most Kell-positive persons are heterozygotes of genotype Kk, but a small minority (theoretically 0.16% of the English population) are homozygous KK, and these if transfused with blood from a kk or Kk individual, or pregnant with a Kk foetus, are liable to become immunized to the k antigen. This was first shown to occur by Levine *et al.*, who named the k antigen "Cellano."⁷ Owing to the great rarity of KK individuals, immunization by k is of very little practical importance.

Immunization by K is, on the other hand, of considerable importance. Unlike Rh immunization, where only a minority of persons are at risk through lacking the immunizing antigen D, the majority of the population are liable to undergo Kell immunization through lacking the antigen K, but the risk is diminished by the fact

that this antigen, unlike D, is present in only a minority of donor bloods. Wiener⁸ has shown that, if D-negative persons are given two widely spaced injections of D-positive blood, 40% of them become immunized. Following Mollison,⁹ we may further assume that in clinical practice (if Rh testing were not performed) such immunization would be detected only during the direct matching test preceding yet a third transfusion, and if the blood intended for use were D-positive; in a similar way we may assume that Kell immunization, if due solely to transfusion, will be detected only on the occasion of a third transfusion or intended transfusion of K-positive blood to a K-negative recipient. From the respective frequencies of the D and the K antigens, it may be calculated that such a state of affairs will arise with only one-hundredth of the frequency with which it arises for D. Hence if D and K were of equal immunizing power, the relative frequencies of detection of immunization by D and by K would be in the ratio of 100 to 1. Since the ratio between the numbers of known cases is in fact of this order, it appears probable that in blood transfusions K is an antigen comparable in immunizing power with D. Using somewhat similar arguments, Wiener, Brancato, and Waltman¹⁰ have shown that, in pregnancy immunization, K is a very much weaker antigen than D. The severity of such cases as do occur of transfusion reactions and of haemolytic disease due to anti-K appears to be comparable to that of the cases due to anti-D. One death has with good reason been attributed to such a transfusion reaction.¹¹ Some severe cases of haemolytic disease have been described, but none of them appear to have been fatal.

Now that most mothers and practically all transfusion donors and recipients are tested for the Rh factor, the danger due to that factor has greatly diminished, while that due to the Kell antigen has presumably remained stationary and hence become relatively more important. But the rarity of anti-K testing sera shows that the absolute danger of Kell immunization is not great. Certainly the supplies of serum would not permit universal Kell testing of blood donors, or even the extensive testing that has been recommended,¹² nor would the diversion of manpower to this task be justifiable while so many other greater medical needs remain unsatisfied. But some action can be taken to avoid or mitigate the effects of immunization by the Kell antigen as well as by other antigens outside the Rh system. Some and perhaps many immunizations due to a combination of transfusion and pregnancy would be avoided if it were an absolute rule never to transfuse a woman with her husband's blood¹³—now a rare practice in England, but probably not so in some countries. Another precaution

is the use of the Coombs test in direct matching of all transfusions, at least to women before and during the child-bearing period and to all persons who either have been transfused or have been pregnant. Needless to say, the detailed serological investigation of all cases of transfusion reaction and of haemolytic disease of the newborn, while not preventing trouble, will prevent its being made worse by further incompatible transfusions. As part of this detailed investigation, it may be found desirable to search for anti-K even in sera already known to contain anti-D, for those persons who readily make anti-D may also show an enhanced capacity to make anti-K. Where such investigations are undertaken, any extensive series of results obtained should be tabulated and published as a guide to the existence or otherwise of such an enhanced immunizability.

FOOD-POISONING

Even more dismal results than in previous years are revealed by the Public Health Laboratory Service's analysis of food-poisoning outbreaks to the end of 1953.¹ In England and Wales in 1953, 5,277 outbreaks were recorded, compared with 3,519 in 1952 and 3,347 in 1951. At least 15,000 persons were reported as having symptoms, and 51 died. The organism causing death was a salmonella in 46 cases, *Staphylococcus aureus* in 2, and unknown in 3. Outbreaks included 492 of a general nature, 422 in families, and 4,363 sporadic cases. The causal organism was *Salmonella typhi-murium* in 2,405 cases, other salmonellae in 709, staphylococci in 132, *Clostridium welchii* in 25, various in 6, and unknown in 2,000. The cause was unknown mainly in those outbreaks which were not investigated because of the long delay between occurrence and reporting.

The types of salmonella isolated included 2,838 endogenous and 243 exogenous types. In this context "endogenous" means common in England and Wales and widely recognized before 1940; "exogenous" refers to organisms little known in this country before then. The endogenous organisms infecting the largest groups of cases were *Salm. typhi-murium* 2,438, *Salm. thompson* 84, *Salm. bovis-morbificans* 81, *Salm. enteritidis* var. *jena* 80, and *Salm. newport* 50. The exogenous organisms infecting the largest groups of cases were *Salm. anatum* 30, *Salm. oranienburg* 29, *Salm. bareilly* 25, *Salm. montevideo* 18, and *Salm. minnesota* 17.

As in previous years, about two-thirds of the outbreaks were attributed to infected meat, and about 80% of these outbreaks were associated with processed, made-up, or reheated meat. Milk was the vehicle of infection in 12 outbreaks (7 due to fresh, 4 to dried, and 1 to canned milk). Two of the outbreaks caused by fresh milk, due to *Salm. typhi-murium*, were large: one, which affected about 300 persons, was caused by unpasteurized T.T. milk; the other, which affected over 100 children, was caused by pasteurized school milk. In the latter

outbreak the milk was infected during bottling and after pasteurization. Of the outbreaks caused by dried milk (also infected with *Salm. typhi-murium*), one attacked about 100 schoolchildren in Yorkshire and another consisted in a series of related school outbreaks in Surrey and London which were traced to the same dried-milk plant. Infected eggs caused 25 outbreaks, of which 18 were due to duck's eggs. In 21 of the 25 outbreaks due to eggs the causal organism was *Salm. typhi-murium*. Infected sweetmeats caused 27 outbreaks: 12 of these were associated with cream buns and cream cakes and 9 with trifle, vanilla slices, and custards. Investigation of 166 outbreaks showed the source of infected food to be as follows: 58 in canteens, 42 in restaurants, 30 in shops (butchers' shops 13, cooked-meat shops 10), 21 in institutions, and 15 in private parties.

The reported incidence of food-poisoning and dysentery (reviewed in these columns recently²) is increasing. Whether the rise is due to better reporting or not—and the reported cases are only a fraction of the true incidence—it is evident that these conditions are responsible for a vast amount of preventable illness and in 1953 for almost 100 deaths. Far too many handlers of food have deplorable standards of hygiene, combining dirty habits with an attitude of indifference. The task of reducing the menace they are to the community was discussed at some length in Parliament last year, and the Food and Drugs Amendment Bill received its third reading on November 11.³ The Food Hygiene Advisory Council to be set up under this new legislation may well recommend that carefully devised propaganda, among other measures, should be directed at all food-handlers who serve the public, and the cost would probably be small against the benefit it would bring the public. Certainly the high and still rising numbers of food-poisoning and dysentery outbreaks point to an urgent need for preventive action.

TREATMENT OF ANURIA

The prognosis of acute renal insufficiency is good provided the patient can be kept alive long enough to permit structural repair and resumption of function in the distal tubule.¹ During the anuric phase treatment is by controlling so far as possible the disorders of water and electrolyte metabolism which result from the temporary exclusion of the kidneys as working organs from the system. The undesirable effects that arise when the kidneys are out of action depend partly upon inability to eliminate water, except in necessarily small amounts through the skin and bowels, and partly upon the accumulation in the extracellular fluid of toxic end-products of endogenous protein breakdown which are normally excreted in the urine. The danger of forcing fluids in these cases has been emphasized.^{2,3} Water intake should be restricted to that amount which will allow for the insensible loss, usually about 1 litre in 24 hours, depending on the surface area of the patient and his bodily and environmental temperature. To this should be added an amount of water equal to whatever

¹ Monthly Bull. Minist. Hlth (Lond.), 1955, February, 34-42.

² British Medical Journal, 1955, 1, 401.

³ *ibid.*, 1954, 2, 1236.

may be lost by abnormal routes, such as by vomiting or diarrhoea. Fluids may be given in the form of a mixture of carbohydrate and fat, whose high-calorie content minimizes the breakdown of endogenous protein and release of potassium.⁴ The diet may increase the tendency of uraemic patients to vomit, and Bull *et al.* give an emulsion of peanut-oil and dextrose solution by continuous intragastric drip.³ This lessens the tendency to vomiting, and fluid loss is minimized by returning any vomit, filtered, into the drip. If vomiting is so troublesome that the patient cannot retain the gastric tube, slow intravenous infusions of 20–50% dextrose solution given through a catheter into the superior⁵ or inferior vena cava⁶ have been given successfully.

Large quantities of carbohydrate help to keep down the level of potassium in the extracellular fluid. In concentrations of more than 8.0 mEq/l. potassium is toxic to the heart, as is shown in cases of pure hyperkalaemia by abnormalities of the electrocardiogram. Phosphate may accumulate in the plasma from much the same causes as potassium may. This leads to a depression of plasma calcium, which enhances the toxicity of potassium excess, and obscures the abnormality of the electrocardiogram due to it.¹¹ In an emergency potassium may be driven back temporarily into the cells by the administration of insulin and glucose,⁸ but Bull believes that toxic concentrations are not often encountered if the patient receives the conservative protein-free high-carbohydrate solution.⁹ Meroney and Herndon⁷ found that American battle casualties in Korea with acute renal insufficiency could not tolerate oral fluids even when given by tube. Calcium, added to the intravenous solution they employed, mitigated the toxicity of potassium. Although ion-exchange resins in the sodium phase have been used successfully to withdraw potassium into the bowel, Meroney and Herndon's patients could not take them, and when they were given rectally they were not effective. If such relatively simple expectant measures fail, the more heroic and rather more risky procedures of peritoneal¹⁰ or intestinal¹ dialysis, or the use of the artificial kidney,¹¹ or exchange blood transfusion¹² are often beneficial.

It is also important to combat infection and so prevent further tissue breakdown. Therefore any devitalized tissue should be widely excised.¹¹ Bull⁹ recommends that all anuric patients should receive a single daily prophylactic injection of 1 million units of penicillin. Nevertheless antibiotics given even in ordinary doses to patients unable to excrete them may be toxic.¹³

SCOTTISH HOSPITAL COSTS

Recently we drew attention¹ to the annual costing returns of hospitals in England and Wales. Those for Scottish hospitals for the same year (1953–4) have now appeared.² They, too, are drawn up under subject headings. The claim is made for these returns, as it was for the English and Welsh ones, that they enable comparisons to be made between the costs of maintaining a patient in hospitals of the same size and the same type. But to what extent are comparisons between Scottish and English hospitals valid, for at first sight it is cheaper to maintain a patient north of the border? The cost per patient per week in a general hospital of more than 300 beds is £13 9s. 9d. in England and Wales and £11 5s. 5d. in Scotland. In both cases this calculation makes allowance for what is called the vacant-bed factor—that is, for beds staffed but not used. In fact, the Scottish returns are drawn up on a basis that distinguishes between expenditure that is directly dependent on the numbers of in-patients, expenditure that is partly dependent on numbers and partly standing, and expenditure on hospital overheads such as rates and maintenance of buildings and administration. The English returns merely divide the expenditure between running charges—lumping the cost of patients' and the staff's food together—and standing charges, and adjust the total cost by the vacant-bed factor. Further, the Scottish returns extract out-patient expenditure "on the basis of the actual or estimated costs of the services rendered"; in England and Wales the gross total cost of maintaining an in-patient is again merely adjusted by the arbitrary formula that five out-patient attendances equal one in-patient day. This difference in methods of costing invalidates any comparison of items of expenditure in English and Scottish hospitals. The Scottish system of extracting out-patient expenditure altogether, instead of including it under all the subject headings and then making an adjustment in the total expenditure, certainly makes it easier for a Scottish hospital to compare its figure for, say, drugs and dressings with that of another. But what makes the total cost of maintaining a Scottish patient lower by comparison with England is the exclusion of specialists' salaries in the Scottish returns. Their inclusion would probably make the Scottish weekly expenditure much the same as the English.

One contrast can, however, be pointed out. In Scotland the cost of maintaining a patient in a teaching hospital is only 15s. to £2 a week higher than in an ordinary general hospital. In England and Wales the higher cost is about £3 10s. for provincial teaching hospitals and as much as £9 for London teaching hospitals. Scottish teaching hospitals come within the sphere of the regional boards, and the distinction in status between a teaching and non-teaching hospital are not so marked as in England. The high extra cost of independence ought to set some boards of governors thinking.

EMERGENCIES IN GENERAL PRACTICE

OBSTRUCTED LABOUR

BY

JOHN PEEL, F.R.C.S., F.R.C.O.G.

Obstetrician and Gynaecological Surgeon, King's College Hospital

The end-result of obstructed labour, if unrelieved, is rupture of the uterus, unless the mother dies of exhaustion and shock before rupture takes place. If the uterus ruptures, the maternal mortality varies with the cause of the obstruction and the availability of expert obstetrical care, but it is always very high. It is rare for the foetus ever to survive. These considerations serve to emphasize the seriousness of neglecting actual or potential obstruction during labour.

In modern obstetric practice in Britain, rupture of the uterus following obstructed labour is rapidly becoming a rarity, although it still presents a problem of major importance in backward countries, where adequate antenatal care is not available to the large mass of the population. Obstruction is nearly always the result of malposition of the foetus or else of contraction of the maternal pelvis; less commonly it is due to atresia of the soft tissues of the birth canal or obstructing tumours. Reference to any standard textbook of obstetrics will supply a list of the malpresentations, the different types of pelvic contraction, and the soft-tissue tumours that may lead to obstruction, and there is no point in enumerating such a series here. In any case they are mostly well known and obvious. Nor will space permit of a detailed description of every individual condition that may cause obstruction. It must therefore suffice to discuss in general terms the prophylaxis and early detection of potential obstruction, and the principles underlying the management of established obstruction.

Theoretical Considerations

Within recent years we have come to understand the behaviour of the uterine muscle in labour much more clearly as the result of the work of Reynolds and others using the Lorand tocograph and other methods of obtaining tracings of uterine contractions for accurate study and analysis.

FIG. 1.—Prolapsed arm: retracted upper segment, thinned lower segment.

This confirms two fundamental facts about uterine action in obstructed labour.

1. In the presence of obstruction the pattern of uterine contractions is essentially normal: that is to say, the upper segment muscle contracts more and more strongly while the lower segment remains passive. The lower segment becomes progressively thinner (Fig. 1), and through this thinned lower segment rupture will ultimately take

place. Before this occurs, however, a pathological retraction ring (Bandl's ring), which is detectable clinically, forms at the junction of the two segments.

2. The response of the primiparous uterus to obstruction is in marked contrast to that of the multiparous one. In the former the response is a gradual increase in tonus, associated with diminishing activity. The lower segment may therefore not dilate and labour may be very prolonged, with less risk of rupture. In extreme cases the mother may die, undelivered, of shock and exhaustion; if she is ultimately delivered and survives, extensive soft-tissue sloughing may occur as a result of prolonged pressure causing ischaemia and fistulae between the rectum or bladder and the genital tract: before either of these disasters occurs the foetus may die of anoxia from progressive increase in uterine tone. In the multiparous patient, on the other hand, the response to obstruction is rapidly increasing contractions and thinning of the lower segment. Hence the uterus may rupture soon unless the obstruction is overcome relatively early in the course of labour. This difference in behaviour of the uterus is of great practical importance, and is mentioned to emphasize the greater need for urgency and speed in the management of obstruction in the multipara than in the woman labouring for the first time.

Apart from the danger of rupture of the uterus or extensive post-partum soft-tissue sloughing, there is the danger to the mother of ascending infection. This risk is especially great if the membranes rupture early and labour is protracted. In addition to the risk of injury from direct pressure, the foetus may perish from placental anoxia due to a hypertonic uterus; if it survives a prolonged labour, pulmonary or other infection, initiated during labour, may develop in the neonatal period.

From the practical point of view it will be best to consider potential or actual obstruction at different levels in the pelvis, because there are important clinical differences.

Obstruction at the Pelvic Brim

The commonest causes of this are: (a) maternal: contraction of the pelvic inlet, fibroids, or ovarian cysts; and (b) foetal: transverse lie, brow presentation, and hydrocephalus. In all these conditions there is no foetal presenting part in the pelvic cavity during the last weeks of pregnancy and in the early stages of labour, and the diagnosis is usually made before the onset of labour. However, in many cases it may be necessary to allow labour to start before certain obstruction can be detected. It is often surprising how a fibroid, even when low down in the uterus and below the foetal head, may become drawn up during labour, thereby allowing the head to descend into the pelvic cavity. Only a cervical fibroid must inevitably lead to obstruction, unless caesarean section is carried out. Should obstruction develop owing to an ovarian cyst impacted in the pelvis, caesarean section is again necessary. Such a cyst is usually adherent, and attempts to displace it upwards as recommended in older textbooks may result in rupture of or haemorrhage into the cyst.

The problems of brim contraction are many and varied, and can only be discussed here in general terms. Inlet contraction should be suspected in all cases of high head in the last weeks of pregnancy or early in labour, although disproportion and obstruction will develop in only relatively few of such cases. In the presence of a normal-sized foetus obstruction to labour is almost certain if the true conjugate is less than 9 cm., whereas if it is more than 10 cm. over

95% will end in spontaneous or assisted vaginal delivery. It is in the intermediate cases with conjugate measurements of between 9 and 10 cm. that trial of labour is especially indicated.

It is sometimes stated that it is impossible to determine whether there is or is not true cephalo-pelvic disproportion unless and until the cervix is fully dilated so that the head can descend in the birth canal. While this may be true in theory it is not entirely true in relation to inlet contraction. Early in the course of labour in these cases the membranes rupture and if the presenting part is unable to pass the pelvic brim because of disproportion the cervix may never become fully dilated, and yet obstructed labour may develop and the lower uterine segment become so thinned that it ruptures. In this type of case the differential diagnosis between delay due to cephalo-pelvic disproportion and that due to inco-ordinate uterine action of the hypertonic variety may be very difficult indeed. This in point of fact is a not uncommon clinical problem. Errors in judgment account for some at any rate of those patients whose first labour is terminated by caesarean section for alleged cephalo-pelvic disproportion and who are subsequently delivered successfully per vaginam of a similar-sized or even larger baby. Whilst trial of labour steers the patient between the Scylla of unnecessary caesarean section and the Charybdis of dangerous induction, it is not an infallible means of determining cephalo-pelvic disproportion in all cases.

The management of inlet contraction can be considered briefly under three headings.

1. Prophylaxis

Careful assessment of the high head in the last weeks of pregnancy is essential. In the multiparous patient who has previously lost a baby during the course of an obstructed labour, premature induction of labour is often advisable. Remember that the size of the baby tends to increase in succeeding pregnancies, and that obstructed labour may develop in a woman who has had several successful vaginal deliveries.

2. Early Detection

It is important to diagnose as early as possible that delay in labour is due to disproportion which will eventually cause obstruction if neglected. Early detection while the mother's condition is good and the foetus still alive and well is imperative if good results are to be obtained. Marshall's figures presented to the 12th British Congress of Obstetrics and Gynaecology, analysing 2,276 caesarean sections, showed no maternal mortality if caesarean section was undertaken within six hours of the onset of labour, 0.35% if undertaken within six to twenty-four hours, but 2.49% if labour had lasted over forty-eight hours. Nevertheless, the differential diagnosis of the cause of delay during the first stage of labour between disproportion and inco-ordinate action is sometimes far from easy. In some cases both conditions may in fact be present.

In cases of disproportion the pattern of uterine action is essentially normal. Upper segment tone increases, but at first there is normal relaxation between contractions which are regular and of normal strength. As the duration of labour increases the lower segment becomes more and more dilated and thinned until ultimately a Bandl retraction ring is formed which is visible in the abdomen. With the drawing upwards of the junction between the upper and lower segments the bladder too is drawn up, so that it becomes easily visible even though it may contain only a few ounces of urine. On vaginal examination the cervix tends to hang down from the head, which is lodged tightly in the brim and becomes progressively more oedematous from prolonged pressure. There is no spasm of the cervix during a contraction of the upper segment. A large caput forms on the head and moulding is excessive. In brim contraction asynclitism is exaggerated and posterior parietal presentation is a bad prognostic sign. The head cannot be pushed down between contractions, nor does it descend during a contraction. Moir and others have shown the value of lateral radiography

during labour in helping to arrive at a prognosis. Once the labour is obstructed lower segment caesarean section must be carried out before foetal distress or death occurs.

3. The Management of Established Obstruction

In some cases the foetus may be dead, and in multipara rupture of the uterus may be imminent. The alternatives of caesarean section and craniotomy are often debated. There is a natural tendency to avoid caesarean section if the foetus is already dead, but the hazards of craniotomy if the head is above the brim, the lower segment dilated and on the point of rupture, and the cervix not completely obliterated cannot be stressed too strongly. In such cases perforation and embryotomy carry a grave risk of shock, haemorrhage, and trauma. Modern antibiotics have made caesarean section the safer alternative for the mother even though the foetus is dead. The exception to this is the hydrocephalic head. Here, perforation alone is all that is necessary to collapse the head and spontaneous delivery will take place.

The management of obstruction due to the impacted shoulder or brow presentation requires equally careful consideration. In the absence of pelvic contraction the brow

FIG. 2.—Internal podalic version.

presentation can usually be corrected manually to a face or vertex if the cervix is at or near full dilatation, and then a forceps delivery can be carried out. If diagnosed earlier in labour, very soon after rupture of the membranes, bipolar podalic version may be safely undertaken (Fig. 2). Sound obstetric judgment and experience are necessary to decide whether it is safe to carry out internal version when an arm or shoulder presents. If this is done the uterus should always be explored afterwards to make sure that the lower segment has not been ruptured. It is seldom if ever necessary to do a caesarean section for an impacted shoulder presentation with a dead foetus. Decapitation, using a decapitation saw, is not too dangerous or difficult to be undertaken by an experienced obstetrician. The patient is nearly always a multipara and the birth canal dilated so that the neck can be pulled well down into the pelvis before decapitation is undertaken. The transverse lie in the primigravida, due to gross inlet contraction, placenta praevia, or uterine fibroid, is an entirely different problem and always calls for caesarean section even though the child is dead.

Obstruction Associated With Mid-Pelvic Contraction

Mid-pelvic contraction occurs at the level of the ischial spines, the interspinous diameter falling below the normal 10 cm. and the posterior sagittal diameter of the mid-pelvis falling below 5 cm. Mid-pelvic contraction is often associated with the android-shaped pelvis, the fore-pelvis being narrowed and the anterior surface of the sacrum straightened. Often the head descends in the transverse instead of the oblique diameter of the pelvis and becomes arrested at this

level—deep transverse arrest. It is also at this level in the pelvis that obstruction may develop if contraction is present and the foetus is presenting as an extended breech.

The development of obstruction in the mid-pelvis will in most cases only become apparent in the second stage of labour. At the beginning of labour the head may be fixed in the brim, if not actually through it; the first stage proceeds normally and often rapidly, but delay occurs in the second stage. In some cases which are complicated by inco-ordinate action the cervix may not become quite fully dilated. This seldom occurs if uterine action is normal.

Failure to recognize mid-pelvic contraction accounts for a great many stillborn babies, because only rarely is the contraction so great that the child cannot be pulled through the contracted diameters with axis-traction forceps if enough force is used. In many cases if the occiput is posterior or transverse, correction of the position with consequent reduction of the diameter of the foetal head will enable a successful forceps delivery to be completed. In many cases the position of the foetus is favourable and yet the application of forceps fails to deliver the baby when reasonable force is used. Only experience can educate the obstetrician to know just what strength of pull is reasonable and safe following application when the head has not yet passed the ischial spines.

The application of forceps at this level has come to be known in recent obstetric literature as a trial of forceps. It is something that should never be undertaken deliberately outside hospital and then only by an experienced obstetrician. Few cases of trial labour should be carried to this limit, but it is important for the doctor to realize the possibility of failure of forceps being due to mid-pelvic contraction which may not have been diagnosed before labour. He may encounter such an emergency unexpectedly in domiciliary practice. If the head is very moulded he may think it is below the mid-pelvis, but in that case need experience no shame at removing his forceps and sending the patient to hospital. Caesarean section may be undertaken even at that late stage.

In hospital trial of forceps is legitimate practice, even when these difficult cases have been studied thoroughly by radiography during the antenatal period. It requires much more experience and courage to admit that the baby cannot be delivered safely by forceps than it does to pull out a dead or damaged baby by sheer force. If the baby is already dead, owing to obstruction at this level, perforation and extraction is usually preferable to caesarean section and does not carry the same risk of maternal shock and trauma as when the foetus is obstructed at the pelvic brim. Mid-pelvic contraction may cause difficulty in the delivery of the extended breech, because impaction and obstruction may occur. It is deemed by some that a trial of labour is not possible in a breech delivery. It is reasonably fair to say, however, that if the extended breech is delayed in the mid-pelvic cavity the cause of the delay is not primarily the extended legs but disproportion, due either to mid-pelvic contraction or a very large child. Bringing down the leg may enable the baby to be delivered, but the foetal loss associated with this particular procedure at this level of obstruction is very high and in my opinion caesarean section is justified under these circumstances.

Obstruction at the Outlet

While delay at the outlet is relatively common, true obstruction is rare. It may occur if the foetus is abnormally large and/or in the posterior position. It may occur if there is true bony contraction. Some authorities deny the existence of the latter in the absence of inlet or mid-pelvic contraction, but most obstetricians of experience encounter the occasional funnel pelvis. Contraction of the intertuberous diameter below the normal 10 cm. does not necessarily lead to outlet dystocia provided the posterior sagittal diameter is generous, so that the head can be born posteriorly instead of close to the symphysis pubis. Very rarely obstruction at the outlet is due to extensive stenosis of the vaginal introitus due to scarring, or to soft-tissue tumours of the vagina

(fibromata, cysts of Gartner's duct, etc.). Vulval scarring enough to cause outlet dystocia is hardly ever seen in this country, but in the Kikuyu women of Kenya and in other native tribes where female circumcision is still practised it is a relatively common occurrence.

The management of outlet obstruction is always difficult if the foetus is still alive and normal. Generous episiotomy, if necessary passing wide of and behind the anus, increases the available space enormously, so that the baby may be delivered safely with forceps even face to pubis. Bony contraction so gross as to cause genuine outlet obstruction only rarely remains undetected until so late in labour. The choice in such cases falls between a difficult caesarean section and the operation of symphysiotomy. The latter operation has received something of a revival lately, but is only rarely undertaken and then only at the hands of those who are experienced in the operation. If the child is already dead or is abnormal—for example, hydrocephalic—perforation is not difficult or dangerous at this level.

While outlet contraction and disproportion are not uncommon in a minor degree and in association with contraction of the brim or cavity, true outlet obstruction due to bony contraction is very rare. Delay and minor disproportion can usually be overcome by generous episiotomy, an operation also necessary in cases of gross cicatrization of the soft tissues.

Space does not permit of more than a passing mention of obstructed labour associated with organic rigidity, stenosis, or atresia of the cervix. Suffice it to say that it is a relatively uncommon condition, most cases of so-called rigid cervix being in fact examples of cervical spasm or associated with hypertonic uterine inertia. Nevertheless, cases of organic stenosis do occur; reports of complete annular detachment of the cervix from the pressure of the advancing head have been recorded. In most cases caesarean section is necessary, but incision of the cervix (Dührssen's incisions) may be carried out, but only if bony disproportion at all levels in the pelvis can be ruled out for certain.

Modern antibiotics have made caesarean section late in labour a procedure which is relatively safe for the mother and child. By its use we can often escape from the consequences of poor judgment and carelessness. The better our antenatal care the fewer will be the examples of obstructed labour that we shall encounter, except those which occur during the course of a planned trial of labour. A steady decrease in the incidence of obstructed labour is one of the most spectacular successes of modern antenatal care.

Next article on Emergencies in General Practice.—“Haematemesis and Melaena,” by Dr. T. Hunt.

Refresher Course Books.—Copies of the first two volumes of collected articles from the Refresher Course for General Practitioners published in the *Journal* are still available at 25s. (postage 1s.) each. The first volume contains 55 articles and the second 60. Each article has been revised and brought up to date by its author.

These books may be obtained from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller.

An outstanding problem in Singapore to-day, according to the *Medical Department Annual Report, 1953*, is the provision of facilities for out-patients. Immediately before the 1939-45 war the annual attendance of out-patients was 87,000, in 1947 it was over 305,000, while by 1953 the figure had reached 957,000. “This development,” writes Dr. W. J. VICKERS, the director of medical services, “is quite different to that in the United Kingdom and elsewhere in that the public has created and demands a direct patient-clinic service without the intervention of the private general medical practitioner.” The demand has been met by the Government providing a National Health Out-patient Service in its hospital divisions.

PROGRESS IN CANCER REGISTRATION

A SURVEY OF THE DEVELOPMENT OF A
CANCER RECORDS BUREAU FROM
1945 TO 1954

BY

REGINALD M. VICK, M.Chir., F.R.C.S.

Director of South-western Regional Cancer Records Bureau;
Consulting Surgeon to St. Bartholomew's Hospital

The first steps in the introduction of a scheme for recording cases of cancer on a national basis were taken by the Radium Commission, which, from 1930 until the National Health Service Act of 1946, controlled the supply of radium to the radiotherapy centres. During the war the collection of records from the centres was suspended.

In 1939 the Cancer Act required the council of every county and county borough to make and submit for the approval of the Ministry of Health arrangements for adequate facilities for treating cancer patients in their area. They were also advised to provide for the keeping of records, which were to be submitted ultimately to an authority designated by the Ministry. In 1944 the Ministry instituted registration cards and abstract cards for approved centres. The Radium Commission introduced similar arrangements for their centres. In June, 1945, the Radium Commission was nominated temporarily as the statistical bureau for collection and analysis of cancer records. This duty was taken over by the General Register Office in 1947, with whom it rests to-day.

Formation of the South-western Regional Bureau

When the war was over, the county councils of Gloucestershire, Somerset, and Wiltshire and the county boroughs of Bristol, Bath, and Gloucester got to work. They formed a cancer advisory committee and appointed the late Professor Rendle-Short as medical adviser. At that time they were responsible not only for records but for the facilitation of the diagnosis of cancer, for the treatment of patients suffering from that disease, and for the payment for care, maintenance, and travelling expenses of all such patients. One other point should be emphasized here—the principle, strongly supported by the Ministry, was that hospitals should not be recognized for service under the Cancer Act unless the surgical staff were whole-time consultants not engaged in private practice. This caused many delays and hampered the development of the scheme.

A records office was, in the first instance, established at the Bristol General Hospital, a records officer was appointed and subsequently four clerks to assist him, the whole under the clinical control of the medical adviser, and the administrative control of the house governor of the teaching group of hospitals. This organization worked smoothly, and by March, 1948, about 2,500 new cases were dealt with annually and 1,900 survivors were followed up, making a total of 4,400 cases handled.

Similar arrangements were made in Plymouth for the counties of Devon and Cornwall, and Mr. Duncan-Wood was appointed director for that area in 1947. It was not until 1948 that the Royal Devon and Exeter Hospital and the Torbay Hospital (Torquay) were included.

The Cancer Act was repealed by the passing of the National Health Service Act in 1946, and on the appointed day in 1948 the Regional Hospital Board took over the whole organization of the South-western Region, with offices at Bristol and Plymouth and cancer record clerks at Redruth, Torbay, and Exeter.

In 1952 the medical adviser at Bristol and the director at Plymouth resigned and one director was appointed in charge of the entire region and the two offices (October, 1952). Some co-ordination between the two areas had already taken place, but each area produced its own report in its own chosen form. In 1952 the reports of cancer statistics for the two areas were combined in one volume, but in 1953 the figures for the whole region were grouped together and critically analysed under each site of cancer in the body.

As both offices had been running—though only covering a much smaller number of hospitals—since 1945, it has been possible to produce a five-year survival rate for the entire region, and since 1948 all hospitals in which cancer is treated have been included. Thus a much more valuable statistical review has been possible.

Advances in Registration

Further advances in cancer registration are being carried out. An effort is being made to get as near the 100% registration as is possible. In order to do this, hospitals of all types (including mental hospitals, geriatric units, etc.) have been prevailed upon to send in records of their cancer patients. Medical officers of health have co-operated by sending in detailed returns of all cancer deaths at regular intervals. The analysis of these returns is providing much useful information, not the least important of which is the pin-pointing of those hospitals which are failing to register their patients with the bureau. It is hoped, ultimately, to register even those patients who never go into hospital at all. Surgeons throughout the region have been asked to register their private patients with the bureau, and the majority of them have agreed to do so.

Every patient registered has a case-history sheet, which contains all the available details, often from more than one hospital. From this history an abstract card is prepared, giving essential information, which is passed on to the office of the Registrar-General. Marginal punch cards are also prepared for every patient registered, and these cards are of inestimable value in any survey that may be required, such as the annual report, and for any special statistical investigation that is carried out. The information they contain is available to any surgeon who asks for it, and we have been able to answer many inquiries.

All these developments have greatly increased the number of registrations and the work of the bureau, which has entailed a small increase of staff.

Personnel of the Bureau

The personnel is now arranged as follows: (1) The director is responsible for the control of the work of the bureau and for the production of an annual report. This involves attendance at the two offices of the bureau, one in Bristol and one in Plymouth. (2) A records officer at each place: both of whom have been with the bureau since before the appointed day. (3) The requisite number of graded clerks—four at Bristol and three at Plymouth. Recently an extra clerk has been appointed at each office to cope with the rising tide of registrations. There are also cancer clerks at Exeter, Torbay, and Redruth.

Annual Report, 1953

Below is given an analysis of the annual report of the bureau for the year 1953—issued in December, 1954. The total population of the Region was 2,897,087 (1951 census), and Table I indicates the work being done.

	Bristol	Plymouth	Combined Total
Total No. of cases registered to end of 1953	23,136	16,043	39,179
No. of new cases registered in 1953	3,883	2,705	6,588
No. of cases followed-up in 1953	10,000	6,183	16,183

The report is circulated to all the regional hospital boards, to every surgeon in the region who treats patients suffering

from cancer, to all hospitals and medical officers of health within the region, to the Ministry of Health, the General Register Office, to all relevant medical committees, including local medical committees, indicating that more copies are available for any interested general practitioners, to all radiotherapeutic departments, to all medical schools in the British Isles, and to the medical press.

It shows the state of registration in 1953 for each hospital in the two areas, the distribution of registrations by counties, and, in the Plymouth area, is accompanied by special tables showing the distribution of cancer registration in clinical areas. The report contains statistical tables which indicate under each anatomical site the total number of patients treated in both the Northern (Bristol) and the Southern (Plymouth) areas, the method of treatment, and the number of survivors. It indicates the five-year+ survival rate under each site and comments on the clinical history of the survivors.

Beneath the heading of certain "accessible" sites—the breast, cervix uteri, and uterus—the patients are classified under the recognized stages (Manchester staging) and the survival rate is indicated under each stage. When the numbers of untreated cases appear to be of statistical significance they are given.

The order in which the malignant growths are taken follows, so far as is possible, the classification of the World Health Organization. Two examples of the way in which the statistical tables are set out are shown in Tables II and III.

TABLE II.—Malignant Growths of Large Intestine (Excluding Rectum)

	Total Cases		Patients Alive	
	Bristol	Plymouth	Bristol	Plymouth
Radical surgery	95	62	41	31
Palliative	71	50	—	5
Not treated	76	35	—	—
Total	242	147	41	36
	389		77	

Five-year+ survival rate=20%.

The comments on survivors in Table II are as follows: Age—youngest 32; sex—men 27, women 50. Treatment:—Partial colectomy, 60; exteriorization and subsequent closure of colostomy, 12; colostomy only, 3; surgery and radiotherapy, 2. Sites:—Sigmoid and pelvic colon, 31; transverse colon, 12; caecum, 7; ascending colon, 6; descending colon, 6; hepatic flexure, 5; splenic flexure, 5; recto-sigmoidal junction, 5.

TABLE III.—Malignant Growths of Mouth (Excluding Tongue)

	Total Cases		Patients Alive	
	Bristol	Plymouth	Bristol	Plymouth
Surgery	11	2	8	1
and radiotherapy	—	6	—	1
Radiotherapy	32	30	3	3
Radium	15	10	7	9
Total	58	48	18	14
	106		32	

Five-year+ survival rate=30%.

The comments on survivors in Table III are as follows: Age—youngest 30, oldest 83; sex—men 23, women 9. The series includes one case of rhabdomyoma of the cheek, treated by excision. Sites:—Floor of mouth, 10; alveolus, 7; palate, 6; cheek, 5; tonsil, 2; lower jaw, 1; fraenum, 1. Biopsy was positive in most cases.

Space does not allow of the setting out of all the tables in *extenso*. In Table IV is given a summary of the figures under each anatomical site. The breast, cervix, and uterus are dealt with in a later table.

TABLE IV.—Summary of Registrations According to Anatomical Site

Site of Malignant Growth	Total Cases	Patients Alive	5-year+ % Survival
Lip	286	142	55
Tongue	141	25	17.7
Salivary glands	54	34	63
Mouth (excluding tongue)	106	32	30
Pharynx, larynx, etc.	170	25	15
Oesophagus	203	4	2
Stomach	492	25	5
Large intestine (excluding rectum)	389	77	20
Rectum	437	61	14
Pancreas	40	1	2.5
Thoracic organs	408	11	2.7
Ovary	179	43	24
Prostate	206	30	15
Testis	59	35	59
Penis	56	24	43
Kidney	59	17	29
Bladder	163	38	23
Skin (malignant melanoma)	79	25	32
Eye	18	11	61
Brain and central nervous system	29	9	31
Thyroid	52	15	29
Bone	137	16	11.6
Lymphadenoma	120	33	27.5
Leukaemia	125	9	7

Comments on some of the five-year+ survival rates shown in Table IV are as follows.

Lip.—It is distressing to note the relatively high mortality for what is, after all, an "accessible" cancer. Many of the patients presented themselves at a late stage and were treated by radiotherapy.

Tongue.—The high mortality of cancer of the tongue is demonstrated. No fewer than 48 of these patients presented themselves late and were treated by radiotherapy alone. Only two of these survived for five years.

Salivary Glands.—Parotid glands involved in 31 survivors, submandibular in only 3. All proved malignant cases.

Oesophagus.—The appalling mortality of cancer at this site is illustrated.

Stomach.—This includes nearly 500 cases with only 5% survival. No fewer than 3 patients thought to be inoperable in 1948 or earlier are alive and well to-day.

Large Intestine.—Already dealt with.

Rectum.—34 abdomino-perineal survivors, 11 perineal, 6 conservative resection, 2 with hysterectomy, and 2 inoperable.

Pancreas.—Evidently no cases of mistaken diagnosis in this series.

Thoracic Organs.—7 of the survivors treated by pneumonectomy, 4 by radiotherapy only.

Testis.—Surprisingly high survival rate. 26 seminomata, 6 teratomata, 1 adenocarcinoma. No pathological report in 2 cases. In only one patient were the testes not in the scrotum.

Malignant Melanoma of Skin.—32% alive and well to-day. All proved malignant melanoma histologically. 5 cases excision only; 15 excision and radiotherapy with 7 removal of glands; 4 wide removal.

Thyroid.—Total thyroidectomy and radiotherapy in 2 cases. Partial thyroidectomy and radiotherapy in 9 cases. Radiotherapy alone 3 cases. Radium after wedge resection 1.

Bone.—Seven cases of osteogenic sarcoma amongst the survivors.

All the figures in Table V and throughout the report cover the work of a considerable number of surgeons, and every patient was treated between 1945 and 1948.

The table indicates that the earlier the condition is diagnosed and efficiently treated the better the prognosis. The later the stage the higher the mortality.

TABLE V.—Some Five-year Survival Rates

Site of Malignant Growth and Stage	Total Cases	Patients Alive	% Survival
Breast:			
I	531	331	62
II	328	130	40
III	107	33	31
IV	228	18	8
Cervix:			
I	73	43	59
II	102	35	34
III	93	17	18
IV	32	4	13
Uterus:			
Early	123	76	62
Late	88	21	24

Summary

An account is given of the gradual development of a regional cancer records bureau.

In view of the increasing interest in cancer registration, it is hoped that this account may help those who are in the process of organizing such centres.

An analysis of the statistical review contained in the annual report of the bureau is given—showing total number of cases under each anatomical site and number of survivors. A five-year+ survival rate is given in percentages under each site. A clinical survey of survivors is detailed.

Under certain "accessible" cancers the survival rate at the various stages of the disease is indicated and the vital importance of early diagnosis and treatment is stressed.

My thanks are due to the officers of the South-western Regional Hospital Board for their unflinching help, and to the cancer records officers, without whose help this report could not have been compiled.

EPISTAXIS

At the clinical meeting for general practitioners held at the Institute of Laryngology and Otology, Gray's Inn Road, London, on February 11, Mr. C. GILL-CAREY discussed "Epistaxis."

Nine out of every ten cases of epistaxis were not serious, he said, in that there would be no grave underlying disease or risk of undue blood loss. But nose bleeding caused alarm, and the doctor's prestige was enhanced by efficient treatment. Most often the source of the bleeding was on the septum anteriorly, and could be controlled without tight packing by using a small plug of some non-irritating material such as gauze or cotton-wool impregnated with petroleum jelly or bismuth, aided by digital pressure on the ala nasi by the patient. If the bleeding recurred and cauterization became necessary, Mr. Gill-Carey suggested local infiltration with procaine and adrenaline injection (B.P.) before the removal of the plug. This would produce temporary haemostasis as well as analgesia of the nasal skin and mucous membrane. For severe bleeding from the anterior part of the septum he advised coagulation by diathermy.

When is it Serious?

Epistaxis, even when mild, might be the first sign of some serious underlying disease, such as a blood disorder, a malignant neoplasm in the nose, hypertension, or diphtheria. These and other possibilities, although not common, had always to be borne in mind.

Arterial disease was responsible for most cases of intractable bleeding, and in a third of them the bleeding artery was relatively inaccessible. Such patients were seldom benefited by a combination of nasal and post-nasal plugging. It was better to ligate the internal maxillary artery via the antrum or the ethmoidal arteries through an orbital incision. In these patients there was a real danger of coronary throm-

bosis if the blood flow was allowed to continue unchecked for too long.

Replying to questions, Mr. Gill-Carey expressed a poor opinion of ice in treatment: it had little effect on the bleeding. Nor did he advocate soaking plugging material in vasoconstrictors such as adrenaline, as vasodilation would follow the vasoconstriction. Packing an already infected nose, he agreed, increased the risk of sinusitis, and if packing was necessary for more than a few hours systemic antibiotic therapy should be given. Asked about the treatment of hereditary telangiectasis by ethinyloestradiol, Mr. Gill-Carey said that one of his own cases had been partially controlled by it, and that the treatment appeared to offer real relief in this grave and crippling disease.

Reports of Societies

CORONARY THROMBOSIS: ROLE OF DIET AND ATHEROSCLEROSIS

A joint meeting of the Sections of Pathology and Epidemiology and Preventive Medicine discussed "Coronary Artery Disease" at the Royal Society of Medicine on March 1. Professor L. P. GARROD, president of the Section of Pathology, was in the chair.

Morbid Anatomy of Atherosclerosis

Professor T. CRAWFORD (Department of Pathology, St. George's Hospital, London) opened the discussion with an illustrated account of the morbid anatomy of coronary atherosclerosis in man. The yellowish-white plaques of atheroma were well known, but it was often difficult to tell from post-mortem examination what effect they had had on the calibre of the vessel. It was certainly not true that large plaques necessarily narrowed the lumen. He had studied this problem by injection techniques using stereoscopic radiography to demonstrate irregularity and narrowing, which were particularly common in the descending branch of the left coronary artery. Normally the intima of the coronary arteries was thicker than that of comparable arteries elsewhere, even in young children. Sections through the earliest lesions showed a slightly thickened intima in which a varying amount of fat had appeared. This might be either diffusely scattered or collected into the cytoplasm of macrophages which came to lie in groups immediately beneath the endothelium. A varying amount of the material was birefringent, and chemical examination showed the presence of cholesterol and its esters as well as neutral fats. In more advanced lesions the fatty material was separated from the lumen by a progressively thicker layer of rather acellular laminated collagen fibres. Eventually the lumen became distorted, and thrombosis was apt to occur.

If the patient survived the initial thrombosis, one of two things might happen: either a lumen was quickly re-established by retraction of the thrombus to the side of the vessel, or there was a more gradual recanalization of the thrombus by fusion of the capillaries which grew into it during the process of organization. These might eventually proliferate to form a type of cavernomatous transformation of the segment of vessel. However, this was often only of temporary benefit to the circulation because the thrombotic process was frequently repeated in the new channels. The most important recent advance in the understanding of atherosclerosis was the demonstration by Duguid that fibrin incrustations occur on the intima and are quickly covered by a fresh layer of endothelium. Organization of these fibrin deposits, continued Professor Crawford, took place both from the vessel lumen and from the vasa vasorum. Small incrustations thus became organized throughout and resulted in nothing more than some fibrous thickening of the intima: but larger or superimposed deposits might be incompletely organized, a layer of unorganized amorphous debris persisting between the zones of surface and medial organization.

Experimental Production of Atherosclerosis

Dr. J. E. FRENCH (Sir William Dunn School of Pathology, Oxford) described some of the ways in which atherosclerosis can be produced in experimental animals. Spontaneous atheromatous lesions were rare in animals, he said, but could be produced artificially by procedures which caused gross disturbance of the normal lipid metabolism. This might be achieved by adding excess cholesterol to the diet of rabbits or chicks, and also by feeding cholesterol to dogs with hypothyroidism and to Cebus monkeys maintained on a diet deficient in methionine. A somewhat different type of arterial lesion had been described in rats on a diet deficient in choline.

The lesions produced by cholesterol feeding in experimental animals showed an accumulation of cholesterol, cholesterol esters, and other lipoids, mostly within macrophages, in the arterial intima, and in this respect resembled the lesions of atheroma in man.

The intimal deposits seemed to be derived from the plasma lipoids. Hypercholesterolaemia was an obvious factor, but was probably less important than the relative proportion of the different plasma lipoids. Thus the severity of lesions might be reduced in rabbits by measures which, even in the presence of marked hypercholesterolaemia, elevated the relative concentration of phospholipid and neutral fat. A further important factor was the type of complex which the cholesterol formed with the plasma proteins. In animals developing atheroma the greater part of the plasma cholesterol was in the form of β -lipoprotein—a reversal of the situation in the normal animal. Analysis of the plasma β -lipoprotein complex in rabbits and Cebus monkeys developing atheroma had suggested further that the severity of the lesions might be correlated with the concentration in the plasma of a particular cholesterol-containing component of this complex. This component was not present in the blood of normal animals. In addition to this component the plasma of cholesterol-fed rabbits contained visible lipid particles responsible for about 50% of the total cholesterol. Unlike the particles present in alimentary lipaemia, the chylomicra, these particles in the cholesterol-fed rabbit were not dispersed by the heparin-clearing reaction and might not be able to leave the blood stream in a diffusible form.

From these considerations, Dr. French suggested that abnormal cholesterol-containing lipid complexes from the plasma might accumulate in the arterial intima in one of two ways: either relatively small molecular components of the β -lipoprotein complex might permeate the endothelium and precipitate in the intimal connective tissue; or the larger particles might adhere to the surface of the endothelium, there being taken up by macrophages and incorporated in the intima by overgrowth of endothelial cells.

Fat in the Diet

Professor H. W. FULLERTON (Department of Medicine, Aberdeen), in considering the role of diet in the production of atheroma, thought that progress had been delayed by two factors: the belief that the lesion is a primary degeneration, and the assumption that cholesterol plays a primary part in causation. The amount of cholesterol required to produce atheroma in animals was enormous, out of proportion to the rather modest amounts in the human diet. Moreover, atheromatous plaques often contained other lipids. The most notable change in the nation's dietary over the last 50 years had been the increase in the consumption of fat, and there was little doubt that the incidence of coronary artery disease had also increased. Fat intake was greatest in the higher-income groups, where coronary disease was also greatest. Mortality rates were high in countries with the greatest consumption of fat: they fell in Norway when fat intake dropped during the war.

The striking incidence of atheroma in patients with hypercholesterolaemia from various causes suggested that the disease might be related in some way to the lipaemia that occurs after fatty meals. Accordingly the speaker had studied the effect of alimentary lipaemia on the mechanism of clotting. He found a striking decrease in clotting time

three to four hours after a meal containing 85 g. of fat, compared with controls on a normal ward diet. Those patients whose clotting time was shortened had also macroscopic lipaemia. Most people at some time must presumably exceed the critical level of fat intake at which clotting tends to increase, but this could hardly be the only factor in atheroma. Constitutional and sex differences were important, and there might be variations in fibrinolytic activity. The blood flow in the coronary arteries was greatly reduced during ventricular systole, and might almost cease in the left coronary: this would facilitate the deposition of preformed fibrin, and might be the starting-point of atheroma.

Atherosclerosis Not the Whole Answer

Dr. J. N. MORRIS (Social Medicine Research Unit of the Medical Research Council) described the preliminary results of a nation-wide inquiry into the epidemiology of coronary atherosclerosis. A curious feature of mortality statistics in the last 30 years had been a flattening out of the death rate in middle-aged males. This was due mainly to the high incidence in them of ischaemic heart disease and carcinoma of the bronchus. In 1950 the highest death rate from ischaemic heart disease occurred in the professional classes and the lowest among semi-skilled workers. Deaths were more common in town than in the country; and sudden death from it was twice as frequent in London bus drivers as in bus conductors.

A review of necropsy records at the London Hospital had not shown any increase in the pathological evidence of coronary atherosclerosis comparable to that which had occurred clinically. There were other puzzling relationships between the atherosclerosis and ischaemic heart disease. It was therefore decided to investigate the prevalence of coronary atherosclerosis and its various manifestations in a large necropsy series. An appeal made to pathologists throughout the country for help had met with a very generous response. The limitations of this kind of investigation were obvious; but some interesting pointers had already appeared from a breakdown of the preliminary figures. A miscellaneous group of patients—those dying from causes other than ischaemic heart disease or conditions liable to give rise to it—were used as the basis of a model of what is going on in the population as a whole. At least three-quarters of men had naked-eye pathological evidence of coronary atherosclerosis by the age of 45, said Dr. Morris. Ten to twenty per cent. of men between the ages of 45 and 70—the percentage rose with age, had many, or severe, lesions comparable to those in patients with ischaemic heart disease (though actually in the group of patients with clinical evidence of the disease one-fifth of the necropsies showed only moderate changes in the coronary arteries). If the results of this analysis could be accepted as roughly applicable to the general population, these estimates of 10 and 20% had to be compared with estimates of 1 and 5% at the same ages for those with clinical ischaemic heart disease, and the annual mortality from the disease of 1 in 1,000 in the former group with that of 1 in 150 in the latter group. It should not be assumed, therefore, that the causes of coronary atherosclerosis are sufficient to cause ischaemic heart disease. Additional social factors might be involved in the production of the clinical disease, and these might offer opportunities for preventive action.

Discussion

In the discussion which followed, Dr. J. E. COTTS (Cardiff) gave details of a small survey of miners in the Rhondda Valley. The incidence of clinical ischaemic heart disease was significantly greater in the heavier miners and in those with higher blood pressures. Dr. Z. A. LEUNER (London) mentioned that the α -lipoprotein concentration was lower in women than in men, and could be decreased by castration and increased by testosterone. A number of questions were asked about the part played by stress. At the moment diet and occupation seemed to be more important factors, but Dr. MORRIS hoped that psychological and endocrinological methods could soon be applied to population studies of cardiovascular disease in middle age.

Correspondence

Gases in Artificial Respiration

SIR.—The interesting and erudite article by Dr. K. W. Donald and Professor W. D. M. Paton (*Journal*, February 5, p. 313) concludes "that in first-aid practice carbon dioxide should not be administered with oxygen in the resuscitation of subjects requiring and receiving artificial respiration." The article is subtitled: "A Report to the Medical Research Council by its Committee for Research on Breathing Apparatus for Protection against Dangerous Fumes and Gases." Therefore, presumably, a main purpose of the article is to influence doctors to advise those likely to administer first aid, such as firemen and mine rescue workers, not to use oxygen and carbon dioxide mixtures. Is this conclusion correct in regard to poisoning by the commonest dangerous gas—carbon monoxide? It may be, but the report does not present much direct evidence on the point but reaches its conclusion by arguments based on general physiological considerations or by analogy with anoxic situations other than carbon monoxide poisoning.

I am not seeking to question that carbon dioxide has been excessively administered to many kinds of anoxic patients. I wish only to focus attention on the special, but

common, first-aid situation of carbon monoxide poisoning in which the main necessity is to accelerate the rate of excretion of carbon monoxide from the blood so that the haemoglobin may again carry oxygen. The use of oxygen with added carbon dioxide in the treatment of carbon monoxide poisoning was introduced by Henderson and Haggard,¹ and the graph of excretion rates of carbon monoxide here reproduced is from one of their papers² and shows curves derived from the treatment of dogs, gassed to the point of death, with (a) air, (b) oxygen, (c) air and carbon dioxide, and (d) oxygen and carbon dioxide. They claim to have confirmed these findings with men gassed up to 50% saturation. Their explanation for the greater efficacy they claimed for oxygen and carbon dioxide, over oxygen alone, was that breathing is markedly reduced when victims are removed from the poisonous atmosphere and that carbon dioxide, by stimulating respiration, facilitates the effective contact of inhaled oxygen with the capillaries of the lungs. The views of Henderson and

Haggard gained world-wide acceptance, and oxygen with carbon dioxide became the standard treatment for carbon monoxide poisoning.

My personal interest in the subject is because I was for nine years (1928-36) responsible for the treatment of all cases of acute poisoning admitted to the Middlesex Hospital. In each of these years I dealt with a few cases of carbon monoxide poisoning (on one occasion five cases at once). In the first two or three years I was not aware of the work of Henderson and Haggard and treated the patients with oxygen. Later I switched to oxygen and 7% carbon dioxide, which seemed to be very much more effective—indeed, life-saving—in roughly comparable cases. I can confirm that the breathing of severely gassed patients is often depressed and that the administration of oxygen and carbon dioxide strongly stimulates it.

The only evidence directly relating to carbon monoxide poisoning, weakening the claims of Henderson and Haggard, cited by Dr. Donald and Professor Paton are papers by Nicloux *et al.*³ and Walton *et al.*⁴ These papers did not flatly refute the findings of Henderson and Haggard, and, indeed, agreed that elimination of carbon monoxide was slightly faster with oxygen and 5% carbon dioxide than with oxygen alone; they only did not find as great a difference as did Henderson and Haggard. All these papers, including those of Henderson and Haggard, appear to be based on rather a slender amount of experimental work. They were published around 30 years ago, and to-day seem almost as little fitted to settle a very important practical question, involving the possible saving of many lives, as indirect physiological reasoning or the very fallible clinical impressions of those, like myself, who have thought oxygen, with 5% or 7% carbon dioxide, life-saving in carbon monoxide poisoning.

I would like to ask Dr. Donald and Professor Paton: (1) Have they personal experience in carbon monoxide poisoning of the comparative effects of treatment with oxygen alone and with oxygen and carbon dioxide? (2) Can they cite from the literature more evidence, directly relating to carbon monoxide poisoning, than appears in their paper? (3) Do they not think that there is need for more comprehensive experimental work in carbon monoxide poisoning (possibly sponsored by the M.R.C. Committee) before a firm and final recommendation is made to abandon oxygen and carbon dioxide treatment?—I am, etc.,

London, W.1.

** We showed Dr. Marriott's letter to Dr. Donald and Professor Paton, and their comments are printed below.—Ed., *B.M.J.*

SIR.—Before turning to Dr. H. L. Marriott's specific inquiries, we must emphasize again that the committee, and our paper reviewing the background of the committee's recommendation (*Journal*, February 5, p. 313), were concerned with first-aid practice, taking account of the full range of emergencies which may be encountered, and of the fact that correct diagnosis of such cases may not be within the power of the first-aid worker. There was no intention of trying to relieve doctors of their responsibilities for treatment in hospital according to their own judgment, although we hope they will consider the arguments we have advanced. Further, we do not quite agree with Dr. Marriott about priorities. The first task, even in cases of carbon monoxide poisoning, is to relieve the anoxaemia; the promotion of carbon monoxide elimination by any harmless means comes second.

As regards his questions: (1) One of the authors has treated a considerable number of cases of coal-gas poisoning, both with oxygen and with oxygen and CO₂, but, like

Dr. Marriott, would attach no weight to his "fallible clinical impressions" in the absence of detailed comparisons. Both authors have had an intensive personal and experimental experience of both respiration-stimulating and anaesthetizing concentrations of CO₂ in oxygen. This may or may not reassure Dr. Marriott, but we do not believe our personal experience to be especially relevant to the discussion.

(2) We should have included a reference to the work of Schwerma *et al.*¹ and express our regret at not doing so. The authors of this modern and detailed work, like Nicloux *et al.*² and Walton *et al.*³ "could not confirm the great increase of carbon monoxide elimination with added carbon dioxide reported by Henderson and Haggard"⁴ (to quote our original words). We were aware that there is some increase in elimination, and chose our words with care. The question is whether the increase is sufficient to justify the use of carbon dioxide in treatment. Schwerma *et al.* think not, and end their paper by saying: "Since carbon dioxide plays no demonstrable part in fortifying cardiac function, and its addition to oxygen confers no further value in resuscitation, the inevitable conclusion is that it is an unnecessary therapeutic adjunct." The various investigations differ in the details of treatment of the CO-poisoned animals. But it is significant that, for instance, Schwerma *et al.*, Nicloux *et al.*, and Walton *et al.* all agree as to the rate of elimination of CO in the untreated animal (50% eliminated in 60 minutes) and differ quite substantially from Henderson and Haggard (15% eliminated in 60 minutes). In the face of this and similar findings we think it dangerous to place too much reliance on the latter's figures.

(3) There is no doubt that more work on all aspects of resuscitation is badly needed, and it is the responsibility, not of an M.R.C. committee alone, but of all those interested in the subject to foster or initiate it. We would, of course, carefully reconsider our conclusions in the light of such work. But a recommendation is needed now, taking into account new knowledge about the actions of carbon dioxide. On the evidence available, we would feel culpable if we made any other recommendation.—We are, etc.,

Topical Analgesia of the Urethra

SIR.—May I suggest a refinement to the method of producing topical analgesia of the urethra described by Dr. R. Bryce-Smith (*Journal*, February 19, p. 462) which I have found most useful in males? It is to pass a short rubber catheter into the urethra and connect the bakelite nozzle and tube to it.

By this means, it is easier to squeeze and massage the "xylocaine gel" into the posterior urethra. Without the catheter, adequate analgesia of the posterior urethra is, in my experience, often difficult to obtain.—I am, etc.,

Rotherham.

B. G. FORREST.

Endocrine Treatment in Psychiatry

SIR.—Dr. R. E. Hemphill in his most interesting paper on "Endocrine Treatment in Psychiatry" (*Journal*, February 26, p. 501) suggests that aggressiveness and paranoid thinking occur "in extreme conditions, and operation seems to be very seldom indicated." This I do not think is true. In my experience the women whose psychoses responded so dramatically to adrenalectomy were suffering from an average amount of virilism and we saw many more severely affected who had no psychosis. I thought that the cases associated with psychosis were those who had a peculiar psyche

and who were homosexually orientated before the adrenal dysphasia. It was the effect of the adrenal hormones on their peculiar mentality which produced mental illness. The psychosis was much more striking than the virilism. I am sure that Mr. L. R. Broster¹ would confirm this.

My reason for pointing this out, and the importance of it, is that I believe that there are many women with virilism in mental hospitals who would benefit from early adrenalectomy but who are never given the chance because it is not generally appreciated that psychosis and virilism are often associated. It was a thousand pities that owing to the war and other reasons our work on the relationship of psychosis and virilism, which seemed so promising, has terminated. Dr. Hemphill is absolutely correct in stating that "further research in the relationship between hypercortical adrenalism and aggressive paranoid behaviour might be well worth while."—I am, etc.,

Treatment of Pulmonary Tuberculosis

SIR.—Being interested in a clinic associated to some extent with Dr. T. W. Lloyd's sphere of action, I should like to comment on his letter (*Journal*, February 26, p. 538), which advocates the abandonment of pneumothorax and pneumoperitoneum treatment.

Our refill clinic sees each week some 30 or so persons, most of them well and cheerful, many of them working, and all of them apparently unaware of the undesirable nature of the therapy that is being wrought upon them. The hardship of regular attendance they sustain with fortitude, and, in a mainly rural community, the occasion is almost festive. On the whole they seem to thrive rather better than our other patients.

Most of these people have been considered and rejected elsewhere for major thoracic surgery, and nowadays a patient has to be in either pretty good or pretty bad trim to slip through that net and find himself at the receiving end of a pneumothorax needle. The suggested alternative is prolonged chemotherapy. I have insufficient experience of this to pass precise judgment, but should be most reluctant, not merely for nostalgic reasons, to close our refill clinic and trust to chemotherapy to replace entirely the beneficial presence of a little air in the right place. Prolonged chemotherapy may perhaps prove to be the treatment of the future, but I rather fancy that, if we were to abandon pneumatic treatment completely in its favour, future years would see an unknown number of long-term chemotherapy cases presenting themselves at the clinic, their gluteal regions indurated by streptomycin, their stomachs ulcerated by P.A.S., and their morale deflated by an isoniazid hangover, beseeching us to do something for their reopened cavities. We might then be glad enough to brush the dust from the pneumothorax box and, after due bronchoscopy—if a bronchoscopist is available—perpetrate yet again a pneumothorax or pneumoperitoneum.—I am, etc.,

Hereford.

T. V. R. PHILIP.

SIR.—It is stated in your leading article (*Journal*, February 12, p. 403). "During the last six years the annual decline in mortality from respiratory disease has averaged 15%, while the average decline for the previous ten years was a mere 1.5%," and, as I anticipated in my publications 10 years ago, this is being attributed to mass radiography, antibacterial drugs, and quantity of medical care. But those of us who began our efforts to stamp out tuberculosis nearly 50 years ago and who have spent some years in studying the homes of the people, learnt that tuberculosis is a disease fostered and spread by bad housing and a low standard

of living. The pioneers in tuberculosis prevention (I rank my late chief, Sir John Robertson, in the foremost field) learnt this, and accordingly they planned sanatoria treatment on the basis of a first-class home, where rest and tranquillity could be secured, while the larger problems of housing and standard of living were slowly improved. Their success with prevention and treatment is shown abundantly in the progressive decline in the deaths. The further contributions to that end, meals and milk at schools, even better housing and standards of living within the last six years, have brought even better results.

As I clearly indicated before its introduction, mass radiography can contribute nothing useful to a good medical service, but its progressive use seems to demonstrate the degeneration of clinical medicine in its revelations of massive disease which has been overlooked. We have as much right to claim that mass radiography has reduced the deaths from tuberculosis as we have to claim that its concomitant increased employment has caused the progressive rise in pulmonary cancer. It has shown what the pathologists taught us 50 years ago, that we have all had tuberculous infection, but that does not matter if it does not affect the mortality or morbidity. For the value of antibacterial drugs, we are told by some tuberculosis specialists that these are now so good the patients can be allowed not only to stay at home but to go to work. The disasters to nurses which have been so treated are recorded in the Prophit Tuberculosis Survey report.¹ If that was true why not put the treatment into the hands of the general practitioner? He with his knowledge of the home can treat the patient better than the specialists, who have lost much clinical sense by a most complete dependence upon the results of tests easily and readily obtained by scribbled initials or even the use of a rubber stamp. Since it has been proved that good housing and standard of living are far more important than "quantity of medical care," why not devote all our resources accordingly?

More particularly during the last 30 years I have watched the progressive exclusion of the practitioner from the treatment by the development of a specialized jargon assisted by the great abuse of radiology and the progressive "refinement" of middle-some interference. It is very doubtful if the success achieved by those measures, used in hundreds of thousands of cases and now quietly being discarded for more modern mutilations—measures which have converted treatment from what was the most pleasant and enjoyable into that which aggravates the disease and induces horror in the patients, the gravity of whose mental distress no one can estimate—can equal that secured by good home treatment. The unfortunate use of the general hospitals has contributed to the selfish aspirations of the specialists, who scoff at the original treatment in sanatoria at the cost of the patients. Dr. P. B. Schofield (*Journal*, February 19, p. 480) is fortunate in his experience, others have lost their lives from "treatments" by those who did not know the risks. I have seen complete recovery in the happiest of circumstances of most extensive disease without "the numerous investigations and treatments" he thinks "the patient needs."

Why not revert to the principles which dictated the development of sanatoria rather than keep those which have brought about their abandonment? Then our improved standard of living will eradicate the disease.—I am, etc.,

Birmingham, 15.

Neon Lighting in Hospitals

SIR.—The ever-increasing use of neon strip lighting throughout hospitals has created a danger which I believe is not fully appreciated by those responsible for its installation. In the less up-to-date hospitals not equipped with a recovery unit in the theatre block patients may return to the wards shocked, and often with depressed respiration following chest or upper abdominal surgery, or following the residual effect of muscle relaxants, etc. These cases are anoxic, and, although the obvious case may be given oxygen, the lesser degree of anoxia will be missed by the masking of the mauve colour caused by the neon lighting. I believe that unless some form of ordinary incandescent light be kept on these post-operative cases deaths will occur from prolonged unobserved anoxia.—I am, etc.,

Manchester.

WILLIAM B. BACON.

Eclampsia

SIR.—Dr. A. W. Bauer's letter (*Journal*, February, 19, p. 481) on the subject of eclampsia will undoubtedly stimulate both interest and criticism. Early on he dismisses the need to discuss hypotheses, but promptly and naively proceeds to invoke a hypothesis himself. For he states, without proving it, that a mechanism of toxin production exists in eclampsia; urges that the source of this hypothetical toxin should be the goal of our investigations; and attributes its existence to the failure of detoxication of foetal metabolic products. His theme is, however, unacceptable, because the toxæmic process, of which eclampsia can be the climax, occurs even in the absence of a foetus, as in hydatidiform mole and in post-partum eclampsia, whilst the death of the foetus is no safeguard against its supervention—exemplified by the history of cases in which recovery from the toxæmic process had occurred during pregnancy to be followed by fits when labour eventually ensued.

Dietetic measures, successful prophylactically, invariably include severe restriction of salt, a factor which may explain the immunity from the disease enjoyed at certain periods (wartime starvation) and in peculiar climates. I suspect that in no small measure this circumstance underlies Dr. Bauer's successful treatment, in which he stimulates a low salt intake.

Two points he raises in his letter are of much importance and call for confirmation, the statement that at necropsy a typical smell of prussic acid is noticeable on opening the skull of the eclamptic, and the claim of the therapeutic value of intravenous thiosulphate both in eclampsia and pre-eclampsia. In this last connexion it is interesting to note that Lambiotte, Blanchard, and Graff¹ found, remarkably, that the thiosulphate clearances in pregnant women (but not in the non-pregnant) were much higher than those of inulin, the ratio invariably exceeding 1.0 with a range of 1.01 to 2.12. This finding caused them to conclude that thiosulphate was excreted by the tubules during pregnancy only. Some connexion may exist between this response of the tubule to thiosulphate peculiar to the pregnant state and its therapeutic action in toxæmia, and could serve once again to emphasize the rôle of the kidney in the disease.

Unlike Dr. Bauer, and in consonance with the cardinal principles of our art, I consider that the acme of therapeutics can only be attained by attack on the aetiological factor. Present-day obstetric policy, however, regretfully displays a zeal for treatment that far outweighs its quest for the aetiological solution on which to found it—an attitude, I consider, impeding advance.—I am, etc.,

London, W.1.

Kaposi's Varicelliform Eruption

SIR.—Correspondence in connexion with Kaposi's varicelliform eruption has recalled to me an incident which occurred in January, 1949, while I was leprologist in charge of the Church of Scotland Mission scheme for leprosy control and treatment in Southern Ogoja Province, south-east Nigeria. I discovered a case of smallpox in one of the leprosy segregation villages under my care, and, fearing greatly for the consequences of spread of the infection, made arrangements for his strict isolation in a house in the village because no hospital was available. I personally vaccinated 269 possible contacts. Vaccination was by crossed linear scratch technique, a clean, dry dressing being bandaged on and left in position as long as the patient would tolerate it. There were no further cases of smallpox in the village and no cases of Kaposi's varicelliform eruption or accidental vaccinia occurred. There were, however, several cases of acute lepra reaction in those vaccinated. The patient with smallpox was treated with sulphapyridine and made a good recovery.

The efficiency with which complete isolation of the patient with smallpox was carried out may be attributed largely to

the excellent propaganda in preventive medicine initiated by my predecessor and the founder of the scheme, the late Dr. Harry Hastings. Incidentally, this illustrates how the effective control of one prevalent endemic disease may assist in dealing with others. The point of interest following the correspondence above referred to concerns the absence of Kaposi's varicelliform eruption. Drs. A. Girdwood Fergusson and W. A. Dewar (*Journal*, February 5, p. 352) define this condition as "a virus infection . . . arising in patients with a damaged skin," and it is therefore worthy of speculation in this instance whether the covering of the vaccination site was adequate and of sufficient duration (a doubtful point in African patients in that area) to prevent virus contamination of leprosy lesions, or is the skin of the leprosy sufferer an unfavourable soil for the growth of the vaccinia virus? The experience of other workers in this field might be of interest.—I am, etc.,

Glasgow, W.2.

JAMES C. P. LOGAN.

Mobile Transfusion Service

SIR.—The life-saving importance of prompt transfusion for severe shock has recently again been stressed by Sir Heneage Ogilvie (*Journal*, January 15, p. 159). The general practitioner cannot be expected as a rule to carry out emergency transfusions at the patient's home, and transport is dangerous in severe shock, especially in cases of internal haemorrhage. A mobile transfusion service is already operating for maternity cases, and, if such a service were made generally available for transfusion of blood, plasma, or "plasma savers" at the patient's home or at the spot of an accident, many lives could be saved and much worry avoided.—I am, etc.,

London, W.1.

F. E. LOEWY.

Hyperpyrexia and Anaesthesia

SIR.—I regret that in my attempt to compress my account of this case (*Journal*, December 25, 1954, p. 1526) I omitted the information desired by Dr. J. D. Whitby (*Journal*, February 26, p. 541). Laryngeal stridor was first treated with pure oxygen—a flow of 10 litres per minute was given for 2-3 minutes. As this produced little effect, nitrous oxide 5 litres/minute, oxygen 1½ litres/minute, and trichlorethylene were resumed, and 500 ml./minute of carbon dioxide was added—a concentration of about 7%. This was continued for 2-3 minutes. At the end of this time pure oxygen was given again—10 litres/minute for about one minute, with the expiratory valve fully open and the reservoir bag frequently emptied.—I am, etc.,

Milngavie, Dunbartonshire.

R. CECIL BROWN.

Fluoridation of Public Water Supplies

SIR.—Drs. H. M. Sinclair and Dagmar Wilson (*Journal*, January 29, p. 284) do less than justice to the positive benefits of fluoridation as well as to its harmlessness in the dosage proposed. It is misleading to say that "water containing 1 p.p.m. of fluoride decreases the incidence of dental caries in children up to the age of about 8 years" as if there was no protection above this age. American reports on communities with artificially fluoridated water are mostly only available for the first eight years, but Dean *et al.*¹ showed a 60% reduction in dental caries in children of 12-14 years who had lived all their life in a fluoride area. There is, moreover, ample evidence of some effect extending into adult life from Russell and Elvove,² Deatherage,³ and McKay⁴ in America, and Forrest *et al.*⁵ in this country.

Drs. Sinclair and Wilson correctly draw attention to differences in feeding habits in this country and the U.S.A.; they suggest that our addiction to tea and our greater consumption of fish may cause adults to get a higher dose of fluoride than is desirable or safe. The fluoride content of tea infusions varies greatly both with the brands used and the strength of the brew. A cup of tea of medium strength contains 0.5-1.5 p.p.m. of fluoride in addition to the fluoride content of the water used. If the whole fluid intake were to be as tea, the total concentration would not exceed 1.5-2.5 p.p.m., a concentration which we know from recent

studies in America causes no adverse effects on general health. Preliminary investigations in this country have shown that children consume relatively little tea (in any case probably weak and milky). The average consumption of fish in this country is rather less than twice the American rate; in 1951 and 1952 it was less than 1 lb. (227 g.) a week per person; the 1953-4 figure is likely to be less. Recent analyses of fish purchased in this country gave figures not higher than 1 p.p.m. F for the edible portion, and at this level the average amount of fluoride ingested would be about 0.03 mg. per day. That this figure is essentially correct is shown by the fluoride content of urine of children and adults in this country of 0.3 to 0.6 mg. per day, which agrees with values found in the United States. There is, however, some disagreement about the fluoride content of various kinds of fish, and, though fish is not a major source of fluoride, the content of fish normally consumed here is being checked.

The strongest evidence against such dietary fluoride having any deleterious effect comes from Leone *et al.*⁶ in a careful comparison of two areas in Texas, one of which had a water supply with 8 p.p.m., the other 0.4 p.p.m. Samples of the population who had lived at least 25 years in each place were thoroughly examined physically, radiologically, dentally, and pathologically in 1953, following a previous examination in 1943. Except for dental mottling in the fluoridated area, there was no relevant difference between the two groups. Similarly an article by Hagan *et al.*⁷ demonstrates no significant difference in the mortality from all causes and from heart disease, cancer, intracranial lesions, nephritis, or cirrhosis of the liver in 64 cities in 16 States, half with a high and half with a low fluoride water supply. The fluoride content of the water in some of these surveys is many times higher than any proposed in this country and well above any additional intake our diet could contribute. Studies in this country have confirmed these facts and other confirmatory studies are being considered.

Drs. Sinclair and Wilson refer to studies in Oxfordshire in which "severe dental fluorosis" was associated with the ingestion of water with fluoride levels of 0.3 and 1.2 p.p.m. This is the only occasion on which a very high degree of mottling of the enamel has been reported and ascribed to fluoride at such levels in a temperate climate. Dean⁸ found no more than mild mottling in 1.5% of 400 children aged 12-14 years examined in an area with 1.2 p.p.m. F in the water. Weaver⁹ reported slight mottling in 3.6% of the 500 12-year-old children examined in South Shields, where the fluoride level was 1.4 p.p.m. A report by Dean¹⁰ on studies of more than 7,000 children in areas with fluoride levels of 0.1 to 2.6 p.p.m. shows that even moderate mottling only occurs with a level of at least 1.8 p.p.m. F, and severe mottling with at least 2.6 p.p.m. F. Dental examination in areas where the water is fluoride-free often reveals opacities and even brown staining of the enamel very similar to those caused by fluoride. Zimmermann¹¹ states that "differentiation from fluorosis opacities has occasionally been difficult," and reports that enamel opacities were noted in 36% of the children examined in an area with no fluoride in the water; Hurme¹² reports an even higher incidence. Dean¹³ says that differential diagnosis must rule out the hypoplasia due to exanthematous diseases and nutritional disturbances during enamel development.

Drs. Sinclair and Wilson fear the additional hazard of industrial fluorosis. The main hazard of industrial fluorosis is to cattle, due to ingestion of grass, etc., on which fluoride dust has settled. The danger to man is remote. Nevertheless, fluoridation of water supplies would not be carried out in the neighbourhoods where such a situation might arise.

They state that the "level at which storage takes place" is unknown, but there is clear evidence that in fact storage takes place at every level, however small,¹⁴ and that under normal conditions there is a steady rise with age.¹⁵ Experiments (about to be published) which have been undertaken with adults in this country confirm the work of McClure *et al.*¹⁶ in America and show that as much as 95% of ingested fluorine is excreted in the urine, faeces, and sweat—not the lower figure found by Largent,¹⁷ who did not measure fluoride lost by perspiration. There is also evidence that equilibrium with a new level of intake is reached in a few days. In any case there is no evidence that retention of fluoride, when the water supply contains anything of the order of 1 p.p.m. F, causes any toxic effects whatever. Even Largent's subjects remained healthy, and did not show any radiopacity. The relation, if any, between malnutrition and fluorosis cannot be regarded as proved, and even if it were it would not seem to constitute a hazard in Britain to-day. There are few countries where calcium intake is more satisfactory.

Drs. Sinclair and Wilson take up the mission's statement that in theory any fluorine compound which will ionize in aqueous solution should have the same action on teeth, and base their disagreement on the cariostatic effect of stannous fluoride, as

compared with sodium fluoride, although more recent work by Buhler *et al.*¹⁷ showed that the cariostatic effect of stannous fluoride was decreased when the pH of the solution was raised from about two to neutrality. Tin is notorious for formation of complex ions, and it is probably true that simple ionization to F ions does not occur in this instance. But no one is proposing to use stannous fluoride, so that even if Sinclair and Wilson were correct their objection would not be a valid one.

We share Sinclair and Wilson's desire for more knowledge. But they have not produced any facts which alter the position taken up by the mission—namely, that there is no scientific evidence that fluorides at concentrations below about 1.5 p.p.m., whether naturally occurring or added to water, have any adverse effects; by contrast, there is indisputable evidence that there is a beneficial effect on teeth.—We, are, etc.,

Errors of Diagnosis in Paediatrics

SIR.—In Dr. B. Schlesinger's article (*Journal*, February 12, p. 369) he refers to "the aches and pains of muscular strain and spasm in genu valgum" as being sometimes mistaken for subacute rheumatism. In my capacity as school medical officer attached to the Leeds school orthopaedic clinic for a number of years, I have seen hundreds of children referred on account of genu valgum. In 1953, I examined 151 such children and in 1954, 131, and none of these children complained of pain. Over the same period a number of children who were referred for pains in the legs proved to be suffering from osteochondrosis of the hips (often bilateral) or from osteochondrosis of the conjoined rami of the pelvis, or from an Otto pelvis. Early diagnosis of osteochondrosis of the hip is essential if the restoration of the capital epiphysis and the avoidance of consequent arthritis of the hip in middle life is to be ensured.

When a careful history is taken and the fact is elicited that the child wakes from sleep and complains of pains in the legs, or that he comes in from play and rests because of such pains, then in my experience a cause is much more likely to be found in the hip-joints or in the pelvis than in the knees. I suggest that the diagnosis of genu valgum as a cause of pain in the legs is as dangerous a label as growing pains, and equally likely to mask the true origin of the symptoms.—I am, etc.,

Leeds.

I. HOLORAN.

Spontaneous Regression of Malignant Melanoma

SIR.—Might I add to Dr. V. B. Levison's account of spontaneous regression of a malignant melanoma (*Journal*, February 19, p. 458) by reporting the following case.

In November, 1950, a white South African student aged 22 consulted me because of an enlarged supraclavicular lymph node. He had attended a colleague 18 months previously because of it and had had a chest x-ray in April, 1949, which was clear. A provisional diagnosis of tuberculous adenitis had been made. On examination, the supraclavicular node was firm, smooth, egg-shaped, and mobile, suggestive of lymphadenoma. A chest x-ray (November, 1950) showed gross enlargement of the right para-tracheal group of lymph nodes. The patient's general health was good. After consultation, he was admitted under Mr. John Gardham to the Hampstead General Hospital and the supraclavicular node was removed for biopsy. It was hard and brown on section. The pathological department of the hospital reported

"a secondary deposit from a malignant melanoma. Only the cells at the very periphery of the mass are living where they merge with the fibrous tissue capsule. The firm greyish piece of tissue which is connective tissue contains a small gland which shows several small groups of melanoma cells in the peripheral sinusoids. The nature of the growth suggests the choroid may be the seat of the primary." The other half of the gland was sent independently to the pathological department at University College Hospital, where it was similarly reported upon.

A search for the primary revealed nothing more than a small pigmented area touching the left optic disk at 5 o'clock. I allowed him to finish his M.A. early in the new year and then advised him to return home. I told him he had "sarcoid" (a disease whose prognosis a student cannot easily get from "the books"), but told his level-headed South African fiancée the true diagnosis and its outcome. I arranged to keep in touch with them and with their South African doctor.

To our surprise and quite without treatment the serial radiograms showed the para-tracheal glands gradually diminishing in size, so that by early 1952 the radiograph was normal to all intents and purposes. He has remained well the whole time, has married, and has now a year-old son. I last heard from them, and a family portrait was sent me, in September last year. It is now nearly six years since he was first seen with the enlarged supraclavicular gland.—I am, etc.,

London, W.C.1.

NICOLAS MALLESON.

Tonsillectomy

SIR.—As a G.P. who has anaesthetized for, and seen the results of, both guillotining and dissection, I have been most interested in the recent correspondence.

Regarding premedication, I support the use of atropine alone. All sedatives increase the risk by respiratory depression, and the way to calm children is proper handling. Regarding the type of operation, if Mr. E. H. Miles Foxen (*Journal*, February 12, p. 413) seeks to convince his readers that guillotining is a deplorable procedure, then he must show the courage of his own convictions by declaring outright that no one at all can achieve consistently good results by doing it. My belief is that, with the proper skill and the proper instrument, in the majority of children guillotining is as good as dissection.

There appears to exist the fallacy that, compared with dissection, guillotining demands less skill in surgeon and anaesthetist. Subscribers to this are indeed unlikely to guillotine satisfactorily. The truth is that guillotining demands just as much skill on the part of both, and the penalties of inadequate skill are heavier than in dissection. Moreover, while co-operation between surgeon and anaesthetist is necessary in any operation, in guillotining it is crucial, even literally vital, that the pair understand each other's problems and are practised at working together. Here I would go farther than Mr. Foxen and say that, however practised the pair, it is impossible with the old type guillotine to achieve a perfect result in every case attempted.

The reason is that the requirements of surgeon and anaesthetist conflict, and the limits within which both are satisfied are too narrow for even long practice to succeed every single time. The surgeon requires (1) anaesthesia of sufficient depth and length, without anoxia; and (2) a clear view of the field, and more so as the instrument is liable to slip as the cut is made. The anaesthetist's problems arise from (1) obstruction of the airway by the tonsils; (2) the impossibility of predicting precisely how long the operation will take; (3) the difficulty of altering the depth of anaesthesia once the surgeon has started, which becomes extreme once the first tonsil is removed; and (4) the certainty that when the first tonsil is removed blood will flood the pharynx and some be inhaled. The anaesthetist, acutely aware of the risks of too deep anaesthesia from blood-clot in the trachea and an absent cough reflex, is inclined to keep the patient too light. This gives rise to a vicious circle, since expeditious removal of the second tonsil is made more difficult and the dangerous stage is prolonged, during which time bleeding persists, making the manoeuvre more difficult and more dangerous still.

The haemostatic guillotine obviates all these snags. With this instrument the tonsil is gripped by a blunt blade before being cut by the sharp one. After induction of anaesthesia the first tonsil can be gripped and lifted, thus clearing the airway, relieving any anoxia, and allowing depth of anaesthesia to be adjusted to a nicety. The tonsil is then quietly excised and removed, little or no bleeding results, and the second tonsil is tackled in the same unhurried manner.

I should add that I have seen the excellent results of this instrument in the hands of Mr. H. Mower, consultant E.N.T. surgeon at the Royal Infirmary, Gloucester, whose consideration for anaesthetist and theatre staff contributes in no small manner to the success of the operation and makes the work a pleasure.—I am, etc.,

Yorkley, Glos.

ROBERT ELLISON.

SIR.—It is very easy to condemn the guillotine from the peace and calm of a teaching hospital, where most of the children's tonsils and adenoids are removed by registrars and house-surgeons. It is quite another matter when one is faced with the harsh realities of a provincial E.N.T. surgeon's life.

A colleague and myself cover between us five sessions a week at a hospital in a neighbouring town. Here we have to keep 19 children's and 15 adults' beds full, and see over 70 new patients, and up to a 100 old patients every week in the out-patient department. A wide variety of cases are dealt with, only major laryngeal surgery and fenestrations being done elsewhere. There is no E.N.T. house-surgeon, and our only help is two general-practitioner clinical assistant sessions a week. No locums are provided for holidays. The waiting-list for children's tonsillectomy is long, but is now slowly improving. Its length is still a great source of worry to the school medical authorities, to the general practitioners, and to many of the parents, and I cannot imagine that they would view any step which would threaten to slow down our progress with anything but alarm. Could Mr. E. H. Miles Foxen (*Journal*, February 12, p. 413), without extra help, manage to dissect all the children's tonsils under these circumstances (which are common in the provinces) without increasing the waiting-list, or would he say that an increase in the waiting-list was of no consequence? At the risk of repeating a dangerous platitude, I would say that the last sentence he quotes from Waugh¹ is nonsense. The complete removal of a tonsil with a guillotine is perfectly possible. The bad results seen were due to the activities of the inexperienced with a sharp guillotine. To-day the blunt guillotine is used, and the majority of cases (in this region at least) are done by consultants. A satisfactory result is the rule.

There are several answers to the problems of the children's tonsillectomy waiting-list which would obviate the need for the guillotine. The one that I like best is a letter used at one teaching hospital which says in effect, "Dear Doctor, I quite agree that these tonsils and adenoids should be removed, and I suggest that you arrange this locally." All the other answers require either extra consultants and S.H.M.O.s, which is unlikely to be acceptable to the Ministry, or the moving of junior medical staff out into peripheral hospitals, which would be unpopular with the teaching hospitals. We are left, therefore, with the guillotine—*circa* 1955.—I am, etc.,

Nottingham.

J. F. NEIL.

The Inelegance of Redundancy

SIR.—I am a student beginning my clinical work, and have recently realized the often unnecessary use of medical jargon. Before I come to accept it as a necessity, may I object to a fine example in your issue of February 19? In it was an article entitled "Intermittent Positive-pressure Respiration in Bulbo-spinal Poliomyelitis: Use of the Radcliffe Respiration Pump." Respiration is by nature intermittent; why say so? To a person who does not realize

that the iron lung works by a negative pressure, the phrase "positive-pressure respiration" is without significance. I submit that the title could have been "Experience with the Radcliffe Respiration Pump in Bulbo-spinal Poliomyelitis" without any loss of precision and with a gain in clarity, brevity, and elegance.

Secondly, too often authors omit those few sentences in a general introduction that would greatly assist the non-specialist reader. In this case the distinction between "positive pressure respiration" and "negative pressure respiration," and between an iron lung and a respiratory pump, should have been made clear at once. Specialists are too apt to refer us for such explanations to a paper that we have neither the opportunity nor the time to read.—I am, etc.,

London, N.W.8.

M. W. HASLITT.

Topical Hydrocortisone

SIR.—Dr. Ronald Church's excellent article (*Journal*, February 26, p. 517) on the use of hydrocortisone ointment and your annotation (p. 530) raise certain serious difficulties under the present conditions of medicine in this country. My experience with local hydrocortisone has been essentially similar to his, though I have been more successful in ano-genital pruritus and less so in nummular eczema; also I have had cases which have responded to the stronger ointment and not to the weaker one.

The difficulty is, however, that hydrocortisone is a suppressive and not a curative agent, and directly it is stopped the patient relapses unless the underlying predisposing factor is removed in the meantime. Unfortunately, this cannot be done with many cases of constitutional eczema, and so the patient may demand to continue with his hydrocortisone ointment for months or even years. Hydrocortisone ointment costs 69s. an ounce (31 g.) for 2½% or 29s. for 1%, and, assuming an extensive case of eczema requires 2 ounces (62 g.) of ointment a day, this would be a prohibitive cost for routine treatment in a non-fatal disease; and yet if hydrocortisone ointment were freely available it would certainly be used extensively, often in ignorance of its cost. I would suggest the following general indications for the use of hydrocortisone ointment: (1) as a temporary measure in a patient suffering great distress from an acute condition such as a severe exogenous dermatitis; (2) as a temporary measure to bring under control an intractable eczematous dermatitis which has previously failed to respond to more orthodox treatment; (3) as a more prolonged form of treatment for skin lesions of small areas—such as pruritus ani—when this has been found to be the most helpful therapy. There may occasionally be some other indications, but these will serve as a guide to the reasonable use of hydrocortisone without its becoming an intolerable burden on the National Health Service.—I am, etc.,

Leeds, 2.

F. F. HILLIER.

Disk Lesions and Low Backache

SIR.—It is with considerable diffidence that I intrude into a discussion by experts on a subject without my province. I think, however, that there is a small but useful point to add to the effectiveness of the valuable exercise described by Mr. W. Grant Waugh (*Journal*, February 12, p. 412). I have also an experience to relate which may have some bearing on the puzzling aetiology of disk lesions.

Leather straps similar to those used in buses so that the hand can be passed through the loop makes the exercise less of a feat of endurance and allows it to be carried out for longer periods. A slight dropping jerk is also feasible which seems to be an important additional manoeuvre. Certainly dramatic relief can be obtained in this way, as Mr. Grant Waugh has said. Indeed, I sometimes wonder if it would not be a good thing for us all to erect a cross-bar in our back gardens to indulge in this atavism and thus counter our tendency to spinal shortening in these days of delible disks.

Some years ago a colleague and myself were asked by a worried timber merchant to investigate the growing incidence of disk lesions among his employees. He said his firm had been unloading timber in exactly the same way for over 50 years, but it was not until after the war that the disability appeared. Accordingly we spent a day at the canal side watching unloading. Here they used the method of stacking the planks on end. A 24-ft. (7.3-m.) plank was positioned so that the man's shoulder was at the fulcrum. Then by long practice in balance and rhythm the plank was carried from the barge to the storehouse. On nearing the storehouse the man started a jog trot, increasing his speed until with spine flexed he rammed the forward end of the plank into the angle between the ground and a roof support, thus running the plank into an upright position by one continuous movement. Clearly, as a method of producing a disk protrusion or arthritis this could hardly be bettered, but there still remained the all-important question of the post-war incidence. We therefore interviewed all the men and collected the data which might constitute a significant environmental influence. Most of the men who had incurred the disability had been in the Services. The only obvious contrasting feature we could find in the pre- and post-war periods was diet. Pre-war, two meat meals had been the rule, and in addition a ham or bacon breakfast. There was in fact an appreciable difference in the amount of first-class protein consumed, and one of the older employees told us that they could never manage the longer pre-war working hours on the present diet (that is about five years ago).

No doubt the matter of deficiency in essential amino-acids and other dietetic factors has been fully investigated and discarded as a possible cause, but this story may have some other aspect of interest to someone working on this subject.—I am, etc.,

Ilford, Essex.

D. LANG STEVENSON.

SIR.—Recent correspondence on backache has been most controversial and thereby intriguing. Does this not show that no one specialty is infallible, and that team work is essential? All of us are doctors, and very many of us have had "backache," but very few indeed have had "disks," and fewer still have been operated upon.

The differential diagnosis of backache is very difficult, and its treatment still more so. It therefore behoves us as consultants to work together as a team in its elucidation, and, if orthopaedic in origin, to carry out the treatment in detail personally. Moreover, it is our duty as doctors to impress upon the public that they must face up to the fact that wear and tear of the spinal column must bring its ills with it: the majority of which are curable by non-surgical means.—I am, etc.,

London, W.1.

B. WHITCHURCH HOWELL.

SIR.—As another general practitioner I gladly take up the challenge of Dr. R. N. R. Grant (*Journal*, February 19, p. 480), since I for one have never been satisfied that "fibrositis" is caused by exposure to draught. If the history is studied, a trauma will usually be traced. Thus the man who "always has a stiff neck after a hair-cut" will blame the cold sensation of the clippers or of the denudation itself, forgetting the extreme flexion into which his neck was forced by the operator. Likewise the railway traveller who returns with a "chill in the back" will admit to falling asleep whilst sitting upright in the railway carriage. The holiday-maker who has "caught lumbago on a windy beach" will have been flattening his lumbar curve either in a deck-chair or upon sand not so much wetted as hardened by a recent tide.

It is moreover idle to argue that the pain did not appear until the following day. If it is true that the disks as a whole can imbibe fluid under traction-treatment sufficiently to increase the measured height of the patient, then surely recumbency is the very position in which a damaged disk

can best swell overnight ready to declare itself by a sudden shift of internal tension when first the victim bends forward on the morrow.—I am, etc.,

Richmond, Surrey.

JOHN DANCY.

SIR.—As a high-spirited youngster skylarking in the Edinburgh Warrender Park Baths in attempting a high dive I felt I was going to hit the bottom, but by doing a quick turn in the air this I avoided. However, I felt I had "ricked" my back, and for two years I had lumbago, as we called it 47 years ago. I had some treatment for what my surgeon called a fractured articular process. I did exercises regularly. Three years later I began to play golf and even tennis. I did not risk rugger—I became a scratch golfer instead.

During the first world war and for years afterwards I had about 15 attacks of acute lumbago. During the war I observed that nearly all the soldiers wore elastic or broadish webbing belts which they said prevented their backache. In 1918 I started to wear a belt and this helped me greatly. Acute lumbago I cured with hot baths and passive movements in the hot bath. The belt relieved the ordinary back pain and I could golf, shoot, and enjoy dancing. In 1951 I had a severe motor accident, and in 1952 I was ill for 18 months and my back returned. In spite of expert orthopaedic treatment, rest, massage, and spa treatment, I was no better. However, it was suggested that I might have some spinal arthritis, and I had a course of deep x ray, and this cured the acute pain. I was greatly relieved, but the growling low back pain persisted.

Reading in the *Fishing Gazette*, April 17, 1954, an article by Ronald Strong, who had a slipped disk, and who could now fish for six hours, even after five years of torment and endless examinations and treatment, I took his advice and had a modified surgical belt made with lumbar and some anterior support. Now for one year I have had practically no pain. I can walk two miles and more, with great benefit to my general health. I am 68 years old and I hope to fish again this spring. On my advice many golfers now wear a firm belt with great benefit. A belt modified and fitted to the patient is the cure for lumbago and low backache. I sleep with a firm belt round my waist. Backache can usually be traced to an injury if a careful history of the patient's story is recorded.—I am, etc.,

Bradford.

DONALD WATSON.

Protein Value of Milk

SIR.—A recent letter (*Journal*, February 12, p. 416) from Mr. R. H. Woodcock, under the title of "Human Nutrition and the Sophistication of Foods and Feeding Habits," is based on a complete misconception and requires correction. Mr. Woodcock stated that the fall in the nutritive value of milk on evaporation or drying and subsequent storage was insignificant, because authors whom he quoted had found insignificant losses of lysine (the amino-acid most liable to damage) in these materials. These estimations of lysine were carried out microbiologically after acid hydrolysis of the proteins. It is well known that in the Maillard reaction, which takes place during the heating or prolonged storage of protein-sugar mixtures, part of the lysine becomes bound to the sugar and cannot be liberated during digestion. Most of it is still present, as indicated by analysis following acid hydrolysis, but it is not available to the consumer. The nutritive value is therefore correspondingly reduced. Chemical or microbiological analyses of proteins carried out after acid hydrolysis may therefore yield no information as to the nutritive value of a protein.

Mr. Woodcock would have done better, instead of quoting references to American chemical work on this subject, to have noted the biological experiments carried out so thoroughly at the National Institute for Research in Dairying, at Shinfield.¹⁻⁴ Among other results, this work showed that the biological value of the proteins of dried skim milk (as measured on young rats) fell from 89 to 66 on storage

at 37° C. for sixty days. Storage at room temperature under conditions which did not exclude atmospheric moisture resulted in a fall from 89 (18 months after manufacture) to 71 three years later.

I may add that I am fully aware that, under normal conditions of feeding, the reductions in biological value likely to be encountered are not important in view of the large quantities of protein being consumed. In this letter I am merely concerned with correcting the scientific inaccuracy.—I am, etc.,

London, E.C.1.

Whither Natural Childbirth?

SIR.—I am very pleased indeed to see the excellent letter of Dr. Constance L. Beynon (*Journal*, February 19, p. 475). Now as so few "family doctors" (if such persons still exist) do any midwifery, normal or otherwise, it is important that the clinics do not run amok. As Dr. Beynon suggests, their army of physiotherapists and other departmental specialists with great schemes for training for "natural childbirth" may defeat their own object by creating apprehension and fear by introspective thought in a perfectly normal and healthy expectant mother.

During more than 25 years of general practice, before retiring at the approach of the N.H.S., my chief interest was obstetrics. I have seen babies delivered in many parts of the world; in world-renowned teaching hospitals and elsewhere. In some I have been horrified at the extremely artificial and pseudo-scientific methods employed, even in normal cases—sometimes with disastrous results. I have seen methods of investigation during pregnancy which might have acquired a Ph.D. for some enthusiastic house-surgeon, but which appeared to me to be entirely unjustified and not likely to benefit in any way the trusting individual being investigated. I would not have allowed some of these experiments to have been carried out on any member of my own family, and therefore I could not acquiesce had they been my patients.

Forty years ago—in my student days—we were taught by brilliant experts how and when to interfere in difficult labour. Later came the preaching against "meddlesome midwifery" which was the cause of many a case being left too long for safe delivery. Since then antenatal supervision has proved its worth. In the clinic there is a multitude of specialists and their minions to bewilder the healthy woman: an ever-changing personnel.

The large number of persons concerned with each pregnancy and confinement is in itself a disadvantage and repugnant to the woman they seek to serve. The methods of Dr. Grantly Dick Read appeared to me to be rational and helped many toward "natural childbirth," but how could his methods be practised under to-day's conditions? The old family-doctor-obstetrician is unfortunately dying out, and apart from the appointment of a few expert surgeons to be called upon in a small minority of cases, I fear, has not been adequately replaced. Let us think again. A most happy caption has been selected for Dr. Beynon's letter, "Whither Natural Childbirth"?—I am, etc.,

Bournemouth.

S. H. WADDY.

Sézary's Syndrome

SIR.—In addition to the seven cases of Sézary's erythrodermia described by Drs. W. E. Alderson, George I. Barrow, and Robert L. Turner (*Journal*, January 29, p. 256) in their interesting paper, we have recorded a further case in a woman of 84.¹ This case may throw light on the nature of the condition, since it is the first to come to post-mortem examination, the histological findings of which are being studied.

So far there is no evidence that the reticulum cell infiltration of the skin and the presence of these cells in the peripheral blood is a malignant process. Alderson *et al.* state their belief that it is an early phase of a malignant reticulosis linking the conditions known as lipomelanotic reticulosis and reticulum cell reticulosis. The term reticulosis is a natural pathological extension of Aschoff's physiological concept. Unfortunately, the limits of its application are even more vague than those of the reticulo-endothelial system from which it derives. We should, however, be able to confine "malignant reticulosis" within closer boundaries and reserve that term for invasive and irreversible proliferation of reticulo-endothelial cells. In Sézary's erythrodermia there is as yet no evidence that the changes are malignant.

The lipomelanotic change in superficial lymph glands is now generally considered to be a reactive hyperplasia. It has been described in association with such benign conditions as varicose ulcer² and lichen planus.³ The histological changes are reversible and if the skin condition clears the glandular enlargement subsides. We feel that the term lipomelanotic reticulosis should be abandoned and prefer the non-specific lipomelanotic lymphadenopathy. We are, etc.,

Press Publicity

SIR.—In regard to this matter of our profession, organs of the Press, and operations on conjoined twins an apposite remark was made on a related subject on March 1 in Parliament by Sir Winston Churchill. He said: "I think the liberty of the individual must be sustained against the tyrant, it must be sustained against the mass, and it must be sustained against the machine."

We stand for the liberty of the patient to keep his disease and treatment private and for the liberty of the surgeon to preserve his modesty. The organs of the press with which we are concerned stand for giving the mass what it wants. The mass, in its day, wanted gladiatorial games, it crowds round street accidents, and it wants the details of the operating theatre.

If we believe in the principles of the Hippocratic oath we should sustain the patient and the surgeon against the mass and the machine that ministers to it. This is no matter of professional etiquette; it is a matter of values. "Prepared statements" are no solution. I would urge that if we compromise we put our profession's soul in jeopardy.—I am, etc.,

Cosmetic Materials

SIR, I am at present engaged in a revision of my book, *Cosmetic Materials: Their Origin, Characteristics, Uses, and Dermatological Action*, the foreword to which is being contributed by a Harley Street dermatologist. In the interests of the industry, the user, and the medical profession, I am anxious to obtain as much information as possible concerning primary irritation or sensitization arising from the use of substances employed in the cosmetic, toilet, and pharmaceutical industries, and for this purpose I would be very glad to receive brief details from any of your British or overseas readers of any instances in which the offending ingredients have been definitely confirmed by skin tests.

Such information should be sent to the address given at the foot of this letter; it will be personally acknowledged and full credit given to the source of the information in the new edition.—I am, etc.,

60, Broad Walk,
Heston, Middlesex.

Medico-Legal

DEATH FROM BENZENE POISONING

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

At the inquest held recently at the St. Pancras Coroner's Court on Dennis William Wood the cause of death was found to be aplastic anaemia due to benzene poisoning, and a verdict of death from natural causes was recorded by the coroner, Dr. W. Bentley-Purchase.

Mr. Wood, aged 22, was a student industrial chemist and had started work at the Portsmouth Electricity Works in 1948. In September, 1953, he fell ill, and was an in-patient at the Royal London Homoeopathic Hospital from May 12 to August 19, 1954, with anaemia, being then discharged improved. He was readmitted in October and November, 1954, for blood transfusions, but died on December 25, 1954, in hospital. He had suffered from a lack of leucocytes and platelets, the platelet count being proportionately lower than the white cell count. Dr. R. Moore, consultant physician to St. Mary's Hospital, Portsmouth, suspected benzene poisoning with entry through the skin, because the anaemia was hypoplastic. Dr. Ethel Browning, Medical Inspector of Factories, agreed that the condition was due to benzene poisoning.

Witnesses from the Portsmouth Generating Station with whom Mr. Wood had worked said that he was employed on general laboratory work. This included performing standard water-and-oil tests with benzene as a solvent, so that he would come into contact with benzene vapour. He would be working with benzene for about 1½ hours per week though not necessarily every week, and he would not get it on his hands or inhale it. The work was not considered dangerous, and the four others doing the same work had been unaffected. Mr. Wood did not work in the fume cupboard.

Dr. Browning said that it was not unusual for such a small exposure to benzene to cause anaemia. Individual susceptibility varied, and it was inhalation which usually caused the trouble.

BROKEN NEEDLE IN GIRL'S THROAT

The emergency which faced a surgeon when a needle broke in his patient's throat and then an electric lamp failed, plunging the operating theatre into darkness, was the subject of a case before Lord Guthrie in the Court of Session, Edinburgh, on March 4. He awarded £850 damages to a Dundee man on behalf of his 14-year-old daughter. The girl, it was stated, received severe scarring of the throat as a result of efforts to find the broken part of the needle after an operation for the removal of her tonsils and adenoids.

James Henderson, of Dundee, claimed on behalf of his daughter Marion £5,000 damages from Mr. G. I. Henderson, surgeon, formerly of Dundee and now practising in Australia, where his evidence was taken.

Lord Guthrie said the action arose out of an operation in Maryfield Hospital, Dundee, on March 21, 1951. (Three weeks before the operation the defendant had arranged to go to Australia, and he left in May, 1951.) At the end of the operation severe bleeding occurred, and the surgeon, by stitching, took measures to control this. While doing so, the needle broke, and two-thirds of it, about ½ in. (12 mm.) in length, remained in the child's throat. A stitch was inserted with a fresh needle, and the bleeding was brought under control. At that point the bulb in the headlamp used by the surgeon failed, plunging the theatre into almost total darkness. Replacement of the bulb took only a few seconds, and continuous anaesthesia by gas was administered to the patient while the broken needle was sought. Lord Guthrie said that the surgeon probed the soft palate

with his finger and the blunt end of the forceps. After about 15 minutes he thought he felt the needle and made an incision with a scalpel. The needle was not found and a stitch was inserted in the incision. The search lasted unsuccessfully for an hour. Next day the child was transferred to Dundee Royal Infirmary. A powerful electromagnet was placed close to her mouth and the missing part of the needle was withdrawn.

Lord Guthrie described the girl's voice as weak, hollow, and nasal, and said that she spoke like a person with a cleft palate. He said he accepted the medical evidence for the plaintiff as to proper surgical procedure in the circumstances. Defendant had departed from that standard. It should have occurred to the surgeon that prolonged probing and stretching of the fibres would have serious and possibly permanent consequences. Had he exercised the care and skill reasonably to be expected of a surgeon, after a few minutes he would have desisted from his blind search. Lord Guthrie concluded by saying that it was right to place on record that in the course of the evidence tribute was paid to the meticulous care which characterized the surgeon's normal conduct of operations.

Obituary

Dr. ADELINE ROBERTS, who died in a London hospital on January 8 in her 82nd year, was for many years distinguished among London medical women, particularly in the fields of public and social work. Adeline Mary Roberts, who was born in 1873, entered the London (Royal Free Hospital) School of Medicine for Women as a medical student in 1893. She took the London M.B. in 1898, the B.S. with honours in the following year, when it could be taken as a separate examination, and proceeded to the M.D. in 1902. After qualification she held a number of resident and other appointments, and then acted as a clinical assistant at Moorfields Hospital for several years before setting up as an ophthalmic consultant in London about 1904. Later, she was appointed consulting ophthalmic surgeon to the South London Hospital for Women. Always interested in social medicine, she was elected a member of the St. Marylebone borough council in 1912, and for some years was the only woman on the council, where she had considerable influence in matters concerning the health of women and children. When war broke out in 1914 Dr. Roberts became increasingly active, and her opportunity to undertake more systematic work came with the formation of the Women's (later Queen Mary's) Army Auxiliary Corps in 1917, when for the first time the organized help of women, chiefly for clerical and domestic duties, was made available as an accessory to the Regular Army in wartime. To provide certain medical services in connexion with this corps a small unit of medical women was formed, being attached to the R.A.M.C. and represented at the War Office by a controller of medical services of the W.A.A.C., a post Dr. Roberts held after serving in this unit for two years, first as president of the London recruiting and medical boards.

For her valuable work in connexion with the war she was appointed an O.B.E. of the Military Division in 1919. Dr. Roberts was elected to the London County Council as a representative of St. Marylebone in 1922, when she gave up medical practice and rendered unstinted service to the council until her retirement 12 years later. She was chairman of the mental hospitals committee of the council, in which she took a keen interest, and her good work as chairman of the committee during the reorganization and development of the Maudsley Hospital was widely recognized at the time. After her retirement from the L.C.C. Dr. Roberts continued to do a good deal of public work as a magistrate and for various voluntary societies, including the Invalid Children's Aid Association. She remained in London during the second world war, but increasing ill-health prevented her, to her great regret, from taking part

in any active medical or social work. Dr. Roberts, who made a worthy contribution to the work done by medical women during the first half of the century, had a clear mind, good judgment, courage, and a high sense of responsibility. As a friend, her wide experience, quiet humour, and personal charm made her a delightful companion, though to many people who did not know her well she undoubtedly presented a somewhat formidable figure. She was unquestionably an outstanding person of exceptional character and attainments, and she leaves a record of good work finely done.—J. H. T.

A memorial service for Sir CHARLES MARTIN will be held in the Chapel of St. John's College, Cambridge, on Saturday, March 12, at 12 noon.

Medical Notes in Parliament

Merit Awards

Mr. BERESFORD CRADDOCK (Spelthorne, Con.) on February 28 asked the Minister of Health on what basis the distinction (merit) award was given to consultants in the Health Service over and above their salaries; and why the identity of the doctors granted these awards from public funds was not published. Mr. IAIN MACLEOD replied that the committee set up to recommend awards was required by its terms of reference to base its recommendations on professional distinction. In his view publication of names would not be in the best interests of the Health Service. Mr. CRADDOCK asked what objection there was to publishing the names, as the grants were paid from public funds. Mr. MACLEOD said the objection surely was that, if it were known which consultants got class A, B, or C awards, patients might think they were getting different forms of treatment. That would not be the case, because factors other than clinical ability were taken into account. The same view had always been taken by his predecessors, and he believed it to be right.

Mr. BERESFORD CRADDOCK also asked the Minister whether he was aware that doctors of the highest distinction in the employ of the Medical Research Council were not eligible for distinction (merit) awards in the same way as consultants in the Health Service; and whether he would provide for such, or similar, grants to be made, in order to remove this anomaly. Mr. MACLEOD replied that, subject to certain rules, doctors employed by the Medical Research Council were eligible for distinction awards if they held honorary consultant appointments in the Health Service. Apart from this, their remuneration was a matter for the Lord President of the Council.

Medicine in the Colonies

Mr. JAMES JOHNSON (Rugby, Lab.) asked the Minister of Health on February 28 whether, in view of the growing numbers of unemployed among British doctors, he would consult with the Secretary of State for the Colonies about their being engaged in the service of Colonial governments. Mr. MACLEOD said that the Colonial Secretary and he already consulted as necessary on the needs of the Colonial governments for medical staff, and vacancies were publicly advertised in all appropriate cases. Mr. JOHNSON said there were 200 applications for each vacant job to-day in the United Kingdom. In Nigeria there were some 61,000 people per doctor and in the Cameroons 71,000. He asked the Minister to ginger things up, and set up a working party to investigate the question of seconding doctors to the Colonies, particularly West Africa. Mr. MACLEOD replied that it was not within his competence to direct doctors to any particular area. Mr. JOHNSON said that people in the Colonies thought the present scheme was not working. He wished the Minister to consider some financial inducement, perhaps a settlement scheme, to induce doctors to go to the

Colonies. Mr. MACLEOD said the problem was largely one for the Colonial Secretary, and he would bring the suggestion to his notice.

Salary Scales

Mr. H. W. BOWDEN (Leicester, South-west, Lab.) asked the Minister of Health what steps he had taken to satisfy himself that the present salary scales were sufficiently attractive to encourage young doctors to enter hospital service rather than enter general practice. Mr. IAIN MACLEOD replied that the salaries of hospital medical staff were a matter for the Medical Whitley Council in the first instance; but he knew that the need to keep a proper balance in recruitment was an important factor in the agreement on increased salaries reached by the council a year ago. Mr. BOWDEN asked if Mr. MACLEOD was aware of the difficulties experienced by many hospitals in the provinces in obtaining junior medical staff. Mr. MACLEOD said that indeed he was. It would be a mistake, however, to link those difficulties entirely with problems of pay. In many cases they arose because the hospitals were remote or unattractive. As for pay, the agreement last year did a good deal to restore the balance that was upset by the Danckwerts award. Mr. J. SNOW (Lichfield and Tamworth, Lab.) said it would be a great pity if the provision of practitioners for the countryside was in any way jeopardized. There were still many rural areas under-doctored.

Manpower Inquiry

Mr. A. BLENKINSOP (Newcastle-upon-Tyne, East, Lab.) asked if the Minister was satisfied that there was sufficient non-professional representation on the committee to inquire into medical manpower. Mr. MACLEOD said that the Secretary of State for Scotland and he were satisfied that the composition of the committee was well adapted to the work before it.

Mr. R. GOWER (Barry, Con.) complained that the medical manpower committee contained no members who had been associated with health administration in Wales, although Scotland had three and England eight. Mr. MACLEOD said the members had been appointed solely on their personal qualifications, and not as representatives of particular areas or interests. The interests of the Welsh health services, which through the Welsh Board of Health were his direct responsibility, would not be prejudiced in any way.

Dispensing Equivalents

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) asked the Minister of Health on February 28 whether he had noted that exactly similar preparations of some drugs, particularly penicillin, were manufactured by different chemical firms and stocked by dispensing chemists; that these preparations had different names; and whether he would authorize dispensing chemists to dispense an exact equivalent, irrespective of the name on the prescription. Miss PAT HORNSBY-SMITH, Parliamentary Secretary, replied that the Minister was aware of the position, but he would not feel justified in authorizing chemists to dispense preparations other than those prescribed. The matter was primarily one for the prescriber. Dr. STROSS said there were four or five oral and stable suspensions of penicillin that were exactly alike and identical in therapeutic effects. He suggested that a child suffering from pneumonia might not get anything to help it for a day and/or a night, although a similar preparation was available. He wondered what ought to be done in such a case. Miss HORNSBY-SMITH said that it would be quite unethical for a chemist to transpose one preparation for another that was ordered by a doctor. In a case of that kind there was no reason why the chemist should not telephone the doctor and ask whether he would agree to change to the comparable preparation.

Coroners' Verdicts

Mr. JAMES GRIFFITHS (Llanelly, Lab.) asked the Minister of Pensions and National Insurance if he was aware of the

concern that was felt in South Wales at the increasing number of cases in which coroners' courts had found that the death of coal-miners was due to, or accelerated by, silicosis or pneumoconiosis and in which the medical boards made contrary decisions; and whether he would consider the setting up of a competent body to investigate and report on the criteria used by the boards in arriving at their decisions. Mr. OSBERT PEAKE, replying on February 28, said he was aware that for some time concern had been felt in South Wales on this matter. He had had discussions with the Home Secretary and his predecessor about it. A circular was issued to coroners in October, 1954, drawing attention to the importance of employing experienced pathologists in cases of this kind.

Mr. GRIFFITHS said the disparity was continuing and causing widespread concern. Would the Minister consult his medical advisers about a closer examination of the problem? Mr. PEAKE pointed out that coroners were independent judicial officers, and there was great difficulty in arriving at a solution. Mr. GRIFFITHS said that a verdict that death was caused by pneumoconiosis or silicosis, after a report by a pathologist, caused much doubt about the decisions of the medical board. Was it not essential that there should be an inquiry, to maintain confidence in the boards? Mr. PEAKE said his information was that in most cases where difficulty had arisen the post-mortem examination had been conducted by a general practitioner. Therefore he thought it would be wiser to see whether the circular had any effect before considering further action.

Effects of Dust Suppression

Mr. GRIFFITHS asked the Minister of Fuel and Power if he would make a statement on the progress made in combating silicosis and pneumoconiosis among coal-miners; to what extent the measures taken were proving adequate; and what further measures were contemplated.

Mr. L. W. JOYNSON-HICKS, the Parliamentary Secretary, stated on February 28 that in South Wales, where full-scale dust suppression first started, the total number of new cases in 1953 was 1,069, compared with 3,774 in 1949. Corresponding figures for the whole country were 4,048 in 1953 and 5,807 in 1949. He was advised that the National Coal Board was making substantial progress with its dust suppression programme, and further investigation was constantly proceeding, under the Board's "twenty-pit" scheme and other types of research.

Genetic Effects of Radioactivity

Mr. F. BESWICK (Uxbridge, Lab.) asked the Parliamentary Secretary to the Ministry of Works, as representing the Lord President of the Council, what steps he had taken to satisfy himself that there was adequate research into the genetic effects of radioactivity; and if, in view of the serious issues involved, he would make a statement.

Mr. J. R. BEVINS replied on March 1 that a programme of research into the genetic effects of radioactivity was in progress under the auspices of the Medical Research Council, and plans were being made to expand and accelerate it. There was frequent consultation with workers engaged in cognate studies in the United States, and the researches in this country were planned to avoid overlapping with the American investigations.

Blindness in West Africa

Mr. A. LENNOX-BOYD, Secretary of State for the Colonies, informed Mr. C. ALPORT (Colchester, Con.) on March 2 that entomological research undertaken by the British Empire Society for the Blind in the Volta region, as part of their West African survey, was nearing completion. This was expected to lead to recommendations for insecticidal campaigns in inhabited areas of the Upper Volta along the tributary and subsidiary streams, where the incidence of river blindness was higher than along the Volta itself. As

regards the Lower Volta, the special measures that might be required if it was decided to embark on the Volta River hydro-electric project had been studied by the preparatory commission for the project, and would be included in its report. Meanwhile, substantial progress was being made by Government medical field units in the treatment of sufferers.

Palestinian Refugees

Lord JOHN HOPE, Under Secretary, Foreign Office, replying to Mr. PATRICK MAITLAND (Lanark, Con.), stated on March 2 that Palestinian refugees suffering from infectious tuberculosis were segregated and cared for in local government hospitals in Gaza and the Lebanon, in the new Government sanatorium in Amman, and in a missionary tuberculosis hospital on the West Bank. Next month the United Nations Relief and Works Agency would open a further 100-bed tuberculosis hospital in Jordan especially for refugees. Mr. Maitland said that more than 4,000 refugees had been living for more than five years in one camp near Jericho, and there were no arrangements whatever for segregation in the camp. The arrangements the Under Secretary had described were utterly inadequate. The Government, having contributed large sums to the Agency for many years, should voice this major scandal. Lord JOHN HOPE said that things might not be perfect, but the Agency was working on the advice of a public health specialist in tuberculosis from the World Health Organization. He was assured that there was no special danger to public health.

Lord JOHN HOPE informed Mr. CROUCH (Dorset, North, Con.) that the number of Palestinian refugees per doctor in the U.N. Relief and Works Agency camps was 3,556.

Recruitment for the Colonies

Mr. F. BROCKWAY (Eton and Slough, Lab.) on March 7 asked the Minister of Health if he would request the committee on medical manpower to consider the question of recruitment in relation to Colonial needs as well as to the needs of the United Kingdom. Mr. IAIN MACLEOD said that the committee's terms of reference covered all branches of the profession, and it would therefore take account of doctors who went overseas as well as those who remained in this country. Mr. BROCKWAY asked whether, in view of the great urgency for doctors in the Colonies, the Minister would consult with the Secretary of State with a view to seeing that there were openings for both British citizens and Colonial subjects to enter medical schools for this purpose. Mr. MACLEOD said that he was in touch with the Colonial Secretary. The manpower committee would be concerned only with medical training in this country, but they must take into account where qualified doctors might go from the universities, and that included the Colonies.

Mercury Teething Powders

Mr. S. SWINGLER (Newcastle-under-Lyme, Lab.) asked the Minister of Health on March 7 if he had considered the recent case of a baby's death from mercury poisoning,¹ and what action he would take concerning the supply of tablets containing mercury to infants. Miss PAT HORNSBY-SMITH said that, while the Minister was advised that mercurial preparations had a proper place in medical treatment, his medical officers had already suggested to medical officers of health that powders containing mercury should be issued from child welfare clinics only on medical advice and with precise instructions. He would consider further whether to suggest that these preparations should cease to be available at clinics at all. Mr. SWINGLER suggested that the Minister's medical advisers might issue a general warning to the public, in view of the concern created by a recent inquest. Miss HORNSBY-SMITH said she thought that the general publicity and the advice given by medical officers of health made this

¹ *British Medical Journal*, March 5, p. 610.

clear, but even if the powders were not given at clinics it would not interfere with the right of a doctor to prescribe a preparation in which this was included.

Charge for Certificates

Mr. V. COLLINS (Shoreditch and Finsbury, Lab.) on March 7 asked the Minister of Health if he was aware that many doctors charged 2s. for medical certificates issued to Health Service patients, and if he would make a regulation to prohibit this charge. Miss PAT HORNSBY-SMITH, Parliamentary Secretary, replied that general practitioners in the Health Service were not required to provide free medical certificates other than those required under the National Insurance Acts and certain other enactments which are set out in Regulations. The Minister saw no reason for altering this system. Mr. COLLINS said that often these certificates had to be paid for after a period of unemployment. If the per capita charge did not cover them, could it be adjusted so that the certificates could be issued free? Miss HORNSBY-SMITH said that certificates required to obtain benefit under any of the regulations were obtainable free, but other types of certificate were not.

Opticians' Registration

Miss PAT HORNSBY-SMITH informed Mr. A. BLENKINSOP (Newcastle-upon-Tyne, East, Lab.) on March 7 that the Government could hold out no hope of introducing legislation for the registration of ophthalmic and dispensing opticians at present. She said that the difficulty was with the Parliamentary time-table.

Mental Nursing.—There is still a shortage of mental nurses, which has been estimated at about 10,000.

Lost in Hospital.—In the three years 1951-2 to 1953-4 the value of articles recorded as lost in Scottish hospitals was respectively £18,479, £25,933, and £16,068.

Fluoridation Tests.—Experiments in the fluoridation of water are to start in Anglesey, Darlington, and Watford during the summer. Special equipment has to be provided, and the local authorities are now inviting tenders.

The Services

Major-General F. J. O'Meara, late R.A.M.C., has been appointed Honorary Physician to the Queen, in succession to Brigadier R. J. Rosie, C.B.E., retired.

Colonel C. M. Marsden, late R.A.M.C., has been appointed Honorary Surgeon to the Queen, in succession to Major-General J. C. Collins, C.B., C.B.E., retired.

Colonel J. B. S. Guy, C.B.E., T.D., R.A.M.C., T.A., has been appointed Honorary Colonel of a T.A. Unit, in succession to Colonel P. Hickey, T.D., R.A.M.C., T.A., whose tenure has expired.

A Supplement to the *London Gazette* has announced the following awards:

Third Clasp to the Territorial Efficiency Decoration.—Major (Honorary Lieutenant-Colonel) T. C. McKenzie, T.D., R.A.M.C., retired.

Second Clasp to the Territorial Efficiency Decoration.—Major (Honorary Lieutenant-Colonel) T. C. McKenzie, T.D., R.A.M.C., retired.

First Clasp to the Territorial Efficiency Decoration.—Lieutenant-Colonel A. Wilcox, T.D., and Majors (Honorary Lieutenant-Colonels) T. C. McKenzie, T.D., retired, and Sir J. C. Nicholson, R.A.M.C.

Territorial Efficiency Decoration.—Colonel G. O. Montgomery, retired, Lieutenant-Colonel T. F. Redman, Majors (Honorary Lieutenant-Colonels) W. I. Gordon and Sir J. C. Nicholson, Majors E. S. Curtiss, D. B. McVittie, E. L. Simpson (retired), and A. J. Thomson, and Captain (Acting Lieutenant-Colonel) H. K. Meller, M.B.E. (now A.E.R.), R.A.M.C.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending February 19 (No. 7) and corresponding week 1954.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1955					1954

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenzal pneumonia.

‡ Includes puerperal pyrexia.

Vital Statistics

Diphtheria Low Record

In England and Wales in 1954 only 9 deaths from diphtheria were reported. This provisional figure may be compared with 23 for 1953 and 722 for 1945. The provisional figure of corrected notifications was 182, also a record low figure. In 1953 they numbered 266, and in 1945, 18,596.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the nine years 1946-54 (influenza, 1952-4) are shown thus ----, the figures for 1955 thus —. Except for the curves showing notifications in 1955, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest fluctuations in the trends of the notifications of infectious diseases in England and Wales during the week ending February 19 were an increase of 1,613 for measles, from 18,363 to 19,976, and decreases of 155 for whooping-cough, from 2,065 to 1,910, 136 for acute pneumonia from 1,156 to 1,020, and 64 for scarlet fever, from 746 to 682.

The largest increases in the incidence of measles were 457 in London, from 1,945 to 2,402, 379 in Kent, from 675 to 1,054, 245 in Warwickshire, from 815 to 1,060, 243 in Derbyshire, from 778 to 1,021, and 111 in Nottinghamshire, from 975 to 1,086. In contrast to the general rise, two large falls in the incidence of measles were reported—of 234 in Lancashire, from 3,277 to 3,043, and 173 in Yorkshire West Riding, from 2,871 to 2,698. The largest fluctuation in the trends of whooping-cough was a fall of 73 in Lancashire, from 243 to 170. The only variations of any size in the incidence of scarlet fever were decreases of 26 in London, from 54 to 28, and 21 in Yorkshire West Riding, from 77 to 56. 16 cases of diphtheria were notified, being 2 more than in the preceding week. Half of the cases were notified in three cities. Manchester C.B. 3, Kingston-upon-Hull C.B. 3, and Middlesbrough C.B. 2.

The 3 cases of paratyphoid fever were all notified in Birmingham C.B.

21 cases of acute poliomyelitis were notified. These cases were 4 more for paralytic and 1 more for non-paralytic cases than in the preceding week. The areas with multiple cases were London 3, Lancashire 3, Devonshire 2, and Nottinghamshire 2.

1,145 cases of dysentery, 35 more than in the preceding week, were notified. The largest centres of infection were Lancashire 445 (Blackpool C.B. 122, Oldham C.B. 106, Blackburn C.B. 72, Manchester C.B. 52, Liverpool C.B. 12, Lytham St. Anne's M.B. 11, Darwen M.B. 10), Durham 71 (Easington R.D. 16), Yorkshire West Riding 60 (Leeds C.B. 26, Sheffield C.B. 17), Northamptonshire 60 (Northampton C.B. 46), London 55 (Southwark 12), Nottinghamshire 46 (East Retford M.B. 27, Mansfield M.B. 10), Northumberland 45 (Newcastle-upon-Tyne C.B. 19), Glamorganshire 44 (Swansea C.B. 16, Cardiff C.B. 13), Leicestershire 42 (Leicester C.B. 21, Wigston U.D. 18), Yorkshire North Riding 36 (Middlesbrough C.B. 35), Norfolk 35 (Norwich C.B. 15), Cardiganshire 27 (Lampeter M.B. 25), Lincolnshire 25 (Scunthorpe M.B. 24), and Staffordshire 23 (Burton-upon-Trent C.B. 12).

Week Ending February 26

The notifications of infectious diseases in England and Wales during the week included: scarlet fever, 675, whooping-cough 1,678, diphtheria 13, measles 23,700, acute pneumonia 924, acute poliomyelitis 21, dysentery 1,237, paratyphoid fever 3, and typhoid fever 4.

Medical News

Endocrine Unit at New End Hospital.—The new department of endocrinology at New End Hospital, Hampstead, was opened on March 2 by the DUKE OF EDINBURGH. The chair was taken by the Hon. JOHN FREMANTLE, chairman of the North-west Metropolitan Regional Hospital Board, by whom the first extension of the department was begun two years ago with the initiation of the radio-isotope laboratory. Among those present were the MINISTER OF HEALTH; Sir THOMAS DUNHILL, founder of the L.C.C. Thyroid Clinic, from which the new department has developed; and the representative of Organon Laboratories, Ltd., who have provided a generous annual subsidy for the research work of the department. The Duke of Edinburgh was conducted through the new premises, housed in the shell of the old maternity unit, by Mr. J. E. PIERCY, the surgeon-superintendent of the hospital, and Dr. RAYMOND GREENE, senior physician to the hospital and the originator of the extension plan. The new department includes 26 beds, a new biochemical laboratory, an extended and improved radio-isotope laboratory, an out-patient department, and a new operating theatre, all in convenient juxtaposition. The transmutation of the thyroid clinic into a complete endocrinological research unit has been made possible by a generous gift of some £50,000 from King Edward's Hospital Fund.

Eli Lilly and Lederle Travelling Fellowships.—The Medical Research Council invites applications *not later than March 28* for these travelling fellowships in medicine for the academic year 1955-6. The fellowships are for graduates resident in Britain who are likely to benefit by a period of work in the United States before taking up positions for higher teaching or research in the United Kingdom. The stipend is \$2,700 per annum for a single fellow and \$3,900 for a married fellow. The funds for the fellowships have been generously provided by Eli Lilly and Company, U.S.A., and the Lederle Laboratories Division of the American Cyanamid Company. Full details and forms of application from the secretary, Medical Research Council, 38, Old Queen Street, Westminster, London, S.W.1.

Professor R. V. Christie, professor of medicine at St. Bartholomew's Hospital, London, since 1938, has been appointed professor of medicine, and chairman of the department of medicine, at McGill University, Montreal. He has also been appointed physician-in-chief of the Royal Victoria Hospital, Montreal. He succeeds Professor E. F. MILLS. Born in 1902, Professor Christie graduated from Edinburgh University, continuing his studies at the Rockefeller Institute for Medical Research, New York, Freiburg University, and McGill University, where he is now going. He was Goulstonian lecturer to the Royal College of Physicians in 1943, and is a Censor of the College. He is also a member of the Senate of London University. Professor Christie is perhaps best known to readers of the *Journal* for his publications on the antibiotic treatment of subacute bacterial endocarditis. He expects to take up his appointment in Montreal in the autumn.

Chairs of Medicine and Surgery at Melbourne.—Melbourne University has appointed two doctors from London to its new chairs of medicine and surgery. Dr. R. R. H. LOVELL, lecturer in medicine at St. Mary's Hospital Medical School, will be professor of medicine, and Mr. M. R. EWING, senior lecturer in surgery at the Postgraduate Medical School of London, professor of surgery. Dr. Lovell, who is 35, graduated at London University and was a Naval surgeon during the war. Mr. Ewing, aged 42, also a Naval surgeon in the war, held a British-American Exchange Scholarship at the Memorial Hospital, New York, in 1950-1, and was a Hunterian professor of the Royal College of Surgeons in 1950, when he lectured on "Villous Tumours of the Rectum."

Order of St. John.—Sir STEWART DUKE-ELDER, accompanied by the Secretary of the Order, Major J. F. C. UNDERHILL, is now on tour in the Middle East. He is looking into the possibility of restoring the Ophthalmic Hospital of St. John in Jerusalem and the establishment, somewhere in the Middle East, of a research institute for the study of trachoma. It is understood that the latter would be administered by the Order of St. John and financed by interested British firms. Sir Stewart is expected to return to London at the beginning of April.

Doctors and the Press.—Dr. H. GUY DAIN, in his capacity as chairman of the Association's Public Relations Committee, has invited representatives of the Press to attend an "exploratory meeting" on March 29 at B.M.A. House to discuss "the relations between the medical profession and the Press, particularly with reference to news from hospitals." This arises as a result of recent correspondence in the newspapers about the reporting of the Keighley and Kano conjoined twins. The Press organizations invited to send representatives to the meeting are the General Council of the Press, the Newspaper Proprietors Association, the Guild of British Newspaper Editors, the Newspaper Society, the Press Association, the Institute of Journalists, the National Union of Journalists, the Newspaper Conference, the Scottish Daily Newspapers Society, and the Scottish Newspaper Proprietors Association.

Chest Diseases Group.—The formation is announced of a clinical group called the South-West Metropolitan Region Chest Diseases Group (Eastern Area). It covers the county areas of Surrey and West Sussex, and that part of the county of London within the geographical area of the regional board. The aim of the group is to promote the study of diseases of the chest, with special reference to the problem of tuberculosis. Membership is open to all doctors in the area with an interest in chest diseases. Further details may be obtained from the honorary secretary, Dr. G. C. TAYLOR, A.S.M.O., South-West Metropolitan Regional Hospital Board, 27, Queen Anne Street, London, W.1.

Trinidad's Lepers.—Dr. ERNEST MUIR, honorary medical adviser to the British Empire Leprosy Relief Association, and Dr. SOUZA LIMA, of the World Health Organization, have been invited to visit the island of Chacachacare to report on the management of the lepers there (see *Journal*, January 15, p. 175). Dr. Muir is familiar with the local conditions, as after his retirement he worked at Chacachacare during the last world war.

Dr. E. A. Wright, experimental pathologist at the Medical Research Council's experimental radiopathology research unit at Hammersmith Hospital, has been appointed to the London University readership in pathology tenable at St. Mary's Hospital Medical School.

Professor J. Cruickshank, who retired from the chair of bacteriology at Aberdeen University last year, will receive the university's honorary degree of Doctor of Laws at the summer graduation in July.

Dr. G. W. Marsh has been awarded the Polar Medal. He was Base leader and medical officer at Hope Bay, 1952-3, while a member of the Falkland Islands Dependencies Survey.

COMING EVENTS

Christian Medical Fellowship.—Mr. ARNOLD S. ALDIS, F.R.C.S., will speak on "The Extent of Medical Responsibility" at the Royal Empire Society, Northumberland Avenue, London, W.C.2, at 7.45 p.m. on March 17.

Airborne Medical Society.—The annual dinner of the society will be held at the Royal College of Surgeons, Lincoln's Inn Fields, on March 18 at 7.30 p.m. Details from the secretary, Dr. J. S. BINNING, Medical Department, Marylebone Station, London, N.W.1.

Institute of Psychiatry.—A series of postgraduate courses in psychiatry will be held at the Maudsley Hospital, Denmark Hill, London, S.E.5, starting on April 4.

Central Council for the Care of Cripples.—Conference on "The Well-being of the Disabled" at Leeds University, April 12-14. Details from the council, 34, Eccleston Square, London, S.W.1.

Brompton Hospital Association.—Dr. G. E. BEAUMONT will preside over the dinner of this association on April 15 at the Waldorf Hotel at 7.15 for 8 p.m. The cost of the dinner will be £1 5s. (excluding drinks). Application should be made to Dr. A. F. FOSTER-CARTER, Brompton Hospital, London, S.W.3.

Society for General Microbiology.—Twentieth general meeting at the Royal Institution, London, April 18-20. On April 18 at 6 p.m. Professor C. B. VAN NIEL will deliver the second Marjory Stephenson Memorial Lecture on "Natural Selection in the Microbial World." On April 19 and 20 there will be a symposium on "Mechanisms of Microbial Pathogenicity."

Postgraduate Course for General Practitioners.—A full-time course at the Cardiff Royal Infirmary and Llandough Hospital, April 25-May 7, has been arranged by the Welsh National School of Medicine. Details from the secretary of the school, 34, Newport Road, Cardiff.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, March 14

BRITISH PSYCHO-ANALYTICAL SOCIETY.—At Royal Society of Medicine, 8.30 p.m., Ernest Jones Lecture by Mr. J. Wisdom: Logic of the Unconscious.

MEDICAL SOCIETY OF LONDON.—8.30 p.m., clinico-pathological meeting.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.—7.30 p.m., Dr. G. Brownlee: The Attack on the Tubercle Bacillus.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.—At Physiology Theatre, 4.45 p.m., Dr. Joseph Needham, F.R.S.: New Light on Physico-chemical Aspects of Morphogenesis.

Tuesday, March 15

CHADWICK TRUST.—At Royal Society of Tropical Medicine and Hygiene, 5.30 p.m., Professor E. J. KING, Ph.D., D.Sc.: Silicosis.

ILFORD MEDICAL SOCIETY.—At King George Hospital, Ilford, 8.45 p.m., Professor W. C. W. Nixon and Dr. Sheila G. Ransom: Training for Childbirth.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. A. D. Porter: Actinic Eruptions.

SOUTH-WEST LONDON MEDICAL SOCIETY.—At Bolingbroke Hospital, 8.30 p.m., Mr. E. G. Muir: Abdominal Emergencies.

WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Mr. J. Minton: Ocular Manifestations in Clinical Neurology (Part II).

Wednesday, March 16

HYPNOTHERAPY GROUP.—At Royal Society of Medicine, 8 p.m., Dr. J. A. Hadfield: Place of Suggestion in Analytic Treatment.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. O. Oliver: Allergy and Immunity in Skin Diseases.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. J. F. Barrington: Indications for Treatment in Enlarged Prostate.

LONDON UNIVERSITY.—At Meyerstein Lecture Theatre, Westminster Medical School, 5.30 p.m., special university lecture in biochemistry by Academician W. A. Engelhardt (Moscow): Mechano-chemistry of Muscle.

MIDLAND MEDICAL SOCIETY.—At Birmingham Medical Institute, 154, Great Charles Street, 8.15 p.m., Professor J. H. Dible: Some Pathological Observations on Peripheral Vascular Disorders.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Weill Lecture by Professor R. McWhirter: Breast Cancer.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. J. Greenwood Wilson: Housing and Health.

ROYAL MEDICAL SOCIETY, Edinburgh.—8 p.m., annual extraordinary general meeting.

ST. MARKLEBONE HOSPITAL FOR PSYCHIATRY AND CHILD GUIDANCE.—5.30 p.m., Mr. G. C. Knight: Neurosurgical Treatment.

WELSH NATIONAL SCHOOL OF MEDICINE.—At Reardon Smith Lecture Theatre, Cardiff, 8 p.m., Fifth William Sheen Memorial Lecture by Sir Geoffrey Jefferson, F.R.S.: Aneurysms of the Cavernous Sinus.

WILLESDEN GENERAL HOSPITAL MEDICAL SOCIETY.—8.45 p.m., Presidential Address by Dr. T. Pearce Williams: Some Comments on the Colon.

Thursday, March 17

BRITISH INSTITUTE OF RADIOLOGY.—8 p.m., Mr. G. E. Flatman and Mr. R. E. Ellis, B.Sc.: Report on the Use of Convergent Beam X-ray Therapy at the Middlesex Hospital; Mr. K. Y. Orfan, B.A.: Rotation Therapy with the 2 MeV Van Der Graaf Generator in Sheffield.

EDINBURGH CLINICAL CLUB.—At 7, Drumsheugh Gardens, 8 p.m., Dr. Alexander Joe: Poliomyelitis—Aetiology, Diagnosis, and Treatment.

LIVERPOOL MEDICAL INSTITUTION.—At Liverpool Ear, Nose, and Throat Infirmary, 3 p.m., afternoon clinical demonstration.

LONDON UNIVERSITY.—At University College Hospital Medical School, 5 p.m., special university lecture in pathology by Dr. Honor B. Fell, F.R.S.: Response of Organs in Culture to Environmental Influences.

NORTH-WESTERN TUBERCULOSIS SOCIETY.—At Clinical Theatre, Manchester Royal Infirmary, 5 p.m., Dr. L. E. Houghton: Corticotrophin in the Treatment of Pulmonary Tuberculosis.

NUFFIELD ORTHOPAEDIC CENTRE.—At Wingfield-Morris Orthopaedic Hospital, 8.30 p.m., Professor O. Scaglietti: Diagnosis and Early Treatment of Congenital Dislocation of the Hip.

ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Lieutenant-Colonel H. N. Stafford: Colonel's Practice and Procedure.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Oliver-Sharpey Lecture by Professor W. Melville Arnott: Order and Disorder in Pulmonary Function.

ROYAL EYE HOSPITAL.—5.30 p.m., Dr. T. H. Whittington: Some Aspects of Refraction Work: (4) Effects of Lenses in Relation to Prescription and Fitting of Glasses.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—At Royal Army Medical College, 7.30 p.m., laboratory meeting.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Sir Paul Mallinson: psychiatry demonstration.

SOCIETY OF CHEMICAL INDUSTRY: MICROBIOLOGY GROUP.—At Medical Society of London, 6.15 p.m., Dr. M. Lumb: Lesser Known Antibiotics.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—At Rembrandt Hotel, S.W., 7 for 7.30 p.m., dinner meeting. Sir John Charles: Counting the Cost.

Friday, March 18

BRITISH INSTITUTE OF RADIOLOGY.—5 p.m., meeting of medical members.

FACULTY OF RADIOLOGISTS.—At Royal College of Surgeons of England, 5 p.m., Radiotherapy Section Meeting. Mr. G. W. Blomfield: An Evaluation of the Clinical Results in Two Million Volt X-ray Therapy.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. F. R. Bettley.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., clinical demonstration by Dr. J. Smart: Bronchitis.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—(1) 2 p.m., Mr. R. S. Murley: Carcinoma of the Female Breast, with Especial Reference to the Evaluation of the Results of Treatment. (2) 4 p.m., Dr. R. A. J. Asher: Medical Uses of Hypnotism.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Dr. J. H. Hutchison: Some New Diseases in Paediatrics.

SOCIETY OF CHEMICAL INDUSTRY: FINE CHEMICALS GROUP.—At Westminster Medical School, 6 p.m., discussion to be introduced by Dr. A. Lawson, Dr. J. H. Wilkinson, Professor N. F. MacLagan, and Dr. I. C. Gilliland: Chemical Aspects of Thyrotoxicosis.

Saturday, March 19

BIOCHEMICAL SOCIETY.—At University College London, annual general meeting, followed by scientific papers.

CAMBRIDGE UNIVERSITY MEDICAL SCHOOL.—10.30 a.m., symposium: Cardiovascular Diseases.

ST. STEPHEN'S HOSPITAL.—At Rheumatism Unit, Fulham Road, S.W., March 19 and 20, 10 a.m., each day, concentrated week-end course in the "Rheumatic Diseases."

APPOINTMENTS

CAMERON, ALICK, M.D., Deputy Medical Officer of Health for the Urban Districts of Sevenoaks; Southborough and Tonbridge and the Rural Districts of Sevenoaks and Tonbridge; Clinical Assistant, Ophthalmic Department, Bromley Hospital.

GRIFFITH, A. H., M.B., B.S., D.P.H., Senior Medical Officer, Cardiff City Council.

LIVERPOOL REGIONAL HOSPITAL BOARD.—P. D. Kelsall, M.B., Ch.B., F.F.A.R.C.S., D.A., Consultant Anaesthetist, Southport, Ormskirk, and North Liverpool areas.

WYLLIS-WILLIAMS, DAVID, M.S., F.R.C.S., Consultant Plastic Surgeon at Nottingham and Derby.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Bisset.—On March 5, 1955, to Dr. Sheona (formerly Lament), wife of Dr. H. W. Bisset, of West Hartlepool, a brother for Christine.

Jeffs.—On February 2, 1955, at Lewisham Hospital, London, S.E., to Doris (formerly Rowland), wife of Harry G. Jeffs, M.B., B.S., a sister for Carolyn Jane—Angela Gail.

Moodie.—On March 1, 1955, to Barbara (formerly Jeffery), wife of Dr. G. Moodie, of Worksop, Notts, a daughter.

DEATHS

Anthons.—On February 22, 1955, at his home, Wilfred Mark Anthony, M.B., B.S., of Church Hill, Walthamstow, London, E.

Ashcroft.—On February 26, 1955, at 25, Oakfield Drive, Upton by Chester, Cheshire, Edward Maynard Ashcroft, M.B., Ch.B., D.P.H., late of Levenshulme, Manchester, and Heaton Moor, Stockport, aged 79.

Browne.—On February 25, 1955, at Northampton, Benjamin Sidney Browne, L.R.C.P.S.Ed., late of Alcester, Warwick, and Cleeve Hill, Glos, aged 91.

Campbell.—On February 23, 1955, at the Royal Northern Infirmary, Inverness, Ranald Douglas Campbell, D.S.O., M.B., Ch.B.

Glaister.—On February 11, 1955, at Chichester, Joseph Glaister, M.B., Ch.B.

Liang.—On November 3, 1954, at Tokyo, Japan, while on his way to the U.S.A., Pow Kan Liang, M.B., F.R.C.S.Ed.

Milton.—On February 19, 1955, in a nursing home, Cheshire, Norman Vernon Milton, M.B., Ch.B., formerly of Savile Grange, and 10, Lord Street, Halifax, Yorks, aged 67.

Nicholson.—On February 14, 1955, at 22, Balliol House, Manor Fields, Putney, London, S.W., John Archibald Nicholson, M.C., M.B., Ch.B., aged 64.

Peacock.—On February 16, 1955, in a nursing home, Frinton, Essex, William Ernest Peacock, M.D.

Simpson.—On February 2, 1955, Cecil Butler Simpson, M.R.C.S., L.R.C.P., late of Fife, Yorks, aged 81.

Spurway.—On February 11, 1955, John Spurway, M.B., C.M., of Bredon, near Tewkesbury, aged 85.

Wareham.—On February 4, 1955, in hospital, Harold Edgar Wareham, M.B., Ch.B., of 16, Merchiston Avenue, Edinburgh, aged 83.

Whitehead.—On February 10, 1955, Brian Whitehead, M.C., M.R.C.S., L.R.C.P., of Hamilton House, Downton, Salisbury, Wilts.

Widdowson.—On February 20, 1955, at Odiham, Hants, Eric Arthur Widdowson, D.S.O., M.B., Ch.B.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Side-effects of Dexamphetamine

Q.—*What are the side-effects from the use of dexamphetamine sulphate or the cumulative ill-effects from the prolonged use of this drug?*

A.—The common side-effects of dexamphetamine are restlessness, insomnia, and lack of appetite; palpitation and extrasystoles occasionally occur, as do dryness of the mouth and flatulence; a persistent rise in blood pressure is very rare. Aberrations of behaviour have occasionally been reported even after moderate doses taken by susceptible persons. An amphetamine habit may sometimes develop in unstable individuals who have come to rely on the drug to restore confidence in the same way as others resort to alcohol when they have to face a difficult situation, but there is no evidence that true drug addiction develops to it, as tolerance, craving, and the withdrawal syndrome are not associated with its use. There is no risk of cumulative ill-effects resulting from even the prolonged administration of dexamphetamine in therapeutic doses.

Premature Detumescence

Q.—*A middle-aged man, happily married, complains that during the last few years, during intercourse, detumescence of the penis tends increasingly to occur before ejaculation, and that he has to satisfy his wife's orgasm by manual stimulation of her clitoris. Intercourse has rarely been more frequent than once a month, and of late years the interval is increasing. Would a hormone such as testosterone propionate help to correct matters, and would there be any risks associated with its exhibition?*

A.—This man's condition is most probably due to psychological causes, in which case testosterone propionate would be ineffective. It might, however, be tried in doses of 50 mg. twice a week: failure of a response within two weeks would confirm the diagnosis of psychogenic impotence. There are no risks attached to its administration, but should it be effective it is advisable to continue maintenance therapy with methyl testosterone in doses of 25 mg. daily by mouth.

Cellular Therapy

Q.—*What is the Niehans system of treatment? Recently there have been several references to it in the lay press. How successful is it?*

A.—A book entitled *Die Zellulärtherapie (Cellular Therapy)* has recently been published by Dr. Paul Niehans, together with 21 other contributors, from the house of Urban and Schwarzenberg (Munich, 1954). Only a review and a publisher's note on this book have been seen by the writer, but Dr. Niehans has also published a brochure on the "Biological Treatment of Diseased Organs in Human Beings and Animals" (Schlaefli, Interlaken, 1948) which has been studied. Dr. Niehans claims that degenerating tissues regain their efficiency when fresh cells are administered. Thus heart muscle cells are injected in myocardial degeneration, thyroid, gonadal, and kidney cells in gout, and cells from hypothalamic centres in hypothalamic obesity. Two injections of ovarian cell cultures are said to have imbued a 79-year-old lady with new life. The cells are taken from healthy foetal, young, or fully developed human beings or

animals, and they are usually injected intramuscularly, though sometimes they are injected near the diseased organ. It is claimed that the cells migrate and can arrive at their place of destination, presumably the diseased organ.

It must be confessed that the evidence presented in Dr. Niehans's brochure is of the testimonial type and unconvincing. Moreover, Professor Charles Rob in a recent lecture on the preservation and transplantation of human tissues¹ stated, "If one accepts the definition that a graft is a transplant of tissue which forms a permanent living union with the host, then one must conclude that—with the certain exception of identical twins and the possible exception of the cornea—a successful homologous graft has yet to be achieved." Dr. Niehans would counter this with the statement that it is possible to graft heterologous tissues into the embryo and that it might therefore be possible to graft embryonic tissues in the adult, though Burnet's review of the subject² makes this appear unlikely. Further theoretical objections are that if human tissues are used there will be a risk of homologous serum jaundice, and whatever tissues are used the treatment is likely to be expensive. Nevertheless, Dr. Niehans's theories cannot be dismissed out of hand, for recently some striking results have been obtained by Leon Jacobson, Lorenz, and others, in the protection of mice from anaemia and leukaemia after irradiation by the injection of emulsions of spleen, bone marrow, embryonic and other tissues (Ciba Foundation Symposium on Leukaemia Research, London, 1954). It is not yet decided whether the effect is a cellular or a humoral one, or whether it would be applicable to man.

Diet in Diabetes

Q.—*Ten minutes with the literature on diabetes mellitus reveals great diversity of teaching on what is best in dieting. The wide differences between what is thought and what is done still further complicate the position. Many diet sheets and cards, sedulously carried around by our patients, and a good many pages of the well-beloved textbooks are quite impracticable. What then is the fundamental principle which should guide us in framing a diet for a diabetic? What do we hope to attain by restricting carbohydrate, and what are the fundamental considerations which should govern the prescription of a diet for a diabetic?*

A.—A raised blood sugar is the cardinal abnormality in diabetes mellitus, and restriction of the carbohydrate in the diet is the common-sense answer to this change. Complete exclusion is not required. Carbohydrate is needed to make any diet palatable, to supply calories, and to facilitate the action of any insulin that may be used. After the introduction of insulin, some workers suggested that restriction of carbohydrate was unnecessary and the use of a "free diet" was advocated, particularly in children. Such advice would seem to be founded on false principles. A diabetic can no longer produce varying amounts of insulin for himself, according to what he eats. Instead, he gives himself a fixed amount of insulin each day, and so, to maintain his blood sugar within the normal range, he requires a fixed amount of carbohydrate.

With the passage of time it has become possible to compare the progress of groups of patients on fixed and free diets, and in every case those patients whose carbohydrate has been restricted have shown fewer bouts of ketosis and less arteriosclerotic complications than those who have eaten as they pleased.

The diet in diabetes should maintain the patient's weight at a few pounds below the average for his height and age and enable him to do a full day's work, whether this be in an office or a coal mine. On no account must a diabetic

be allowed to get fat. A daily ration of carbohydrate will be fixed between 150 and 200 grammes, depending on the total calorie value of the diet required. Fat and protein will be given in quantities to supply the calories required and to make the diet appetizing.

Fat patients with glycosuria are the exception to these rules. They require a drastic reduction in their weight and they should be given a diet containing only 800 or 1,000 calories with, in each case, 100 grammes of carbohydrate.

Whatever diet is prescribed, it should be "tailored" to match the patient's palate as far as possible, or he will not take it for long. Eight ounces (230 g.) of potatoes at one meal may appal a child patient and yet be taken with relish by a dock labourer.

Vincent's Organisms in the Mouth

Q.—I have had several reports back as positive for Vincent's organisms, and the patients' symptoms have settled without any therapy. Are these examples of carriers, and, if so, should any treatment be commenced? Are these organisms pathogenic, or do they invade the damaged tissue secondarily?

A.—This question is difficult to answer without knowing what the patients' symptoms were and what lesion was present. Vincent's infection takes the form of an ulcer of either the throat or the gingival margin, and only in material from such a lesion are the organisms present in such numbers as to be confidently identifiable. It must be remembered that this identification is purely morphological (that is, by film, not culture) and it suffers from the defect of most such methods that a distinction from other closely similar micro-organisms is difficult to make without supporting evidence. There are many spirochaetes in the mouth indistinguishable from *Treponema vincenti*, and bacilli resembling Vincent's fusiform bacillus are not uncommon. In the absence of an ulcerative lesion their presence can be disregarded.

Vincent's organisms are unquestionably pathogenic: the fusiform bacillus belongs to a genus other members of which produce lesions elsewhere characterized by necrosis, some of which can be of a very serious nature. Many conditions predispose to gingivitis, and it has been suggested that a vitamin deficiency may underlie Vincent's infection, but the occurrence of the infection, sometimes in epidemic form, among perfectly healthy and well-nourished people strongly suggests that this is not a necessary factor.

Slippery Elm

Q.—Is slippery elm safe to use for the induction of labour?

A.—Slippery elm is the bark of a tree and is only 1 to 4 mm. in thickness, so that it is obtained in flat strips which are poorly shaped for insertion into the cervix. Indeed, they may take the form of rather sharp splinters. Its reputation as an abortifacient rests on its hygroscopic property: if it is inserted into the cervical canal it swells by taking in fluid and thus causes the cervix to dilate. It is this property which also makes it difficult to sterilize. Slippery elm is therefore neither convenient nor safe to use for inducing abortion and labour.

If something of this kind is required then the obvious choice is laminaria tents, which consist of sea tangle (a kind of seaweed) and which also swell when placed in contact with the moisture of the cervical canal. These are pencil shaped and the difficulty in the matter of their sterilization is overcome by the fact that they can now be purchased already sterilized, each in a sealed glass tube.

The successful use of laminaria tents necessitates a long cervix with a canal sufficiently well formed to hold them and to be stimulated by them—conditions which rarely

obtain in late pregnancy, and, if they do, which usually contraindicate induction of labour. If the cervix is "ripe" for induction other methods such as rupture of the membranes are more certain and more safe. Laminaria tents are therefore most often used, either alone or in combination with another method, to induce abortion, and it is only in some special circumstances that most obstetricians would resort to them for the purpose of inducing labour.

Static Electricity and Car Sickness

Q.—Recently I have heard it suggested that the cause of car sickness is static electricity, and that if a piece of chain earths the vehicle patients with this tendency are no longer liable to it. Can you tell me if there is any truth in this statement? I have always imagined that motion sickness was visual or inner-ear in origin.

A.—There is no evidence that static electricity in a car predisposes to motion sickness. Though the outside of the vehicle may be affected by static electricity, the inside is not.

In aviation there is often much turbulence when an aircraft is affected by static electricity, and the turbulence is enough to account for the motion sickness, the incidence of which is usually in proportion to the turbulence. Few people are airsick when the aircraft flies above the weather, though there may be much static electricity in the clear air.

The present opinion is that the main cause of motion sickness is over-stimulation of hypersensitive labyrinths, induced by slow oscillations, resulting in vagosympathetic disturbance. Vibrations affecting the eyeball also play a part.

Fertility after Prostatectomy

Q.—I recently examined microscopically a specimen of nocturnal emission from a patient who had transurethral prostatectomy six years ago, and I found many motile spermatozoa. Surely this is contrary to all expectations. Are such patients usually fertile?

A.—If the vas has not been tied seminal fluid can still reach the prostatic urethra. After full prostatectomy it enters the prostatic cavity and then usually passes back by the easiest route into the bladder, whence it is subsequently voided. After transurethral resection the prostatic urethra may still be sufficiently tubular for the fluid to be ejaculated in the ordinary way by the urethra. The chance of fertility varies inversely with the amount of prostate removed at the transurethral resection.

Books of "Any Questions?"—Copies of the second and third volumes of "Any Questions?" are available, price each 7s. 6d. (postage 6d.), from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or any bookseller. Each contains some 200 selected expert answers, and volume 3 has a cumulative index to the three published books.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: Aitology, Westcent, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 4499. TELEGRAMS: Britmedads, Westcent, London.

EXCHANGE TRANSFUSION IN HAEMOLYTIC DISEASE OF THE NEWBORN

BY
WILLIAM WALKER, M.D. AND G. A. NELIGAN, B.M., M.R.C.P.

(From the Department of Child Health, University of Durham)

PART I. TREATMENT

In the treatment of haemolytic disease of the newborn we regard it as proved that early exchange transfusion is superior to simple transfusion. The evidence in support of this was obtained in controlled trials carried out in various British centres between October, 1949, and August, 1951 (Mollison and Walker, 1952).

The Newcastle-upon-Tyne cases that formed part of these trials provide a comparison between early exchange and late simple transfusion. All infants in this centre were the result of spontaneous delivery. Those with a cord Hb level of 14.8 g. % or less were selected at random for either exchange or simple transfusion. When indicated, exchange transfusion of at least 60 ml. per lb. (132 ml. per kg.) body weight was carried out within nine hours of birth. A total of 86 children were included in the trial (Table I). In the group selected for simple transfusion this was given if the Hb level fell to 11 g. % during the first fourteen days of life. Apart from the type of transfusion given, all babies received identical care.

TABLE I.—A Controlled Trial of Exchange and Simple Transfusion in 86 Infants with Haemolytic Disease (National Investigation, Newcastle-upon-Tyne Centre, 1949–52)

	No. of Cases	No. with Kernicterus	No. of Deaths
Simple transfusion	42	9	13
Exchange "	44	0	2

Of the 42 babies treated by simple transfusion, 13 died, whereas of the 44 treated by exchange transfusion only two died. Nine of the 42 treated by simple transfusion developed kernicterus, whereas no baby in the exchange transfusion group did so. The probability of such differences being due to chance is about 1 in 1,000.

Five infants had birth weights of 5½ lb. (2.5 kg.) or less. By chance, all were treated by simple transfusion and four died with kernicterus. We have calculated the probabilities after excluding these cases. The findings are still significantly in favour of exchange transfusion, but of course to a less degree. In relation to both mortality and kernicterus P now equals 0.02–0.01.

The purpose of this communication is to describe our experience of 250 consecutive cases treated by adequate exchange transfusion between March, 1947, and March, 1954. The evaluation of the procedure depends on various factors, while its effectiveness is closely related to details of technique. Our experience will therefore

be presented in two parts—the first dealing with indications and results, and the second with technique. We are concerned essentially with the application of our collected observations to daily practice.

Principles

From the start we felt that exchange transfusion was indicated and justified only in the more severely affected cases of haemolytic disease of the newborn, and throughout have tried to confine it to infants in whom there was a real risk of death or in whom transfusion was almost certain to be required sooner or later.

It has been our practice to use partly packed "bank" blood from either sex, and all but one of our 250 adequate exchange transfusions have been performed by the umbilical route, as will be described in Part II.

We have aimed to carry out, within the first nine hours of life, an exchange of 80 ml. per lb. (176 ml. per kg.) body weight. This amount was decided upon because it is equivalent to at least two blood volumes, and Wiener and Wexler (1946) had calculated that this gave 85% exchange, while the use of 120 ml. per lb. (264 ml. per kg.) raises the degree of exchange only by a further 8%. The period of nine hours was chosen because it was one of the rules governing the national trials, and we found that it was a convenient time limit and gave good results. Sometimes, for one reason or another, it is not possible to complete the full 80 ml. per lb. (176 ml. per kg.) and we have accepted as "adequate" any transfusion resulting in the exchange of 60 ml. per lb. (132 ml. per kg.), as again this was one of the rules governing the national trials. Anything less than 60 ml. per lb. (132 ml. per kg.) has been classed as "inadequate." Obviously the nine-hour time limit can only apply to infants seen at or shortly after birth, but we have performed exchange transfusion on many infants seen later than this, and in such cases have begun treatment as early as possible. The effectiveness of exchange transfusion must depend to some extent on the volume of blood exchanged and the age at which it is carried out. We have not made a special point of trying to assess these factors, and any observations that we have made concerning them are incidental.

Material

The material on which this report is based is derived from 272 cases* selected for exchange transfusion between March, 1947, and March, 1954. In 1947 and 1948 only eight adequate exchanges were performed, while 19 were inadequate. During the next five years there have been 242 adequate transfusions and only three inadequate—two in 1949 and

*Cases from the Princess Mary Maternity Hospital, General Hospital, and Babies' Hospital, Newcastle-upon-Tyne, and the Queen Elizabeth Hospital, Gateshead, and a small number treated by us in other hospitals outside this area.

one in 1951. This is a reflection of the increasing experience with the technique and improvement in preparation and maintenance of equipment.

Premature induction has never formed part of our routine practice, but recently we have performed induction in cases in which there was a history of a previous stillbirth due to haemolytic disease and in which the father was homozygous Rh positive. Our experience of this type of case is limited to 10, so it is obviously much too early to draw conclusions from the results. Four of the resulting infants were treated by exchange transfusion and are included in this series. Any other premature infants in this series were the result of spontaneous premature labour or a pregnancy terminated prematurely for some independent obstetrical indication.

Indications For Exchange Transfusion

We have relied on certain criteria of severity to decide if treatment was required in a particular case, and in the light of experience have found it necessary to change these criteria on two occasions.

Our indications for exchange transfusion have been as follows, and they apply both for mature and for premature infants.

1. March, 1947, to September, 1949

(a) Any first affected infant showing jaundice or other clinical signs of disease within eight hours of birth. (b) Any subsequent affected infants showing clinical evidence of disease within the first twenty-four hours. These criteria were helpful, but depended on signs which could be difficult to assess and missed some cases that developed kernicterus, while perhaps 20% were treated unnecessarily.

2. October, 1949, to August, 1951

This was the period of the national trials, and the criterion used was a cord Hb value of 14.8 g.% or less. Eighty-six cases fulfilled this condition, but only 44 received exchange transfusion; the remaining 42 selected at random served as controls and received simple transfusion only for the treatment of severe anaemia.

The level of 14.8 g.% proved satisfactory in that only 4 of the 42 control cases did not require treatment. All four had levels between 13.2 and 14.8 g.%. As the other 11 cases in this range required treatment, we felt justified in retaining the criterion of 14.8 g.%, considering it advisable to allow for error in Hb determination, even if erring on the side of overtreatment. Moreover, 14.8 g.% corresponds with the lower limit of cord Hb in the majority of normal infants.

Ninety-five other infants with cord Hb values greater than 14.8 g.% were born during this period. None received early treatment. Twenty-three had cord Hb levels higher than 17.7 g.%. None died; indeed, only one required transfusion. We therefore felt it safe to leave untreated any infant with a cord Hb level greater than 17.7 g.%.

We were disturbed, however, to find that of 72 infants with cord Hb values between 14.8 and 17.7 g.%, five developed kernicterus, while 16 others eventually required transfusion for the relief of anaemia. One infant with a cord Hb level of 17.5 g.% died with kernicterus, while the Hb values in infants requiring transfusion were evenly distributed throughout this range—that is, 5 out of 20 with cord Hb values between 14.8 and 15.5 g.% and 16 out of 52 with values between 15.5 and 17.7 g.% required treatment. We therefore felt that the criterion of cord Hb alone was not satisfactory, because if the level was set high enough to include all infants at risk it would mean subjecting a large number to unnecessary treatment.

Between the levels of 14.8 and 17.7 g.% some different means of selecting cases for treatment was therefore required. It was in this respect that the cord bilirubin level promised to be of value. We had made cord bilirubin estimations on 52 infants in this range. The lowest level associated with the development of kernicterus was 2.8 mg. per 100 ml. In

fact, 13 infants had cord bilirubin levels of 2.8 mg. per 100 ml. or more, and three of these developed kernicterus, while five others required transfusions. In contrast, only 4 out of 40 infants with cord bilirubin levels of less than 2.8 mg. per 100 ml. required treatment. There were no deaths in this group and none required treatment in the first two weeks of life.

We therefore decided to adopt new criteria for exchange transfusion, and, as relatively few cases would be involved, considered that a controlled trial was not advisable: rather, we would judge their value by dealing with the prevention of kernicterus and the proportion of cases surviving without treatment.

3. September, 1951, to March, 1954

The criteria, still based on cord blood examination, were extended to include any infant with a cord Hb level of 14.8 g.% or less and any infants with cord Hb level between 14.8 and 17.7 g.% associated with a cord bilirubin level of 2.8 mg. per 100 ml. or more.

Since adopting these criteria, we have not seen a single case of kernicterus in a baby with less severe disease than they define. We cannot, of course, say accurately how many babies have been treated unnecessarily, but there has certainly been no mortality among the babies treated because of a high bilirubin level.

In this period we obtained cord blood samples suitable for both Hb and bilirubin estimation from 264 live-born infants with haemolytic disease of the newborn: 162 (61%) met the above criteria for exchange transfusion. A further seven infants were eventually transfused because of anaemia. No infant left without exchange transfusion died, and none required transfusion within the first three weeks of life. Altogether, 95 (36%) survived without any treatment at all. This corresponds closely with the expected proportion not requiring treatment. In a local series (Walker, 1950) collected between 1947 and 1949, when exchange transfusion was being used in only a minority of cases, 42% survived without treatment, while during the period of the national trials 43% survived without treatment.

Present Indications For Exchange Transfusion When Full Cord Blood Results Are Not Available

In cases in which for any reason the cord Hb or bilirubin level alone was available, this has been used as a guide in assessing the severity of disease. Nine infants with bilirubin levels higher than 2.7 mg. per 100 ml., but whose cord Hb was not known, were born at home and seen too late to be treated by exchange transfusion. Two died with kernicterus, three required simple transfusion, while the other four survived without treatment.

When neither cord Hb nor bilirubin estimations were available we have regarded the onset of clinical disease in the first eight hours of life as an indication for exchange transfusion, provided that evidence of brain damage was not already manifest when the infant was first seen.

In infants in whom neither the cord blood results nor the accurate information regarding the early clinical picture were available, Hb and bilirubin estimations on venous blood assisted in assessing the severity of the disease.

Indications For Repeated Exchange Transfusion

Unfortunately, early adequate exchange transfusion does not guarantee that kernicterus will be prevented. The known association of kernicterus and deep jaundice has consequently led to repeated exchange transfusions being recommended "in infants with severe and rapidly increasing jaundice, or if the bilirubin is more than 20 mg. per 100 ml. or likely to go that high." Using these criteria, Diamond *et al.* (1952) found it necessary to do multiple exchange transfusions in 20% of their cases.

In our experience kernicterus has occurred in only 2 out of 196 mature infants but in 3 out of 22 premature infants

treated by early adequate exchange transfusion. This disproportionate risk between mature and premature infants corresponds with our observation that after exchange transfusion 45% of premature infants developed deep jaundice; whereas only 13% of mature infants did so. We therefore feel that repeated exchange transfusion should be necessary only in a very small proportion of cases, and these mainly premature infants. The bilirubin level during the first week of life will probably prove the most satisfactory criterion for selecting cases for repeated exchange transfusion, and we have provisionally taken 25 mg. per 100 ml. as our indication.

Up to March, 1954, we had performed repeated exchange transfusion in only four infants. Three were born at labour induced surgically because of a previous history of stillbirth due to haemolytic disease of the newborn and because the father was homozygous Rh positive.

The fourth, a mature infant, was transfused with blood that, in retrospect, we thought had been overheated. The baby became deeply jaundiced and developed haemoglobinuria the day following exchange transfusion. As intense intravascular haemolysis was occurring, we decided to perform a second exchange transfusion. The response was dramatic; the bilirubin fell from 32.5 to 12.6 mg. per 100 ml. during the procedure. Haemoglobinaemia disappeared immediately and no subsequent haemoglobinuria occurred. Eighteen hours after the second exchange transfusion the bilirubin was 16 mg. per 100 ml., but fell thereafter, and jaundice had practically disappeared three days after the second transfusion.

Altogether in 1954 eight premature infants were treated by exchange transfusion, and two of these required a further exchange transfusion, whereas only 5 of 79 mature infants treated by exchange transfusion required further exchange. It should be pointed out, however, that two of these five were the result of premature induction at 35 weeks' gestation, while a third was first treated at the age of 4 days when the bilirubin level was 60 mg. per 100 ml.

Age at Time of Exchange Transfusion

It has always been our aim to start exchange transfusion within the first nine hours of life, but in 28 cases transfusion was not started until later, usually because the baby was born at home with resultant unavoidable delay. One such case, a mature baby, received an exchange transfusion of 80 ml. per lb. (176 ml. per kg.) at the age of 19 hours, but subsequently died from pulmonary haemorrhage and kernicterus. Of the 222 treated within nine hours of birth, 196 were mature* infants, and only two of these developed kernicterus.

Wallerstein (1947) recorded four deaths due to kernicterus among 27 cases treated by exchange transfusion. All four were treated later than twenty-four hours, when jaundice was already well marked.

We regard it as convenient and satisfactory to start exchange transfusion within the first nine hours of life in infants born in hospital and diagnosed by means of tests on cord blood. We have formed the strong impression that the general condition of infants with haemolytic disease improves during the first few hours of life—as might be expected from experience of the normal baby. If delivery has been difficult, or if the infant's condition is poor for reasons other than haemolytic disease, this preliminary period of acclimatization is all the more important, and oxygen therapy may be helpful. After nine hours we have observed a tendency for the general condition to deteriorate, and in particular a number of babies in good condition at birth were very ill by the time they were admitted to hospital for treatment.

On the other hand, immediate treatment may be called for, as in six cases in which we started the transfusion within the first hour of life. Each infant was desperately ill at birth, with a Hb level less than 6 g.% and signs of

*Weighing more than 5½ lb. (2.5 kg.) at birth.

heart failure. None had shown any improvement in the short interval before treatment started. Three survived, and the clinical improvement during the transfusion was most dramatic. The other three died during the transfusion, and two of these were found at necropsy to be hydropic.

Within these limits we feel that the actual time for exchange transfusion can be decided by convenience and by clinical observation of the individual baby, and prefer, as a rule, to begin treatment at about four to six hours.

Volume of Blood Exchanged

As stated previously, we have always aimed to exchange 80 ml. per lb. (176 ml. per kg.) body weight, or twice the baby's estimated blood volume. This accords with the recommendations of various workers (Wiener and Wexler, 1946; Wallerstein, 1947; Diamond *et al.*, 1952), and should result in about 85% of the baby's blood being replaced by donor blood. The blood required, except in babies weighing more than 8½ lb. (3.9 kg.), can be obtained from two bottles of partly packed "bank" blood. We have not varied the volume of blood exchanged in relation to the cell volume of infant and donor blood, as suggested by Veall and Mollison (1950); therefore, there has been a relatively greater degree of replacement in the more anaemic cases, and this seems to us to be an advantage. The application of Veall and Mollison's nomogram will, however, enable adequate exchange transfusion to be carried out with minimal quantities of blood. Wiener and Wexler (1949) suggested that in very severely affected infants as much as 1,000 ml. should be exchanged, but it seems to us that the slight increase in the completeness of exchange so achieved is offset by the risks of the longer procedure. Indeed, the same authors (1951) later suggested that an exchange of 100–150 ml. of packed red cells was adequate. It is well to remember that as the exchange transfusion progresses, so the relative effectiveness of each 10 ml. of blood exchanged diminishes. Therefore, if the infant's condition gives cause for anxiety towards the end of transfusion it may be wiser to stop, rather than to carry on in an effort to reach the target figure.

Our secondary aim in performing exchange transfusion has been to achieve a final Hb level of between 15 and 17 g.%. This reduces the possibility of further transfusion being required, but, more important, it depresses erythropoiesis and the production of cells liable to rapid haemolysis.

We have made no systematic observations on the relationship between percentage exchange and mortality, but in the period 1947–9, 20 cases selected because of early clinical disease received inadequate exchange transfusions. Seven of the 20 receiving inadequate exchange transfusions died, while 18 of the 51 treated by simple transfusion died—that is, a mortality rate of 35% in each group. Three cases of kernicterus occurred in the exchange and 11 in the simple transfusion groups. It seems, therefore, that exchange transfusion of less than 60 ml. per lb. (132 ml. per kg.) gives no better result than simple transfusion.

Davies *et al.* (1953) claimed that, in their experience, an exchange of 60 ml. per lb. (132 ml. per kg.) did not prevent kernicterus; whereas 80–100 ml. per lb. (176–220 ml. per kg.) exchange or two exchanges each of 60 ml. per lb. (132 ml. per kg.) did so.

Mortality in Cases Treated by Exchange Transfusion

Even accepting that adequate exchange transfusion is superior to simple transfusion, we still require to assess the part it may be expected to play in the management of haemolytic disease. Can exchange transfusion be recommended as a safe routine procedure? Are there special risks associated with the method itself? Are there some cases in which exchange transfusion is ineffective? If adopted as the treatment of choice for all cases likely to require treatment, what order of improvement in survival can be expected?

Although the results of many series of cases treated by exchange transfusion have been published (Hart, 1925;

Wallerstein, 1946, 1947, 1948; Wiener and Wexler, 1946, 1949; Diamond, 1947, 1948; Mollison and Cutbush, 1948; Diamond *et al.*, 1952), the answers to these questions are not readily found. The reason is that many of the series are small and highly selected, so that they do not represent the disease as a whole, nor is one series necessarily comparable with another.

Certain earlier reports cannot be accepted at their face value, because standards of diagnosis were changing as well as methods of treatment. The pitfalls of these interpretations are illustrated by Diamond (1947), who reported reduction in mortality with changes in treatment, as follows:

Period	Treatment	Mortality
Pre-1941	Simple transfusion (probably Rh positive)	40%
1942-4	(Rh negative)	30%
1944-6	Premature induction and simple transfusion (Rh negative)	20%
1947-	Premature induction and exchange transfusion (severe cases excluded)	10%

It seems possible that the reduction in overall mortality was not due solely to improvement in treatment, but could, in part, be explained by improvement in diagnosis. Before 1941, when the diagnosis was made on clinical grounds, only severe cases, mainly those presenting the clinical picture of icterus gravis, would be included. With the increasing use of serological methods of diagnosis one would expect an increasing proportion of the recognized cases to be mildly affected, with a corresponding reduction in mortality irrespective of improvements in treatment. In confirmation of this hypothesis, we found, during a survey of cases in the Northern Region for 1947-9 (Walker, 1950) that there was a mortality rate of 40% in cases diagnosed clinically as icterus gravis, but of only 15% in the group as a whole, which included cases diagnosed on serological evidence alone.

The published series vary in size from 9 to 208 cases and the mortality rate from 6 to 32%. Many are too small to allow evaluation of the results, while in most the indications for exchange transfusion are so numerous and varied that they allow considerable freedom of interpretation and consequent intrusion of personal bias.

More recently, other factors—for example, the use of female blood and the performance of multiple exchange transfusion—have been reported as bringing about a fall in mortality.

Results

The following are our results in all cases in which exchange transfusion of at least 60 ml. per lb. (132 ml. per kg.) was carried out.

In the past five years only 3 out of 245 infants selected for exchange transfusion have not received a transfusion of at least 60 ml. per lb. (132 ml. per kg.). Two were technical failures, while the third, born *in extremis*, died before the transfusion could be completed. It is known that premature infants are at greater risk than mature babies, and we think that infants born in hospitals offering special facilities stand a better chance than infants admitted from "outside"; we therefore present our results in three groups. No case has been omitted, and none has been included in more than one group.

Group I.—Premature Infants. All infants with birth weights of 5½ lb. (2.5 kg.) or less are included. As there are so few cases in this group, we have not subdivided them in relation to the means by which they were selected for exchange transfusion, nor by the age at which this was carried out.

Group II.—Mature infants born at home, or in hospitals not affording special facilities. These cases were selected for treatment usually because of the early appearance of clinical disease as already defined, or, in some more recent cases, because the cord blood specimen taken routinely from the infants of all Rh-negative mothers was found to be Coombs-positive and to have a bilirubin level of 2.8 mg. per 100 ml. or more. Many were not treated until after the age of nine hours.

Group III.—Mature infants born in hospitals affording special facilities, selected on the basis of cord Hb and bilirubin levels and treated within nine hours of birth. This group includes all the national trial cases.

In Table II we have classified deaths as due to haemolytic disease or to other causes. It is realized that when death occurs in a baby suffering from haemolytic disease of the newborn one can never be absolutely certain that this disease played no part in causing death. Post-mortem examinations were made in all fatal cases, and the cause of death recorded is that given by the pathologist.

The causes of death are shown in Tables III and IV, and brief clinical notes on these cases are included in an Appendix.

None of these infants had evidence of kernicterus at necropsy. All but the first and last cases were very ill at the time of transfusion, and in them the diagnosis eventually recorded as the cause of death was made before treatment was started.

TABLE II.—Results in 250 Cases of Haemolytic Disease of the Newborn Treated by Adequate Exchange Transfusion

Group	No. of Cases	Neonatal Deaths		Mortality Due H.D.N.	Kernicterus
		Due to H.D.N.	Other Causes		
I	22*	6	2	27%	2 died (A and WK)
II	37	4	3	11%	1 survived (Mu)

* Died at 6 months with terminal respiratory infection. At necropsy, cytomegalic inclusion bodies were found. In the absence of proof to the contrary, this death has been attributed to haemolytic disease. No abnormality of the central nervous system could be demonstrated histologically.

Severity of Disease

The severity of disease in any particular series may differ from that in another, and this will obviously influence the results. The distribution of the factors most likely to influence the results—birth weight (Fig. 1), cord Hb (Fig. 2), and sex of baby—are shown, to serve as a means of comparison with other series.

Follow-up

First Six Weeks.—All infants were kept under observation during the first six weeks, and during this period 28 out of 229 (12%) required "topping-up" transfusion because the capillary haemoglobin level fell to less than 8.5 g.%. In 10 of these the explanation was that the infants were very severely affected and therefore exchange transfusion was

completed at a negative balance. In the remainder we could find no particular reason for the development of anaemia, but none required secondary transfusion during the first three weeks of life. These findings are in contrast to those

FIG. 1.—Birth weight of 250 infants treated by exchange transfusion. Males, 128; female, 116. Weight was not recorded in three cases.

FIG. 2.—Severity of H.D.N. measured by cord Hb in 209 infants treated by exchange transfusion.

icterus, one a mature baby and one a premature infant (F and Mu) and a third was regarded as a probable case (McD.). Another infant was mentally defective, but was regarded as a primary ament, not due to haemolytic disease. The remainder were judged to be normal children.

(Since this paper was submitted the remaining 50 cases have been seen at the age of 6 months or more, and all are apparently normal.)

Later Follow-up.—Some of these infants form part of a group being followed up for a longer period, and the results will be published later.

Conclusions

Although various methods of treating haemolytic disease of the newborn have been suggested from time to time (Hardwick and Lloyd, 1941; Homburger, 1946; Kariher and Miller, 1947; Carter, 1949, 1951; Pickles, 1949), so far there is no means of preventing immunization in an Rh-negative woman, or of protecting an Rh-positive foetus against the action of antibodies, once formed. Exchange transfusion, first recommended by Hart (1925), has, however, proved of great value in treating affected infants.

Exchange transfusion is a safe routine procedure and is recommended as the treatment of choice for the 60% of liveborn affected infants requiring treatment.

In experienced hands exchange transfusion carries a very low operative risk, and this risk is practically confined to infants whose chance of survival would be very poor if treated by other means.

In our experience, premature infants have a significantly worse chance of survival than mature infants, owing mainly to the increased risk of kernicterus. Therefore, prematurity should be avoided whenever possible.

In areas where exchange transfusion is adopted as the treatment of choice for all cases likely to require treatment, a survival rate of 98% of all live-born affected infants can be expected. Confirmation of this claim is to be found from consideration of the two years 1952 and 1953 (Walker and Murray, 1954), during which 217 infants with haemolytic disease were born in the Newcastle hospitals: 15 were premature, 125 (58%) were treated by exchange transfusion, while five more (2%) required simple transfusion. Seven died, but only four of these deaths were regarded as due to haemolytic disease—a mortality rate of 2%.

We believe that cord Hb and bilirubin levels permit selection of practically all cases likely to require treatment, and consider that exchange transfusion of 80 ml. per lb. (176 ml. per kg.) body weight, carried out within nine hours of birth, is indicated in these cases.

APPENDIX: CASE SUMMARIES FOR FATAL CASES

Not Attributed to Haemolytic Disease of the Newborn

Group I

H.—B. wt. 5 lb. (2.3 kg.). Cord Hb 12.7 g.%. Cord bilirubin 3 mg. per 100 ml. Infant became ill on the fourth day and died. Mild jaundice (bilirubin 3.6 mg. per 100 ml.) at time of death. P.M.: Cerebral haemorrhage; no kernicterus.

McA.—B. wt. 3 lb. (1.4 kg.). Cord bilirubin 5.6 mg. per 100 ml. Normal respiration never established; cyanosed whenever removed from oxygen; died during exchange transfusion. P.M.: Cerebral birth injury; medullary herniation.

Group II

Th.—B. wt. 6 lb. 8 oz. (2.9 kg.). A sick child with moaning respiration, treated at 11 hours. Died at 18 hours. P.M.: Bilateral bronchopneumonia; sticky mucus in trachea; haemorrhagic exudate in pleural cavities.

T.—B. wt. 6 lb. 12 oz. (3.1 kg.). Difficult delivery with foetal distress. Died at 2 days. P.M.: Cerebral birth injury.

A.—B. wt. 8 lb. 12 oz. (4 kg.). Precipitate labour. Severe haemolytic disease and respiratory difficulty regarded as cerebral in origin. Died at 2 days. P.M.: Cerebral birth injury; large subdural haematoma.

Group III

K.—B. wt. 6 lb. 1 oz. (2.7 kg.). Cord Hb 8 g.%. Cord bilirubin 15 mg. per 100 ml. Died at 3 days. P.M.: Atelectasis; pneumonia; no evidence of kernicterus, heart failure, or haemorrhage.

P.—B. wt. 7 lb. (3.2 kg.). Cord Hb 8 g.%. Admitted with marked cyanosis and asphyxial haemorrhages. P.M.: Atelectasis.

F.—B. wt. 6 lb. 9 oz. (3 kg.). Cord Hb 16 g.%. Cord bilirubin 4.1 mg. per 100 ml. Overlaid one week after discharge aged 3 weeks.

Attributed to Haemolytic Disease of the Newborn

Group I

W1.—B. wt. 3 lb. 3 oz. (1.4 kg.). Cord Hb 4.6 g.%. Cord bilirubin 2.7 mg. per 100 ml. Twin of classical hydrops foetalis. Died during exchange transfusion. P.M.: Hydrops foetalis.

E.—B. wt. 4 lb. 10 oz. (2.1 kg.). Hb 4.8 g.%. Cord bilirubin 6.5 mg. per 100 ml. Died at end of exchange transfusion. P.M.: Hydrops foetalis.

WK.—B. wt. 5 lb. 8 oz. (2.5 kg.). Cord bilirubin 4.1 mg. per 100 ml. Died at 4 days, when bilirubin was 30 mg. per 100 ml. P.M.: Kernicterus.

A.—B. wt. 5 lb. (2.3 kg.). Cord Hb 17 g.%. Cord bilirubin 7.4 mg. per 100 ml. Died, deeply jaundiced, at 63 hours. P.M.: Kernicterus.

O'H.—B. wt. 5 lb. 3 oz. (2.4 kg.). A very ill infant that died at end of exchange transfusion. P.M.: Heart failure.

Be.—B. wt. 5 lb. (2.3 kg.). Cord Hb 11 g.%. Cord bilirubin 4.8 mg. per 100 ml. An infant the result of premature induction at 35 weeks, because of previous history of stillbirth due to haemolytic disease of the newborn. Second exchange transfusion was performed at 47 hours and the infant died suddenly during the procedure. We regard this death as caused by cardiac arrest due to hyperpotassaemia. P.M.: Nothing abnormal detected. This case is described more fully in Part II.

Group II

G.—B. wt. 7 lb. 3 oz. (3.3 kg.). Exchange transfusion at 19 hours, when deeply jaundiced. Died at 48 hours with kernicterus and massive pulmonary haemorrhage.

Do.—B. wt. 7 lb. 6 oz. (3.3 kg.). Given additional 70 ml. of blood at end of exchange transfusion. P.M.: Heart failure and dilated right heart.

D.—B. wt. 7 lb. 1 oz. (3.2 kg.). A very ill baby treated immediately after delivery. Collapsed and died during transfusion. P.M.: ? Heart failure.

Ath.—B. wt. 7 lb. 2 oz. (3.2 kg.). Very ill on admission, suddenly collapsed and died during exchange transfusion. P.M.: Heart failure.

Group III

B.—B. wt. 8 lb. (3.6 kg.). Cord Hb 5.9 g.%. Cord bilirubin 11.5 mg. per 100 ml. A very ill baby that improved dramatically during exchange transfusion but suddenly, when the transfusion was almost completed, collapsed and died. P.M.: ? Heart failure.

H.—B. wt. 7 lb. 8 oz. (3.4 kg.). Cord Hb 10.3 g.%. Cord bilirubin 1.9 mg. per 100 ml. Deteriorated towards end of exchange transfusion. Was semicomatose, with moaning respiration for 12 hours; death occurred. Had been given prophylactic vitamin K. P.M.: Haemorrhage into abdomen, pleura, pericardium, cranium; umbilical vein intact; hepatic necrosis.

Da.—B. wt. 7 lb. 4 oz. (3.3 kg.). Cord Hb 5.7 g.%. Cord bilirubin 4.9 mg. per 100 ml. Given prophylactic vitamin K. Twenty-four hours after exchange transfusion had fit, and six hours later developed pulmonary haemorrhage and died. P.M.: Haemorrhage into lungs, adrenal, kidney, and stomach; liver necrosis.

O.—Cord Hb 4.5 g.%. Bilirubin 8 mg. per 100 ml. Progressive jaundice and hepatosplenomegaly. Died aged 6 months. P.M.: Cytomegalic inclusion disease.

L.—B. wt. 8 lb. 2 oz. (3.7 kg.). Cord Hb 14 g.%. Cord bilirubin 2.9 mg. per 100 ml. Sudden death fifty minutes after exchange transfusion. P.M.: Nothing abnormal detected.

PART II. TECHNIQUE

The results of exchange transfusion in cases of haemolytic disease of the newborn, presented as Part I of this article, have convinced us that early adequate exchange transfusion is the treatment of choice for all cases in which treatment is likely to be required. The primary justification of this conviction lies in the infant's greater chance of survival, but exchange transfusion also has the very real advantage that it will avoid the necessity for frequent haemoglobin estimations and perhaps multiple transfusions.

The successful application of the principles set out in Part I depends on the performance of a series of technical procedures. In the past seven years we have attempted exchange transfusion in 272 babies, and 250 of these have been technically satisfactory. Only 3 of the 22 failures have occurred in the last five years, and this we attribute to increased experience of the procedure and improved maintenance of apparatus.

We have tried to develop a simple straightforward technique and hope that a description of the method we use and the difficulties we have encountered may be of help to others concerned with the practical management of these cases.

General Routine Governing Treatment

1. The disease is predicted antenatally by serological tests, and delivery in a hospital providing special facilities for the care of these infants is advised.
2. The umbilical cord is clamped about 15 cm. from the abdominal wall as soon as possible after delivery. Using a dry syringe and No. 1 needle, the midwife or the doctor collects 10 ml. of blood from the umbilical vein on the maternal side of the clamp. Half of the blood is transferred to a plain tube for serological tests, and half into one containing dry anticoagulant for haematological estimations.

3. If exchange transfusion is indicated, according to the criteria described in Part I, a time within the first nine hours is selected, dependent on the baby's condition.

4. Exchange transfusion is performed by the umbilical route, aiming to achieve 80-90% replacement.

5. The baby is kept in the special nursery for sick babies for a few hours; then, if well enough, he is taken to his mother in the lying-in ward.

6. Haemoglobin estimation, using skin-prick blood, is performed next day and repeated as indicated until discharge from hospital (usually on the tenth day). All babies are seen for examination and haemoglobin estimation at the age of 1 month, and a few need a further test at 6 weeks. This routine is followed in the straightforward case whether the infant has received early exchange transfusion or has been left without early treatment. If the haemoglobin level falls to less than 8.5 g.% during the first six weeks of life a simple scalp-vein transfusion is given.

Blood For Exchange Transfusion

For a baby weighing 8½ lb. (3.9 kg.) or less, two M.R.C. bottles of "bank" blood are required, usually Rh negative and of the same ABO group as the baby.

Compatibility Tests.—Blood is selected on the basis of tests in saline and serial dilutions in albumin, and by the indirect Coombs technique; ideally, both the mother's and the baby's serum are used. When the mother's serum is not available, or in an emergency, Rh-negative blood is used without performing a full compatibility test. In such circumstances we consult the record card to ensure that there is nothing unusual about the maternal antibody.

Age of Blood.—We prefer to use blood no more than three or four days old, but, on occasion, have used blood as old as 20 days without apparent ill effect. That there are advantages in using relatively fresh blood was made clear to us recently. Baby Be, a 5-lb. (2.3-kg.) premature infant with a cord haemoglobin level of 11 g.%, was treated by exchange transfusion at the age of 2½ hours. In spite of this the bilirubin rose, and at 44 hours was 24.7 mg. per 100 ml. A second exchange transfusion was carried out and a bottle of blood from the hospital bank was used. When 230 ml. exchange had been completed the baby suddenly became cyanosed, with grunting respiration, and death occurred almost immediately. At 200 ml. exchange the baby had been very well and the venous pressure 5 cm. As he had tolerated the first exchange well, and as the only unusual feature was that the blood used for the second transfusion was 15 days old, we wondered whether there might be some biochemical explanation. We found that the serum potassium level in the infant at the start of transfusion was 20.8 mg. per 100 ml. and at the time of death 57 mg. per 100 ml. The level in the transfused plasma was 65 mg. per 100 ml., and we therefore attribute this death to cardiac arrest consequent on hyperpotassaemia. This danger has been pointed out by Miller *et al.* (1952).

Hb Content of Blood.—Having been collected into acid citrate dextrose (A.C.D.), bank blood is likely to have a haemoglobin content of only about 11.5 g.%. Therefore, in order to achieve a haemoglobin level of 17 g.% at the end of the transfusion, it is necessary: (a) to give the baby considerably more blood than is withdrawn, or (b) to adjust the haemoglobin content of the transfused blood to approximately 17 g.% by removing about 200 ml. of plasma from each bottle. This latter method has been our constant practice since the very early days, because we regard overloading of the infant's circulation as a very real danger. Mollison (1951) also recommends using concentrated blood, but Diamond *et al.* (1952) advocate the use of whole blood.

On isolated occasions, when suitable bank blood has not been available, we have called donors, and have preferred to collect the blood into heparin rather than A.C.D., thus minimizing the degree of dilution.

Sex of Donor.—Allen *et al.* (1949) drew attention to the possibility that the sex of the donor might influence the

efficacy of exchange transfusion. In their series of 208 cases, 42 infants received blood from female donors, while 137 received male blood. No deaths occurred in the group treated with female blood, whereas 27 (20%) of those treated with male blood died. They claim that this is a significant difference, and state that it cannot be accounted for on the ground that blood with a high cell volume (and therefore generally from male donors) was purposely used for the most severely affected cases. However, Sacks *et al.* (1950), in their series in which the total mortality was similar to that of Allen *et al.*, found that 12.5% of cases transfused with male blood died, as against 21.8% of those treated with female blood. This suggests that the preferential use of female blood is of doubtful value. It has not been our practice to have the donor blood "sexed" before use, but we have been able to trace the sex of the donors in 158 cases. Fifty-five received male blood, 54 female blood, and 49 blood from both male and female donors. The mortality was the same in the three groups. We have taken account of the donor's sex in 12 fatal cases and in 9 very severely affected infants who survived, but could find nothing to suggest that female blood is superior to male blood. It would therefore seem unnecessary to take account of the sex of the donor when selecting blood for exchange transfusion.

Apparatus For Exchange Transfusion

The following material is required: Cord ligatures; gauze swabs; two transfusion stands; oxygen apparatus; cruciate frame; hot-water bottles; three pairs of small artery forceps; one pair of large scissors; exchange transfusion set; "polythene" catheters of two sizes, internal bore 2 mm. and 1 mm.; two short cannulae to fit tightly within catheters (S.W.G. 10 and 18 respectively); blood for transfusion; blood-collecting bottle containing acid citrate dextrose for waste.

Polythene tubing in 8-in. (20-cm.) lengths is stored in a rubber-stoppered glass tube containing 1% cetrimide and after 24 to 48 hours is sterile and ready for use. The catheter tip is cut square because a pointed catheter is more likely to perforate the vein and produce a false passage. We have found side holes a disadvantage. In 247 of our 250 cases we used a catheter with a 2-mm. bore and a 0.75-mm. wall, especially extruded for us by Messrs. De La Rue. This catheter proved satisfactory even with infants

weighing as little as 3 lb. (1.4 kg.) at birth. In two of the three remaining cases only a catheter of 1 mm. bore and 0.25 mm. wall could be passed, while the third was transfused by another route.

Transfusion Set

Many pieces of apparatus for exchange transfusion have been described. Our experience is limited to two—one described by Henderson (1950) but modified to take the larger polythene tubing, and one made for us by Messrs. Baird and Tatlock. This latter set, which we use almost exclusively, is illustrated in Fig. 3. It is very simple, and with the catheter attached the dead space is only 0.5 ml. The essential component consists of two two-way taps machined in one block with large bore throughout, and since it is very light a single operator can use it for long periods, as in the case of two immediately consecutive transfusions. The present pattern is Sima-fitting and made so that a syringe locks on to one end and a cannula on to the other. The locking device is of the pin-slot type, and this sometimes gives rise to air leaks. Therefore we have had a Luer-lock apparatus* made that is otherwise similar to that illustrated. The apparatus is completed by fitting two standard transfusion "giving sets" to the side limbs, but the one intended for waste blood is assembled without either filter or drip-chamber.

We have found "Everett" syringes absolutely satisfactory and prefer the metal-and-glass to the all-glass variety. All-glass syringes tend to stick, because any blood leaking back along the plunger is exposed to the air intermittently and dries. As a lubricant for taps and syringe silicone fluid† is used.

The ease of the operation depends on the use of a large-bore catheter, and, employing 2-mm.-bore tubing, we have not found a Tuohy adapter necessary. In most cases the same apparatus is used from start to finish without having to disconnect the syringe or wash out any part.

Sterilization.—The apparatus, apart from the catheter, is sterilized by autoclaving and is kept constantly ready for use; the syringes and cannulae in glass tubes, the set and instruments in separate "cellophane" packages.

Route of Transfusion

We normally use the umbilical vein route introduced by Diamond (1948), and, with one exception, our successful experience is limited to this route. We have found it absolutely satisfactory. Wallerstein's (1946) fears that it would be feasible only if a decision regarding transfusion were made before birth have proved unfounded. We disagree with the opinion of Field and Hawkins (1951) that many cases are seen too late for the umbilical vein to be used and that, in any case, it is dangerous because of the manipulations required and the rapid rate of transfusion.

Other routes have been recommended from time to time. The original method (Hart, 1925), also used by Wallerstein (1947, 1948), was that of saphenous or arm vein infusion, combined with the withdrawal of blood from the jugular vein or fontanelle. In our earlier cases we tried this method, but found it technically difficult, and we were able to achieve a satisfactory exchange in only one of the six cases attempted. The method also appeared to involve undue risk of bleeding from the punctured vessels.

We have practically no experience of the saphenous vein and radial artery technique originally used by Polayes and advocated by Wiener and his co-workers (1946, 1949).

No doubt anyone taking enough trouble to master a technique will in the end find it reliable, but the umbilical route, in addition to its technical simplicity, has the following very real advantages: (1) No artificial wound is made; (2) the balance between the volume of blood given and withdrawn can be maintained very accurately or varied at will; (3) venous pressure can readily be measured directly

Fig. 3.—Apparatus for exchange transfusion.

when a transparent catheter is used; and (4) no important artery is ligated, for, although Field and Hawkins (1951) claim that ligation of the radial artery does no harm, Wallerstein (1948) maintains that there is a risk of ischaemia.

Technique of Transfusion

1. The transfusion is carried out in a warm room, if possible with a temperature of 75 to 80° F. (23.9 to 26.7° C.). The blood is placed in water at 98° F. (36.7° C.) for about 15 minutes before use. The baby, wrapped in gamgee so that only the face and umbilical areas are exposed, is bandaged to the cruciate splint in such a way that no bandages cross the abdomen or chest. A hot-water bottle is placed on each side of the trunk and held in place by a blanket which also forms a hood round the head.

2. Everyone entering the room wears a mask. The operator scrubs up and puts on a sterile gown, while his assistant, usually a nurse, merely washes. She records the amounts of blood exchanged throughout the procedure and notes the time taken for each 100-ml. exchange. She attends to the baby as necessary, including the administration of oxygen if required, and changes the blood bottles when indicated.

3. The cord is swabbed with 1% cetrimide and the baby is covered with a sterile towel, in the centre of which is a small hole. The apparatus is assembled and the blood and waste bottles are suspended from the transfusion stands. By manipulating the taps, blood and A.C.D. in turn are allowed to fill the rubber tubing, thereby expelling all air, while the citrate washes out any blood from the taps.

4. The umbilical cord is divided no more than 2 cm. from the abdominal wall and the stump is brought up through the hole in the towel and packed round with sterile gauze. The vein is readily identified, as it has a larger lumen than the two arteries, which usually lie close together and, because of their thicker walls, tend to protrude from the cut surface. The vein wall is grasped with artery forceps at two points opposite to each other and the closed third forceps is used as a blunt dilator to dilate the vein to a point just beyond the skin margin. A catheter is then introduced gently about 8 to 10 cm. to a point where blood flows freely back along it. If difficulty is experienced at the junction of cord and skin, the cord is gently pulled down in the direction of the pubis and the catheter rotated backwards and forwards, when it will usually pass without difficulty.

5. A direct measurement of the venous pressure can be made by elevating the external part of the catheter and measuring the height of the blood column above the abdominal wall. The measurement can be regarded as satisfactory only if the baby is quiet and relaxed and there is free fluctuation of the blood with respiration. We regard a pressure of less than 10 cm. as normal, but Diamond *et al.* (1952) regard 6 cm. as the upper normal limit.

6. The metal cannula is now inserted into the polythene catheter, attached to the tap unit, and the transfusion begun. 10 ml. of blood is first withdrawn from the baby, and, after turning the appropriate tap, is ejected into the waste bottle. Then 10 ml. of donor blood is taken into the syringe via the other tap, and, with both taps once more in line, is slowly injected into the baby. This cycle is repeated as often as necessary to complete the transfusion, and we aim to take ten minutes for each 100 ml. exchanged. On occasions we have taken as little as six minutes for 100 ml. without apparent ill effect, but too rapid transfusion often distresses the baby. Some experienced workers recommend carrying out the exchange in 20-ml. amounts, but this increases the completeness of the replacement by barely 1%, and we feel that the smaller volume is safer.

From beginning to end the operation takes about 75 minutes, which agrees with the recommendations of Wallerstein (1947), and Diamond *et al.* (1952). It is appreciably shorter than the time recommended by Mollison (1951) and Field and Hawkins (1951).

Difficulties, especially in withdrawing blood, often occur, but can usually be overcome by altering the position of the catheter slightly. Once the best position is found, every effort should be made to keep the catheter absolutely still. Gentle traction on the cord sometimes overcomes difficulties, presumably by straightening out a kink, but we have the impression that excessive traction tends to cause vomiting. The surest way to stop the flow is to suck too hard.

Defects in the apparatus can readily be located by testing it after disconnecting from the catheter.

If desired, additional blood may be given at the end of the exchange, either by the syringe in 10-ml. amounts or by slow drip, the donor set being connected direct to the cannula for this purpose. Unless it is certain that the infant will tolerate additional blood, none should be given. If necessary, a simple transfusion given several days later will serve the same purpose with greater safety.

At the end of the operation the cord is ligated in the normal way if long enough. If not, a purse-string suture is used, or a ligature tied round the skin-covered portion of the cord and removed 24 hours later.

Technical Difficulties

Introducing the Polythene Catheter

Difficulty in inserting the catheter can usually be avoided by cutting the cord sufficiently short, so that the remaining vein is not tortuous. It is also important to be sure that the lumen has been entered, for it is easy to make false passages, either alongside the vein or between the coats of the vessel wall. If the catheter has been introduced 8 to 10 cm. and blood has failed to flow, it should be suspected that the catheter is not in the vein. If suction produces only a small amount of yellow fluid this is certain. The remedy is to cut the cord shorter, if necessary flush with the skin, and start again.

Very occasionally the umbilical vein runs an atypical course, and, if varying the line of approach does not succeed, a curved probe can be used to determine the exact path of the vein. In such circumstances the introducing cannula described by Diamond *et al.* (1952) should be of value.

On one occasion we could pass the catheter only about 5 cm. beyond the skin margin, and withdrawal of blood was very difficult. We therefore cut down on the vein above the umbilicus (as described by Pinkus, 1948) and, presumably because of the more direct approach, were able to manipulate the catheter past the obstruction.

If the cord has been tied off short or occluded near the skin margin by means of a metal clip, it should be cut off close to the skin, and no difficulty should be encountered.

In the small number of secondary exchange transfusions that we have performed we have found it satisfactory in most cases to divide the cord close to the skin margin by means of a scalpel. The vein is identified and the catheter introduced in the usual way. Where we have failed with this method we have cut down on the umbilical vein. The technique employed has been to make a transverse incision through the skin about 1 to 2 cm. above the umbilical cord. The skin is then reflected back on to the cord and an aneurysm needle passed behind the cord tissue. This is incised, the vein identified, and the catheter introduced.

Once the catheter is in position the transfusion is conducted as in any other case and technical difficulties are no more frequent.

Maintaining a Satisfactory Flow

Sometimes, even when one is confident that the catheter has been introduced correctly, blood fails to flow or flows only when the catheter is withdrawn a little. This suggests that a clot is present in the vein, and if it cannot be withdrawn through the catheter then the catheter should be carefully withdrawn while gentle suction is applied. It is usually

possible by this means to withdraw the clot, after which a straightforward exchange can be performed. Occasionally parts of the clot may be left behind and cause trouble for the first 30 to 40 ml. Clotting very rarely occurs in the apparatus, but when it does we have found it satisfactory to wash out the taps and cannula with sterile water, followed by saline, then to proceed as usual. Defects in the apparatus and sticking syringes should be rarities, avoided by scrupulous care in their maintenance and preparation. No technical difficulties were encountered in 217 of our 250 "adequate" exchange transfusions. In the remainder the difficulties were as follows: introducing the catheter, 10 cases; clotting in apparatus, 5; leaking apparatus, 4; sticking syringes, 4; maintaining the flow, 10.

General Management

Oxygen Therapy.—Oxygen is not required in the uncomplicated case, but should be available for any baby who becomes cyanosed or distressed. A plastic funnel covering the baby's face is usually satisfactory, but in very ill infants a more efficient method is required. On three occasions the whole procedure has been carried out in an "isolette" incubator, because the infants were premature, grossly anaemic at birth, and showed signs of heart failure. Recently we have used a "perspex" box which fits over the baby and cruciate frame as far down as the groins (Fig. 4).

Fig. 4.—Apparatus for oxygen therapy.

By placing two hot-water bottles in the box a temperature of 85° F. (29.4° C.) can be maintained. A concentration of 50 to 60% oxygen is achieved with a flow rate of four litres a minute, and under these conditions the carbon dioxide concentration remains less than 1%. A swinging panel is provided in one wall of the box so that any necessary attention can be given to the baby. Severely affected babies benefit from a period in oxygen both before and after the transfusion.

Use of Calcium.—Theoretically, hypocalcaemia and tetany may be induced when large amounts of blood collected into citrate are used for transfusions of this kind. Therefore many workers (Wallerstein, 1948; Wiener and Wexler, 1949; Diamond *et al.*, 1951, 1952) recommend that calcium gluconate should be given at the end of, or periodically during, every exchange transfusion. We have not investigated this problem biochemically, but clinically have not recognized any signs of tetany. We gave calcium gluconate to four babies whose condition seemed unsatisfactory without any obvious explanation, but were not convinced that it produced improvement in any case. It is possible that, in removing 200 ml. of plasma from the donor blood, we also remove the main excess of citrate, but we have on occasion used whole blood without apparent ill effect.

Use of Heparin.—We have never thought it desirable or found it necessary to use heparin as advocated by Vogel (quoted by Wallerstein, 1947) and Wiener (1946, 1947, 1949).

After-Care

In the straightforward case, the baby's management following exchange transfusion does not differ from that of the normal newborn.

Antibiotics and Chemotherapy.—The prophylactic use of penicillin and sulphadiazine in all cases was recommended by Diamond *et al.* (1951, 1952). At one time 48 hours' penicillin therapy formed part of our routine in a proportion of cases, but as we found that a high percentage of organisms in the hospital concerned were resistant to penicillin we have abandoned this practice. Infection due to exchange transfusion has never occurred in our cases so far as we know. In the occasional case in which infection appears to be a real risk due to an undue amount of manipulation we have preferred to use streptomycin or chloramphenicol prophylactically.

Vitamin K.—This is given intramuscularly at birth as a routine in all cases, and has been continued for five days in many. We feel that this continued administration is not essential. Diamond *et al.* (1952) no longer recommend the use of vitamin K.

Haematinics.—There is no rationale for giving haematinics in this disease.

Breast-Feeding.—We encourage breast-feeding unless there is some other contraindication. Among over 1,000 cases of haemolytic disease we have recognized only two cases of prolonged haemolysis due to transmission of antibody in the mother's milk.

Complications of Exchange Transfusion

Many hazards have been attributed to exchange transfusion, and some apply no matter what route is used, while others concern the use of only one particular method.

Sepsis.—This should be an extremely rare sequel, and we have indicated the steps we take to prevent it in cases exposed to more than average risk. Van Loghem and Bartels (1949) recorded four deaths from infection in their series.

Air Embolism.—Wiener and Wexler (1949) have criticized the umbilical vein route on the grounds that there is a great risk of air embolism. Pickles (1949) and Mollison (1951) also list this as a possible complication. We have never experienced this calamity and consider that the use of a transparent catheter should ensure that no air enters through its lumen. Air could enter the baby by passing up the umbilical vein alongside the catheter, but this can be prevented by tying a ligature round the cord and catheter, or by closing the vein tightly round the catheter by means of an artery forceps. Van Loghem and Bartels (1949) recorded deaths from air embolism, but they elected to use rubber rather than plastic catheters.

Thrombosis of Portal Vein.—Wiener and Wexler (1949) give this as a complication, but it has never happened in our experience.

Perforation of the Umbilical Vein.—This risk, which diminishes with the experience of the operator, is always present. Unless perforation occurs within the abdomen, no serious harm is likely to result. We have made a careful examination of the umbilical vein in all of our fatal cases, but, apart from minimal bruising, have discerned no injury.

Reaction Due to Incompatible Transfusion

Van Loghem and Bartels (1949) reported this as a cause of death in their series, and obviously the risk exists as with any transfusion. We feel that in the newborn, and particularly using exchange transfusion, the dangers are less likely to be serious than in simple transfusion of older subjects. On two occasions we unwittingly used blood which was frankly incompatible.

Case 1.—A baby was given Rh-positive instead of Rh-negative blood by mistake. He pursued an uneventful course; in particular, only mild jaundice, lasting less than one week, developed, and further transfusion was not required. We were able to

demonstrate that the transfused cells were eliminated rapidly although no free antibody was detected in the infant's cord blood.

Case 2.—This was an infant with an Rh-negative mother and an Rh-positive father, but antibodies had not been demonstrated antenatally. The routine cord-blood specimen was Coombs-positive and early jaundice occurred. Exchange transfusion was carried out, using Rh-negative blood of the same ABO group as the baby, but without full compatibility tests. It was later discovered that haemolytic disease was due to ABO incompatibility. This infant also progressed satisfactorily, and, although all transfused cells were eliminated within fourteen days, no additional transfusion was required.

Overloading of the Circulation

This is a very real danger in infants grossly anaemic at birth and one that we encountered early in our experience. A baby admitted from the domiciliary practice of the hospital had a capillary haemoglobin level of 7.3 g.% at seven hours. As his condition remained satisfactory during exchange transfusion, we decided to give an additional 70 ml. of blood slowly at the end of the exchange. The baby became deeply cyanosed and stopped breathing. The catheter was disconnected and blood poured from it, obviously under increased pressure. We allowed bleeding to continue until the pressure was normal. The baby rallied, only to die three hours later, and at necropsy signs of heart failure were found. Because of this early experience we give additional blood only to infants fit at the start and throughout the transfusion, and then never more than 30 to 40 ml. If there is the slightest doubt we do not expose the infant to this risk.

That the possibility of heart failure can never be ignored was once again made clear to us only recently. A baby was born outside and admitted with severe clinical disease. The venous pressure at the start of the transfusion was normal, but, even so, we discarded 10 ml. before carrying out the exchange. At 510 ml. out/500 ml. in, the baby was well and the venous pressure normal. We decided to replace the 10 ml. to complete the transfusion. Having done so, we disconnected the catheter, and simultaneously observed the infant to be deeply cyanosed and the venous pressure to be very high. The removal of 40 ml. of blood, artificial respiration, and the intravenous and intracardiac administration of stimulants were of no avail. The infant died, and at necropsy evidence of heart failure was found. From this we learnt two important lessons: first, 10 ml. of blood is enough to precipitate fatal heart failure, and, second, one should always carefully assess the severity of the case before undertaking treatment. The haemoglobin level at the start of exchange transfusion was only 6 g.%, but unfortunately we did not make this estimation until after the baby was dead.

Before beginning treatment we would recommend that the venous pressure be measured, and, if desired, the manometer described by Mollison (1951) may be used for this purpose. If the pressure is higher than 10 cm. more blood should be withdrawn than is given until the pressure is normal. Most infants with a cord haemoglobin level of 11 g.% (75%) or less appear to benefit by having less blood injected than is withdrawn. As a very rough guide, the negative balance should be about 10 ml. for every 10% of haemoglobin below this level. Whenever the cord haemoglobin is less than 7.4 g.% (50%) we feel that the transfusion should be carried out at a negative balance, even if the venous pressure is within normal limits.

If the venous pressure is high we aim to reduce it as early as possible by removing from the baby 20 ml. of blood and replacing it with 10 ml. This is repeated until the venous pressure is reduced to normal. We regard the high venous pressure as partly compensatory for the anaemia, and consider that the above routine, using blood with a haemoglobin content of about 17 g.%, has the advantage of raising the haemoglobin level at the same time as the venous pressure is reduced. Diamond *et al.* (1952) also use this system, which we suggest is better than the practice of removing 50 ml. of blood from similar cases before injecting any.

Reaction of the Infant to Exchange Transfusion

In about 40% of infants treated by exchange transfusion the general condition deteriorates during transfusion, and in many cases no obvious cause is evident. The risk does not appear to be related in any simple way to the baby's condition at the start, to the birth weight, to the technical difficulties encountered, or to the rate of exchange. Certainly, severely ill babies usually give cause for anxiety throughout the transfusion, but it is not uncommon for an infant with relatively mild disease and in good condition at the start to deteriorate during the transfusion. Collapse is usually due to one of two factors.

(1) **Heart Failure.**—This is usually, but not always, limited to babies grossly anaemic at the start, with a high venous pressure. The main features observed in these cases are cyanosis (readily observed in the lips, but often first noticed because the blood being withdrawn from the baby has become dark in colour), rapid shallow respiration, increased heart rate, and a high venous pressure. The baby, having been active and crying, may become limp and silent or have sighing or grunting respiration with some frothing at the mouth. Oxygen, withdrawal of blood until the venous pressure becomes normal, and slowing the rate of the procedure often result in improvement. If, in spite of this, the baby's condition deteriorates, we would suggest that the transfusion be stopped and the baby placed in an oxygen box. We have done this with benefit in eight instances, and have had no technical difficulty in restarting and completing the transfusion. The catheter is clamped and left *in situ*, and is replaced by a new one when the transfusion is recommenced; alternatively, the cord may be ligated.

(2) **Shock.**—Although some babies show some degree of shock, becoming pale and quiet, with rapid shallow respirations, this is seldom severe enough to cause great anxiety, and they usually recover with warmth and slowing of the transfusion. However, in one or two such infants we have experienced difficulty in withdrawing blood. The giving of 20 to 30 ml. of blood without any being withdrawn resulted in dramatic improvement; the procedure once again became easy and all remained well. But if there is the slightest possibility that the clinical deterioration may be due to heart failure, extra blood should not be given. It is wiser to stop the transfusion, because placing the baby in an oxygen box brings improvement, whichever the cause, and the clinical distinction may be very difficult.

We foresee that full investigation of the biochemical and other factors involved may eventually explain the deterioration in the clinical condition of some of these cases.

Conclusion

We believe that exchange transfusion forms an essential part of the treatment of babies suffering from relatively severe haemolytic disease of the newborn. In practical hands it is a safe and satisfactory procedure. Linked with laboratory prediction beforehand and skilled care afterwards, it should ensure a satisfactory outcome in the great majority of cases.

The cases with which this report is concerned have been collected from a large part of Northumberland and Durham, and but for the good will of the obstetricians, family doctors, and antenatal clinic staffs this material could not have been concentrated in one centre. The Regional Blood Transfusion Centre in Newcastle-upon-Tyne has undertaken the antenatal and cord-blood serological tests necessary for the diagnosis. It is because of the efficiency of this service that such a large proportion of cases have been diagnosed antenatally, and this has materially contributed to the results. As this report deals with cases collected over a period of eight years in the Newcastle-upon-Tyne group of hospitals, it is obviously impossible to mention by name all those to whom we are indebted for help. We would like to thank our medical and nursing colleagues in these hospitals for their continuous help.

A STUDY OF THE ACTION OF TRICYCLAMOL CHLORIDE

BY

PAMELA AYLETT, M.B., B.S., D.C.H.

Research Fellow, Guy's Hospital

AND

A. H. DOUTHWAITE, M.D., F.R.C.P.

Senior Physician, Guy's Hospital

In the search for efficient treatment of gastric and duodenal ulcer the primary object of prolonged reduction of free HCl concentration in the gastric juice has been achieved (Douthwaite and Thorne, 1954). It was postulated that the failure of single large doses of antacids was due to their rapid expulsion from the stomach, especially in cases of duodenal ulceration. Drugs which will reduce the rate of emptying should therefore prolong the antacid effect; at present this is obtainable only by the slow sucking of alkaline or buffering tablets. The difficulty of controlling nocturnal secretion might in this way be overcome.

The belladonna alkaloids and, to a far greater extent, hexamethonium (Douthwaite and Thorne, 1951) by injection, have been used for this purpose.

The object of this communication is to report our experiences with tricyclamol chloride (DL-N-methyl-3-cyclohexyl-3-hydroxy-3-phenylpropyl pyrrolidinium chloride), shown in animal experiments to have an antispasmodic and parasympatholytic action. It is an odourless crystalline substance, which is freely soluble in water. It may be given by mouth or by subcutaneous injection. The doses employed have varied from 25 to 100 mg. and are indicated in respect of each experiment.

Our object has been to test the effect on gastric and duodenal motility and tone; the influence on gastric acidity; and the effect of a single dose of antacid on the pH of the gastric juice during the action of tricyclamol.

Tricyclamol chloride

Methods

The effects of tricyclamol upon gastric and duodenal motility were observed on the x-ray screen during a barium meal and films were taken. Comparison was made with barium meals given without the drug. The influence of tricyclamol on gall-bladder emptying was shown by cholecystography with and without a dose of tricyclamol.

The effect of tricyclamol on the pH and levels of free and total acid of test-meal samples were observed and compared with control meal samples obtained without the drug. In three patients tricyclamol was given immediately after passing a Ryle tube—50 mg. intramuscularly in two cases and 50 mg. orally in one case. The meal was eaten and samples of gastric contents were taken every 15 minutes. In a fourth patient 100 mg. of tricyclamol was given orally half an hour before starting the meal.

Two of the patients also received an alkaline mixture (aluminium hydroxide gel B.P.C., 8 ml.) immediately after swallowing the meal. The stomach was not emptied of its resting contents. We wished to discover how effective tricyclamol might be in reducing the acidity of gastric contents under ordinary conditions, since, in actual treatment of peptic ulcer, drugs given to decrease acidity are used in the presence of some secretions still in the stomach. To be of value the drug should reduce acidity in the presence of previously secreted gastric juice.

Three of the four patients were given a "standard breakfast" of one boiled egg, two slices of toast, and two cupfuls of tea. Such a meal allows the response of the stomach to normal food to be measured in terms of pH and acidity, and probably represents a more usual gastric stimulus than a gruel meal. It has the disadvantage of not being directly comparable to series of test meals done in the past, when gruel was commonly used for the meal. One of these four patients received a gruel meal.

In an attempt to reduce sampling error (James and Pickering, 1949), about 30 ml. of gastric contents was aspirated at each time. After agitation of the syringe contents, about 7 ml. of the mixture was retained and the remainder returned to the stomach; 5 ml. of each sample was titrated within 24 hours of collection. (Storage at 4° C. before the estimations.) The pH was measured electrometrically. Titration to pH 3 with 0.5N NaOH solution was taken to represent the level of free acid in the samples. The level of total acid was measured by titration to pH 7.

Results

1. **Effect on Gastric and Duodenal Motility and Tone.**—Radiological observation of barium meals showed that gastric, duodenal, and small-intestinal motility and tone were considerably reduced after a dose of tricyclamol (Figs. 1 and 2 show typical appearances.) Yet in a patient with a partial gastrectomy and symptoms of the "dumping syndrome" emptying of the stomach occurred even more rapidly than usual when 50 mg. of tricyclamol was given intramuscularly before a barium meal. This was associated with extreme flaccidity of the stomach, very well seen on

FIG. 1.

FIG. 2.

FIG. 1.—Control. Four hours after barium meal. FIG. 2.—The same patient as in FIG. 1. Four hours after barium meal. Tricyclamol chloride, 25 mg., was given intramuscularly 20 minutes before the meal.

screening. In a patient in whom a cholecystogram was done the gall-bladder emptied somewhat more slowly after 50 mg. of intramuscular tricyclamol, given half an hour before a fatty meal, than in a control cholecystogram. A little dye could still be seen in the gall-bladder three hours after the fatty meal, while in control films the gall-bladder was empty two hours after the fatty meal.

2. *Influence on Gastric Acidity.*—In two patients, 50 mg. of tricyclamol given intramuscularly produced some rise in pH. This effect was short-lived and of relatively small degree. Free acid was again present after one hour in one case and after three-quarters of an hour in the other, a man with a gastro-enterostomy for many years recently complicated by a stomal ulcer. In these two cases intramuscular tricyclamol caused little change in the level of total acid, but there was a slight fall in one of the patients.

3. *Effect of Single Dose of Antacid on pH of Gastric Juice During Action of Tricyclamol.*—Two patients received tricyclamol tablets by mouth. A dose of aluminium hydroxide gel was given as soon as the meal had been eaten. One patient receiving 50 mg. of tricyclamol and 8 ml. of aluminium hydroxide gel showed a moderate rise in pH. Free acid was absent for 1½ hours and then returned in relatively low concentration. There was a smaller fall in total acidity. Another patient was given 100 mg. of tricyclamol by mouth with the additional dose of alkaline mixture. In this case there was a greater rise in pH. Free acid was absent for 2½ hours and then returned and increased in amount. There was a slight reduction in total acidity (see Fig. 3).

Uncomfortable dryness of the mouth, dilated pupils, and blurring of print on reading were noticed in most of the patients. These effects seemed more pronounced after the intramuscular than after the oral use of the drug. In one

patient who had 50 mg. of tricyclamol orally no side-effects were observed.

Discussion

Tricyclamol chloride has a marked effect in reducing the motility of the stomach and duodenum, and to a far greater extent than the results produced by hyoscyamine (Douthwaite, 1947). This action may be of value in controlling the pain of peptic ulceration, since it is likely that the pain, at least in part, is due to spasm. Certainly, in the patient with gastro-enterostomy and stomal ulcer, already mentioned, quite severe pain was relieved after repeated oral doses of 50 mg. of the drug.

Tricyclamol has been shown to have some effect in reducing the concentration of free acid in gastric contents after a meal of normal food or gruel. This might be due to diminished secretion of acid juice, or to delay in gastric emptying with a resulting larger volume of gastric contents to dilute gastric secretion, or there might be a combination of both factors.

However, the change in the level of free acid was not marked nor long-lasting when tricyclamol was given alone, and seemed too small to be of much value of itself in the treatment of peptic ulcer. There might be some additional pain-relieving effect due to the association of this factor with the much more powerful spasmolytic action of tricyclamol. Given with an alkaline mixture, tricyclamol potentiated to a certain extent the fall in the level of free acid shown to be due to alkali alone (Douthwaite, 1939). A dose of 100 mg. orally was more effective than 50 mg. Such a combination might assist the process of healing in which free hydrochloric acid is undoubtedly a deterrent factor. It is suggested that a combination of 100 mg. of tricyclamol chloride by mouth with a full dose of antacid might go some way towards overcoming the difficulty hitherto experienced in controlling nocturnal secretion in the treatment of duodenal ulcer.

Although tricyclamol decreased gastric motility, paradoxically gastric emptying became more rapid after giving the drug to a patient with partial gastrectomy. This seemed to be due to the extreme flaccidity of the stomach with greater dependence of the stoma, allowing barium to pour through at a very fast rate. Symptoms of "dumping" were not produced in this patient after taking a barium meal preceded by tricyclamol.

Side-effects sufficient to cause slight discomfort were observed in most of the patients in whom the effects of tricyclamol were studied.

Summary

A preliminary report is presented on the effects of a new parasympathetic blocking drug, tricyclamol chloride.

FIG. 3.—Graphs showing effect of tricyclamol on the acidity of the gastric contents in comparison with aluminium hydroxide gel and a control. ----, Free acid. —, Total acid.

The drug had a marked effect in reducing gastric motility and tone.

There was a smaller effect in reducing acidity of the gastric contents.

Tricyclamol prolonged the reduction of gastric acidity obtained by a dose of alkali.

We wish to thank Dr. J. D. Dow for the x-ray films, Professor W. R. Spurrell for providing facilities for the analysis of test meals, and Messrs. Burroughs Wellcome and Co. for supplies of the tricyclamol chloride used in these investigations.

EFFECTS OF VALSALVA'S MANŒUVRE ON THE NORMAL AND FAILING CIRCULATION

BY

E. P. SHARPEY-SCHAFFER, F.R.C.P.

Professor of Medicine, London University

(From the Department of Medicine, St. Thomas's Hospital, London)

The Valsalva manœuvre (Valsalva, 1707), by producing a rise in intrathoracic pressure, causes an acute decrease in the effective filling pressure of the heart, with consequent changes in the stroke output. An analysis of continuous arterial pressure tracings in the normal subject performing the Valsalva manœuvre has shown that a decrease in pulse pressure occurs when intrathoracic pressure is raised, and that this is followed by a phase of raised diastolic pressure (the "overshoot"). The latter phase has been interpreted as a baroreceptor response to the decreased pulse pressure of the former (Sharpey-Schafer, 1953).

Cases of heart failure might be expected to respond to the Valsalva manœuvre in a different manner, since a decrease in effective filling pressure produced by venesection may cause an increase in stroke output (Howarth *et al.*, 1946). Preliminary observations, using continuous arterial pressure records, indicated that this was in fact so (Sharpey-Schafer, 1952).

This paper presents the accumulated data on normal subjects and observations on cases of heart failure of varied aetiology. The results have been interpreted in terms of baroreceptor responses to acute changes in pulse pressure.

Material and Methods

Sixty-two subjects with a normal circulation and 63 cases of heart failure were studied. All the cases of heart failure were in sinus rhythm and had a jugular venous pressure raised from 2 to 25 cm. above sternal angle level: 19 were cases of hypertensive heart failure, 9 had ischaemic heart disease, 21 had disease of the mitral or aortic valves, 7 had cor pulmonale (emphysema), 3 severe anaemia, 2 severe thyrotoxicosis, and there was 1 each of the following: primary pulmonary hypertension, pulmonary embolus, haemochromatosis, and chronic myocarditis.

Continuous arterial pressure records were obtained using capacitance manometers (Hansen, 1949), which were also employed for the measurement of intrathoracic pressure

(Dornhorst and Leathart, 1952). In some observations a differential manometer system was used (Lee *et al.*, 1954), usually differentiating intra-arterial and intrathoracic pressures.

The Valsalva manœuvre was performed by blowing a mercury column to 40 mm. Hg and maintaining it at that level for about 10 seconds. This was easily accomplished by patients with heart failure, however breathless, and by quite young children for a small monetary reward. The procedure is without risk in heart failure for reasons that will become apparent. All subjects were supine with the trunk raised to 45 degrees with the horizontal.

Results

The difference in response between normal subjects and cases of heart failure was conspicuous (Figs. 1, 2, and 3).

Factors Affecting Response in the Normal Subject

When the intrathoracic pressure is suddenly raised to 40 mm. Hg this pressure is rapidly transmitted to all the arteries and to those veins without valves. The immediate supply pressure to many internal organs, such as the brain, is therefore essentially unaltered. In skin and muscle, however, the venous valves shut and initially the arteriovenous supply pressure is raised by approximately the same amount as the intrathoracic pressure. Since the blood-flow to a part depends on supply pressure and the calibre of the arterioles,

FIG. 1.—Continuous arterial record showing effect of Valsalva manœuvre in normal subject. Calibration in mm. Hg and time marker in seconds in this and subsequent records.

FIG. 2.—Hypertensive heart failure, showing effect of Valsalva manœuvre on arterial blood pressure.

the blood-flow to skin and muscle is initially increased. Thereafter the local venous pressure rises steadily at a rate which depends on previous vasomotor tone, the rise being more rapid in a hot limb than in a cold limb (Fig. 4); as the arteriovenous pressure difference falls the blood-flow to the part decreases. These effects may be seen directly in the capillaries of the nail-bed.

It has already been observed that the accumulation of blood in peripheral veins behind closed valves causes the central effective venous pressure to fall (Lee *et al.*, 1954), with a consequent decrease in stroke output and a fall in arterial mean blood pressure and pulse pressure. The rate at which mean arterial pressure and pulse pressure will decrease depends, therefore, on the initial state of vasomotor tone, being more rapid and considerable in the vasodilated subject. It was shown previously that the rate of fall increased after hyperventilation, which causes vasodilatation of muscle vessels (Howard *et al.*, 1951). The same results have since been found in vasodilatory states produced by indirect heating and by sympathetic blocking agents, and in cases of thyrotoxicosis. It has also been shown that if the rate of accumulation of venous blood in the periphery is decreased by cold or by a pressure suit, then arterial mean pressure and pulse-pressure changes are also decreased.

Under normal environmental conditions the arterial pressure begins to rise again after 5 to 10 seconds, with the onset of peripheral constriction (Sharpey-Schafer, 1953). Simultaneously, there is a decrease or stoppage of blood-flow in the capillaries of the nail-bed.

FIG. 3.—Severe hypertensive heart failure, showing increase of pulse pressure during Valsalva manoeuvre and decrease of diastolic pressure after release of the raised intrathoracic pressure.

FIG. 4.—Simultaneous venous pressure records from the ante-cubital veins of both arms of a normal subject. The upper curve is from an arm previously heated; the lower from an arm at a cool environmental temperature. The Valsalva manoeuvre is signalled by an interruption of the time marker. The venous pressure rises more rapidly in the heated limb.

The results are summarized in the "normal" part of Fig. 5, in which maximum percentage change in arterial pulse pressure during the phase of raised intrathoracic pressure is plotted against the maximum change in diastolic pressure during the "overshoot." There is a direct relationship in

FIG. 5.—Normal subjects—black circles; cases of heart failure—open circles.

$$\text{Percentage decrease of pulse pressure} = \frac{\text{Control pulse pressure} - \text{maximum change in pulse pressure during Valsalva}}{\text{Control pulse pressure}} \times 100$$

$$\text{Percentage increase of diastolic pressure} = \frac{\text{Maximum change in diastolic pressure after Valsalva} - \text{control diastolic pressure}}{\text{Control diastolic pressure}} \times 100$$

the normal subject. In each individual a series of points may be obtained on the "normal" part of the curve by altering the initial vasomotor tone by methods described above.

Response in Heart Failure

The results fall into two groups. In the first, comprising the majority of the cases, there was no measurable change in pulse pressure during the Valsalva manoeuvre, and no subsequent "overshoot"; the classical heart-rate changes occurring in normal subjects were also absent (Fig. 2). It would appear, therefore, that in most cases the failing heart is unable to change its stroke volume immediately in response to a rapid fall in filling pressure. Since the pulse pressure remains essentially unaltered, the absence of the "overshoot" is to be expected, if the theory that the latter is due in the normal subject to a decreased pulse pressure is correct. The peripheral constriction in some cases of heart failure must of course modify the response, especially over a short period; but in spite of this an appreciable fall in central venous pressure has been measured.

In the second group of cases there was an increase in pulse pressure during the Valsalva manoeuvre, and a subsequent decrease in diastolic pressure, indicating vasodilatation (Fig. 3). It is suggested that these cases, which were clinically the most severe as judged by the height of the venous pressure and course of the illness, were on the falling limb of the Starling filling pressure-output curve, and responded to a decreased filling pressure by an increased stroke output and therefore an increased pulse pressure. The vasodilatation which followed is interpreted as a baroreceptor response to the increased pulse pressure, similar to that occurring with other increased pressure transients (Sharpey-Schafer, 1953).

The results are summarized in Fig. 5. In the first group, where no pulse-pressure changes occurred, there was no change subsequently in the diastolic pressure; whereas in the second group the increased pulse pressure was followed by a fall in diastolic pressure, the reverse of the normal.

Discussion

It has been shown previously in animals (Ead *et al.*, 1952) and in man (Sharpey-Schafer, 1953) that increased pressure transients in the circulation give rise to reflex vasodilatation by a baroreceptor mechanism. The evidence reported here confirms the theory that, with nervous pathways intact, a decreased pulse pressure produces vasoconstriction and an increased pulse pressure produces vasodilatation. The theory has been shown here to apply not only to the normal but also to the failing circulation. Baroreceptor reflexes are active in heart failure provided that the necessary stimulus is applied, as is shown by the cases with increased pulse pressure and subsequent vasodilatation. The lack of baroreceptor response in those cases showing no pulse-pressure change is in accordance with this view. Further evidence of baroreceptor activity in heart failure in response to pressure changes using other stimuli will be presented elsewhere.

The cases of heart failure reported here were all cases with a raised venous pressure and sinus rhythm. Many other cases of heart disease with a normal venous pressure and patients with abnormal cardiac rhythms have also been investigated, and the results lie on the curve shown in Fig. 5; as might be expected, some are in the normal and some in the pathological part of the graph, with others intermediate in position.

Previous workers (Hamilton *et al.*, 1944; Goldberg *et al.*, 1952; Price and Conner, 1953) have recorded "square wave" patterns on arterial-pressure records in cases of mitral stenosis and occasionally other conditions during the Valsalva manoeuvre. The explanations offered have been unsatisfactory, probably because it was not recognized that all forms of heart failure show this phenomenon.

It is of interest that the majority of cases of heart failure did not respond to the acute fall in filling pressure produced during the Valsalva manoeuvre by an increased stroke volume, as did the majority of all cases of heart failure studied by the Fick method and venesection (Howarth *et al.*, 1946). The difference in duration of the two sets of observations and the heart-rate changes occurring in the latter group may be sufficient to explain the discrepancy.

Clinical Uses

The main effects of the Valsalva manoeuvre may be observed by feeling the pulse in the majority of cases. Rate changes are easily detected, but pulse-pressure changes may also be appreciated. It is usually possible to be certain that the response to the manoeuvre is normal by feeling the pulse. Occasionally a spurious "heart failure" response may arise from weak blowing, generally seen in young women who lack the competitive spirit of males and children, or from cheating, which appears to be confined to Royal Air Force personnel who have learned to apose tongue and soft palate, thereby maintaining a mercury column indefinitely without any rise in intrathoracic pressure.

The Valsalva manoeuvre may be used to elicit the presence of heart failure in difficult cases and to establish the relative innocence of certain noisy hearts. When used, however, to assess the progress of established cases of heart failure, it shows only too often that little real change has been achieved when they are discharged "compensated" from hospital.

It is also possible by auscultation during the Valsalva manoeuvre to decide whether a murmur arises on the right or left side of the heart (Zinsser and Kay, 1950). If the murmur is from the right side it will return immediately on release of the intrathoracic pressure rise; if from the left, a delay of a few beats will be observed. This physical sign is present only if the heart is responding in a normal manner. In most cases of heart failure, since there is no change in stroke output there is no differential accentuation of a murmur. The value of the sign is therefore limited.

Summary

The Valsalva manoeuvre causes an acute reduction in the effective filling pressure of the heart and has been used to study the circulation in 62 normal subjects and 63 patients with heart failure. Continuous arterial records showed conspicuous differences in the two groups.

In the normal subjects decrease in arterial-pulse pressure was followed by a rise in diastolic pressure (overshoot). In heart failure from any cause there was usually no change in pulse pressure and no overshoot. In the remaining severe cases the pulse pressure was increased and was followed by a decrease in diastolic pressure.

The results in normal subjects and in heart failure are compatible with the general theory of baroreceptor responses to acute pulse-pressure changes. Thus decrease in pulse pressure was followed by vasoconstriction, and increase in pulse pressure by vasodilatation; unchanged pulse-pressure was without effect peripherally.

The Valsalva manoeuvre appears to be the simplest repeatable method available at the moment for studying the differences between the normal and failing circulation. It can be used clinically by feeling the pulse.

VENOUS PULSE IN ATRIAL SEPTAL DEFECT: A CLINICAL SIGN

BY

JOHN REINHOLD, B.M., M.R.C.P., D.C.H.

From the Hospital for Sick Children, Great Ormond Street, and the Paediatric Unit, St. Mary's Hospital Medical School, London, W.2

The value of observing the venous pulse in the neck is widely recognized, but accurate identification of the waves by timing them against the heart sounds is less commonly practised. This need not be a difficult procedure provided there is no marked tachycardia, particularly where identification of the *a* and *v* waves is concerned, as the former immediately precedes the first heart sound and the latter occurs directly after the second heart sound. Careful observation of the venous pulse in those types of congenital heart disease that predominantly affect the right side of the heart may be of value in establishing the diagnosis. The importance of the large *a* wave in pulmonary stenosis is well recognized (Abrahams and Wood, 1951; Campbell, 1954). It is surprising, therefore, that little attention has been paid to the venous pulse in atrial septal defect. Wood (1950) mentions that it is usually normal, although the venous pressure may be raised in some instances; and Luisada

(1948) states that there may be a very high auricular wave. The purpose of this communication is to describe the pattern of the jugular phlebogram in this condition, and to emphasize that its most important characteristics may be observed by simple inspection of the neck veins.

Material and Methods

Twenty-five patients with atrial septal defect and 16 normal subjects were included in this investigation. Their ages ranged between 3 and 15 years. The diagnosis in the patients with atrial septal defect was made on the accepted clinical and radiographic criteria (Bedford *et al.*, 1941), and all showed incomplete or complete right bundle-branch block on the electrocardiogram (Barber *et al.*, 1950). The diagnosis was confirmed by cardiac catheterization in 19 patients, and in five of these operation for closure was performed and the nature and size of the defect ascertained.

Synchronous jugular phlebograms with phonocardiograms and electrocardiograms as reference tracings have been recorded from each patient. In the majority of cases recordings have been taken on an Elmquist five-channel "klinik" recorder. With this method the venous pulse was usually recorded direct from the internal jugular vein, the pulsations being transmitted to a crystal of Rochelle salt by a fine metal stylus which rests gently on the skin of the neck overlying the vein. In an occasional case the jugular bulb gave a more satisfactory tracing. It was found that certain precautions were necessary to ensure that satisfactory tracings were obtained, and these apply equally to clinical observation of the venous pulse. First, the patient was propped up to about 45 degrees from the horizontal; secondly, the sterno-mastoid was relaxed by keeping his head in the midline; and, lastly, the point of pulsation from which the recording was made was palpated to be sure that there was no superimposed carotid impulse. Tracings were taken with breathing arrested in mid-respiration.

The height of the *v* wave has proved to be of importance in this investigation, and so an attempt has been made to measure this in each individual by comparing it with the height of the *a* wave in the same complex. The height of the *a* wave has been measured from the upstroke denoting the onset of auricular systole to the peak of the wave, and the height of the *v* wave from the point of maximum systolic collapse (*x*) to the peak of the wave. It may be

argued that the *v* wave should be measured from the point of pulmonary valve closure rather than from the maximum systolic collapse, as the two do not usually coincide in patients with atrial septal defect. However, the above measurement has been adopted because the large wave observed in the neck following the second heart sound is due to the combined effect of a deep systolic collapse and the large *v* wave itself, and it is with the clinical recognition of this wave in relation to the *a* wave that this investigation is concerned.

Results

So far as could be estimated by cardiac catheterization and by other data, the septal defect was of moderate or large size in all these patients. Five patients were known to have associated pulmonary hypertension, and these are considered separately. No patient was in congestive cardiac failure when the tracings were taken. The 16 subjects with normal hearts were included to demonstrate the normal phlebogram by the methods used in this investigation and to indicate the normal ratio of the size of the *a* wave to that of the *v* wave.

Normal Subjects.—Phlebograms from three of these subjects are shown in Fig. 1. The height of the *a* and *v* waves has been compared in each individual; in six they were of equal amplitude; in three the *v* wave was larger than the *a* wave, but in none was it more than one and a half times as great; in two the *a* wave was slightly larger than the *v* wave, and in five it was up to twice as large.

Atrial Septal Defect.—The level of venous pulsation above the sternal angle was measured in each patient with the trunk at about 45 degrees to the horizontal; in all it was raised, the measurement varying between 2 and 6 cm. The characteristic pattern in those cases uncomplicated by pulmonary hypertension was of a normal *a* and *c* wave, a deep and steep systolic collapse, followed by a tall sharp-rising *v* wave (Fig. 2). In those with pulmonary hypertension proved by cardiac catheterization the size of the *a* wave was increased, and the *v* wave, although still abnormally large, was not as tall as in the uncomplicated cases.

An analysis of these waves has been made in each individual.

The *a* Wave.—This wave was normal in 17 patients and larger than normal in the five with associated pulmonary hypertension (Fig. 3). The remaining three cases showed either no *a* wave and presystolic collapse or an insignificant *a* wave.

The *c* Wave.—This was normally registered in all cases.

Systolic Collapse (*x*).—In 17 out of the 20 cases uncomplicated by pulmonary hypertension the systolic collapse was deeper and steeper than normal. This is clearly shown in Case 2 of Fig. 2.

The *v* Wave.—In all the 20 cases without pulmonary hypertension the *v* wave was taller than normal and tended to rise sharply to a peak immediately after the abnormally deep systolic collapse; following pulmonary valve closure (Fig. 2) the steepness of this ascending limb was further accentuated in many cases. The height of this wave has been compared with the *a* wave in these patients; it has been termed "normal" if it was slightly greater than, equal to, or smaller than the *a* wave; "large" if it was one and a half to three times as large as the *a* wave; and "giant" if it was more than three times as large as the *a* wave. By these criteria the *v* wave was giant in seven patients and large in thirteen. In three instances it was eight times the height of the *a* wave.

In all but one of the five patients with pulmonary hypertension the *v* wave was also larger than normal, but this change was less

marked than in the uncomplicated cases. Because the *a* wave was also of increased amplitude in these patients, the height of the *v* wave could not be profitably compared with it.

Diastolic Collapse.—The diastolic collapse was well marked in most patients. In two cases in which no *a* wave was recorded it was continuous with the presystolic collapse.

Discussion

A raised venous pressure with an abnormally large *v* wave has been shown to occur in 20 children with atrial septal defect. This wave is usually sharply defined and can be seen on inspection of the neck veins and identified from the *a* wave by its relationship to the second heart sound. Its differentiation from a large *a* wave helps to distinguish this condition from pulmonary stenosis. We have

Ratio of Height of *v* Wave to *a* Wave in Normal Subjects and in Children with Atrial Septal Defect

Ratio of <i>v</i> Wave to <i>a</i> Wave	Classification of <i>v</i> Wave	Normal Subjects	Atrial Septal Defect (Without Pulmonary Hypertension)
1 : 2	Normal	5	0
1 : <2		2	0
1.5 : 1		6	0
1.5 : 1	Large	3	0
1.5 : 1		0	13
>3 : 1		0	7
Total		16	20

found a large *a* wave in some mild and moderate cases of the latter as well as in more severe cases; and it is these lesser degrees of pulmonary stenosis that may be confused with atrial septal defect because of the occurrence of a widely split pulmonary second sound in both conditions (Leatham, 1954; Bonham-Carter *et al.*, 1954).

The finding of a large *a* wave in a patient suspected of having an atrial septal defect or the development of such a wave in a known case over the course of time suggests the presence of pulmonary hypertension.

The larger wave following the second heart sound in these patients is probably caused by two separate factors. The deep and steep systolic collapse that is often present is thought to be due to a hyperdynamic right ventricle causing an exaggerated descent of the auriculo-ventricular septum. Following maximal systolic ejection there is a rebound of this septum into the cavity of the right auricle, and the height of the sharply rising wave so produced is then accentuated following pulmonary valve closure by overfilling of the right auricle from the left auricle through the septal defect. Immediately the tricuspid valve opens at the end of the second heart sound there is a sharp fall in pressure in the auricle as blood enters the ventricle, and a steep diastolic collapse wave is produced.

FIG. 1.—Jugular phlebogram in three normal children. 2 L.I.S. = Second left intercostal space. Pcg. = Phonocardiogram. L.F. = Low frequency. M.F. = Medium frequency. H.F. = High frequency. 1 = 1st heart sound, 2 = 2nd heart sound.

FIG. 2.—Jugular phlebogram in three patients with uncomplicated atrial septal defect. X = Systolic collapse.

FIG. 3.—Jugular phlebogram in two patients with atrial septal defect and pulmonary hypertension, proved by cardiac catheterization.

The large *a* wave preceding the first heart sound in those cases complicated by pulmonary hypertension is probably caused in a similar way to that found in pulmonary stenosis (Laubry and Pezzi, 1913). As a result of peripheral pulmonary vascular resistance right ventricular hypertension occurs, and this then constitutes an obstruction to auricular systolic ejection, which in turn produces increased auricular systolic contraction and a large *a* wave in the venous pulse.

Summary

Inspection of the neck veins in children with atrial septal defect reveals a raised venous pressure and exaggeration of one of the waves of the venous pulse. Simultaneous auscultation identifies this large wave, by its time relationship to the second heart sound, as the *v* wave. When pulmonary hypertension is present in these patients the *a* wave also becomes larger than normal.

Recordings of the venous pulse in 25 patients with atrial septal defect compared with those of 16 normal children have confirmed these findings. They have also shown that there is exaggeration of normal systolic collapse in these patients, and this contributes to the prominence of the large *v* wave.

An attempt has been made to explain the haemodynamics of these changes in the venous pulse.

It is believed that the large *v* wave in atrial septal defect is a useful clinical sign, particularly in differentiating this condition from pulmonary stenosis.

I am indebted to Dr. Alexander Nadas for permission to include eight patients in this investigation who were seen at the Children's Hospital, Boston, Mass., and who have been mentioned in a previous communication (Reinhold and Nadas, 1954). I am also indebted to Dr. R. E. Bonham-Carter for his constant help and encouragement during this investigation and to Drs. J. F. Goodwin, C. H. M. Walker, M. G. Thorne, and J. P. M. Tizard for their constructive criticism of this paper. Mr. G. H. Bryant gave valuable assistance in helping to obtain the recordings.

Writing in the *Scientific American* (February, 1955) on "A Study of the Anti-scientific Attitude," Bernard and Judith Mausner (respectively a social psychologist and a physician) ask: "Can scientists draw any lessons from the anti-fluoridation outbreaks?" These writers attribute the strength of the opposition to the fluoridation of water supplies to three main factors. "Firstly, the anti-fluoridation arguments are understandable, easy to follow. Their weaknesses are often difficult for a layman to grasp. Secondly, these arguments are grounded in some of the most widely held ideas and emotions of our culture. In their appeal to respect for individual rights, to fear of poison, to a watchful conservation of public funds, they ring a bell for most people. Thirdly, they are clearly related to the *Zeitgeist*, the current suspicion of scientists, the fear of conspiracy, the tendency to perceive the world as menacing. In contrast, the proponents of fluoridation have all too often ignored public psychology in presenting their case. They have relied too heavily on the fiat of organized science, and have tended to dismiss opponents as 'crackpots' and to deride their arguments. The greatest flaw has been the failure to prepare the public adequately. As a result there develops a polarization of attitudes which makes it very difficult to change opinion."

FRACTURES OF NECK OF FEMUR INCIDENCE AND IMPLICATIONS

BY

I. M. STEWART, M.B., F.R.C.S.Ed.

Registrar, Eastern Region (Scotland) Orthopaedic Service

This investigation is concerned in assessing current and future problems in the organization of treatment for fractures of the neck of the femur.

In June, 1952, a fracture and orthopaedic unit was opened in the Royal Infirmary, Dundee, to which all fractures in the city and environs are referred. This survey has been made in the belief that the 190 cases encountered in the two years completed are the total incidence and unselected. The technical details of treatment and results have not been considered except in so far as they bear on principles involved.

The series is thought to be unselected for the following reasons: (1) The region is small and the fracture and orthopaedic service complete. Fractures are no longer treated in the general surgical wards of the teaching or other hospitals. (2) All such cases are treated in a 66-bed unit in the teaching hospital, which is associated with a 280-bed country orthopaedic hospital carrying out most of the interval orthopaedic treatment for the region. (3) No recent fracture of the neck of the femur from Dundee or the environs was treated in the country hospital. (4) No case was refused admission for any reason whatsoever. (5) The small number of nursing-home cases has been included.

Classification

Study of the age incidence shows a clearly defined distribution, as is apparent in Table I. It seemed significant that two female patients under 50 had had violent falls at work,

TABLE I.—Pattern of Incidence (Female): City of Dundee Census Area

Age (Years)	Cases, 1952-3	Cases, 1953-4
Under 50	0	0
50-54	1	1
55-59	4	1
60-64	3	3
65-69	7	3
70-74	11	13
75-79	8	10
80-84	10	8
85-89	3	7
90-	1	3
Total	48	49

while none over 50 had. In the men, however, major accidents are equally scattered over the normal life-span. The average age of the male patients is lower, as shown in Table II. The average for the female patients of 75 years is higher than in previous series (Stebbing, 1927, 69 years; Watson-Jones, 1935, 60 years; Murray and Frew, 1949, 62 years). This bears out the unselected nature of the series and, presumably, the significance of the ageing trend of population distribution. The source of the classical fractures of the upper end of the femur is thus determined by age.

TABLE II.—Average Age (190 Cases)

Sex	Fracture Type	Average Age	Cases in 2 Years
Male	Cervical	66.8	14
	Trochanteric	65.5	36
Female	Cervical	75.8	67
	Trochanteric	75.4	73

The further classification of the cases as cervical or trochanteric fractures follows the accepted anatomical and prognostic points of differentiation.

Inferences from the Survey

For the reasons stated it has been found possible not only to analyse accurately the problems in management and disposal but also to relate the cases to the known population at risk. The figures thus obtained are thought to give the first accurate estimate of the incidence of these injuries. Of the 190 cases recorded, 130 arose in the districts included in the population census for the city of Dundee in 1951. The latter alone have been considered in calculating fracture rates per 100,000 population of like age and sex. It was impossible to relate the country cases to the rural population: some patients from outlying districts go to hospitals in other regions. This group of cases has been included only in analysing management and disposal.

Finally, the fracture rates have been applied to the projected population estimates for 1965 and 1975, with a view to determining the effect of the expected change in distribution by age of the population, and this is shown in Table III. The calculation has not been presented for male cases.

TABLE III.—Total Incidence (Female)

Age Group (Years)	1952-3		1965		1975	
	Population at Risk	Annual Cases	Projected Population	Expected Cases	Projected Population	Expected Cases
50-54	6,393	1	6,300	1	6,500	1
55-59	5,494	2	6,400	3	5,400	2
60-64	4,864	3	5,900	4	5,700	4
65-69	4,191	5	5,200	6	5,400	6
70-74	3,327	12	3,900	14	4,500	16
75-79	2,416	9	2,800	10	3,400	13
80-84	1,136	9	1,700	13	2,000	16
85-	513	7	900	12	1,000	14
Totals		48		63		72

It is difficult to distinguish the classical fractures of elderly men from those due to violent accident. It is for the same reason that the annual male incidence is variable as compared with the regular, annual, and inevitable group of female cases.

Incidence

The two yearly totals of female cases did not differ; and the distribution followed such an orderly pattern that the picture does not appear to have been distorted by any gross inaccuracy (Table I). The cases from the specified

FIG. 1.—Risk of injury (females).

area, and not resulting from major trauma, have been related to the population at risk. Fracture rates per 100,000 of each age group have thus been calculated on the basis of the average annual admissions. It is clear, with the continuing trend towards a greater proportion of elderly people, that the incidence of these fractures must increase. This increase has been estimated on the Registrar-General's projected population tables. The estimate is probably conservative, as it appears that the risk of this injury increases greatly with age.

A graph showing this increasing risk is produced when the fracture rates are plotted against the age groups to which they apply (Fig. 1). Thus, not only will there be more elderly people at risk, but their average age, by being higher, will fall in an age group even more prone to these injuries. Since the incident of fracture is related to the senile state of the bone rather than to a particular mechanism, these cases must always occur. Accordingly the tendency to house ever more elderly people in institutions is in itself no safeguard. Indeed, four cases in this series came from such institutions. This is in agreement with the finding that the commonest single accident of those thus injured at home was a fall at the bedside.

The annual number of such fractures is important in planning an accident service. The cases in this series constituted 7% of the male and 20% of the female admissions.

FIG. 2.—Seasonal incidence (females).

The fuller implication of this is to be found in analysis of the actual stay in hospital. Even when 78% of cases were treated operatively the average duration of stay was a few days more than that of all the other types of cases. The female cases actually occupied 22% of the bed-days for their ward in a year.

A seasonal increase in incidence was found to be a reality, as shown in Fig. 2. The explanation of this is not clear. In two consecutive wintry weeks in which came the highest number, no patient was injured in a fall out of doors. Most probably the physical integrity of elderly people is so delicately balanced that the slightest indisposition can upset it. On the other hand, the gale of 1953 which caused so many national disasters blew over three old people in the street, thus increasing the incidence for that month by 50% in a single blast.

Implications

Certain general observations on management seemed relevant to the organization of treatment.

1. Two methods of operative treatment were used. The standard operation was the insertion of a stainless-steel Smith-Petersen nail of the King type or of a similar nail bolted to a McLaughlin plate. Standardization of procedures in this way obviates the necessity for a multiplicity of internal fixation appliances and instruments related thereto. It also familiarizes the surgical and nursing team with the method. This surgical technique had an interesting sequel in one case. The patient first had a cervical fracture nailed. One year later, while freely ambulant, she sustained a

trochanteric stress fracture. This was successfully treated by bolting a plate to the nail already in position. Only two cases were treated by other surgical means.

2. No matter how skilful or experienced the surgeon, the insertion of a nail-plate and screws requires so many separate actions that the minimum time taken is considerable. The insertion of a Smith-Petersen nail alone is delayed only by difficulties in reduction or radiography. The introduction of such advances as xeroradiography will be a matter of importance in reducing the time taken. The hours spent on fractures of the femoral neck give some index to the number of surgeons, anaesthetists, and other staff required to meet the inevitable increase in cases.

3. The patients in this series were treated by a group of surgeons with similar views favouring early operative intervention. Thereafter, immediate mobilization was encouraged by the nursing and physiotherapist staff; no weight-bearing was allowed for approximately three months, at which time walking was recommenced with crutches. Operation was performed on 78% of the patients; only one died within twenty-four hours of operation and none during it. Forty-four patients were treated otherwise. Incidental medical conditions were the contraindication on 26 occasions. The length of time since injury was a reason 15 times. Other reasons were: undisplaced trochanteric fractures, 5; grossly comminuted and technically subtrochanteric fractures, 5; refused operation, 2; suitable internal fixation material not available, 2; trochanteric fracture, opposite leg short, 1.

4. The assessment of the patient's general condition was frequently time-consuming. The 190 patients presented a total of 151 significant pathological states. No less than 58% were discovered to have one or more incidental medical conditions of such severity as to influence decisions on treatment and prognosis. In the making of these decisions much help was given by the anaesthetists and physicians, who, as the series progressed, found noticeably fewer absolute contraindications to what were often regarded as life-saving operations. It is difficult to decide at which stage a patient with chronic exudative bronchitis will fare worse from surgery than from the restrictions associated with anything short of superlative non-operative measures. Deaths from chest complications in patients known to be bronchitic were, as expected, less common after nailing than during traction. In this connexion, too, difficulty was encountered in deciding the primary cause of death in fatalities. The cause given was found to vary more with the individual house officer than with any other consistent factor. Frequently it was not easier for the senior staff to decide.

5. The patient's general condition often appeared to improve for at least the first twelve hours after admission. After that, the opportunity for surgery, if not soon taken, seemed lost. This physical reaction, whether due to stress and its subsequent exhaustion or not, was paralleled in the mental reactions.

6. It rarely seemed necessary to intervene within hours of the accident; and such routine early operating could lead too readily to a reputation for ruthlessness which might not be entirely unfounded.

7. There were on average three of these operations a fortnight, each occupying one to one and a half hours' theatre time. A considerable load could thus be placed on the night staff if emergency reduction and internal fixation were routine. This was, however, sometimes done. One session included four cases. Accordingly, 76% were carried out within 24 hours and 93% within 48 hours of admission; 70% of the patients had been admitted within 24 hours of fracture.

8. The later ward management demands attentions other than the all-important one of devoted nursing. The proportion of elderly patients, when high, has a deleterious effect on ward morale. This is due largely to the nocturnal disturbances of those disorientated by senile cerebral

ischaemia. In the series no fewer than 9% had cerebral arteriosclerosis to the point of having had a catastrophe resulting in paresis; a greater number were disorientated. This aspect of ward management has already had deserved publicity with regard to the nursing of adolescents (Stuart-Clark, 1953). The sounds associated with the inevitable deaths and the utterances of the senile arteriosclerotic demented are not for young ears. It appears, therefore, that some form of segregation is necessary. In view of the expected large total increased incidence it seems probable that the answer will be found in total segregation of the female cases in special accommodation.

9. The high percentage returned to normal is discussed under the heading of disposal of the patients. This factor alone would supply an incentive to those nursing cases of fracture of the neck of the femur which is not enjoyed in geriatric wards. Further, this branch of nursing is a specialized matter which segregation would facilitate.

Disposal

In recent years much has been said of the difficulties in discharging elderly patients from hospital. Here, considerable help was forthcoming from patients' relatives, friends, and general practitioners, as shown by the disposal of 114 patients (Table IV). Of those who went home, 16 had previously lived alone. They spent an average of 46 days in hospital, a time not greatly beyond the general average.

TABLE IV.—Disposal of 114 Patients

Discharged to own home or to relatives or friends	80.7%
Discharged to the geriatric unit	12.3%
Previously lived alone	7
Previously lived with someone	5
Previously lived in institution for elderly	1
Originally admitted from geriatric unit	1
Discharged to nursing-home, cottage or other hospital	7.0%

In this series, in which mortality was high and morbidity low, the main problem was not one of the institutional disposal of an invalid, but of the delay in gaining access to the care of a relative for rehabilitation, whether the patient lived alone or not (Ferguson and MacPhail, 1954). It was noted, however, that some aged patients progressed less well after return home, for no other apparent reason than that discharge from hospital removed the only remaining incentive to the will to live.

Results

It is appreciated that results of treatment cannot be assessed at this stage. The comment, however, seems justified that, on a short-term basis, morbidity was low.

The mortality figures at the end of the two-year period are shown in Table V. The high mortality rate for trochanteric fractures in women needs explanation. In the first instance

TABLE V.—Mortality (190 Cases). Overall Mortality = 31.6%

Sex	Fracture Type	Operative Treatment		Conservative Treatment	
		No.	Deaths	No.	Deaths
Male	Cervical	12	5	2	1
..	Trochanteric	21	7	15	3
Female	Cervical	61	16	6	3
..	Trochanteric	52	20	21	5

a high overall mortality reflects the veracity of the unselected nature of the series. The 52 operation cases presented with a total of 41 serious incidental medical conditions, whereas the 21 treated without operation presented with only six serious incidentals. The explanation for this is that the majority of the cases treated conservatively happened to be so treated for reasons not likely to affect the prognosis adversely—namely, undue time from fracture till admission, gross comminution, lack of suitable internal fixation

apparatus, or patients' refusal to avail themselves of surgery. Finally, no death occurred in this group other than among those treated conservatively because of some serious incidental condition.

Summary

The total incidence of fractures of the femoral neck during two years is analysed.

The inevitable increase in incidence, which is applicable generally, is calculated.

Additional staff and accommodation will probably be required for this contingency.

The suggested segregation of female patients is discussed.

Problems in treatment and disposal are outlined.

I am indebted to Mr. I. S. Smillie, surgeon in charge, Eastern Region (Scotland) Orthopaedic Service, for much encouragement and constructive criticism; also to the surgical and secretarial staff for all their help.

SULPHAEMOGLOBINAEMIA

A REPORT OF FIVE CASES

BY

THOMAS B. BEGG, M.B., Ch.B., F.R.F.P.S.

Formerly Ure Research Fellow in the University of Glasgow

(From the Department of Materia Medica and Therapeutics, and Stobhill General Hospital, Glasgow)

Cyanosis in warm skin, in the absence of obvious disease of the cardiovascular and respiratory systems and of polycythaemia, calls for spectroscopic examination of the blood, and in a proportion of such instances either methaemoglobin or sulphaemoglobin, or both, may be identified.

Methaemoglobin consists of oxidized haem linked to native globin, and is present in traces in normal erythrocytes, in which an enzyme system constantly reduces any methaemoglobin. This enzyme system is probably defective in congenital methaemoglobinaemia. Sulphaemoglobin, in contrast, is invariably a pathological product. Its exact chemical constitution is unknown, but it is thought that a sulphur atom has been incorporated in the pyrrole components of the haem molecule and that the mode of linkage of the haem to the globin moiety is altered. There is no intracellular mechanism for the reconversion of sulphaemoglobin to haemoglobin, nor can reconversion be effected by any known drugs. Sulphaemoglobin remains in the erythrocyte, an irreversible product of haemoglobin metabolism and a harmless though inert pigment, until the cell is destroyed, and there is no evidence that the formation or retention of sulphaemoglobin shortens the average life span of the cell. The only ill effect that can be attributed to it is anoxia, due to the immobilization of oxygen-carrying haemoglobin in the form of an inert pigment.

Both pigments are identified by the presence of an absorption band in the red part of the light spectrum—

the methaemoglobin band at 625–655 millimicrons, and the sulphaemoglobin band at 615–630 millimicrons. The absorption band of methaemoglobin is dispelled when a few drops of 5% potassium cyanide are added to the laked blood. This procedure leaves the absorption band of sulphaemoglobin unchanged, but it disappears on adding hydrogen peroxide alone.

In the human subject sulphaemoglobinaemia may follow the ingestion of compounds belonging to two groups: (1) nitrogen-containing compounds such as potassium nitrate, sodium nitrite, or nitroglycerin; and (2) aromatic amino-compounds, such as the sulphonamides or the aniline derivatives acetanilide and phenacetin.

Many cases of sulphaemoglobinaemia due to drugs have been reported in recent years, and the following five patients present few new features, but several aspects of their histories merit discussion.

Case 1

A spinster aged 70 came into hospital on October 26, 1951, complaining of feverishness and of pain in the right iliac fossa and in the back for two weeks. She was accustomed to taking saline aperients regularly, and her bowels were more constipated than usually. She had taken only a few aspirin tablets for the pain.

She was febrile, pale, ill, and not cyanosed. The fingers were clubbed. A blood count showed: Hb, 11.9 g. % (Sahli); red cells, 3,860,000 per c.mm.; P.C.V., 40%; M.C.V., 104 cubic microns; M.C.H.C., 29.75%; white cells, 9,200 per c.mm.; E.S.R., 73 mm. in one hour (Westergren). The urine showed a trace of albumin, no excess of urobilin, and no other abnormality. Clinical and radiological examination suggested a resolving pneumonia, and acute osteomyelitis of vertebrae D 12 and L 1 was diagnosed later. Both conditions resolved with antibiotics.

Aspirin was prescribed for her pain. On October 31 she was cyanosed, and spectroscopic examination of the blood showed a well-marked band in the red due to sulphaemoglobin. On December 17 sulphaemoglobin was still present in a 1 in 20 dilution of blood, examined in a 1 in. (2.5 cm.) thickness. On January 7, 1952, during chloramphenicol therapy, the patient developed loose stools from which type-specific *Bact. coli* (beta type) was grown. The diarrhoea stopped on January 16, and five days later no sulphaemoglobin was detected in a 1 in 5 dilution of blood. The patient went home on March 5.

She was readmitted in October, 1952, with gastric carcinoma. There was no cyanosis, and no sulphaemoglobin was detected.

Case 2

A widow aged 66 had suffered from a duodenal ulcer for 16 years, and was admitted on October 12, 1953, following a haematemesis. She had been subject to headaches most of her life, and had taken an occasional "askit" powder to relieve them. For a year her headache had been very severe and persistent, and her weekly consumption of powders had been two to three dozen. At night she took two compound codeine tablets. For 16 years she had regularly taken a powder thrice daily after meals, which was prescribed by her doctor to prevent her ulcer pain and to keep her bowels regular. For six to seven months she had had paraesthesiae of the hands and feet.

On admission she was slightly cyanosed. The haemoglobin was 4.2 g. % and R.B.C. 2,070,000 per c.mm. The urine showed green to Benedict's solution; no albumin or excessive urobilin. Next day sulphaemoglobin was detected in a 1 in 75 dilution of blood. Its concentration slowly declined, and on December 3 it was detectable only in 1 in 20.

A barium-meal examination on November 17 showed an ulcer deformity of the duodenal cap but no crater. The patient improved slowly, but the blood urea was constantly raised. Pyuria occurred in late October, and it was thought that renal function was impaired by chronic pyelonephritis. The patient returned home on December 29.

She was readmitted on June 9, 1954, following a further haematemesis. Her headaches had persisted but she had taken only aspirin for them, as instructed. She was not cyanosed, and no sulphaemoglobin was detected.

Case 3

A married woman aged 49 was admitted on March 18, 1954, for restabilization of diabetes mellitus, which she had had for four years. She had occasional headaches, and for six months had had paraesthesiae of the feet and legs. For about three months she had had pruritus vulvae with ulceration. For many months she had taken two or three askit powders a day, not to relieve pain but for their "tonic effect."

She was pale and not cyanosed. The haemoglobin was 9 g.%, R.B.C. 4,100,000 per c.mm., and W.B.C. 19,200 per c.mm. The blood was examined spectroscopically on account of the history of regular consumption of powders, and sulphaemoglobin was present. It was still detectable on April 6 in blood diluted 1 in 7.

Case 4

This patient, a woman aged 58, separated from her husband in 1936, had no children, and lived alone. She had a history of psoriasis in childhood, and of three "nervous breakdowns." She had recurrent varicose ulceration, and dressed the ulcers herself, but had neglected them recently. She had taken askit powders regularly for two years, usually three or four a day, but at times nine or ten. She had been accustomed to taking one for occasional headaches all her life, but in the past two years she took them not so much to relieve pain as to "buck her up" if she felt depressed. For several years her face had been puffy.

She was admitted on March 12, 1954, because of post-"influenzal" asthenia and constipation. She was cyanosed, dyspnoeic, and extremely weak, and had a puffy "moon face." The signs of congestive cardiac failure were present, and gravitational ulcers almost encircled the lower thirds of the legs. The pulse rate was 100; B.P. 120/50 mm. Hg. Crepitations were heard at the lung bases; knee- and ankle-jerks were absent. The anal sphincter was lax, and the rectum filled with scybala and a foul watery fluid. A blood count showed Hb. 6.3 g.%; red cells, 2,060,000 per c.mm.; P.C.V., 24%; M.C.V., 116 cubic microns; M.C.H.C., 26%; white cells, 11,700 per c.mm. The serum showed no sign of haemolysis. The red cells were normal in size and shape, and were slightly deficient in haemoglobin.

The sulphaemoglobin absorption band was seen in a 1 in 80 dilution of blood. The marrow was normoblastic and active. The W.R. was negative. The urine showed albumin, R.B.C., and red-cell casts; no excessive urobilin.

Penicillin injections were given and the ulcers dressed with eusol. On March 14 a bottle of packed red cells was given. Vitamin therapy was begun and an olive-oil enema and nightly liquid paraffin were ordered. The facial oedema steadily diminished. She refused further blood transfusion and resisted all attempts at venepuncture; at times she refused other therapeutic measures such as enemata, and was morose and difficult throughout her stay in hospital. On March 25 sulphaemoglobin was detected in 1 in 50; most of the decrease was attributable to dilution by the transfused blood. It was detected in 1 in 40 on April 6, 1 in 10 on April 29, and not at all on May 19.

The anaemia improved rapidly with oral iron therapy, and the ulcers healed. On April 22 the patient was allowed up. She had no spontaneous bowel movements during her rest in bed, and frequent enemata were given. The patient went home on June 5.

Case 5

A coal-miner aged 42 was referred by his doctor because of cyanosis. He had had rheumatoid arthritis for six years, but had been working regularly for the past five years despite some pain. Every fortnight for five years his doctor had prescribed 100 powders for him, containing aspirin, phenacetin, and codeine. He admitted that he took them "more as a habit than anything." For two weeks he had been taking three askit powders a day, unknown to his doctor.

He had cyanosis, with no dyspnoea even when he ran, and no cardiac or gross respiratory disease. Rheumatoid changes involved both hands, both feet, and the right elbow. Chest x-ray examination showed no abnormality, and the E.S.R. was 55 mm. in one hour (Westergren). The blood contained sulphaemoglobin.

He was sent home and instructed to avoid all tablets unless prescribed by his doctor, who was asked to avoid prescribing phenacetin.

Discussion

Acetanilide and phenacetin have often been followed by sulphaemoglobinaemia (Morgan and Anderson, 1940; Lazarus, 1945; Brandenburg and Smith, 1951), and constipation has appeared to facilitate the formation of the pigment in many cases. Finch (1948) postulated that an oxidizing drug and either constipation or a sulphur-containing medication were necessary for the production of sulphaemoglobinaemia. In the present series four patients had taken phenacetin, and two of these were constipated, and the fifth patient had been taking magnesium sulphate for constipation. *In vitro*, sulphaemoglobin is easily produced by the addition to laked blood of hydrogen sulphide and *para*-aminophenol, a possible breakdown product of phenacetin in the body (Campbell and Morgan, 1939). *In vivo*, *para*-aminophenol or a related compound may act upon red cells along with hydrogen sulphide absorbed from the bowel. Such absorption would be increased by intestinal stasis, and one might suggest that the sulphide content of the bowel is increased by sulphate medicaments, since *Bact. coli* is known to reduce sulphate to sulphide.

Brandenburg and Smith (1951) noted that a large percentage of their 62 patients with sulphaemoglobinaemia were neurotic. In the present small series neurotic tendencies were observed in all four patients who took analgesics.

The analgesic of choice with the four patients was the askit powder, which, incidentally, is manufactured locally. Its appeal is twofold: 0.55 g. (8.25 gr.) of aspirin and 0.4 g. (6 gr.) of phenacetin endow it with potent analgesic properties, and 0.11 g. (1.7 gr.) of caffeine citrate provides significant cerebral stimulation, even without the other 0.1-0.2 g. of caffeine in a cup of tea. (The corresponding quantities in the *B.P.C.* tablet are 4½ gr. (0.29 g.) of aspirin, 3½ gr. (0.23 g.) of phenacetin, and ½ gr. (32 mg.) of caffeine.) The attraction of askit to the neurotic patient is undoubtedly the stimulant effect, mild though it is. Of the 62 cases of sulphaemoglobinaemia described by Brandenburg and Smith (1951), at least 44 were due to analgesic preparations containing caffeine, and Morgan and Anderson (1940) recorded a case of habituation to a tablet containing acetanilide, phenazone, and caffeine. They also pointed out that true addiction implies physical dependence on a drug, and this has not been demonstrated in the case of antipyretics or caffeine; nor did any of the present patients develop any symptoms which could be attributed to withdrawal. Their dependence had been purely psychic, and habituation is the more correct term than addiction. However, the same type of personality is liable to become a true addict, and this danger must be recognized before one prescribes alternative treatment.

Anaemia is not a usual accompaniment of sulphaemoglobinaemia, but four of the present patients were anaemic. The cause of the hypochromic anaemia in Cases 1 and 3 was not clearly established; Case 2 had a bleeding duodenal ulcer, and Case 4 a chronic superficial infection and haemo-

dilution due to water retention caused by salicylates. In none of the cases was there any evidence of haemolysis.

Treatment followed the usual lines: the offending drug was withheld and aspirin alone was given to relieve any slight pain; constipation was relieved by enemata and liquid paraffin; severe purgatives were avoided lest hyperaemia of the intestinal mucosa facilitate absorption of hydrogen sulphide and perpetuate the sulphaemoglobinaemia. Blood transfusion was required for Case 4 because of anoxia, and appeared almost life-saving. No specific treatment is of any avail. Treatment of the concomitant diseases was not altered by the presence of sulphaemoglobin, and no sequelae attributable to sulphaemoglobin were noticed.

Summary

Five cases of sulphaemoglobinaemia are described. One case followed the administration of magnesium sulphate as an aperient and the other four cases were due to analgesic preparations containing phenacetin. The presence of caffeine in such preparations is thought to induce habituation, particularly in neurotic personalities. Anaemia was present in four of the cases, but was not attributable to sulphaemoglobinaemia. The principles of treatment are enumerated.

RISE OF SEDIMENTATION RATE AT LOW LABORATORY TEMPERATURE ITS VALUE AS A LIVER-FUNCTION TEST

BY

K. D. GUPTA, M.D.

Lecturer in Medicine, S.M.S. Medical College and Hospital, Jaipur, India

Most authors believe that a high laboratory temperature increases and a low one decreases the erythrocytic sedimentation rate (E.S.R.). Temperature, however, has been shown to exert an inconstant effect on the E.S.R., and in many cases a higher fall is recorded at a lower temperature when the test is performed simultaneously in hot and cold atmospheres (Weingarten, 1946; Buttaro and Tosti, 1946). It was also observed by Weingarten that a greater fall at lower temperature occurred in those cases which had some hepatic damage. Gupta (1954) proved that the higher fall at a lower temperature is due to a qualitative change in the euglobulin fraction of the plasma proteins. Since most of the flocculation reactions that test the liver function depend on the euglobulin fraction of the plasma proteins (Dyke, 1947), it was thought worth while to investigate if such a simple observation could be used to determine the liver damage.

Material and Method

Cases having definite liver damage were selected for investigation. These included cases of cirrhosis and cancer of the liver, infective and amoebic hepatitis, and chronic malaria and kala-azar. Most of the malaria patients had an enlarged liver, and all had an enlarged spleen and fever for more than three months.

Blood was collected in the morning, the patient having been kept fasting overnight. The E.S.R. was carried out by the Westergren method at temperatures of 99 and 44° F. (37.2 and 6.7° C.) in an incubator and a refrigerator respectively. The readings were taken every ten minutes for a

period of one hour. If the E.S.R. was found more than 10% higher at 44° F. (6.7° C.) it was adjusted to be a higher fall in the cold—that is, a positive reaction for liver damage—while a greater fall at 99° F. (37.2° C.) was regarded as a negative reaction; and if the difference between the two readings was less than 10% the reaction was regarded as indeterminate.

After having observed a fairly large number of cases a comparative study was made with a number of well-established liver-function tests as controls. The control reactions were the Takata-Ara, thymol turbidity, hippuric acid synthesis, blood proteins, and the Weltmann. The tests were performed in 17 cases of cirrhosis, 10 cases each of infective and amoebic hepatitis, 12 cases of chronic malaria, and 4 cases of cancer of the liver.

The Takata-Ara, thymol turbidity, and intravenous hippuric acid tests were performed according to the technique described by Dyke (1947), and the Weltmann test as described by Tyagi (1947). Proteins were estimated in the beginning of our series by the biuret reaction (Harrison, 1947), but later on the "lumetron" photoelectric colorimeter was substituted.

Observation and Results

The results of the cases studied by the fractional estimation of the E.S.R. in the hot and cold chambers are given in Table I and those of the comparative study in Table II.

TABLE I.—Results of E.S.R. in Hot and Cold Temperatures

	No. of Cases	Positive	Negative
Cirrhosis	71	51 (72%)	20
Infective hepatitis	12	0	12
Cancer of liver	10	7 (70%)	3
Amoebic hepatitis	14	9 (64%)	5
Kala-azar	2	2 (100%)	0
Chronic malaria	19	15 (79%)	4

TABLE II.—Percentage of Positives with Various Tests

	No. of Cases	Thymol Turbidity	Takata-Ara	Weltmann Reaction	Hippuric Acid	Blood Protein	E.S.R. Hot and Cold
Cirrhosis	17	76%	82%	76%	88%	71%	76%
Infective hepatitis	10	90%	70%	50%	0%	50%	0%
Cancer liver	4	25%	100%	100%	50%	75%	75%
Amoebic hepatitis	10	50%	50%	50%	50%	25%	60%
Chronic malaria	12	66%	75%	83%	58%	75%	58%

It will be seen that 51 out of 71 (72%) cases of cirrhosis of the liver gave a positive result. Cases which showed a negative reaction were usually of long standing, some of five years' duration; and it could be concluded that in many of them the activity of the disease had come to an end. In 10 out of 20 cases which showed a negative reaction, the E.S.R. at the end of one hour was less than 20 mm., while the remainder showed a tendency towards a declining E.S.R., indicating that the activity of the lesion was waning. The positive results with other tests varied between 70 and 84%. It is of interest to quote the observations of Ernst and Dotti (1948), who while doing the thymol turbidity test on 33 cirrhotics found positive results in 22 (67%). They concluded that the compensated cirrhotics in whom there is considerable fibrosis with abdominal ascites, but in whom the remaining liver parenchyma is functioning adequately for bodily needs, do not show a rise of thymol turbidity. When, however, the remaining cells are damaged by an infection, or by a toxin, or by anoxia, then the thymol reaction becomes positive. The only three cases of alcoholic cirrhosis met with in our series gave completely negative results. It is interesting to note that Kunkel (1948) also got similar findings with the thymol turbidity and the cephalin-cholesterol flocculation tests, and in a large percentage of cases a negative reaction was consistently obtained with the two tests.

In amoebic hepatitis and abscess a high percentage of positives was obtained. Out of five cases which showed a negative

reaction four had a well-formed abscess, and the E.S.R. in the fifth was only 10 mm. It may be possible that as abscess formation took place the localization of the disease allowed other liver cells to recover and to function normally. Other tests gave positive results in about 50% of the cases. In the hands of Gminder (1939) the Takata-Ara test gave 71.4% positive, while the serum colloidal test gave completely negative results (MacLagan, 1944). In four cases of amoebic hepatitis Wahi (1946) found 100% positive results with the hippuric acid excretion test.

A negative reaction in the presence of definite carcinoma of the liver remains unexplained. In the present series 2 cases out of 10 showed a negative reaction, and in a third it was indeterminate. Ernst and Dotti (1948) also observed that in several cases of carcinoma of the stomach with extensive metastasis in the liver the thymol turbidity was not raised. He also found that primary carcinoma of the liver very often gave negative results. The thymol turbidity and colloidal gold tests gave positive results in 40% (Ernst and Dotti, 1948) and 12.5% (Cates, 1941) cases respectively.

The cases of infective hepatitis showed a general slowing of the E.S.R. This is in accord with the reports of Miles (1945) and Boveri *et al.* (1947). The one-hour reading never exceeded 20 mm. in any of them. Sedimentation in the cold chamber was, however, still lower in all; so that all the patients gave a negative reaction. The general slowing of the E.S.R. was assumed to be due to the presence of bile salts. Damodaran (1948) found that in infective hepatitis concentration of the bile salts in the blood may reach 1 in 500. According to our investigations with the same concentration of bile salts *in vitro*, the E.S.R. came to a standstill. The presence of bile salts therefore considerably handicapped the evaluation of the effect of temperature on the E.S.R. Positive results from 66% (Watson *et al.*, 1945) to 99% (Wahi, 1946) have been reported with the thymol turbidity test. Serum colloidal gives 93% positives (MacLagan, 1944), while the Takata-Ara test gives 84% positives (Wahi, 1946).

From time to time workers have reported dysfunction of liver in malaria. As reported by Carter and MacLagan (1946), the thymol turbidity test gave positive results in 80% of the cases and serum colloidal gold in 94% of them. The E.S.R. was positive in 79% of the cases of malaria and in 100% of the cases of kala-azar.

Discussion

It is seen that the percentage of positives with individual tests differs in different diseases. Tests like hippuric acid synthesis, and plasma proteins, depend on the actively functioning liver tissue, and would be positive only if a sufficient amount of the liver tissue was destroyed. Other tests which appear to depend on the quantitative and qualitative variations of globulin fraction would give a negative reaction so long as the abnormal fraction is absent or present in only small amounts.

The common flocculation tests depend on the euglobulin fraction of the plasma proteins (Dyke, 1947). A closer link between the Takata-Ara test and the higher fall of E.S.R. in the cold chamber becomes evident from the observations of Baur (1948). He observed that in many cases of parenchymal disease of the liver verified at necropsy the Takata-Ara reaction was occasionally negative when done at room temperature, but became positive when done in a refrigerator. Furthermore, in cases of hepatic damage the cold Takata-Ara reaction becomes positive sooner and remains so longer than if the test is done at room temperature.

The flocculation in the Takata-Ara test is originated by mercuric chloride and sodium carbonate, and this flocculation is enhanced when exposed to refrigerator temperature, an observation very much akin to the present one, in which rouleaux formation is influenced favourably by low temperature.

It could be said that a higher fall of the E.S.R. at low laboratory temperature will in the large majority of cases indicate liver damage. The uniformly negative results in

infective hepatitis, however, cannot be adequately explained, and this is a drawback of the procedure. The general slowing of the E.S.R. in these cases was proved to depend on bile salts, yet all the cases showed a higher fall in the hot atmosphere—that is, a negative reaction.

The basis of the test is the euglobulin fraction of the plasma proteins (Gupta, 1955). The decrease of albumin and fibrinogen and the rise of euglobulin appear to be characteristic of failing liver function. It would be supposed that the diseased liver cells would not be capable of producing a special protein fraction in more than the normal quantities, and it is justifiable to assume that the euglobulin arises from extrahepatic sources, possibly the reticulo-endothelial system.

Summary

The general consensus of opinion is that the sedimentation rate of red cells increases with the increase of laboratory temperature, and vice versa. In a particular group of cases the E.S.R. is higher in a cold than in a warm temperature and (1) the accelerated E.S.R. in the cold is indicative of parenchymal liver damage; (2) the results are comparable with those obtained with other flocculation tests in general use except that the cases of infective hepatitis gave uniformly negative results; and (3) the reaction is an elaboration of a test already in universal clinical use and can be easily performed without any additional equipment: it also does not require any experience with more complicated methods, which remain the preserve of the clinical pathologist.

My thanks are due to Dr. R. J. Weingarten for his encouragement and guidance throughout the work.

The Institute of Psychiatry of the University of London, located at Maudsley Hospital, is the only university school in Britain devoted wholly to postgraduate education in psychiatry. The report from mid-1953 to mid-1954 states that the number of postgraduate students, including registrars, who received training during the year was 230, not including case workers who have spent varying periods in one or other of the departments. Students from abroad came from 25 countries. Rather more than two years ago the Guy's-Maudsley neurosurgical research unit was opened, and this has extended the clinical facilities of the Institute for teaching and research, and a number of collaborative investigations are in progress. The wider experience of temporal lobectomy for the relief of epilepsy has provided much more material than has been available hitherto, and studies to elucidate the relationship between the site of epileptic foci, the site and nature of associated lesions, the seizures, and the psychological changes have been started. In the teaching carried on at the Institute, although systematic instruction has to be given, particularly to those preparing for the D.P.M., the emphasis is on free discussion, related to reading and clinical experience.

LOW BACK PAIN TREATED BY MANIPULATION

A CONTROLLED SERIES

BY

ANTHONY B. COYER, M.B., B.S., D.Phys.Med.
Senior Registrar, Physical Medicine Department

AND

IAN H. M. CURWEN, M.B., Ch.B., D.Phys.Med.
Assistant, Physical Medicine Department
St. Thomas's Hospital, London

The patient suffering from low back pain provides one of the commonest problems encountered by the general practitioner. Working hours lost through this form of disability must add up to a vast total. The possible causes of backache are legion, and accurate diagnosis may be difficult. In 1951 the Mayo Clinic reported a series of 2,000 cases in which the cause of chronic back pain was investigated, and in 20% no definite diagnosis was reached.

Patients complaining of acute low back pain, however, form a definite clinical group. The onset is often related to strain or trauma. The lesion in such cases must be in the region of the intervertebral joints and adjacent structures. Various controversial opinions are held concerning the exact nature of these lesions and are expressed in such terminology as fibrositis, muscle strain, sacro-iliac strain, slipped disk, etc.

Manipulation as a method of treatment for such cases has been recommended by a few clinicians but condemned by the majority, although it is regularly practised, with apparent satisfaction to the patients, by the medically unqualified manipulator. To the best of our knowledge, no attempt has been made to compile a controlled series to settle the dispute. In this preliminary report we have not entered the controversy on diagnosis; we have simply sought to establish whether or not manipulation has a place in the treatment of recent low backache. Certain established concepts of the causation of low back pain are, however, worthy of mention, as their consideration has led to the form of this investigation.

The normal spine, with its series of interlocking bony units and intervertebral disks, is a resilient structure. The adoption of the upright posture and resultant curvatures provide areas where stress and strain are maximal. Boyle (1954) showed that spondylosis in the dorsal and lumbar spine most commonly affected the joints between the seventh and eighth dorsal and the third and fifth lumbar intervertebral bodies. Degenerative disk changes are common in these areas and begin early in life, leading to fibrosis, desiccation, fissuring, and possible protrusion of the cartilaginous or pulpy portions of the disk. Cyriax (1945) has postulated that minor protrusions bulging the posterior longitudinal ligament, not severe enough to cause nerve-root pressure and sciatica, can cause pain; and that this latter is due to pressure on the adjacent dura mater. Though derangement of the intervertebral joints is undoubtedly responsible for much acute lumbar pain, it is obvious that the pendulum has swung too far and diagnosis of a "disk lesion" is apt to be made too readily. Tears of adjacent muscles and ligaments may occur, or avulsion fractures of transverse and spinous processes. Spondylolisthesis, the presence of transitional vertebrae, and other minor

congenital abnormalities may predispose to stress and strain injuries of the lower lumbar spine by altering local mechanics. Willis (1929) found the fifth lumbar vertebra partially sacralized in 4.7% and completely sacralized in 1.5% of 1,500 skeletons. Partial lumbarization of the first sacral vertebra in 1.2% and complete lumbarization in 4.1% of the same series were discovered.

Crisp (1952) stressed the possibility of injury to apophyseal joints and nipping of synovial fringes as a cause of acute lumbar pain which is amenable to dramatic relief by manipulation.

Whenever manipulation is considered one must always be aware of the rarer and more serious causes of low back pain. These must be excluded by careful clinical and radiological examination. Such causes include osteomyelitis, tuberculous caries, ankylosing spondylitis: fractures, vertebral collapse, and other sequelae of trauma, osteoporosis, or neoplasm: Paget's disease, intraspinal lesions, and pain referred from pelvic structures. These conditions are, of course, absolute contraindications to treatment by manipulation.

Method

It was decided to divide into two groups, without selection, all patients presenting with recent low back pain. One group was treated by manipulation of the lumbar spine, without anaesthesia, according to the methods described by Cyriax (1950). The other group was treated by bed rest, the use of a lumbar pillow, and analgesics. All patients were advised on the posture to be maintained while standing and sitting, and told to avoid spinal flexion and especially bending and lifting. It was of course essential that there should be no contraindication to manipulation in any of these cases, as determined by full clinical and radiological investigation. Any patient complaining of pain radiating below the buttock, or with neurological signs such as diminished reflexes in the lower limbs, muscle weakness, or paraesthesiae, was rejected for the purpose of the present investigation. A detailed history, based on a carefully considered plan, was taken in every case and a full clinical examination made by one of us. The lumbar spine and pelvis were x-rayed in all cases. The information was transferred to a series of punch cards, facilitating the future assessment of each case. Each patient was seen at weekly or shorter intervals for assessment of signs and symptoms indicating improvement or deterioration. The basic features noted in the history and examination were as follows.

(1) Sex. (2) Age group. (3) Number of previous attacks of pain. (4) Site of pain, whether bilateral or unilateral. (5) Radiation of pain. (6) Whether aggravated by coughing or sneezing. (7) Whether pain is experienced on rising from bed. (8) Whether cramps are present. (9) Whether a soft or sagging bed is used. (10) Whether employment is significant (strain). (11) Whether there is a history of associated trauma. (12) Whether improving spontaneously. (13) Whether any leg shortening ($\frac{1}{2}$ in. (1.3 cm.) or more). (14) Lumbar lordosis. (15) Lumbar kyphosis. (16) Scoliosis—adolescent; scoliosis—relevant. (17) Other deformities. (18) Hip-joints. (19) Back flexion restricted. (20) Back extension restricted. (21) Back lateral flexion restricted. (22) Back rotation restricted. (23) Straight-leg raising restricted. (24) Any abnormality of knee-jerks, ankle-jerks, or plantar reflexes. (25) Any muscle weakness in lower limbs. (26) Any loss of sensation in lower limbs. (27) Any sign of sacro-iliac joint disease. (28) Radiological evidence of congenital abnormalities, disk degeneration, or bony disease of any kind. (29) Type of treatment employed. (30) Time in weeks after treatment started before patient is free of signs and symptoms.

As previously stated, the patients in this series were placed alternately on either manipulative treatment or rest in bed and analgesics. Some of them did not carry out instructions or did not report for assessment, and have been discarded from the final series. Thus the original two groups, each of 76 patients (152 patients in all), are unequal in the final figures (76 and 60).

Results

The results of the investigation are given in tabular form. The patients treated by manipulation are referred to as Group I and those treated by rest and sedation as Group II. Age and sex distribution are shown in Table I. It was remarkable that the proportion of males was the same in each group, being 62%.

TABLE I.—Age and Sex Distribution

Age	Group I (76)			Group II (60)		
	Total	M 47	F 29	Total	M 37	F 23
	No. %	No. %	No. %	No. %	No. %	No. %

Discussion of Results

From the information obtained, we have selected certain groups of figures which we regard as of significant value. Statistical analysis has not yet been applied, because the present preliminary figures are inadequate for this purpose.

The distribution of male to female patients was 3:2. Most patients were in the age group 30-59 years and had suffered no previous attack or only one previous attack of pain. About 70% of each group complained of central lumbar pain. Unilateral and bilateral lumbar pain were much less common (see Tables I, II, and III).

There was no obvious percentage difference between male and female patients except in the group of "significant employment." As one might expect, there was a great predominance of males. Aggravation of pain by coughing occurred in about 65% of each group and each sex. The use of a sagging type of mattress, often a feather bed, may be an important factor, being noted in about 20% of all cases. Trauma might be expected to play an important part, and about 50% of the patients in each group gave such a history, with disability coming on within a short period of time (see Table IV).

The commonest signs found on examination were painful restriction of lumbar spinal flexion, occurring in about 60% of each group, and diminished straight-leg raising predominantly on one side, which occurred in about 50% of each group (see Table V).

There was a higher percentage of congenital abnormalities present than in the general population, by comparison with Willis's findings, especially of sacralization or lumbarization of L5-S1 vertebrae. This suggests that such malformations make the back mechanically unsound and prone to lesions causing backache in later life (see Table V).

Of the patients manipulated 50% were free of signs and symptoms at the end of one week as compared with 27% in the control group (see Table VI). At the end of six weeks only 12% of Group I were suffering from signs and symptoms, while 28% of Group II were still affected.

Perusal of that Table as a whole shows how simple manipulation of the lumbar spine, in the type of case described, results in freedom from symptoms and disability more quickly than does rest. It should be remembered, moreover, that the spinal manipulations were carried out by both physiotherapy students and trained staff, and the figures thus include many cases treated by relatively unskilled therapists.

It may be noted that of the patients in each group who were well after one week, over half had diminished straight-leg raising originally. If a Lasègue sign is taken to indicate a disk lesion, albeit of slight degree, then manipulation had helped to relieve it.

Of the patients in each group who still had signs and symptoms after six weeks, only a small proportion had Lasègue's sign originally on examination. It may also be noted that few of these patients had congenital abnormalities.

A relatively high number of this resistant group had radiation of pain initially, and this may be an important symptom in predicting response to treatment in either group.

Conclusion

In the patient with acute low back pain in whom the probable lesion is derangement of an intervertebral joint, including minor protrusion of a disk, and in whom irritation or pressure on adjacent structures occurs, then treatment by manipulation, without anaesthesia, seems a logical method of gaining relief from signs and symptoms.

Summary

A group of 152 patients suffering from acute low back pain were selected at random and treated either by manipulation or by bed rest and analgesics.

Full clinical and radiological examination was carried out in every case, and progress, whether improvement or deterioration, was noted at weekly intervals.

Of the patients manipulated, 50% were symptom-free and discharged within one week and 87% were discharged within three weeks.

Of the patients treated by rest in bed and analgesics, 27% were symptom-free and discharged within one week and 60% within three weeks.

After six weeks, 12% of the patients treated by manipulation, and 28% of the patients treated by rest in bed and analgesics still suffered pain and disability.

Medical Memoranda

Amyotrophy Due to Hypoglycaemia

Neurological disturbances often occur in hypoglycaemia. Transient aphasia and hemiplegia are not uncommonly seen in hypoglycaemia due to insulin overdosage. More profound disturbances may occur, particularly in cases of islet cell tumour, when considerable diagnostic difficulty may be encountered. Lawrence *et al.* (1942) have described in detail the changes in the brain in six fatal cases of hypoglycaemia. There was widespread degeneration and necrosis of the nerve cells, particularly in the cortex, putamen, and caudate nucleus, with slighter changes in the brain-stem and cerebellum. The changes are probably due to failure of the normal cellular oxidative processes from glucose lack, although vascular factors may play a part. Rarely, lesions of the lower motor neurone, probably on the same pathological basis, may occur. Moersch and Kernohan (1938) mention loss of the anterior horn cells from a segment of the lumbar cord in an account of the changes in the nervous system from a fatal case of hypoglycaemia. Tom and Richardson (1951) describe a case of islet-cell adenoma, undiagnosed in life, which showed severe muscle atrophy of the legs. Histological examination of the spinal cord from this case showed destruction of the anterior horn cells. Roxburgh (1954) mentions wasting of the small hand muscles in the report of an islet-cell tumour in a child of 5½ years. Other cases have been described by Lidz *et al.* (1949) and Silfverskiöld (1946). The latter described two cases under the title of "polyneuritis hypoglycemia." There is no record concerning the degree, if any, of recovery, but in the

case recorded by Lidz the mental state and ataxia improved after removal of an islet-cell adenoma, but the muscle-wasting remained unaltered.

CASE REPORT

The patient was a married man aged 28 years. His past medical history was uneventful and there was no family history of nervous disease. He worked as a fitter in a large factory, but was not exposed to danger of poisoning by heavy metals or organic compounds. For at least twelve months prior to admission to hospital he complained of feeling weak, tremulous, and "queer" after any undue exertion. This often happened at his work, particularly just before lunch, after which he felt quite well again. There were times when he was unable to concentrate on his work, and his memory became rather capricious. During a holiday in June, 1953, he was found unconscious one morning and admitted to the local hospital. On examination he was found to be conscious but aphasic and there were signs of a right hemiparesis. The blood sugar concentration was 30 mg. per 100 ml., and he recovered fully and promptly following an intravenous injection of 20 ml. of 50% glucose. As he was on holiday he was given a high-fat, high-protein, low-carbohydrate diet and told to report to his doctor on his return home. His doctor referred him to Walton Hospital on August 13, 1953. He was then feeling better and refused in-patient investigation. He remained well until January, 1954, when his symptoms recurred. His wife stated that it became very difficult to wake him in the mornings until he was given a sweet drink. He had short episodes of mental confusion terminating in an attack of sweating, and was amnesic for these episodes. Both he and his wife realized that taking sugar prevented these symptoms, and he eventually carried sugar with him.

He was admitted for investigation on February 8, 1954, with the provisional diagnosis of spontaneous hypoglycaemia. He was tall and spare of build; his colour was good; and examination of the chest, heart (blood pressure 130/70 mm. Hg), and abdomen showed no abnormality. He gave the impression of being a little slow mentally. The pupils reacted normally and no abnormality was seen in the fundi; ocular movements were full, but there was nystagmus on extreme lateral gaze in both directions. There were no cranial-nerve palsies. The musculature of both shoulders and upper arms appeared to be a little wasted, but there was no detectable weakness. Both hands showed marked wasting of the intrinsic muscles, the interossei and hypothenar groups in particular. There was a little weakness of the extensors of the fingers. The tendon reflexes in the arms were brisk and equal and there was no subjective or objective sensory loss. Co-ordination was normal. The abdominal reflexes were present and equal. There was symmetrical wasting of both quadriceps, with marked fasciculation and fibrillation. The glutei and hamstrings were powerful, but there was some weakness of dorsiflexion of the left foot with a little associated wasting of the anterior tibial muscle group. The knee- and ankle-jerks were brisk and equal, and the plantar responses flexor. There was no objective sensory loss, and tests of co-ordination were normal.

Three successive fasting tests resulted in hypoglycaemia after periods of approximately twelve hours: blood-sugar values were 40, 40, and 35 mg. per 100 ml., and administration of intravenous glucose resulted in prompt recovery on each occasion, thus fulfilling Whipple's criteria. A glucose-tolerance test following a diet containing 350 g. of glucose for three days gave the following figures: fasting, 85 mg.; half an hour after 50 g. glucose, 100 mg.; 1 hour after, 85 mg.; 1½ hours after, 70 mg.; 2 hours after, 50 mg. per 100 ml. The haemoglobin was 93% and the white cell count 11,000 per c.mm., the differential count being normal. Liver function tests, including serum bilirubin, thymol turbidity, and serum alkaline phosphatase, were normal. X-ray films of the chest, skull, and cervical spine showed no abnormality. Lumbar puncture revealed clear fluid under

normal pressure, with one cell per c.mm. and a protein content of 32 mg. per 100 ml. The blood Wassermann reaction was negative. The electroencephalogram showed rather excessive low amplitude, slow activity.

At operation (Mr. N. O. K. Gibbon) on February 28 a single plum-coloured growth the size of a pea was found in the head of the pancreas and removed without undue difficulty. Convalescence was uneventful. Post-operative hyperglycaemia was not observed, the fasting blood-sugar values falling between 95 and 114 mg. per 100 ml. A glucose-tolerance test done ten days after operation gave the following results: fasting, 95 mg.; half an hour after 50 g. glucose, 130 mg.; 1 hour after, 120 mg.; 1½ hours after, 100 mg.; 2 hours after, 100 mg. per 100 ml.

Section of the tumour revealed an insulinoma, which was thought to be benign. The patient was discharged, symptomless, on March 20. When seen in the out-patient department six weeks later he felt very fit. He was working regularly and was symptom-free. The nystagmus had disappeared, but the muscle-wasting was unchanged.

Foster Kennedy Syndrome Produced by Myelomatous Deposits in the Skull

The complete Foster Kennedy syndrome comprises an association of anosmia, primary optic atrophy and central scotoma, and contralateral papilloedema. The essential features of the syndrome are the atrophy and papilloedema, either or both of the other two components often being absent. The syndrome was first described in detail by Foster Kennedy (1911). It is usually produced by olfactory groove or sphenoidal meningiomas or by frontal-lobe tumours (Walsh, 1947). Its occurrence in any other condition is a rarity, and it is accordingly commonly seen in the 40-60 age group. Clearly, the syndrome may be due to any space-occupying lesion near to the olfactory tract.

The case described below is exceptional in that the compression was due to myelomatous deposits. Multiple myeloma also occurs most frequently after the age of 40 (Snapper, 1949). In this case the patient was unusually young, and the manner in which the case presented was more suggestive of a cerebral tumour than of myelomatosis.

CASE REPORT

A male steel worker aged 34 was first seen on July 30, 1953, complaining of generalized aches and pains which he had had for six months. These had at first affected his back and pelvic region. Later his shoulders and neck were involved. After these pains had been present for four to five weeks he developed severe frontal headaches. All these symptoms, with the exception of the headache, disappeared spontaneously five to six weeks prior to admission to hospital.

For five to six weeks before admission he had noticed that his left eye was beginning to protrude. There was no associated deterioration of vision. At the same time he developed intractable vomiting, which occurred 10 to 15 times a day. He also complained of general weakness, loss of weight, and recent nocturnal frequency of micturition. On inquiry he admitted that his food had recently become tasteless.

On examination he was clinically anaemic, but otherwise appeared in fair general health. There was marked proptosis and epiphora of his left eye. The patient had no sense of smell. There was neither diplopia nor ophthalmoplegia. The left fundus showed primary optic atrophy with

an occasional blotchy haemorrhage near the disk. In the right fundus the whole disk was ill-defined, the veins were prominent, and the complete lack of contour and blurring of the edge of the disk indicated a moderate degree of papilloedema. In addition several blotchy haemorrhages were present, mostly near the disk. The visual fields were normal, but the visual acuity of the left eye was diminished to 6/9, while that of the right eye was 6/6. He was tender over the fifth and sixth ribs on the left side. No further abnormalities were found.

Several laboratory investigations were carried out. The urine contained Bence Jones protein, but showed no other abnormality. The blood urea was 155 mg. per 100 ml. and his urea clearance was 15% of average normal standard clearance. The findings in the serum were: alkaline phosphatase, 13 K.A. units; acid phosphatase, 3 Gutman units; total protein 8.8 g. per 100 ml. (albumin 5.7 g., globulin 3.1 g.); sodium, 135 mEq/l.; potassium, 6.5 mEq/l.; alkali reserve, 18 mEq/l.; chloride, 88 mEq/l.; calcium, 12 mg. per 100 ml. The peripheral blood examination showed: haemoglobin, 51% (7.5 g. per 100 ml.); red cells, 2,500,000 per c.mm.; C.I. 1; leucocytes, 6,000 per c.mm. (neutrophils 3,000, eosinophils 60, lymphocytes 2,340, monocytes 600); no plasmacytes were seen; platelets, 250,000 per c.mm. (Lempert); E.S.R. (Westergren), 124 mm. in one hour.

Marrow smears from the right and left iliac crests and from a radiologically evident myelomatous deposit in the left clavicle showed gross infiltration with cells of the plasmacytic series, consistent with a diagnosis of myelomatosis.

Pentamidine isethionate was given by intramuscular injection on alternate days to a total of 4 g. over a period of six weeks. The patient also received deep x-ray therapy, 2,500 r depth dose to the anterior fossa of the skull, between August 12 and 28.

After these measures the proptosis and papilloedema disappeared, whilst the vomiting gradually ceased. It was at first thought that the vomiting may have been due to chronic renal failure, but as the blood urea level did not fall concurrently with the decline in vomiting it was concluded that the latter was caused by the raised intracranial tension.

COMMENT

This case presents several unusual and interesting features. Multiple myelomatosis in a man of 34 is rare. The youngest in Bayrd and Heck's (1947) series of 83 cases was 37. Though myeloma deposits are often found in the skull, producing the characteristic radiological appearance, it is relatively rare to find the tumour extending beyond the confines of these bones. This was observed in only two cases in the series quoted above. Accordingly, only exceptionally is intracranial tension raised in myelomatosis. Snapper (1949) states: "Although myeloma so often involves the skull, no convulsive seizures have been observed and the optic disks never show evidence of increased intracranial pressure." In the present case there were definite signs of raised intracranial tension—namely, papilloedema, retinal haemorrhages, and vomiting. Lumbar puncture was thought to be inadvisable in these circumstances, and so no direct measurement of the C.S.F. pressure was made. The only component of the Foster Kennedy syndrome that was lacking was the central scotoma.

I wish to thank Professor E. J. Wayne for permission to publish this case; Dr. E. K. Blackburn for the interpretation of the marrow smears and other haematological data; and Dr. G. M. Wilson for his help and encouragement.

Reviews

ACTIVE TRANSPORT AND SECRETION

Active Transport and Secretion. No. VIII, Symposia of the Society for Experimental Biology. (Pp. 516+vi; illustrated. 45s.) Cambridge University Press, 1954.

The transfer of substances and ions across membranes and diffusion barriers in general is a most important subject of study by experimental biologists at the present time. Much is now known about the intracellular enzymes which are concerned with intermediary metabolism, but how a substrate reaches its specific enzyme system within the cell is still obscure. The existence in the cell of structures which possess their own membranes—for example, mitochondria—shows that the selection of the desirable substrate from among the diversity of substances presenting at the cell surface is only one of many problems to be considered.

This volume contains the papers read at a symposium of the Society for Experimental Biology held in July, 1953, and includes contributions emanating from departments of agriculture, botany, zoology, physiology, biochemistry, biophysics, pharmacology, clinical pathology, and experimental medicine. The subject-matter of the papers is as diverse as their origins, but some unification is achieved in a final article by J. F. Danielli entitled "Morphological and Molecular Aspects of Active Transport." Professor Danielli discusses six morphological levels at which it is profitable to consider active transport: (1) the simplest known cellular membranes such as those of red blood cells; (2) cell membranes which are specialized for the performance of active transport, such as those of intestinal epithelial cells, kidney tubule cells, and motor end-plates; (3) mitochondria; (4) vacuoles; (5) pinocytosis—the absorption of environmental fluid as discrete droplets by undulating membranes; and (6) extracellular processes, such as the flow of lymph and pumping activity of intestinal villi. Each morphological unit can display different processes of transport—for example, simple diffusion, facilitated diffusion, and active transport. Simple diffusion is the movement of molecules in an unrestricted manner under the driving force of thermal agitation; facilitated diffusion occurs also under the driving force of thermal agitation, but is restricted both by structural and by steric factors and has been recognized as occurring only at "active patches" in the cell surface; in active transport molecules, etc., are transferred across barriers by the use of an energy supply other than, or in addition to, that of thermal agitation. The energy supply needed for active transport will clearly be derived from metabolic processes, and so the study of enzymes and the effects of enzyme poisons in relation to the processes of active transfer is a rapidly developing one. Various molecular models for the intimate mechanism of active transfer have been postulated, of which that of a propelled shuttle moving forwards and backwards across the membrane, and that of a molecular carrier rotating within the membrane, are the most fashionable. The idea that, in relation to active transport, enzymes may possess important mechanical as well as catalytic functions is an interesting one that needs much further investigation. All these matters will be of significance to those, among many others, who are interested, for instance, in the processes of kidney secretion and absorption, in the mechanisms involved in nerve conduction, in the absorption of fat from the intestine, and in the transference of passive immunity from mother to foetus.

This volume, apart from one isolated instance, contains no record of the discussion that took place at the symposium; but, since the book in its present form contains over 500 pages, the inclusion of the discussions would have made it somewhat unwieldy. A more serious omission is that of an index, in the absence of which the book loses much of its potential value for reference to the present views of active investigators in a field that is necessarily somewhat diffuse.

Nevertheless this volume, which represents a valuable conspectus of expert opinion on a subject of wide importance, can be read with profit by all those to whom the mechanisms of transport and secretion are of interest.

LEUKAEMIA RESEARCH

Ciba Foundation Symposium on Leukaemia Research. Editors for Ciba Foundation: G. E. W. Wolstenholme, O.B.E., M.A., M.B., B.Ch., and Margaret P. Cameron, M.A., A.B.L.S. Assisted by Joan Etherington. (Pp. 297+xiv; 56 illustrations. 30s.) London: J. and A. Churchill Ltd. 1954.

The symposium of which this is a transcript was arranged in order to take stock of the present position of research in leukaemia. There is suggestive evidence that leukaemia is increasing, and that this is a true increase and not merely an improvement in diagnosis. The disease is inevitably fatal, and research is therefore attended by a certain sense of urgency. Among the main topics discussed was, first, the relevance of animal research in leukaemia to the human disease. Though most of our knowledge of leukaemia has come from observations in man—as, for example, the therapeutic value of arsenic, x rays, nitrogen mustard, and the folic-acid antagonists—and though the transmitted strains of leukaemia used by experimentalists differ in many ways from the spontaneous disease, we shall probably be increasingly indebted to animal research for new remedies against leukaemia and related maladies. A second main topic was the role of a virus in the aetiology of leukaemia, and particularly the interesting results obtained by L. Gross in the transmission of leukaemia to the newborn mouse. A third topic was the induction of leukaemia by ionizing radiations and the protection obtained by shielding the spleen or injecting emulsions of spleen, bone marrow, or other cells.

The symposium was an exciting one to attend, and this monograph will be a stimulus to existing and would-be researchers in this field. It will join the list of key books on leukaemia, which already includes Claude Forkner's *Leukaemia and Allied Disorders in Man*, unhappily not revised since its publication in 1938, and Engelbreth-Holm's *Spontaneous and Experimental Leukaemia in Animals*, published in 1942.

THE TRIAL OF CRAIG AND BENTLEY

Trial of Christopher Craig and Derek William Bentley. Edited by H. Montgomery Hyde, M.P. (Pp. 264; illustrated. 15s.) London, Edinburgh, and Glasgow: William Hodge and Co. Ltd. 1954.

On November 2, 1952, Craig and Bentley were observed breaking into a warehouse; the police were informed, and subsequently Craig shot and killed P.C. Miles when the latter, with other policemen, was attempting to apprehend him. Bentley had already been arrested. Craig, the leading spirit, could not by law be hanged, as he was under 17 years of age. He was apparently an aggressive, callous, illiterate youth, being unable to read, owing, it is claimed, to word-blindness. The reasons for the indignation aroused by the hanging of Bentley (aged 19) were pitifully expressed in Parliament by Mr. R. T. Paget, Q.C., M.P.: "A three-quarters witted boy is to be hung for a murder he did not commit and which was committed 15 minutes after he was arrested." In his address to the jury the Lord Chief Justice explained the law concerning the common responsibility of accomplices in crime in the following terms: "When two people are engaged on a felonious enterprise—and warehouse-breaking is a felony—and one knows that the other is carrying a weapon and there is agreement to use such violence as may be necessary to avoid arrest and this leads to the killing of a person, both are guilty of murder." Interesting legal problems were: How long does common responsibility endure? What are the criteria for its termination? Might not the fact of arrest be considered to terminate it? And, if not necessarily so, in what conditions would it not be so?

It would seem that Bentley made legal history by being the first to be hanged as an accomplice in a crime for which the principal in the first degree could not be executed on the grounds of age. Moreover, Bentley was considerably below average in intelligence, and it was said, according to the editor of this book, that he had been reported as mentally deficient at an approved school and had been rejected on mental grounds for National Service. Like Craig, he was illiterate.

This trial doubtless possesses considerable legal interest; from the medical point of view the interesting thing is that the medical aspects—the apparently low mentality of the two boys, and particularly of Bentley—were not raised in their defence. The introduction is clear; but Mr. Montgomery Hyde might have spared us his views on the causes of juvenile crime and such *obiter dicta* as that “it is a sad reflection on our times that both these youths were found at their trial to be practically illiterate.”

DESMOND CURRAN.

SOCIAL MEDICINE

The Meaning of Social Medicine. By Iago Galdston, M.D. (Pp. 137+viii. 22s.) Cambridge, Mass.: Harvard University Press. London: Oxford University Press. 1954.

Beatrice Lillie used to include in her wartime repertory a soprano launched on a song which she and her audience soon recognized was beyond her resources. As she approached the top note it became clear to all concerned that she wasn't going to make it, so she hastily dropped an octave and tried to pass it off as though nothing had happened. This essentially is the procedure followed by Dr. Galdston in his discussion of the meaning of social medicine. He provides an interesting account of the development of modern medicine, which he suggests has failed because it has been concerned with the treatment of disease rather than with the promotion of health. As a result, lowered mortality rates have not been accompanied by a commensurate improvement in health and well-being. Social medicine, apparently, is to put this right. But at the point at which we should expect to be told how this is to be done the subject is dropped, and the book ends on a different note, with two chapters on “Social Medicine and Medical Education” and “Social Medicine in Great Britain.” It is not the first time that recognition of a problem has been mistaken for its solution.

It is hard to see why people still find it necessary to make exaggerated claims for a new subject. One would have thought it quite sufficient if in, say, ten years the decision to establish departments of social medicine seemed in retrospect to be a right one. But the late Professor René Sand regarded social medicine as “the final flowering of the preventive and curative arts,” and Dr. Galston conceives it as “the corrective and fulfilment of the modern biological sciences.” These are claims which would tax the combined resources of the Royal Colleges and the Royal Society. Fortunately we can accept less; we shall certainly have to.

THOMAS MCKEOWN.

“BALANCED” ANAESTHESIA

The Practice of Balanced Anaesthesia. By Sylvan M. Shane, D.D.S. Preface by Juan White Morquecho, M.D. (Pp. 196; illustrated. \$5.75.) Baltimore: Lowry and Volz. 1953.

In case the reader is uncertain about the meaning of “balanced anaesthesia” a definition is supplied in the preface written by Professor Juan White Morquecho, of Mexico City, who says that balanced anaesthesia “consists of a series of proceedings in which the pharmacodynamic qualities of different therapeutic agents are taken advantage of in a rational manner.” This definition clearly covers practically the whole of clinical anaesthesia. Indeed, though the author says that his book is “not a treatise on anaesthesia,” it is just that—though not a very good one. The central theme is the use of a “balanced mixture”

consisting of oxygen, nitrous oxide, and cyclopropane in certain proportions; but the author does not hesitate to add morphine, barbiturates, and other drugs before, and barbiturates, relaxants, and analgesics during, the operation. The full range of spinal and local analgesia is also employed.

The dust cover says that the book was written for the physician, dentist, nurse, and veterinarian. In this country, at all events, only the last three might find the book of use. Postgraduates will find the standard far below the level they must aim at, while the general practitioner will almost certainly not extend his practice to this extent. The list of references given is inadequate for any serious purpose. The book hardly represents a worthwhile addition to the medical literature on anaesthesia.

W. W. MUSHIN.

A GREAT HOSPITAL

The Brompton Hospital: The Story of a Great Adventure. By Maurice Davidson, M.A., D.M., F.R.C.P., and F. G. Rouvray, O.B.E. (Pp. 152+viii; illustrated. 21s.) London: Lloyd-Luke (Medical Books) Ltd. 1954.

A hundred years ago patients suffering from consumption were not admissible to the voluntary general hospitals in London. It was owing to the enterprise and energy of Philip Rose, and to a lesser degree of John Labouchere, that the Brompton Hospital for Consumption and Other Diseases of the Chest was opened in 1842. At first the out-patient department was in Great Marlborough Street, and the in-patients were accommodated in the Manor House, Chelsea. In 1854 the north wing of the present structure was opened. We were interested to learn that in the early days the applicants for the post of assistant physician to the hospital were submitted to a clinical test of their competency before they were considered eligible for the post. In 1871 Miss Cordelia Angelica Read left £100,000 to the hospital, which enabled the south wing to be built and opened in 1882. The will containing the legacy was found in the locked drawer of a spinet, which (we are glad to know) is still preserved in the hall of the hospital.

In this beautifully produced book Dr. Davidson and Mr. Rouvray graphically describe the development of this world-famous hospital, and give pen-pictures of many of the distinguished physicians who helped to build up its reputation. They also point out how the rapid growth of surgery of the chest has improved the treatment and prognosis of many conditions. They rightly emphasize the importance of the hospital in undergraduate and postgraduate teaching. “L'Envoi,” with which the book ends, is a beautiful and moving termination of a noteworthy record of a great hospital.

ZACHARY COPE.

The distinguished French medical historian Charles-Victor Daremberg, who died in 1872, left unfinished a comprehensive bibliography of medicine. This was completed by Alphonse Pauly and published in 1874. It was intended to include all important works published to that date, including all titles found in Haller, Choulant, and Ca'llisen, arranged chronologically under each subject. This *Bibliographie des Sciences Médicales*, out of print for many years, has now been reproduced in facsimile and published by Derek Verschoyle, 13, Park Place, London, W.1, for £8 8s. Its appeal will be chiefly to collectors and bibliographers.

There have been no major changes in either the arrangement or the content of the *Hospitals Year Book 1954-55*, although a minor addition is of a list of British Standards relating to hospital equipment. There is, however, an editorial article of some importance on the best use of hospital resources, which gives a report on the progress made in hospital services since 1948 and outlines the main weaknesses and problems which require consideration if the service is to be run efficiently and economically. The *Year Book*, which costs £2 2s., can be obtained from the Institute of Hospital Administrators, 75, Portland Place, London, W.1.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MARCH 19 1955

THE DISCOVERY OF PENICILLIN

The discovery of penicillin introduced a new epoch in the treatment of disease. It has been followed by an intense search for other “antibiotics,” and a whole range of bacterial infections have now come within the effective control of substances produced, for the most part, by moulds, among which *Penicillium notatum* holds pride of place not only historically but also therapeutically. We stand so close to a bewilderingly rapid sequence of discoveries that as yet we probably fail to understand fully the revolution in medicine that has taken and is taking place as a result of Alexander Fleming's discovery. It is natural that the world will acclaim a medical advance “great” in proportion to the curative benefits it brings, and on this count alone Sir Alexander Fleming has his place among the immortals. And close beside him will be Sir Howard Florey and Dr. Ernst Chain, who in a systematic investigation of antibacterial substances ten years later hit upon the technical ways and means of fulfilling the promise Fleming held out for penicillin in 1929. Fleming had the real naturalist's capacity for observation and the scientific imagination to see the implications of the observed fact—a capacity and an imagination which, it is true, only the prepared mind can compass, and which in the great discovery seem invariably to be joined to a mind that is essentially humble. As there have been some popular misconceptions of the part Fleming played in discovering penicillin it may not be inappropriate at this time of his death to recall in his own words some of the observations he summarized in his historical paper in the *British Journal of Experimental Pathology* for June, 1929:

“A certain type of penicillium produces in culture a powerful antibacterial substance.”

“The active agent is readily filterable and the name ‘penicillin’ has been given to filtrates of broth cultures of the mould.”

“The action is very marked on the pyogenic cocci and the diphtheria group of bacilli.”

“Penicillin is non-toxic to animals in enormous doses and is not irritant. It does not interfere with leucocytic function to a greater degree than does ordinary broth.”

“It is suggested that it may be an efficient antiseptic for application to, or injection into, areas infected with penicillin-sensitive microbes.”

The discovery recorded in Fleming's paper is a milestone in the history of medical progress, and the “penicillin” he discovered and named has come nearer than any other remedy to Ehrlich's ideal *therapia sterilisans magna*.

ANTICHOLINERGIC DRUGS FOR PEPTIC ULCER

During the past few years a spate of anticholinergic drugs have been introduced for the treatment of gastro-intestinal disorders, particularly peptic ulcer and enterospasm. Belladonna has had a time-honoured role, and these new preparations have sought to emulate its action but with fewer undesirable side-effects. “Banthine” (methantheline bromide) blazed the trail and has been followed by a bewildering number of other drugs, including “antrenyl,” “bentyl,” “centrine,” “lergine,” “lytensium,” “merbentyl,” “monodral,” “pamine,” “prantal,” and “wyovin,” and much has been written on both sides of the Atlantic about their pharmacological and clinical effects. In the *Journal* this week a special study of lergine (tricyclamol chloride) is presented by Drs. Pamela Aylett and A. H. Douthwaite.

All these drugs have much in common. Their chemistry is complex; they achieve an anticholinergic effect like atropine by blocking transmission either at autonomic ganglia or at the peripheral effector site; they reduce basal secretion, slow the emptying time of the stomach, and lessen intestinal muscular activity. Although side-effects are generally claimed to be slight, in practice the usual atropine-like disturbances of impaired vision and dryness of the mouth are quite common, and sometimes there may be constipation and difficulty in urination. Moreover, the response varies considerably between different patients and even in the same patient at different times.

The therapeutic contribution of these new drugs is not impressive, and they have not greatly advanced the therapy of peptic ulcer. Nor were they likely to do so, since atropine and related drugs, although undoubtedly beneficial for smooth-muscle spasm, have never been conclusively proved to give great benefit in cases of peptic ulcer, though most clinicians would agree that belladonna can help to relieve pain, particularly night pain, in duodenal ulcer. According to Nicol¹ even large doses of atropine had very

¹ Nicol, B. M., *Lancet*, 1939, 2, 881.

² Rowlands, E. N., *et al.*, *ibid.*, 1952, 2, 1154.

³ Friedlander, P. H., *ibid.*, 1954, 1, 386.

⁴ Texter, E. C., and Barborka, C. J., *Postgrad. Med.*, 1954, 16, 449.

little effect on the acid of the stomach when measured over 24 hours, and no better success seems to have been achieved by ganglion-blocking agents in this respect.² It has been postulated that slowing the stomach's rate of emptying would allow the more effective use of antacids, but this hypothesis is by no means proved. The distension of the stomach is itself an important stimulus to secretion, and slowing of the rate of emptying may well mean more prolonged secretion, which would offset the neutralization. However, using tricyclamol, Drs. Aylett and Douthwaite have prolonged the period of achlorhydria from 1½ to 2½ hours after a dose of aluminium hydroxide, but details of only two patients are given. Again, the inhibition of other intestinal secretions, particularly pancreatic, might offset any benefit to the duodenum from lowering of the gastric acidity. Indeed, in so far as these drugs are supposed to help the healing of peptic ulcer, the administration of them is still based on doubtful hypotheses and insufficient clinical study with control series.

The clinical evidence of the value of methantheline in controlled observations is unimpressive apart from some reduction of pain, and P. H. Friedlander³ did not find that the natural history of duodenal ulcer was improved. E. C. Texter and C. J. Barborka⁴ followed 250 patients with proved peptic ulcer for two years. The patients were treated identically with diet and the usually recommended forms of treatment, the only difference being that half the patients received 100 mg. of methantheline four times a day, while the remainder received 0.4 mg. of atropine sulphate four times a day. After the two years these authors, without knowledge of which drug had been given, then assessed the patients' progress: they found that those taking banthine were symptomatically improved and had had somewhat fewer and milder recurrences than those taking atropine. The recurrence rates were high in both groups—75% in the banthine group and 90% in the atropine group. When the results were separated into mild, moderate, and serious cases, the best results occurred in the group whose ulcers had been classified as mild before treatment, whereas in the group with severe ulcers it mattered little whether atropine or banthine had been used. Complications and the need for surgery were of the same frequency in the two groups. Therefore the conclusion was that, although these drugs often gave symptomatic improvement, the eventual course of the disease was not altered.

But, while the natural history of the disease is not materially influenced, greater relief of pain is important to the patient and justifies the administration of any of these preparations during the phase of active

ulceration, though it would seem reasonable to see whether the desired effect cannot be obtained with the traditional belladonna before prescribing the new, and much more expensive, preparations. The *tab. belladonnae et phenobarb.* of the *National Formulary* contains ¾ gr. (50 mg.) of phenobarbitone and ¾ gr. (26 mg.) of the dry extract of belladonna and is convenient to prescribe when some sedation is required as well.

It may be unfashionable to say so, but patients appreciate brand-new treatments, and it is an advantage to have a variety of compounds available for the management of a chronic and relapsing disease. Apart from some difference in side-effects, it is unlikely that any one of the many new preparations will prove to be superior to its rivals, and the family doctor need not feel that he must personally evaluate each preparation.

EXCHANGE TRANSFUSION

No effective prophylaxis is yet available against maternal iso-immunization from rhesus and other blood-group incompatibility between mother and foetus. The problem of preventing stillbirths from this cause is still unsolved, in spite of attempts to reduce the effects of foetal haemolytic anaemia by cortisone administration to the mother¹⁻³ or inducing labour early in a few selected cases.⁴ Treatment has therefore been concentrated on the 70% of affected babies who are born alive. The main complications in untreated infants are anaemia at birth in about two-thirds, which may be progressive, and kernicterus after 36 hours in up to a quarter. Adequate exchange blood transfusion with fresh compatible packed cells not only corrects severe anaemia without increasing blood volume but also reduces the risk of kernicterus by removing up to 1,000 mg. of bilirubin contained in over 85% of the infant's sensitized red blood cells. In our opening pages Drs. W. Walker and G. A. Neligan, of Newcastle, report the results of 250 exchange transfusions, with a remarkably low mortality of only 15 deaths attributable to haemolytic disease of the newborn. A follow-up of 200 of the survivors showed only 3 suffering from kernicterus, confirming the good long-term prognosis found by P. Armitage and P. L. Mollison.⁵ They also discuss the modern indications for the procedure

⁸ Mollison, P. L., and Cutbush, M., *Advances in Paediatrics*, Chapt. 5, 1954, London.

and the increasingly important technical details of it, and underline the advantages of exchange over simple transfusion. A. S. Wiener *et al.*⁶ have also emphasized this recently and reported a reduction in mortality (including kernicterus survivors) from 46.4% to 15.5% in comparable severe groups.

The greatest benefit is obtained from exchange transfusion when it is carried out within a few hours of birth with not less than 60 ml. of packed cells per lb. (170 ml. per kg.) on affected infants who are anaemic, premature, or are considered likely to develop kernicterus. Treatment is probably ineffectual once neurological signs of kernicterus have appeared, so prediction is essential. Consequently treatment may be said to begin with routine antenatal care, parental blood grouping, and maternal antibody determinations during pregnancy. These measures enable the arrival of most of the affected infants to be predicted, and hospital delivery can be arranged: birth is followed by the rapid performance of the direct Coombs test and rhesus blood-group test on the baby's cord blood. Treatment is then planned in accordance with haemoglobin levels in the cord blood. If necessary bilirubin determinations and normoblasts and reticulocyte counts can be done. The mortality of full-time babies delivered in hospital in Walker and Neligan's series was only a quarter that of babies admitted after birth, a cogent argument in favour of hospital delivery when maternal sensitization is discovered. About 60% of all serologically affected babies receive exchange transfusion. They include all babies with positive direct Coombs tests, with the exception of full-time infants with a cord haemoglobin level above 15 g. per 100 ml. Above 17.5 g. per 100 ml. there appears to be no danger of kernicterus, but the borderline group with cord haemoglobin between 15 g. and 17.5 g. per 100 ml. appear to run a 10% risk of kernicterus if untreated. However, if all in this group have exchange transfusions, the percentage of babies receiving replacements would rise considerably and many would be subjected unnecessarily to a procedure which carries a definite mortality, though small in skilled hands. The policy in the past has been to practise expectant treatment in this borderline group, unless jaundice develops rapidly after birth or an affected infant has been born to these parents previously. Here, Walker and Neligan make another important contribution, for they found that a cord bilirubin level of less than 2.8 mg. per 100 ml. carried no risk of kernicterus in the borderline group, in which it occurred in four-fifths. Thus routine testing of bilirubin levels in cord blood may help in the prognosis of difficult cases. Exchange transfusion cannot entirely prevent kernicterus, but among over 200 Newcastle babies receiving

exchange transfusion were only 5 cases of kernicterus in spite of limiting a second exchange transfusion to 4 babies. The authors recommend re-exchange if the bilirubin level rises above 25 mg. per 100 ml. after the first transfusion. Other authorities have re-exchanged up to 20% of babies, including also those who are premature or who have a history of a previously affected sibling. The kernicterus rate in Diamond's⁷ series of 257 affected babies, 87% of whom received exchange transfusion once and 20% twice, was 2%, and total mortality 13%. Mollison, however, points out that a second exchange transfusion is only one-seventh as effective in removing the infant's bilirubin.⁸ The effect of modern treatment can be gauged by the results in 125 receiving exchange transfusion out of 217 affected babies born in hospital in Newcastle in 1952 and 1953; the mortality was as low as 3.5%, including those due to anaemia and kernicterus, a figure which would be difficult to surpass even with wider indications for repeated exchange transfusion. It is a tribute to the skill and efficiency of a trained team.

The indication for late simple transfusion after replacement is usually a haemoglobin less than 8.5 g. per 100 ml. in the first six weeks of life, during which serial haemoglobin determinations should be made even after adequate exchange transfusion. The use of fresh donor blood within three days minimizes the dangers of transfusion reaction or hyperkalaemia due to leakage of potassium from the donor red cells into the plasma. Neligan and Walker met no complications from infection, air embolism, or portal thrombosis, but they emphasize the dangers of perforation of the umbilical vein. The umbilical route is convenient, for it usually requires no separate incision and may be patent for several days. The venous pressure can be measured before beginning exchange transfusion, and the danger of overloading the circulation in anaemic babies can be avoided by preliminary withdrawal of 10–50 ml. of blood. Because of the danger of circulatory failure, great care should be exercised if this deficit is made up later in the transfusion. Exchange transfusion should also be borne in mind in the treatment of premature infants, some of whom develop hyperbilirubinaemia and kernicterus in the first ten days of life in the absence of any blood-group incompatibility. The only prophylaxis would appear to be exchange transfusion, which many centres for the care of premature babies are beginning to carry out as soon as deep jaundice appears. Thus, exchange transfusion may continue to be carried out on newborn babies even if a method of preventing blood-group incompatibility is discovered.

REGIONAL COLITIS

As B. N. Brooke¹ points out in the opening paragraph of his recent monograph, there was, for a long time, a tendency to diagnose as ulcerative colitis almost any case of chronic diarrhoea for which there was no obvious cause. Closer study of the clinical features and of the pathology of such cases (and for this the increasing interest of surgeons in their management has been largely responsible) has now made it possible to group together certain patients in whom the disease seems to follow a distinctive pattern. Although granular proctitis or procto-sigmoiditis may be regarded by some² as a mild, but occasionally progressive, form of ulcerative colitis, there are several clinical features typical of this group of which spurious diarrhoea, with real constipation, and rectal bleeding seem to be the most constant. Much less frequently the surgeon sees patients in whom shallow ulceration of the mucous lining of the small intestine seems to be the primary lesion, the colon being attacked only by its later extension distally. They constitute a second and smaller (and a more controversial) group best known as ileo- or entero-colitis.^{3,4} Disordered small-bowel function and anaemia are prominent symptoms, and, in general, surgery has little to offer in their relief; it is, in fact, best avoided.⁵ Apart from the remaining majority of cases with the familiar diffuse ulceration affecting predominantly the distal part of the colon—and ending so often in total colectomy—is yet another distinctive group—namely, regional (or segmental) colitis.

Although the early reports of this form of ulcerative colitis (the term being used in its widest sense) date from the days of Moynihan,⁶ Mayo Robson,⁶ and Dalziel,⁷ its wide recognition belongs to more recent times, when Crohn and his colleagues⁸ first described a granulomatous lesion affecting the ileum. This is the commonest site of the disease, which on this side of the Atlantic is so often associated with his name. It has since been clearly established that segments of the large gut may be similarly affected. Since both the prognosis and the treatment differ considerably from those of ulcerative colitis, it is important that the condition should be clearly recognized, and therefore two recent reports from the Mayo Clinic,^{9,10} one clinical and one pathological, are specially welcome.

It used to be the practice to refer to this form of segmental colitis as "right-sided colitis,"¹¹ but the term seems to be no longer suitable, for in this series the left side of the colon was affected almost as often as the right. The segments of affected bowel seem to the naked eye to be sharply marked off from the adjoining healthy gut, and even microscopically the disease seldom spreads further than a distance of 6 cm. As in the small gut, skip areas are sometimes found, as is direct

extension to the rectum and to the ileum (one in four cases). The bowel is reddened, contracted, thickened, and inelastic; there is a noticeable increase in the subserous fat and fibrous tissue as well as great thickening of the submucosa, with stricture as an occasional complication. Although ulceration of the mucous membrane is one of the prominent features, and although polypoid hyperplasia may result, the threat of cancer seems to be less urgent than in true ulcerative colitis.

It is a disease of rather young people, the maximum incidence falling between 20 and 30. The onset may be so acute that the patient may come to immediate laparotomy as an abdominal emergency.^{12,13} More often it is insidious, and the urgency of the symptoms thereafter varies considerably. Diarrhoea is by far the most common symptom, accompanied usually by griping abdominal pain and by obvious rectal bleeding in about half the cases. Physical examination is often quite unhelpful apart from evidence of weight loss and anaemia. Of the complications, perirectal and perianal suppuration is the most frequent. In a group of 201 patients⁹ rather more than one in ten when first seen already showed evidence of infection in this situation and eight had already undergone operations on this account before the underlying disease was recognized. Medical treatment by rest in bed, dieting, and the cautious use of antibiotics was tried in 150 cases, but two out of three later relapsed. Although the group surgically treated was only a third as large, the recurrence rate was appreciably lower. Experience seemed also to show that a short-circuiting procedure has a higher record of success than a resection, whether immediate or staged. In any event, there seems to be very good reason in such cases not to overlook the diagnosis, and every justification to expect a cure by some surgical manoeuvre short of an ileostomy and colectomy.

SULPHAEMOGLOBINAEMIA

Chronic cyanosis unaccompanied by signs of cardiac or respiratory disease or by polycythaemia may be due to the presence of sulphaemoglobin or methaemoglobin in the blood. Methaemoglobin results from the oxidation of haem, while sulphaemoglobin is thought to be due to the entry of sulphur into the pyrrole component of haemoglobin. The methaemoglobin disappears rapidly, but sulphaemoglobin persists as an inert compound in the erythrocyte until the cell is destroyed, and is therefore more commonly encountered in clinical practice. Both pigments can be identified spectroscopically by the presence of characteristic bands in the red part of the light spectrum. The patient, in spite of a striking leaden cyanosis, suffers no ill effects, apart from the theoretical disadvantage of a decrease in the blood's capacity for carrying oxygen. Sulphaemoglobinaemia is almost invariably caused by drugs, the most important of which are the coal tar derivatives, acetanilide and phenacetin, the earlier sulphonamides,¹ and nitrogen-containing compounds such as nitrites and nitroglycerin.

¹ Archer, H. E., and Discombe, G., *Lancet*, 1937, 2, 432.
² Harrop, G. A., and Waterfield, R. L., *J. Amer. med. Ass.*, 1930, 95, 647.
³ Brandenburg, R. O., and Smith, H. L., *Amer. Heart J.*, 1951, 42, 582.

It is difficult to estimate the incidence of the condition from reports in the literature, but it is probably uncommon.

Dr. T. B. Begg reports five patients with sulphaemoglobinaemia on p. 701 of the *Journal* this week, and points out certain interesting features. Four were taking a proprietary compound containing phenacetin, and the fifth used magnesium sulphate to treat her constipation. G. A. Harrop and R. L. Waterfield² induced sulphaemoglobinaemia in dogs by aniline derivatives and sulphur, and it seems likely that cyanosis results from the combined action on the red cells of an oxidizing agent and hydrogen sulphide. *Bacterium coli* in the gut is known to reduce sulphates to sulphides, and three patients in the present series suffered from constipation; this is probably more than a coincidence,³ and would presumably facilitate absorption of sulphides. Women are more commonly affected than men, and neurotic traits are often present. Begg suggests that the patient becomes habituated to the stimulant effect of the caffeine in tablets containing aspirin, phenacetin, and caffeine, originally taken for their analgesic properties. Treatment is obvious: removal of the offending drug and its substitution if necessary by aspirin, relief of constipation without purging, and the correction of anaemia if present. A low-residue diet which is free from sulphur-containing foods, especially eggs, is sometimes prescribed. The cyanosis will persist for at least two months because of the life span of the red cells. No way is yet known of increasing the elimination of sulphaemoglobin.

OPHTHALMIA NEONATORUM

For purposes of notification ophthalmia neonatorum denotes conjunctivitis occurring in the newborn infant and includes almost everything from frank gonococcal ophthalmia to slight crusting of the lids. At the end of the last century gonococcal ophthalmia of the newborn was a common cause of blindness and its prevention a major public health problem. It was Credé's⁴ introduction of cleansing the eyes of newborn infants and instilling silver nitrate drops that did much to alter this state of affairs. But social changes and the efficient treatment of gonococcal infection have combined to make maternal gonorrhoea a rarity in most hospitals, and this has led to a revaluation of the use of prophylactic drops. In a recent paper from Australia Ida Mann⁵ finds that silver nitrate has some effect in preventing "sticky" eyes, though she considers that it is responsible for provoking a sterile discharge in the first day or two of life in some babies. In general her findings agree with the earlier work of Taylor and Calman⁶ at Queen Charlotte's Maternity Hospital, and like them she feels that the use of silver nitrate is unnecessary in a modern hospital. Furthermore, in an institution where adequate bacteriological examination of all infected eyes is a routine, the very rare case of gonococcal ophthalmia is diagnosed so early and treated so readily as to present no cause for anxiety.

⁶ *J. Obstet. Gynaec. Brit. Emp.*, 1948, 55, 642.
⁷ *J. Amer. med. Ass.*, 1951, 145, 1052.
⁸ *Lancet*, 1952, 1, 347.

Other forms of prophylaxis have been suggested from time to time. The instillation of a single drop of penicillin solution appears to have no rational basis, but the use of an ointment containing 100,000 units per gramme of penicillin, originally suggested by Davidson and his colleagues⁷ from the Johns Hopkins Hospital, appears to have more to recommend it. There are two distinct objectives in the use of prophylactic drops. The first is its original purpose of preventing gonococcal ophthalmia, and the second is to reduce the incidence of "sticky" eyes. Most of the latter are staphylococcal in origin, and penicillin ointment would be unlikely to be of much value, since so many hospital strains of staphylococci are penicillin resistant. On the whole it seems that in hospitals serving a population in which gonorrhoea is rare the best treatment of the babies' eyes is simple cleansing, though the medical attendant on the spot may decide that local circumstances warrant other treatment. Elsewhere some form of prophylaxis should still be practised. As a prophylactic agent silver nitrate has some dangers—in particular, it can become dangerously caustic if concentrated by evaporation, and it can also decompose on exposure to light—so the use of penicillin ointment has something to recommend it. Other antibiotics can be incorporated in an ophthalmic ointment, and might well be effective in reducing "sticky" eyes in the days immediately after birth, though O'Brien⁸ found terramycin ointment of only slight value for this purpose. The danger in recommending their widespread use for prophylaxis would be that the hospital strains of staphylococci might rapidly become resistant. Unfortunately, too, no amount of drops or ointment placed in a baby's eye at birth can prevent the numerous cases of staphylococcal eye infections occurring later in the puerperium.

VITAMIN A AND HYDROCEPHALUS

For several years Continental paediatricians, especially in France and Spain, have reported the transient appearance in infants of symptoms of acute intracranial hypertension following the administration of large doses of vitamin A. The French workers J. Marie, G. Sée, and R. Sauvage have recently summarized¹ this work, and they add further observations which define the disturbance more precisely. Thus, the ingestion of 350,000 international units of vitamin A results in malaise, restlessness, either insomnia or torpor, and often vomiting; occasionally the temperature rises. Within 24 hours the anterior fontanelle is obviously bulging, but no further abnormal physical signs appear; the fundi and electroencephalograms are unchanged. The cerebrospinal fluid is of normal composition, but the pressure is up to 150–230 mm. water, rising to 200–230 mm. on jugular compression. The disturbance fades after 24 hours, and after 48 hours the infant returns to normal. In parallel with this the level of vitamin A in the blood serum shows a sharp rise at 6 hours after ingestion, falling again after 12 hours. The authors have

also reproduced a similar disturbance in young puppies, and they find evidence that it can occur in older human subjects whose fontanelles have closed.

They argue that the intracranial hypertension is attributable to an acute hydrocephalus resulting from the excessive transient formation of cerebrospinal fluid. Here it should be noted that vitamin A does not pass the blood-brain barrier, and the alternative possibility that the disturbance is due rather to cerebral oedema is not discussed. Since it is reproducible in young animals, the possibility could readily be tested. Should it eventually be established that excess of vitamin A promotes a sharp increase in the flow of cerebrospinal fluid, it would be peculiarly difficult to reconcile such a finding with the work of Millen and his co-workers at Cambridge, who claim that internal hydrocephalus is produced in young animals by too little vitamin A. Although in their first publication on this subject,² which was noticed in this *Journal*,³ they attributed the hydrocephalus to stenosis of the aqueduct, in a later publication⁴ they found reason to shift their ground. Intensifying the degree of maternal hypovitaminosis, they obtained earlier stages of the disease in their newborn and foetal rabbits. In these the aqueducts were not obviously different from those of controls, and they concluded that the stenosis observed in later stages was somehow a secondary effect of the hydrocephalus. In seeking for the cause of the hydrocephalus they were driven to the conclusion that excessive formation of cerebrospinal fluid was the only feasible mechanism. We are thus faced with the unlikely proposition that either too much or too little vitamin A can promote this disorder. It remains to be seen which is correct.

PHYSIQUE AND CHARACTER

Comparing Oxford undergraduates with Chelsea pensioners, Lipscomb and Parnell¹ have found that the pensioners as young men were nearly 4 in. (10 cm.) shorter and 25 lb. (11.3 kg.) lighter than the undergraduates. At the average age of 73 the fifty pensioners' heights had not altered significantly, but they were then only 5 lb. (2.3 kg.) lighter than the undergraduates. In spite of this weight gain they still had less subcutaneous fat than undergraduates, and a greater proportion of the weight was contributed by bone and muscle. Somatotyping showed them to be mainly mesomorphs, with a few mesomorphic-ectomorphs. Those who gained most weight rated most highly in endomorphy. By means of his "clock" method² of simplified somatotyping,³ based on height, weight, and three skin-fold measurements, Parnell found that over 95% of the pensioners were muscular and wiry, compared with fewer than 40% of undergraduates. The results of this investigation illustrate the value, as pointed out by Parnell in an early paper,⁴ of this method of clinical examination "in the practice of medicine, the study of healthy people, care of orphans or children in approved or ordinary schools, investigation of the benefits or otherwise of games and physical training, study of fertility or populations, personal relationships within the family or in communities,

nutritional requirements, in surveys of crime, delinquency, and indeed almost every study of mankind. In short there is hardly a topic of social interest from murder to matrimony on which records of constitution do not touch and cannot quicken interest." Sheldon and Stevens⁵ correlated different character traits with different somatotypes. They found that among mesomorphic people "group action was the keynote, vigour of thought, vehemence of expression, aggressiveness and energetic reaction, bold directness of manner, love of exercise, adventure, chance and combat, these were the prominent features. Problems were met by action, not by submission or by acceptance." And now the be-medalled heroes of the Royal Hospital, Chelsea, who have exhibited these very character traits more convincingly perhaps than any other single group of men in the world, are found to be "mainly mesomorphs with a few mesomorphic-ectomorphs." Surely the important bearing that this might have on physical standards of recruiting cannot be missed.

MacQueen⁶ has pointed out that it is possible to augment the musculature by modern techniques of progressive resistance exercise, probably well beyond the one-unit difference on the seven-point scales mentioned by Parnell.⁷ Muscular bulk so achieved is maintained with little subsequent training,⁸ and it is tempting to believe that by influencing the physique towards mesomorphy the character traits of this somatotype may also be developed. Rigorous physical training in the preflight schools of the American Army Air Forces tended to level the differences between endomorphic and ectomorphic aviation cadets.⁹ Parnell¹⁰ has found that mesomorphic students seek psychiatric advice least often, and endomorphic-ectomorphs have the highest prevalence of psychiatric and psychosomatic disorders. It is possible that a physical training regimen may reduce the incidence of these disorders in students and may even have some therapeutic value in psychiatric and psychosomatic medicine.

Kretschmer's original system of somatotyping has been superseded by that of Sheldon and his collaborators.^{11,12} To Parnell we owe the evolution of a greatly simplified method¹³ which can be quickly learned and applied in routine clinical examination. It may yet be questioned whether medical students learn enough of the variations of normal human constitution. The culture of the physique together with the culture of the mind was a prominent feature in ancient civilizations, and its present lack may be a fault in modern living.

EMERGENCIES IN GENERAL PRACTICE

HAEMATEMESIS AND MELAENA

BY

THOMAS HUNT, D.M., F.R.C.P.

Senior Physician, St. Mary's Hospital, London, W.2

It is estimated that between 20,000 and 30,000 patients are admitted to hospital annually in England and Wales for serious gastro-duodenal bleeding. In most cases this is sudden, dramatic, and urgent, and the haemorrhage is obvious, either as a frank haematemesis or as a sudden and unmistakable tarry stool, often with diarrhoea. The vomit may be dark, like coffee-grounds, owing to the conversion of haemoglobin into acid haematin in the stomach, or it may be fresh and red just as it comes from an arterial haemorrhage. In either case it usually differs from a severe haemoptysis by being acid in reaction and non-frothy, unlike blood brought up from the lungs. The patient may be severely shocked and actually faint, or he may only become cold, weak, and restless. The pulse is quick, the blood pressure low, a cold sweat develops, and the patient, especially if elderly, often becomes confused and delirious. Pallor may be intense, and a peculiar pinched appearance of the face and nose is sometimes very striking.

In some cases, however, bleeding is insidious and difficult to recognize, so that it may continue unsuspected for long periods. It is important to remember, not only that blood oozing from the upper part of the alimentary tract may be insufficient in amount to turn the stools black, but also that patients do not in all cases take notice of dark stools, even if they are passed. In any cases of unexplained pallor, fainting, weakness, or symptoms of anaemia such as dyspnoea on exertion or oedema of the ankles the patient should be questioned about the colour of his motions and asked to notice them, particularly if he has not previously done so; it must not be forgotten, however, that many "tonics" and dyspeptic mixtures contain iron or bismuth, which darken the stools, and that much meat or green vegetables such as spinach have the same effect. A history that the patient has passed dark stools must not, therefore, at once be accepted as evidence of bleeding, and whenever possible this must be checked by a chemical test for occult blood. These tests are simple to perform, require no elaborate technique or materials, and can be carried out easily by the practitioner himself; the finding of such melaena demands, of course, a full history, examination, and investigation.

The simplest test is the Gregerson,* and for this it is not necessary to ban chlorophyll-containing foods, meat, or iron mixtures from the diet, as an immediately positive result definitely indicates blood, whilst a faintly positive one may be ignored. The possibility that the blood has come from the mouth, or from piles, or from swallowing sputum must, of course, be remembered in assessing the significance of a positive test.

*Gregerson's Test. A powder containing 0.29 g. of barium peroxide, with 0.025 g. of benzidine, is dissolved in 5 ml. of glacial acetic acid and a few drops of the solution are run on to a thin smear of faeces on a filter paper. A blue colour appearing at once or within a few seconds indicates the presence of blood, but appearing only after 20 to 30 seconds is of no significance.

Causes of Bleeding and Differential Diagnosis

Many large series of cases of haematemesis have been published, and from these and from my own experience the main causes, with their percentage incidence in Britain, may be approximately classified as follows:

Chronic duodenal ulcer	40	} 70
Chronic gastric ulcer	30	
Acute ulcer (gastro-duodenal erosions)	20	
Cirrhosis of the liver	5	
Carcinoma of the stomach	3	
Other causes	2	

In practice, the distinction between a chronic duodenal ulcer and a chronic gastric ulcer may be impossible to make and is, in fact, of relatively little importance compared with the vital distinction between an acute erosion and a chronic ulcer. This is a matter of extreme importance, since in the former case any form of surgical treatment is contraindicated, whilst in the latter it may be urgent and life-saving. In some cases the diagnosis is clear, since previous radiological examination may have shown an ulcer, and the history may be typical. In others it may be highly suggestive from the characteristic periodicity and the pain-food relationship.

It is rare, but by no means unknown, for a patient who has a chronic recurrent ulcer to deny any previous indigestion, but as a rule sudden haematemesis, with no history of any preceding pain or dyspepsia, is likely to be due to an acute erosion. This cause of bleeding is not well understood. It is certainly not infrequent, and, if all those cases in which no exact cause can be found and barium-meal examination is negative are grouped under this heading, it probably accounts for some 20 to 30% of all gastro-duodenal haemorrhages.

In some cases there is a strong presumption that an irritant drug may have caused the haemorrhage, and it is always important to inquire whether the patient had a cold, toothache, or a headache before the bleeding, as he may very well have forgotten that he had taken aspirin, "veganin," or some similar tablet, which might have caused the erosion. Drugs in tablet form are particularly concerned, and in a few cases the patient may know that he is sensitive to aspirin. In others expectorant mixtures containing quinine or ipecacuanha, or drugs such as phenylbutazone or para-aminosalicylic acid, precipitate bleeding, as may some sedatives, such as "sedormid."

Bleeding from an acute gastric erosion is often very severe, and often occurs in young people in apparently perfect health, and for no apparent reason that they can give. There is no tenderness or evidence of ulcer, and no history pointing to liver disease or primary blood dyscrasia. In a few cases the haemorrhage has recurred on several occasions, as neither the patient nor his doctor has been able to discover any cause.

Recurring haematemesis, however, for which no ulcer or other lesion has been found, may have some other less frequent, but important, causes, one of which is particularly characteristic—namely, hereditary telangiectasia. In this condition, multiple angiomas occur and as a rule can be found on examination, especially on the face, lips, or mouth, and there is a family history of gastric bleeding. The patient has almost always suffered from severe epistaxis during infancy and childhood. In one patient, aged 71, there had been over a dozen severe gastric haemorrhages since the

age of 30, on almost every occasion needing transfusion, and he had been once explored and eight times submitted to x-ray examination for ulcer, with negative results. There had never been any pain or indigestion, but, on questioning, he admitted to dangerous bouts of nose-bleeding when he was a small boy. On examination a few naevi were found on the skin, and at a second operation, which was undertaken after a radiologist had demonstrated a supposed gastric ulcer niche after a barium meal, no sign at all of any ulcer was found and the diagnosis of hereditary telangiectasia was confirmed.

In cases of portal hypertension with cirrhosis of the liver the haematemesis is also painless, but there is often a history of dyspepsia and the patient may have been a heavy drinker or have had recurrent jaundice (hepatitis); spider naevi may be found on the skin, with sometimes a characteristic facies. The liver is often palpable and in some cases the spleen also; but absence of these findings does not by any means exclude cirrhosis. The distinction from chronic ulcer, whilst often very difficult, is an extremely important one, since morphine, anaesthetics, and operation all carry serious risks in cases of cirrhosis.

Other causes of bleeding are much less frequent but may sometimes present difficulties in diagnosis. Blood diseases, such as leukaemia or purpura, heart failure, and hypertension may occasionally lead to haematemesis, and the rather more frequent hiatus hernia, with oesophagitis or ulcer, and carcinoma of the oesophagus or stomach must also be thought of. In rare cases a gastric polyp may be a cause of recurrent severe haemorrhage without pain.

Treatment of Severe Cases

The atmosphere of panic and alarm which a severe haematemesis produces in the patient and in those around him may easily spread to the doctor, and it is vital to keep calm and to give an air of reassurance and confidence as much as possible. In actual fact it is rare in these cases for a few minutes to become a matter of life and death, and it is a good thing to stress the favourable aspects of the emergency, the high recovery rate, and the well-understood lines of treatment. It may, with advantage, be pointed out that a loss of 10 to 12 pints (6 litres) of blood is not more than the body can tolerate without very serious danger, and a pint (about half a litre) is a usual amount for a blood donor to give. The degree of haemorrhage can be roughly estimated by the pallor, coldness, sweating, and collapse of the patient, the rate of the pulse, and the level of the blood pressure.

The first essential is to keep the patient warm by blankets or hot-water bottles, but this does not mean overheating. It is indeed important not to overdo it, for though the skin temperature may be low, this is partly nature's protective means of conserving internal heat, and it is unwise to promote undue dilatation of skin vessels and increase perspiration, which of course favours dehydration. Provided, however, that fluids are allowed—as they should be—some external warmth is advisable and is certainly of much comfort to the patient.

If there is much dyspnoea oxygen should be given, but this is of relatively little value if the haemoglobin to carry the oxygen is very low, and in any case is almost useless if given by the old method of holding a funnel in front of the patient's face. Some means, such as a plastic bag, a mouth-piece fitting the patient, or a nasal catheter must be adopted, but even if this is done it is not likely to be of much help if there is only pallor without cyanosis. If the haemorrhage is severe, the home conditions are bad, the patient is alone or in a hotel, or has little help available, admission to hospital is essential. The dangers of an ambulance journey are far less than those of remaining at home—but it is usually quite safe to wait a short time before having the patient moved. During this time, if the blood pressure is very low, it is worth raising the foot of the bed, but drugs to raise the pressure, such as noradrenaline, are not advisable unless a blood trans-

fusion can be given simultaneously to replace the blood lost. When telephoning the hospital it is helpful to give details of age, pulse rate, and blood pressure rather than the bare statement of a haematemesis. The use of morphine, $\frac{1}{2}$ gr. (16 mg.) hypodermically, to calm the patient and relieve shock is at this stage usually advisable, but the exact dose and the time it is given must be told to whoever takes the patient to hospital. The dangers of morphine in haematemesis are of causing undue depression of the medullary centres, especially in elderly patients with emphysema, or of the case proving to be one of cirrhosis of the liver, in which even the normal dosage may cause deep coma. It must not be forgotten also that in a very appreciable number of patients morphine itself causes vomiting, so that a dangerous vicious circle may be set up. These dangers do not, however, loom so large in the case of the initial dose given at the time of the bleeding, which greatly helps the patient to withstand the ambulance journey to hospital, as in subsequent doses.

During the first hour or two after a severe haemorrhage it is often advised to give the patient nothing by mouth at all, but frequent small drinks of cold water or fruit juice, 2 to 3 fl. oz. (60 to 90 ml.) at a time, are both safe and necessary and give some slight feeling of confidence also.

No medicines, other than morphine, are indicated at this stage, either orally or by injection, but later a sedative is often advisable, and then paraldehyde, 3 or 5 ml. intramuscularly, is very useful, or soluble phenobarbitone, 3 gr. (0.2 g.) subcutaneously, may be used. Alkalis have little if any place in treatment. If the patient remains in his home a nurse should be in attendance, and blood should be taken as soon as possible for grouping and estimation of the haemoglobin. More elaborate analysis of the blood chemistry—non-protein-nitrogen, sodium, chloride, and potassium—requires a skilled laboratory and hospital facilities.

Intravenous Therapy

In cases of moderate severity the question of intravenous therapy may not arise, but in more serious cases, if vomiting continues at all, an intravenous drip must be set up at once. The main indications for giving intravenous fluids are thirst, a dry tongue, oliguria, and a low blood pressure. If a drip is needed, intravenous glucose-saline should be given at the rate of about 100 drops a minute for the first one or two litres, after which the rate must be slower and accurate control of the electrolyte balance of the body becomes essential.

Blood transfusion may be a life-saving measure, but should not be given as a routine. It is the only effective and really physiological means of raising blood pressure if the patient is intensely blanched, shocked, and dyspnoeic; in this case the use of packed cells may enable a large oxygen-carrying capacity to be given in a relatively small volume. Any risk that such transfusion may provoke further bleeding is very small indeed, and if the blood is given slowly is almost negligible, whereas the continuation of a seriously low blood pressure is an urgent danger to life and far outweighs any fears of fresh bleeding resulting from the rise of pressure after transfusion.

In less urgent cases blood need not necessarily be given unless the haemoglobin is below 50% and the systolic blood pressure falls below 80. The patient's pulse should be charted hourly, and if the rate remains at about 120 a minute this generally means that bleeding is continuing, and is one of the clinical indications for blood transfusion. It must be remembered that the haemoglobin estimation immediately after haemorrhage may be deceptively high owing to the concentration of the blood which follows the bleeding, whilst later it is proportionately reduced by dilution with tissue fluids drawn into the circulation to maintain the blood volume. In elderly patients with emphysema it must also be remembered that there may have been some pre-existing polycythaemia and perhaps hypertension which may give a false impression of the haemoglobin and blood pressure.

Less Severe Cases

In many cases, however, the condition is not serious enough for any more elaborate measures to be needed than rest, warmth, and careful feeding. There need be no fear of giving some food and drink at the earliest stage. If the patient is thirsty he must be encouraged to drink in frequent small amounts, and cold milk or fruit drinks may be left at the bedside. Light solids may also be given from the beginning, though here it may be left largely to the patient's feelings whether he takes them or not. In younger patients solids, such as bread-and-butter, apple jelly, cream cheese, boiled egg, custard, junkets, or stewed fruit are usually welcomed within an hour or two of the bleeding, but with older patients it is often better to offer them only purées, malted-milk drinks, or jellies, without pressing them to take more. Chicken, fish, and lightly cooked tender meat may be given on the second or third day if the patient desires. At all costs thirst and hunger must be prevented, and even if the patient is afraid to eat or drink he should be encouraged to do so.

Operation

The later treatment depends upon the cause of the haemorrhage. If the patient is known to have a chronic ulcer, the question of emergency surgery must be considered from the start. Immediate operation, carried out with the help of blood transfusion, offers the chance of stopping the bleeding and radically treating the ulcer by partial gastrectomy at one and the same time, and is often advisable if expert surgical and hospital facilities are at hand. Such treatment is urgently called for if the patient has a second haematemesis within 24 to 48 hours of the first, if his age is over 50, and if there has been a long ulcer history with previous episodes of bleeding. If operation can be safely done at once, the patient is saved both the risk of further bleeding and the time spent on medical treatment, which he may well grudge if after a few weeks he has then to give more time for the resection of his ulcer. The operation, however, tends to be rather easier for the surgeon and safer for the patient if it can be held over till the ulcer has begun to heal well and the bleeding has stopped, so that if the diagnosis of chronic ulcer is not certain then the advantages of immediate laparotomy are less clear and the indication for operation is more uncertain. As a rule, if the haemorrhage continues, the history is suggestive of ulcer, and if the patient is over 60 immediate surgery is usually advisable, but the risks are certainly considerable (see below). A good blood bank and expert nursing are essential requisites.

Later Progress and Management

The stools should be watched for the disappearance of melaena, but if, as is advisable, iron is given early their colour will remain dark, even though the bleeding has stopped, and chemical tests must be utilized to show the presence or absence of blood. The bowels do not usually require any special attention for the first few days, when there is often some diarrhoea with offensive tarry stools. Later, constipation is usual—as may be the case from the beginning—and a weak soap enema may be given on the fourth or fifth day. At the same time a mild laxative such as liquid paraffin and magnesium hydroxide emulsion (*N.F.*, 1952), $\frac{1}{2}$ fl. oz. (14 ml.) once or twice a day should be ordered. It is important to keep the bowels open at this stage, for the altered blood in the intestines is thought to cause pyrexia, which may be a source of anxiety and uncertainty, and, though it is possible that the temperature is, in fact, due to general metabolic changes in body proteins after haemorrhage, it nevertheless often settles after the bowels have been emptied. It is not always easy to decide when a barium-meal examination may safely be undertaken, but in most cases this can certainly be carried out within the first ten days. It is best to do the examination at the earliest moment possible, as the healing of an ulcer is often very rapid after

a haemorrhage, and radiological examination two to three weeks after the bleeding has stopped may give an indecisive result. The dangers of early x-ray examination—within a few days of the bleeding—are slight and consist more in the risk of syncope and exhaustion of the patient than in the barium meal itself causing further bleeding, even though the radiologist may have to palpate fairly deep to demonstrate an ulcer satisfactorily.

Oral iron may be started from the beginning of treatment, and certainly within a week of the bleeding. Organic iron is more readily absorbed than inorganic, and not more than about 25% of such a salt as ferrous sulphate is, in fact, utilized by the body. Some preparation of ferrous gluconate, saccharate, or succinate is the most useful and least irritant, and it is estimated that about 30 mg. of iron in this form will raise the haemoglobin by 1%. Intravenous iron may be necessary but is not always easy to give; it is advisable only when there is extreme intolerance to oral preparations or the blood fails to improve after adequate oral dosage. A suitable oral preparation is ferrous gluconate, 0.3 g. three times a day. The official iron and ammonium citrate mixture very often causes gastric disturbance, as do the pills of ferrous sulphate unless specially coated to reach the intestine undissolved. Ascorbic acid should be given with iron as an aid to healing and to quicken the rate of recovery of the anaemia; the dose should be 200 mg. daily, or double this amount if the patient has for any reason been on a deficient diet before the haemorrhage.

Prolonged bed rest is not advisable after haemorrhage, and the patient may be allowed to get up for the commode from the beginning unless the bleeding has been very severe. He may go to the bathroom and sit in a chair for short periods as soon as his blood pressure has risen to a satisfactory level and the haemoglobin is above 60%.

In most cases he may be allowed out after three to four weeks, but the future treatment must, of course, be guided by the causative condition. The risk of post-haemorrhagic thrombosis is increased by long immobility in bed and can probably be lessened by early ambulation and the free administration of fluids.

Treatment of Oesophageal Varices

Oesophagoscopy will usually show the presence of varices, as may in many cases a barium swallow. Numerous methods of local treatment have been devised, including injection of the veins with sclerosing fluids, but none has given much success. Various operations designed to reduce portal tension of the porto-caval shunt type have been shown to reduce the varices in some cases, and ligation of the splenic artery has also been advocated, but with little to support it. Spontaneous disappearance of the varicosities is not unknown.

Prognosis

The risk of immediate death from haemorrhage is highest in cases of ruptured oesophageal varices secondary to portal hypertension, and it is a frequent mode of death in Banti's syndrome; in cases of cirrhosis over half the patients die within a year of the bleeding. In cases of haemorrhage from chronic peptic ulcer occurring in patients under 40 years of age death is rare; the risk is less than 1 in 20 amongst patients under 50, but rises to at least 1 in 10 in those over 60 and to about 1 in 5 in those over 70. In bleeding due to acute erosions death is also rare, even though the bleeding may be very severe, and the mortality in younger subjects is certainly not more than 1%. Loss of blood by vomiting is in general associated with a worse prognosis than when there is only melaena, perhaps because the loss is more rapid in the former case.

MANIPULATIVE METHODS IN
ORTHOPAEDICS*

BY

J. F. BOURDILLON, B.M., F.R.C.S.

*Consultant Orthopaedic Surgeon, North Gloucestershire
Clinical Area*

Cyriax (1955) has recently drawn attention to the fact that back lesions very often require manipulative treatment. He also mentions that members of the profession have actually recommended osteopathy to their patients (in spite of the G.M.C.'s warning notice).

My interest arose out of a chain of events. Not long after starting to do laminectomies for disk lesions I worked under a surgeon who regularly manipulated backs and necks under anaesthesia. He obtained very gratifying results without producing cauda equina lesions or other noxious sequelae. I then chanced to see a patient with recurrent low back pain and sciatica who was away from home and who showed me what her own doctor did to relieve her. I performed this rotatory manipulation quite gently and with the desired effect. Her symptoms and signs were what I regarded at that time as indicating a disk lesion. Thirdly, a young woman patient came to see me, complaining of pain in the back of the leg which was not severe unless she did certain things, but which had been present on and off for four years since a fall in which she fractured her eleventh dorsal vertebra. She had been treated in a plaster jacket for four months, so there seemed no point in trying this again. Physiotherapy and a corset were of no avail, so, wishing to avoid laminectomy if possible, I manipulated her under an anaesthetic. She lost her pain completely, but only for a week. After further trial of other methods without relief I did it again, with the same result. After the third manipulation, which again relieved her for a short time, it became clear that if she was to be treated by manipulative methods it must be done without anaesthesia. By repeated manipulation at slowly increasing periods she was eventually relieved completely and has since been able to do bending work without pain, even over prolonged periods.

I started manipulating other patients, and found that by these measures I could relieve some in whom other methods short of operation had failed. I also found some surprising results, including the complete relief of a pain localized to the inner side of the knee and associated with some limitation of extension. The more I manipulated the better my results, but there were still failures, and I was interested when one or two of these patients let me know later that they had been cured by osteopaths.

I decided that I must learn more about osteopathy, in spite of my early indoctrination against it, and by chance I met a qualified doctor now practising osteopathy in London. I spent a week seeing his patients with him, and very quickly realized that there was a lot that I could learn from him. I emphasize that I am not an osteopath but an orthopaedic surgeon.

A Fresh Approach to Back Pain

The first thing that surprised me was the way in which he examined a back. He tested each and every joint for movement and tenderness. When he found a stiff joint he examined it for position. I was also surprised to learn that the

*A paper delivered to the Gloucestershire Branch of the British Medical Association on January 13, 1955.

sacro-iliac joint is a mobile joint and that when stiff it is frequently the cause of symptoms. I was intrigued to learn a simple method of testing for its mobility.

Having been shown the technique of localized spinal examination, localized treatment was the logical sequel, and I was quickly shown a variety of methods. The principle is that the joints above and below the one to be manipulated are "locked" by positioning, and force is then applied to the joint, either directly or by using the locked spine as a lever. Needless to say, it is most important that the joint should be moved in the right direction.

Until this visit I had never used manipulation on patients with recent acute back pain, but there seemed to be no definite dividing line, and when I asked I was told that even the most acute cases would respond very well to this treatment. I have since proved this amply to my own and the patients' satisfaction.

What, then, is the acute incident that happens to produce a sudden attack of, say, "lumbago"? Surely not a displacement backwards of a piece of softened disk material (but see Cyriax, 1955). The pressure on the disk in flexion is said to be very high, and if a pathway has been made by a protrusion of disk material there is no doubt in my mind that even if it can be replaced it must protrude again as soon as the spine is flexed. Cyriax (1955) agrees that manipulation can cure these patients. I believe that the cause of the pain is to be found in a derangement of the zygapophysial joints and that this derangement is mechanical in nature. The pain may result from stretching or pinching of the capsule or of adhesions, or from reflex muscle spasm round the deranged joint.

What is a disk protrusion, and what has it to do with the joint lesion? I think this conception of the initial pathological process can perhaps throw some light on problems that have so far been obscure.

The intervertebral disk has no blood vessels: it has only lymph channels. The method of nutrition appears, therefore, to be by an osmotic pump. The osmotic pressure of disk material is high, and with the spine at rest fluid is sucked in. In the erect or, still more, in the flexed position fluid is squeezed out by a rise in the hydrostatic pressure. If relative motion of the vertebra above and below is prevented by the joint derangement and the muscle spasm round it, the pump cannot work and the disk receives no nutriment. Softening follows, and maybe protrusion.

On this theory the degeneration of teen-age disks as well as the delay often seen between injury and protrusion can be explained. This restriction of motion in the zygapophysial joint is the so-called osteopathic lesion.

It is now widely recognized that intervertebral joint derangements can cause dysfunction in somatic nerves, and it seems illogical to deny that the autonomic nerves can be similarly affected. If, however, one admits this the field of possible secondary symptoms is very much widened.

One difficulty in theorizing about the sacro-iliac joint is to find any explanation of the sites to which pain is referred in derangements of this joint. In my experience pain is referred principally to the back, to the groin and perineum, to the inner side of the knee, or to the heel. Sacro-iliac joint derangements are often accompanied by circulatory changes in the leg, which strongly suggests some involvement of the sympathetic.

One of the main reasons for having a mobile spine is to permit the eyes to be turned quickly to any direction. This function involves complicated interaction of spinal joints and muscles. If a joint becomes stuck in other than its normal position compensatory alterations of position of joints at other levels take place. In time this can lead to the production of secondary joint lesions. Lesions in the sacro-iliac joints can be either primary or secondary. The former is the common cause of acute pain in the back and leg after parturition. The latter very commonly follows lumbar joint derangements.

When considering spinal balance it is clearly of interest to know if the legs are equal in length. It follows that a

constant unilateral strain is thrown on sacro-iliac and low lumbar joints if the legs are uneven. It is very surprising to find how many patients with back trouble have legs that are unequal by more than $\frac{1}{4}$ in. (0.3 cm.), and it is equally surprising to find how much some patients' symptoms are relieved by partial correction by a heel lift.

It is clearly insufficient to measure with a tape from the anterior superior spine. The error due to movement of the sacro-iliac joint may be more than $\frac{1}{2}$ in. (1.3 cm.). Examination of both anterior and posterior superior spines in the erect position, with assessment of the heights of the iliac crests, gives a useful clinical appreciation. The only accurate method is to have the pelvis x-rayed with the patient erect and with the feet together and the knees straight. If the cassette holder is adjusted to the horizontal the relative heights of the femoral heads above the lower edge of the film give the difference.

One other structure of the effects of which the explanation is obscure is the sacro-tuberous ligament. This ligament, of course, is one of those bridging—at a distance—the sacro-iliac joint, and is commonly found to be thickened, tense, and tender in patients with chronic low back pain. I do not know what the pathological process is, but if the ligament is pressed on for upwards of half a minute it gradually gives way and in the process an aching pain is often felt in the leg or in the back. Personally I use the technique although I cannot explain its effects, because I find it helps some patients very much.

Methods of Diagnosis

The spine is usually examined erect first. Leg inequality is looked for, the relative positions of the anterior and posterior superior spines is observed, and the mobility of the spine examined in flexion, extension, and side-bending.

The usual neurological examination is then made, but in addition the mobility of the sacro-iliac joints is tested with the patient supine. This is done by using the leg as a lever. When the leg is externally rotated with a little flick with the knee flexed by about 60 degrees and the hip abducted by about 30 degrees the innominate is moved posteriorly on the sacrum. The reverse movement is obtained by internal rotation in neutral abduction and almost full extension. If the sacro-iliac joint is mobile the leg becomes apparently longer and shorter as the first and the second movements are made. The shift should be at least $\frac{1}{4}$ in. (1.3 cm.), and is best observed by comparing the levels of the medial malleoli before and after each movement.

If one sacro-iliac joint is stiff it is essential to discover what its position is. The relative levels of the superior spines have been examined already for this purpose, but confirmation can be obtained from the relative prominence of the posterior superior spines in the prone position.

The patient is then laid on the side and the upper leg is fully flexed at the hip and knee. The examiner uses his abdomen to control the leg, flexing and extending gently while palpating the interspinous intervals with the fingers. By this means it is possible to determine exactly which joints are mobile and which stiff. Interspinous tenderness is also elicited. When the stiff joints have been found the position of the joint can be determined by palpating the transverse processes with the patient still in the lateral position. The transverse process of a bone that is causing trouble will be made more prominent not only by its rotation but by the tender area of muscle spasm over it. If it cannot be felt on the one side the patient is turned over and the examination repeated on the other side.

The joints of the dorsal spine are most easily examined in the sitting position with the legs over the edge of the couch, the hands linked behind the neck, and the elbows together. The patient bends forwards, resting loosely on the forearm of the examiner, who palpates the interspinous interval with the fingers of the other hand. The determination of position is most easily done prone, when with the flat of the finger a bar of what is apparently muscle spasm can be felt overlying the transverse process, and of course rib, on the side that is displaced posteriorly.

The neck is examined in the same position with the examiner standing behind the patient and the forehead supported in one hand while the other palpates the interspinous intervals. In all these procedures it is essential that the patient should relax in order to allow whatever free movement is possible. The rotation in the cervical region is determined by palpating the transverse processes, and can be done sitting, supine, or prone with the head flexed.

Radiographs are, of course, essential in almost all cases, particularly to determine unsuspected bony abnormalities and leg length. As, however, every joint in the back is examined, the likelihood of missing infective or neoplastic processes is much less than with the orthodox type of examination.

Treatment

The basis of treatment is the replacement into its more normal position of any bone that is causing symptoms as a result of its displacement. It is therefore essential first to know which bone is displaced and in which direction. If a bone is pushed further into the wrong direction the joint is strained more and the symptoms can be made much worse.

The intervertebral joints lock in certain positions, so that they cannot be strained. Full flexion and full extension are the simplest, but are not always suitable. Side flexion with rotation also locks the joints and is most useful. A valuable technique for the lumbar spine is performed thus:

The patient is in the lateral position with the lesion uppermost. The upper part of the body is raised by pillows or by raising the end of the couch, and the shoulder is pushed backwards until the tissue tension can be felt to indicate that the joints above the lesion are locked. The leg is then flexed on the trunk until the tension can be felt to come up to the lesion from below. A thrust forwards on the transverse process then completes the manipulation when combined with a slight exaggeration of the backward rotation of the shoulder and of the flexion of the hip. Thus the upper part of the spine is locked by side flexion and rotation, the lower by flexion. In all these procedures the thrust should be of high velocity but low amplitude, a sharp thrust that is stopped almost as soon as it has begun.

The accurate perception of tissue tension is probably the most difficult part of the whole technique for the beginner to learn. It is essential, and until the art is acquired many patients will suffer unnecessarily, often without receiving any benefit.

Description of other techniques is beyond the scope of this paper.

Results

I regret that I have as yet no figures, and I cannot possibly claim not to have any failures. I am satisfied, however, that my results are much better than they were by orthodox methods alone. I still use physiotherapy, supporting garments, and occasionally plaster jackets for selected cases.

Of particular interest are certain somewhat surprising results, one of which I have already referred to—namely, pain on the inner side of the knee due to sacro-iliac joint derangement. This is often associated with some limitation of extension and a synovial effusion. It forms a most important differential diagnosis of torn medial meniscus because it is very common. I believe it to account for most of the negative explorations of the inner side of the knee-joint. The differential diagnosis can usually be guessed at on the history alone, but unfortunately some patients date the trouble accurately to an injury when "something went click in my knee." The injury is not usually such that one would expect a meniscus tear, and I presume the explanation to be that the click arose in the sacro-iliac joint but was thought to come from the knee because it was to the latter joint that the pain was immediately referred. The treatment is to manipulate the sacro-iliac joint, and the expression on the patient's face is worth watching when the knee will extend fully after the back alone has been treated.

The frozen shoulder is another condition that I have found can be relieved or, if seen in time, aborted. The

joint which is most constantly deranged in this condition is that between the second and third dorsal vertebrae. There is always associated cervical trouble, but I have been driven to the conclusion that trophic changes from sympathetic dysfunction are the prime cause.

Tennis elbow is usually associated with lesions in both dorsal and cervical regions, but for some reason the less localized variety with pain extending to the fingers seems easier to cure.

Migraine in a high proportion of cases, as well as much headache, is associated with upper cervical joint derangements, and can be relieved by their treatment. Disturbance of the sympathetic control of the vertebral artery is a possible mechanism.

The Psychological Factor

Many patients with back pain have a hysterical overlay. This has only too often been encouraged by the well-meaning but misguided remarks of our colleagues who have been unable to find the cause.

Only in a very small proportion is the overlay not relieved by successful treatment of the physical cause.

I can add my own experience of the debilitating effect of chronic back pain. I have had it, and I would recommend it as a very useful lesson to those who would treat the condition in others.

VOLUNTARY SERVICE FOR STATE HOSPITALS

The annual meeting of the National League of Hospital Friends, held in London on March 9, was addressed by Lord Beveridge, who was elected president at the meeting, and by Mr. Iain Macleod, M.P., Minister of Health. Mr. Percy Wetenhall was in the chair.

LORD BEVERIDGE said that the League concerned itself not only with helping hospitals and their patients but with patients suffering from chronic illness who were or could be treated in their own homes. It did so, not merely to save expenditure on hospitals, but because such patients, given reasonable home conditions, were likely to be much happier in familiar surroundings. The problem was to extend the possibility of medical and nursing treatment outside the hospital by means of assistance of various kinds. He appealed to women who were not fully occupied otherwise to serve as home helps. The problem of the chronic sick, with which was linked the problem of the infirm aged, was assuming larger and larger dimensions. In another quarter of a century there might well be ten million old people in this country. The need for help for such people, not only in household jobs but in the provision of companionship and occupation, would become more and more pressing.

The general practitioner, Lord Beveridge continued, had a great part to play in all this. If he could be made responsible for seeing that these domiciliary patients not only had the necessary medical and nursing care but everything else for their comfort and welfare, in which the co-operation of the local authority might have to be enlisted, it would be an ideal arrangement. Notwithstanding the existence of the National Health Service there remained a wide sphere for voluntary action, the great merit of which was that it was not tied down by regulations and Acts of Parliament.

THE MINISTER OF HEALTH, in a brief speech, said it was not known exactly how many Leagues of Friends existed in the hospital world, because many were not affiliated with the National League and many hospitals had such voluntary bodies but working under other names. He was sending out a questionnaire to the heads of all hospitals in the country in order to find out exactly how much voluntary effort was going on, and the Ministry would not be content with progress in this field until every hospital had its own local body of devoted voluntary helpers. His impression was that they were much nearer the goal than might be supposed.

Whenever he visited a hospital in any part of the country he made it a rule to ask about the associated voluntary effort, and it was very unusual to find a hospital which had not some organization of this kind. It had been suggested to him that he might send out new instructions to hospitals about enlisting voluntary service, but he did not think that much could be done by circularization; it must be left to local initiative.

One of the great opportunities for service still open in the field of voluntary effort, said Mr. Macleod, was in the treatment of the chronic sick, and it might be that the Leagues of Hospital Friends could do something to mitigate the difficulties in providing home helps and in assisting in general domiciliary treatment. The treatment of the mentally sick found us still in many ways out of date in our thinking and in our laws. There was still amongst unenlightened people an attitude towards the mentally ill that they must do all they could to change. There were special difficulties because mental hospitals were sometimes remote and difficult of access, but they must not rest content until mental hospitals no less than others were covered by "friendship." The Leagues should set themselves not to supplant but to supplement other agencies, such as the Red Cross and St. John and the W.V.S. They should not be too precise in their work. For example, a hospital might be prevented from providing some amenity because it had to install new treatment facilities, and it was here that the Leagues of Hospital Friends came in.

Nova et Vetera

DR. EDWARD HARRISON, OF HORNCASTLE, AND THE LINCOLNSHIRE MEDICAL BENEVOLENT SOCIETY*

The year 1954 marks the 150th anniversary of the foundation of the Lincolnshire Medical Benevolent Society. The society owes its origin to the indefatigable zeal and crusading spirit of a pioneer medical reformer, Dr. Edward Harrison, of Horncastle, Lincolnshire. Born in Bankfield, Lancashire, in 1766, of an old Lancashire family, he qualified in Edinburgh, and practised medicine for many years in Horncastle (later in London), and became an outstanding figure in the history of medicine, whose fame extended far beyond the boundaries of the county.

In 1820 he published a treatise† on "Remarks upon the different appearances of the back, breast, and ribs, in persons affected with spinal disease, etc." He wrote various other works during his lifetime, and his main interest was clearly in orthopaedics. He survived until his 79th year—no mean achievement for the times—and the medical tradition of the family was carried on by his nephew, Richard Harrison.

Edward Harrison's interests were not by any means wholly confined to medical reform and orthopaedic surgery, for he carried on a busy general practice, and was one of the honorary physicians of the Horncastle Dispensary, founded in 1789. Horncastle in those days was a thriving and important country market town, as readers of George Borrow will recall.

In addition to these other activities Dr. Harrison maintained a large house in West Street, Horncastle (still used as a doctor's residence), and, finding it unnecessarily commodious for his needs, he conducted there a small private mental asylum. He seems to have been a man not only of catholic medical interests but also of indefatigable energy. In the opening years of the nineteenth century he devoted much of his time and characteristic zeal to a crusade designed to raise the status of the medical profession, which had fallen to a low ebb, particularly in the remoter provinces.

*Extract from an address delivered by Dr. Allan H. Briggs, Mayor of Lincoln, at the 150th Anniversary celebrations.

†His name thus became associated with Harrison's grooves or sulcus, but it is now contended (see Naish, J., and Wallis, M. R. E., *British Medical Journal*, 1948, 1, 541) that the grooves were first described by Dr. Edwin Harrison (1779-1847), physician to the St. Marylebone Infirmary.

Quackery was rife; the qualified practitioner earned a precarious living in competition with a host of accoucheurs, apothecaries, druggists, and medical pretenders of every kind; there were no adequate standards for such remedies as were available, and medicines were unreliable and frequently adulterated. He wrote, "It appears from authentic documents that the regular faculty do not constitute one-ninth of the practitioners now occupying physic for emolument in the County of Lincoln, and that besides the errors and unintentional injuries which are daily committed by ignorant quacks upon their too credulous patients there is great reason to fear that some of them acquire large sums of money and do irreparable mischief to many pregnant women and their harmless offspring by trying to relieve the former from the natural consequences of their indiscreet and unauthorized familiarities."

The early records of the Lincolnshire Medical Benevolent Society were to show all too clearly what a laborious and hazardous occupation the practice of medicine and surgery was in those days of primitive transport, ignorance, and penury. The chance of accident or disease might quickly reduce the most successful doctor to distress and want; there was often little margin.

Dr. Harrison set about tackling these problems energetically: he determined upon the foundation of a benevolent society. He prepared a comprehensive set of rules and an "Address to the Public," which he circulated among those likely to be interested, and the first recorded meeting of the society (at which he was not unnaturally elected president) took place at the Bull Inn, Horncastle, on September 21, 1804. Some twenty founder members attended, and the preparatory work had been so well done that a substantial sum of money (£53 13s.) was already in hand. To overcome the formidable travelling difficulties the county was divided up into districts under the charge of vice-presidents, and this valuable feature of the society is still preserved, although sound finance and improving communications have rendered it necessary for the charitable work of the society to be transacted through an annual anniversary meeting, which has travelled round the country from year to year for the past century and a half.

Although the primary function of the society was benevolent Dr. Harrison had other ideas in mind: he saw in it an invaluable means of furthering his ambitions for medical reform, and also the makings of a professional society where members might hear and read dissertations on medical topics.

These multiple objects proved too much to achieve at a single stroke: medical reform was to come—the Anatomy Act of 1832, the Registration Act of 1838, and the Public Health Act of 1848. How far local agitation in Lincolnshire (and elsewhere) contributed to these measures is difficult to estimate, but the indirect influence may well have been considerable. Medical reform thus gradually dropped out of the society's affairs, and the formation of the British Medical Association (1832) and the Lincoln Medical Society (1864) covered many other purposes which Dr. Harrison had sought to serve before his time.

The benevolent functions of the society have, however, gone on from strength to strength, surviving the changes and chances of succeeding generations: the old minute-book reflects the passing of the horse chaise as a means of transport and the introduction of the railway; it saw the introduction of the penny post; it was begun before Waterloo and goes on after two world wars without interruption. Benefactions in ever-increasing volume have been a regular feature of the anniversary meetings, and the annual disbursement from subscriptions and investment income average over £300. During the first century of its life the society dispensed over £7,000, and, during the last fifty years, over £10,000 more.

This long tale of generous assistance to impoverished or disabled medical men, and to their orphans, widows, and dependants, forms a fine and impressive memorial to a great doctor, pioneer reformer, and medical visionary born before his time: Dr. Edward Harrison, of Horncastle.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Post-maturity and Breech Presentation

SIR.—Until recently post-maturity was one of the most controversial subjects in obstetrics. The majority of obstetricians will now agree that this controversy ended when James Walker¹ published his work in 1954. He showed that the oxygenating capacity of the placenta rapidly diminishes after the 40th week; by the 43rd week there is hardly any reserve in the oxygen supply to the foetus. It is therefore much easier to kill the foetus at 43 weeks. He also produced clinical evidence that the still-birth rate at Aberdeen was far greater when the foetus was post-mature, and he quoted Gibberd's similar findings at Queen Charlotte's. In both cases all deaths where disproportion or some other factor contributed to the result were excluded. Unfortunately, this valuable work has not yet reached the more widely read medical journals. Furthermore, when this dangerous complication coincides with a breech presentation, the risk to the foetus is indeed very considerable. The danger of intracranial injury from too rapid delivery is continually being stressed, and quite rightly so. The danger of too slow delivery must be almost as great when the placenta has diminished in efficiency and the oxygen supply to the foetus is only just enough to maintain its life before the delivery of the trunk. Following the delivery of the trunk, when the oxygen supply must be almost completely cut off, such a foetus cannot possibly survive if there is a delay of minutes.

There have, of course, been many obstetricians in the past who appreciated the danger of post-maturity. Yet until a year ago no authoritative textbook was prepared to admit that post-maturity constituted a danger in itself. There would appear to be two reasons for this. First, most obstetricians have at some time or another seen a satisfactory result despite an abnormally long gestation. Some placentae, like human beings, are capable of functioning efficiently well beyond the average allotted span. Secondly, there is a tendency to reason that, when a placenta is so degenerate that it cannot maintain the life of the foetus, neither will it produce an adequate amount of the hormones which are necessary for pregnancy to continue. The foetus is thus saved from death by the mother going into labour and expelling it from the uterus. This quite likely is true in the majority of cases, but not in all. It must be remembered that the maintenance of foetal life is dependent on a sufficiently large area where foetal and maternal blood are in intimate relationship, whereas an adequate production of hormones is dependent on a sufficient number of secreting cells. It is obvious, therefore, that occasionally extensive infarction may result in an insufficient area where foetal and maternal blood are in intimate contact for satisfactory oxygenation to take place and yet the production of hormones is sufficient to continue pregnancy.

This communication is prompted by a recent case where the writer was called to deliver a breech in a primigravida aged 35, and she was three weeks post-mature. The month was exposed within five minutes of the birth of the breech, and yet the foetus made no attempt to breathe. I am certain that this foetus died of asphyxia. The management of breech deliveries, more than most obstetric operations, depends on the skill of the attendant: the object of this letter is merely to stress the added risk to the foetus when the pregnancy is also post-mature.—I am, etc..

Anaesthesia and Cortisone Therapy

SIR,—The introduction of cortisone and related drugs into general medical practice has brought with it further hazards for the anaesthetist. It may not be generally known that patients on cortisone therapy are sensitive to anaesthetic agents; this is particularly true of opiates and barbiturates.¹ Moreover, such patients tolerate blood loss badly, and Fraser *et al.*² have reported the death of a patient from post-operative shock in spite of normally adequate therapy.

It has been stated³ that all patients who have received cortisone therapy within six months prior to the proposed date of operation require special preparation. We would endorse that view, and would suggest that all patients should be asked specifically about cortisone therapy and, where indicated, the necessary preparations carried out. The pre-operative management of these patients has already been adequately described by Pender.³—We are, etc.,

Standards of Fitness of Commercial Vehicle Drivers

SIR,—Dr. Josefine Webb (*Journal*, February 26, p. 515) draws attention to the need for improvement in certain medical aspects of the present system of granting driving licences to professional drivers. Some months ago, however, the Association made recommendations to the Ministry of Transport and Civil Aviation for this purpose.¹

Dr. Webb has fallen into the trap of failing to compare like with like. The medical reasons for rejection of men for military service do not necessarily bear any relation to their safety as drivers; severe flat feet may indeed be a good reason for driving. It is also possible that many of the drivers whose papers were examined by Dr. Webb had declared their defects on the application form and had nevertheless been issued with a licence. The responsibility for issuing licences lies not with the applicant but with the licensing authority. The applicant's responsibility is limited to a declaration (under severe penalty) of his defects. Over three million driving licences of different kinds are issued annually, and until some new method emerges of taking medical histories on a large scale the statutory declaration will have to serve.

The pride of many public service drivers in their safe driving awards is fully justified. I wonder how many of us could maintain the accident-free record which many of these men do for 20 or more years of several hours' driving a day?—I am, etc.,

LESLIE NORMAN.

Septic Injuries in Industry

SIR,—Your leading article (*Journal*, March 5, p. 591) on septic injuries in industry refers to work done in 1949 and 1952 on the incidence of penicillin-resistant forms of *Staphylococcus aureus* in infections of the finger, and remarks that "more recent bacteriological studies are not available."

It may help if I refer to a letter written to one of your contemporaries last December.¹ In it I reported that the casualty department at Sunderland Royal Infirmary has carried out a sample "bacteriological survey" of this problem every year since 1950. As recently as the date of that letter we have been able to confirm that there is no significant increase in penicillin resistance in these infections, provided that the examination is made on closed lesions at the time pus is first obtainable. Discharging lesions show a higher incidence of penicillin-resistant forms than closed lesions, but they show also a higher incidence of gram-negative organisms, so that it is probable that many

antibiotic-resistant staphylococci in discharging lesions are the result of secondary infection in medical or nursing clinics.²

There is, I believe, always a certain incidence of resistant forms in any series of staphylococcal infections, and it is possible that there always has been. This incidence is somewhere between 5% and 10%.³ In this area, at least, we have no evidence that it has materially increased in the last five years. The degree of resistance is usually not very high (0.16 to 0.4 U. per ml. *in vitro*), and these cases also almost always respond to a very short course of penicillin administered in large doses, combined with surgical intervention as soon as there is an indication for it.

Your leading article very rightly emphasizes the cost to individuals and to the community of this type of minor sepsis. We estimated that the annual cost to the Exchequer in sickness and injury benefit of all cases attending casualty departments is (by pure coincidence) about £1 per new case annually. Our own department sees about 15,000 cases, and a rough estimate of the cost of disability comes to £15,000. To reduce this disability by 10% repays the expense of enlisting experienced skill in treatment, and in many clinics it can be reduced by much more than 10%.—I am, etc.,

Dublin.

Sudden Death in Labour

SIR,—While the cause of death in the case described by Dr. Patricia E. Campbell (*Journal*, January 8, p. 87) may have been due to amniotic embolism or, as Mr. R. C. Bell suggests (*Journal*, February 19, p. 480), accidental intravenous injection of the procaine penicillin, there seems to be ample evidence that penicillin itself can cause anaphylactic shock.

In a review of eight cases of anaphylaxis and death following shortly after the administration of penicillin, Rosenthal¹ concluded that, because of the diversity of the types of penicillin used in these cases, no one type of penicillin could be regarded as the sensitizing antigen, and that penicillin *per se* must be regarded as the antigen.—I am, etc.,

Anaphylaxis After Procaine Penicillin

SIR,—Dr. Patricia E. Campbell reported a fatal case of anaphylaxis following an injection of procaine penicillin (*Journal*, January 8, p. 87) and Mr. R. C. Bell queried the cause of death in this case in a letter (*Journal*, February 19, p. 480). This correspondence prompts me to report the following case, which, although fortunately not fatal, leaves no doubt that procaine penicillin can produce alarming anaphylactic reactions.

The patient, an obese woman aged 42, had a history of rheumatism and recurrent attacks of bronchitis. She had a moderate degree of mitral stenosis, fairly well compensated. In August, 1953, she was admitted to hospital for bronchitis with cardiac strain. She was given a course of crystalline penicillin with good results. In October, 1954, she developed bronchitis and was treated at home with six daily injections of "distaquaine" suspension (300,000 units daily), again with good results. On February 2, 1955, the patient was seen at home again suffering from bronchitis with pyrexia: heart regular. She was given distaquaine suspension 300,000 units intramuscularly, and the usual precaution was taken of attempting to withdraw the piston to ensure that the needle was not in a vein. About 10 minutes later the doctor was asked to call at once as it was thought that the patient had died.

On arrival the patient was found to be in an alarming condition. She lay flat on her back, cyanotic, covered in sweat, and gasping for breath. Her pulse was not perceptible at the wrist, but auscultation of the heart revealed marked tachycardia with very faint sounds. The end of the bed was raised and an intramuscular injection of adrenaline hydrochloride 1/1,000 was

commenced, 2 ml. being administered over a period of 15 minutes. Gradually her condition improved so that she could be propped up in a sitting position, and at this point auscultation of the chest revealed sibilant rhonchi and moist rales throughout both lung fields. The patient was by this time able to drink some hot sweet tea which had been optimistically ordered up at the commencement of the adrenaline therapy. She complained of substernal tightness plus difficulty in breathing. Two hours later the patient's colour had greatly improved, her pulse was of good volume, and there was less evidence of pulmonary congestion. A few days later she was quite well and her bronchitis had cleared up.

The rapid onset of the reaction following the injection, with the collapse, cyanosis, sweating, and gasping for breath, is surely typical of anaphylactic shock. Accidental intravenous injection can be ruled out in this case. Whether the reaction was caused by the penicillin or by the procaine could not be determined, as the patient was unwilling to be subjected to an intradermal injection of 0.1 ml. of 1% procaine hydrochloride solution. Her reluctance is quite understandable considering her recent experience.—I am, etc.,

Peterborough.

DAVID C. WRIGHT.

Whither Natural Childbirth?

SIR,—Dr. Constance L. Beynon, in her letter "Whither Natural Childbirth?" (*Journal*, February 19, p. 475), seeks to halt the trend towards wider provision of preparation for childbirth. She states that "to any other generation" special training for childbearing "might seem absurd"—an argument which will carry little weight when we recall the attitude of other generations to analgesia and asepsis in obstetrics. Perhaps the term "natural childbirth" contributes to the confusion by implying something we cannot hope or wish to recapture as civilized, social beings. For civilized people, however, "painless childbirth" would seem an appropriate aim, although not always to be realized at present. This phase, however, appears to arouse Dr. Beynon's wrath, for she apparently hopes to wean women away from demanding it. As she seems to deny, by implication, the possibility of achieving painless childbirth, I feel justified in quoting my own extremely limited experience in general-practitioner domiciliary obstetrics, without claiming any special knowledge and recognizing that so small an experience presents nothing that a statistician need bother to read, let alone disprove.

It is my practice to give my patients a brief series of talks in the latter months of pregnancy, the total time taken being a little over an hour. In them, I explain the course and sensations of labour, encourage an attitude of interest and participation, rather than of resignation, and give instruction in the art of conscious physical relaxation and of rhythmical breathing for the first stage, and in deep breath-holding for the second stage. Nobody, of course, attempts to give a "balanced grasp of midwifery" in such classes, and it is absurd to suggest that they do. Once labour is well established, I remain with the mothers and assist them to apply what they have learnt. Although working in all sorts of homes and with midwives giving varying (but increasing) co-operation, I feel justified in promising mothers treated in this way that their pain will be diminished considerably in nearly all cases and entirely abolished in some.

The experience of the last 12 mothers whom I have prepared and delivered is summarized as follows. Three cases (1 primipara, 2 multiparae): no pain at any stage. Three cases (all multiparae): moderate pain for less than 10 minutes at the end of the first stage. Four cases (all multiparae): moderate pain for up to half an hour, one taking gas-and-air, another wishing to for one very painful contraction, but it was not available. One multipara had backache for about one hour, but did not want gas-and-air. One primipara, while maintaining excellent control and relaxation, required pethidine and gas-and-air for the latter three hours of the first stage.

While this method of preparation and conduct of labour undoubtedly does aid morale (and I cannot see that the maintenance of morale should be regarded as extravagance) it is not merely a case of instilling fortitude; rather it is a means of suppressing pain so that powerful uterine contractions, while still causing a powerful sensation, are not painful. As regards the many experts who find no influence on length of labour, complication rates, etc., I believe that one cause for this lies in the gulf which usually

separates the antenatal class from the labour ward. It is still rare for labour ward staff to have the time, interest, or knowledge to assist mothers to apply their methods, and few mothers are able to retain control without encouragement. The experience of the Paris polyclinic "Pierre Rouquès," where great stress is laid on labour ward support, has been definite in finding a reduced duration of labour, a reduced complication rate, and improved neonatal health.¹⁻⁴ In a recent paper on methylpentynol in labour, Bourne⁵ showed how this drug allays anxiety and facilitates relaxation, and comments that labour in these cases is often speeded up. This statement has caused no adverse comment; why, then, should we be surprised if the alleviation of anxiety by explanation and assistance, combined with instruction in relaxation (a more physiological approach), has similar effects?

As regards the second stage of labour, it is true that bearing down, like defaecation, is a reflex act. Unlike defaecation, however, this reflex is often distorted by fear, panic, fatigue, and the influence of drugs. Antenatal explanation and training in deep breath-holding ensures that when this second stage starts the mother bears down more quickly and more efficiently, which, in turn, ensures freedom from pain and normal progress.

Dr. Beynon is concerned at the sums of public money being spent on antenatal classes. Questioning hospital patients leaves little doubt that the consumer in this case appreciates the efforts made. I believe there may be a case for simplifying and shortening the preparation, and I am certain that the full effect of preparation on the course of labour will only be achieved when labour ward management is based on the principles of the classes. Meanwhile, I hope no false consideration of economy will halt a development which I believe to be both humanely and medically desirable.—I am, etc.,

The National Formulary, 1955

SIR,—It is clear that the criticism of certain aspects of the *National Formulary* 1955 voiced in your leading article (*Journal*, February 12, p. 402) was misdirected. The writer ascribes to the *Formulary* the function of helping practitioners to develop "sensible, honest, logical, and economical prescribing habits." Dr. W. N. Leak, writing with authority as a member of the joint committee which revised the *Formulary*, deplores this attitude in the *British Medical Journal*, and is at pains to point out in his admirably frank letter (*Journal*, February 26, p. 541) that no such consideration guided the members of the committee in their task (the strongest corroborative evidence for this view is surely to be found in the arrangement of the book). Instead, it seems that the committee's aim was to produce a documentary report on the pattern of prescribing observed in this country during the first half of the present century. They evidently regard the gratitude of the social historians of the future as a more fitting reward for their labours than the ephemeral applause of their contemporaries. The practitioners who confided to Dr. Leak their fear that the *Formulary* "is in some way an attempt to direct their prescribing" had no reason to be apprehensive.

Dr. Leak does well to remind us of the classical experiments of Chassar Moir, which vindicated the ergot alkaloids; and he has the intellectual courage to deduce from this episode that no reliance is to be placed on contemporary opinion of the therapeutic merits of drugs. His defence of the readmission to the *National Formulary* of mist, ammon. et seneg. (which he translates for the *in-illuminati* as ammonia and senega mixture) is not based on such uncertain ground, but on the incontrovertible evidence supplied by the experience of "three generations of doctors and patients." The most hardened sceptic who could do no better than cite the contrary experience of two generations of academic doctors would clearly be outmaneuvered.

Dr. Leak takes a cautious view of the modern tendency to prescribe tablets, but is tantalizingly vague about the nature of the "overpowering burden" which this places on the

prescriber. Can he mean that, tablets being more portable than mixtures, the practitioner may be tempted to carry them in his bag? Or does he refer to the strain which is imposed on the memory by "tab. digoxin," as compared with, say, "mist. pot. brom. et valerian."? The "added expense to the State" which he mentions as a consequence of the practice is also hard to understand, since the dispensing fee charged for tablets is approximately half that for liquid preparations.

None will dispute Dr. Leak's contention that the use of bottles of medicine allows "flexible control" of dosage. The range of individual variation in volumetric capacity of domestic measures like "teaspoonfuls" is so wide that dosage is not so much "flexible" as speculative. It is readily conceded that the therapeutic effect of mist, ammon. et seneg. is largely independent of the size of dose administered. But would Dr. Leak agree that certain other drugs demand accurate rather than "flexible" dosage? I offer for his consideration digitalis, which has been well spoken of by at least eight generations of doctors and patients.—I am, etc.,

Edinburgh, 3.

T. W. G. KINNEAR.

Encephalo-trigeminal Angiomatosis

SIR.—Of all the names suggested for the Sturge-Weber-Kalischer syndrome the best up to date seems to me that which I have lately heard of—namely, the "encephalo-trigeminal angiomatosis." There can, I think, be no doubt that both the encephalic and the facial constituents of the syndrome belong to the class of haemangiectatic hamartomatous errors of tissue development roughly grouped together as haemangiectatic naevi. But the area of face involved is not always limited to the trigeminal region of one side. The haemangiectatic abnormality of development may sometimes, in various degree, involve both sides of the face and indeed portions of both sides of the body.

In spite of the coexistence of various concomitant features in most typical cases, such as congenital glaucoma on the side of the encephalic lesion, and hemiparesis of the limbs of the opposite side of the body, I think that encephalo-trigeminal angiomatosis, or better still encephalo-facial haemangiomas, is the best term for the developmental syndrome in question.—I am, etc.,

London, N.W.1.

F. PARKES WEBER.

Positive-pressure Respiration in Bulbo-spinal Poliomyelitis

SIR.—The interesting and detailed article by Drs. J. R. Harries and W. E. Lawes (*Journal*, February 19, p. 448) prompts me to record four similar cases treated by intermittent positive-pressure respiration (I.P.P.R.) in the poliomyelitis unit of the Rush Green Hospital during the past year. They were a girl of 11 years who recovered, and three males, aged 6, 24, and 28 years, all of whom died. In all four cases tracheotomy was performed under local anaesthesia and I.P.P.R. was carried on with the Beavor (mark I) respirator. Despite the obvious shortcomings of this machine—for example, the fixed rate and indifferent pressure control—it proved simple and reliable in use and gave efficient ventilation with only minor signs of CO₂ disturbance, as judged by clinical, biochemical, and fluoroscopic evidence. The cuffed tubes used were of a modified Machray pattern, for which the British Oxygen Company made me a special rubber flange fitting tightly over the tube and corresponding in shape to the "body" of an ordinary Parker or Cubley tracheotomy tube. This was secured round the neck by tapes in the ordinary way, so preventing the tube from slipping down either bronchus.

The patient who recovered was able to dispense with the tracheotomy tube after 11 days, and was finally discharged with only slight palatal weakness. The course of the illness in all three fatal cases was very similar—dramatic improvement after tracheotomy, gradual and then rapid rise of temperature over a period of three or four days to 106° or 107° F. (41.1° or 41.7° C.), followed by cyanosis, coma,

and circulatory failure which was unaffected by noradrenaline drip or other anti-shock measures. I cannot agree with Drs. Harries and Lawes that general anaesthesia is best for tracheotomy in these patients. Certainly it gives the surgeon excellent operating conditions, but there must be more than an element of risk in giving thiopentone and a short-acting relaxant to such patients who, as the authors say, are often in poor condition. Certainly we have met with no major difficulty when using local anaesthesia, and I believe this to be the safest agent.

Chlorpromazine has now been shown to increase the patient's oxygen need slightly. Moreover, it can produce prolonged hypotension, and, despite its ability to give some protection against traumatic shock, different in origin from the so-called "shock" found in poliomyelitis, I think it is more likely to do harm than good. I was glad to see the authors' insistence on an adequate, trained staff. Only those who have treated such cases can appreciate fully the nursing demands. If we should be called upon to treat any considerable number of patients needing I.P.P.R. simultaneously, this would be a major problem.

To sum up, I would say that I.P.P.R. gives dramatic relief for a time, and that it is usually easy to maintain adequate ventilation and CO₂ control, but that the outcome of the illness depends upon the extent to which the virus invades the medulla, pons, and basal ganglia. In two adults in whom necropsy was carried out, these were found to be extensively involved. This process is at present beyond our control.—I am, etc.,

Romford, Essex.

E. JAMES.

Complication of Epistaxis

SIR.—I was fortunate in witnessing the result of a spontaneous remission of a possible fatal complication occurring in a case of severe epistaxis.

An atheromatous lady of some 63 years with a typical blood pressure (170/75) developed a minor nose-bleed which became more severe as the day wore on. In spite of some temporary remissions the bleeding continued on the following day, when, in the early afternoon, I was called to deal with the haemorrhage. By the aid of digital pressure followed by plugging with an adrenaline-soaked swab the epistaxis was finally brought under control. After six hours, however, I was again called and found the patient had again developed a brisk epistaxis. She volunteered the information that she had suddenly experienced severe dyspnoea followed by a violent coughing attack which terminated in the expulsion of an object which she showed to me. It was a perfect blood cast of the whole of one main bronchus and its first division, which must have been some 6–8 in. (15.2–20.3 cm.) in length.—I am, etc.,

Woodford Green, Essex.

J. CRAUSE.

Making the Cap Fit

SIR.—During my work in several family planning clinics the problem of the patient who fails to return has been much on my mind. Sometimes one of these women returns after an absence of several years. During this time she has discontinued using her cap and has gone back to the method of coitus interruptus, with the result that she has had one or more unplanned pregnancies. These "defaulters" are nearly always the women from the poorer social strata: the very women who need our help most. As children they have been exposed to too much lack of privacy. Such women grow up with an intense prudishness and guilt about all sexual matters.

The middle-class woman will ask freely about her sexual problems and be willing to discuss them, and will demand and expect a contraceptive method which will be completely comfortable and enable her to enjoy her sexual intercourse to the full; her poorer sister, on the other hand, will have the greatest difficulty in broaching the matter at all, and will feel that it is perhaps even wrong to ask for a contraceptive that will help enjoyment of a "guilty" pleasure. If she experiences discomfort with her cap or

dislikes the paste or has some difficulty at all with the organizing of the contraceptive technique, she feels that this is her lot in life and will not complain or ask for help easily.

At a clinic we may be somewhat divorced from the reality of our patient's living conditions. It may be as well to remember that there is probably no bathroom or even inside lavatory, and that the whole family may share one room, and perhaps the cap can only be inserted in bed in the dark, or perhaps put in hurriedly hours beforehand when there may be just a moment of privacy. Where a doctor and nurse habitually work together it should be possible for them to co-operate in being imaginative in their teaching and to find out what each individual patient's difficulties and dislikes are, and to make the method of instruction more flexible to suit the patient's needs.—I am, etc.,

London, N.W.1.

ROSALIE TAYLOR.

Benzpyrene and Human Carcinogenesis

SIR.—In your admirable summary of the status of the carcinogens possibly concerned in the origin of bronchogenic carcinoma (*Journal*, November 20, 1954, p. 1213), the statement is made that "there is no doubt that benzpyrene is a dangerous carcinogen to man and animals." Although there is good evidence that certain coal tars are carcinogens to the human skin, and that such tars contain benzpyrene, a substance inducing tumours in certain animal species, there is still no proof that benzpyrene is the responsible agent in human carcinogenesis. Tar contains other carcinogens, as yet unidentified, that induce tumours in the skin of the rabbit and not the mouse.¹ The atmospheric dusts, also suggested in the origin of bronchogenic carcinoma, contain some benzpyrene in certain localities, but also contain other unidentified carcinogens active in mice.² Assuming benzpyrene to be active in man and using this assumption to make quantitative deduction may prove to be somewhat shortsighted, and in my view is likely to hinder a solution of the problem. There is no doubt that there are many more carcinogens yet to be identified, a procedure fraught with difficulties, but it will only be possible to make any confident prediction after this basic information has been gathered.—I am, etc.,

Chicago, U.S.A.

PHILIPPE SHUBIK.

Surgical Treatment of Carcinoma of the Lung

SIR.—Mr. T. Holmes Sellors (*Journal*, February 19, p. 445) is to be congratulated upon the five years' survival rate in his patients subjected to resection. However, it would be interesting to know what proportion these formed of the total number he saw with a view to surgical treatment. In my own experience the possibility of surgery is pathetically poor, even when first seen by the physician. Post-operative pain and discomfort are too frequently comparable with that following radiotherapy.

It is essential for the profession to see this problem in perspective. During the years 1940–53 Mr. Sellors and his colleagues, after tremendous efforts, have 140 patients surviving treatment at the end of three years. It is probable that, in England and Wales, 1,500 people had their lives similarly prolonged. Meanwhile, 132,000 had been certified as dying of this cancer. The yearly toll mounts steadily. In 1953 it was 15,100. Dr. Doll and other statisticians assure us that this figure will reach 25,000 within the next fifteen years, if present trends and habits continue. This means that more than 1,000,000 of our patients and our profession will die before the end of the century.

The evidence from many countries confirms the findings of Bradford Hill and Doll that tobacco consumption, especially in the form of cigarettes, is the main factor in the aetiology of this cancer. The Ministry of Health

attempts to shroud this fact in mystery. The Chancellor of the Exchequer asks that the population continue to smoke, and meanwhile there is joy in the City over increased dividends from the sale of this carcinogen. Surely, Sir, it is time we asked the Minister of Health constantly to inform the population that this toll of death is preventable. No narcotic has ever caused such widespread havoc as tobacco now does throughout the Western world. The later days of the patient dying of cancer of the lung are tragic; the later years of the chronic bronchitic clutching his cigarette are pathetic. By our example and by precept we could raise preventive medicine to the place it must occupy if much lung disease is to be eradicated.—I am, etc.,

London, N.W.10.

HORACE JOULES.

Salt's Valve

SIR.—I would like to write to you about the combination of Salt's valve with Langton Hewer's thyroid mask which we use at the General Hospital, Rochford.

Salt's valve is used by some anaesthetists for assisted or controlled breathing by the semi-closed method. Some find it difficult, especially when they have to keep the chin up and at the same time press upon the top of the valve with the same hand.

This can be overcome by fixing the top of Salt's valve into the hole made in the Langton Hewer's mask as shown in the figure. I would like to thank Mr. R. F. Cooper, our operating theatre technician, who made it for me and arranged for the photograph.—I am, etc.,

Rochford, Essex.

P. M. MEHTA.

Chicken-pox Quarantine

SIR.—Is it really necessary to exclude children with chicken-pox from school? Every year tens of thousands of children each miss several weeks' school on account of this trivial disease, the mortality from which is virtually nil and which causes less general disturbance in a child than does the common cold. Despite the exclusion of cases from school, all but a very small number of children contract the disease before leaving. The only conceivable reason for continuing to isolate cases is the possibility of confusion with smallpox, but this is really a remote likelihood unless a case of adult smallpox has already been reported in the neighbourhood. Naturally those children who are feverish for a day or two at the onset of the disease could be kept at home until they felt better, but after this their mothers could be spared the joys of trying to keep a perfectly fit child amused all day for several weeks on end. The public would not need much educating to this new attitude; most mothers already know that the disease is a triviality and many do not bother to call the doctor if they know that there is chicken-pox about.—I am, etc.,

Margate.

M. CURWEN.

Mercury and Pink Disease

SIR.—In the recent case report in your medico-legal column (*Journal*, March 5, p. 610) it is twice stated that mercury was the cause not only of the death but of the disease. Is it really true that it is now an accepted fact that pink disease is caused by ingestion of mercury?

In my late practice I had three cases of pink disease in 12 years. In two of these there was ample evidence that no mercury had ever been taken. In the third, which died, it had undoubtedly been taken. The mothers of the children who survived were members of my mothers' club and their evidence that no teething powders were given would be quite reliable. On no occasion did I or my assistant prescribe mercury in these cases. I therefore maintain that death from pink disease may be due to mercurial poisoning, but that the disease itself has another aetiology. The symptoms described in the case you quote for which the mercury was given suggest to me that the child already had pink disease.—I am, etc.,

Cockermouth.

F. CHARLOTTE NAISH.

SIR.—A third inquest has been held on a child in Stoke-on-Trent who died of acrodynia associated with excessive ingestion of mercury (*Journal*, March 5, p. 610). At the second inquest in December, 1953, the manufacturers of an extensively used powder reported that mercury was being withdrawn from the formula of their products (*Journal*, December 12, 1953, p. 1330). This action has already reduced the incidence of the disease in these areas. Since January 1, 1954, however, ten cases of acrodynia (two fatal) and two cases of mercury nephrosis have been diagnosed at the major hospitals of Stoke-on-Trent and Shrewsbury. In every case there has been a history of the administration of mercury and the level of urinary mercury (estimated by Dr. E. C. Butterworth) has been high. Four patients have received grey powders on medical and one on a chemist's advice. In one case inunction of a mercury ointment was added for the skin condition. The remaining seven patients took mercury-containing teething powders.

We wish to draw attention to the fact that many of the old type of powders are still being offered for sale by retail shopkeepers. We are also concerned to find that doctors continue to prescribe a drug of dubious therapeutic value, but with known toxic properties to small infants. During 1954 the Poisons Board refused to include inorganic salts of mercury in Schedule 1 of the Poisons List. How many deaths will be required to reverse that decision?—We are, etc.,

J. G. DATHAN,
Stoke-on-Trent,
J. C. MACAULAY,
Shrewsbury.

Disk Lesions and Low Backache

SIR.—The extensive correspondence which has appeared during the past two months on the above subject has shown that there is a singular lack of unanimity in the profession in regard to the diagnosis and treatment of low back pain. One opinion it may be allowed to have established—that is, that prolapsed disk material is not the only cause of backache and the like.

I have already made some observations on the subject in a letter published in your columns (*Journal*, January 9, 1954, p. 97). I do not propose to enlarge upon them, but would like to repeat that the community has not benefited from the discovery of the association of disk lesions and sciatica as much as was hoped. Many of your correspondents have suggested that the terms lumbago and fibrositis, if not scientific, do represent recognizable clinical states. I am inclined to think it would be a good thing if we could agree to let these terms persist until we have gained a clearer view of the pathology of the conditions in question. We might then hope that the general practitioner would treat acute cases on old-fashioned lines and refrain from suspecting lesions of the disk unless there were evidence of major nerve involvement or an unusual frequency of recurrence. Such a practice would at least prevent the undesir-

able inculcation in the patient's mind that there was something radically wrong with his spine. It would also contribute to a reduction in the crowding of hard-worked orthopaedic clinics and ease the pressure on busy departments of radiology and physical medicine.—I am, etc.,

Faversham, Kent.

MAX PAGE.

SIR.—May I be allowed to join in the controversy between those in favour of manipulation in the treatment of backache and those who are not? There are so many different clinical syndromes in backache, all of which have their typical signs and symptoms, and which often pass through different phases, but for each of them the treatment of choice may be totally different. All of these conditions may have protective muscle spasm, which may denote joint and disk changes, as one of their predominant signs. Charnley¹ has shown how a disk undergoes degeneration, and this suggests that Cyriax's² conception of a disk slipping in and out may be true only in a limited number of cases. Recent articles go to prove that pain in the shoulder and arm are often produced by root cuff fibrosis³ and arthritis of the joints of Luschka.⁴ Unless we see the structures involved, as we do at operation, the actual pathology must frequently be one of surmise.

However, I believe, as Cyriax does, in gentle manipulation of all painful back conditions, but with certain provisos. In certain cases rest and other forms of treatment must be instituted with the manipulation. Manipulation is not considered in an established case of true sciatica with a positive Laségue sign, absent reflexes, and impaired sensation. In a case of this type it may cause the disk to prolapse further, resulting in a cauda equina lesion. In manipulating I never allow flexion of the spine beyond a few degrees, as a flexion strain tends to force a degenerated disk backwards towards the spinal cord. Also great care is taken in hyperextension, as a piece of loose disk may be impinging on the posterior edge of two adjacent vertebrae, with the result that it may be squeezed out by this manoeuvre towards the spinal cord.

That a patient may become symptom-free given a particular treatment does not necessarily signify that the right treatment has been given. For example, a young patient may recover from an attack of low back pain for which manipulation has been given, but his condition may keep on recurring. It may be that the best results would have been obtained by a period of complete rest in bed followed by periods first in a plaster cast, then in a McKee brace, and finally in a low back belt.

The non-manipulators would stress these points, but I would point out to them that often a gentle manipulation, especially if combined with physiotherapy and injections, frequently makes the patient symptom-free in one session. Besides, I believe that, unless manipulation is given, the joint movements, both voluntary and involuntary, are not restored to their normal range. For ordinary use movements require to be only 80% of normal, but when strenuous exercise is undertaken they need to be 100%. I believe that this 100% should be achieved wherever possible.

Many overlook the importance of the muscles. I believe that the muscles are affected at three different stages. In the first stage, because of postural strains, the antigravity muscles become tender. Secondly, later, as the result of postural strains, the antigravity muscles which should have been taking the strain fail in their duty, and strain is thrown on the joints which they should be supporting. As the condition of strain persists it causes changes in the joint, and a time comes when the condition produces, either gradually or acutely, a protective muscle spasm of all or of some of the muscles in an endeavour to prevent the joint being used. Thirdly, with the development of osteoarthritis the surrounding muscles undergo definite fibrotic changes.

If a positive attitude is taken by the practitioner, the patient is encouraged to help himself by home treatment, correct posture, how to avoid strain on the back, and the right attitude towards his disability. If the time factor is not important I would agree with the non-manipulators that rest, followed by a course of exercises and support, may be the treatment of choice, but I consider that gentle manipulation combined with rest, physiotherapy, injections, and support, often hasten a recovery, and I maintain support as long as is necessary. On the other hand, if one particular course of treatment, including manipulation, fails to

produce an improvement within a given time a different course is adopted according to the indications, even to immobilization in bed with traction, or plaster cast, or operation.—I am, etc.,

A.C.T.H. and Agranulocytosis

SIR.—Far from being unaware of the use of A.C.T.H. in agranulocytosis as your correspondents suggest (*Journal*, February 12, p. 412), we have used it in a case of chronic neutropenia, and this would have been apparent to Drs. D. G. Wraith and F. Dudley Hart had they read the reference (Hutchison and Alexander, 1954¹) given in our memorandum (*Journal*, January 22, p. 207) to which their letter refers. In that case no effect on granulocyte production was evident in serial examination of both peripheral blood and marrow throughout the period of exhibition of the drug, although in other cases of a similar nature improvement has been recorded.^{2,3}

In acute amidopyrine-induced neutropenia the theoretical indications for the use of A.C.T.H. derive chiefly from the work of Moeschlin and Wagner⁴ and Moeschlin, Meyer, Israels, and Tarr.⁵ These investigators provide evidence that the neutropenia is an immunological phenomenon due to elaboration by the patient of anti-leucocytic antibodies, and that the "maturation arrest" in the marrow is in fact due to exhaustion following excessive peripheral destruction of white cells instead of a direct toxic interference with the production of granular cells as had formerly been thought. A rational case for the use of A.C.T.H. could therefore be presented so long as it was believed that it depressed antibody formation in man; but now even this appears to be in doubt.^{6,7} A.C.T.H. may, of course, be employed empirically or in the hope of reducing the destructiveness of antigen-antibody union in a non-specific way, but the possibility exists, in theory at least, of aggravation of the acute infection in these patients, the most serious risk to which they are exposed. In our case clinical improvement had occurred with antibiotics alone when death took place suddenly from pulmonary embolism, and it is difficult to see how A.C.T.H. could have prevented this.—We are, etc.,

Silver Stool Sign

SIR.—It would be unfortunate if the striking condition described as silver or aluminium paint stool were to become associated with any one pathological process whether benign or malignant. In this laboratory I have seen a few watery stools which, when shaken, gave an appearance strongly reminiscent of aluminium paint, but I have seen very many more showing the same sheen or lustre but to a less striking degree. Such appearances have always been associated with the finding of fatty acid crystals in wet films examined microscopically, the number of crystals present varying with the degree of sheen as seen with the naked eye. Fresh or altered blood has not been recorded.

In a fluid stool a swirling motion serves to emphasize the less obvious degrees of this condition, and there can be little doubt that the acicular fatty acid crystals provide the physical basis for this curious appearance. A similar shimmering lustre may be seen in old exudates which contain large numbers of cholesterol crystals. The streaming effect of the fluid would seem to impart uniform shifts of alignment among the crystals, which, like a shoal of fish

in a stream, now flash broadside and a moment later almost disappear as they twist along the line of sight.

This excess of fatty acid crystals in either a formed or watery stool may have many pathological causes, but in the everyday routine specimens submitted to this laboratory, which deals mainly with cases of suspected infectious disease, I have come to associate these naked-eye or microscopical appearances with the condition (or conditions) variously known as epidemic nausea,¹ the winter vomiting disease,² viral gastroenteritis,³ etc. In its epidemic or sporadic form this disorder may attack very large numbers of children and adults, but few of these consult their general practitioner, and consultants may never see cases outside their own domestic circle. Many samples of faeces received from such cases do not show fatty acid crystals, and it is difficult to guess at the incidence of this change at some stage of the disease, but experience in this area strongly suggests that these acute but benign gastro-intestinal upsets account for the vast majority of silver stools.—I am, etc.,

NORMAN WOOD.

Medical Numismatics

SIR.—I have an old token about the size of a farthing and made of copper; on the obverse is a phoenix and above and below the words "Health restored." The reverse side has "Dr. Eady, 38, Dean Street, Soho," surrounded by a laurel wreath. According to H. R. Storer,¹ it was minted about 1820, but I have not been able to obtain any other information about it.

Many of these nineteenth century "tokens" are not in fact tokens at all, but are advertisement tickets. It is possible that Dr. Eady issued his token either for advertisement purposes or as a receipt for prepayment, to be surrendered when future treatment or medicine was given. I should be grateful to learn whether any of your readers can throw further light on Dr. Eady and the use to which his token was put.—I am, etc.,

London, W.3.

Water Intoxication in Hypopituitarism

SIR.—The interesting paper by Mr. V. Wynn and Dr. O. Garrod (*Journal*, February 26, p. 505) stresses the abnormality of water balance in patients suffering from hypopituitarism, and in order to avoid the complication of water intoxication they suggest that a water excretion test should not be carried out unless the serum sodium exceeds 130 mEq per litre. We should like to reinforce this timely warning and briefly record a severe attack of coma associated with water retention following a Kepler test in a patient under our care at the present time.

During the recent cold spell a lady of 56, who had had a severe post-partum haemorrhage 26 years previously, but had not hitherto been diagnosed as suffering from hypopituitarism, was referred for admission to hospital through the bed bureau with the descriptive diagnosis of "query cerebral." On arrival in the ambulance she was found to be comatose and was taken straight to the ward, where the correct diagnosis of hypopituitary coma was made at a glance by the ward sister (who had seen previous cases). Since the rectal temperature, measured with a bacteriological thermometer, was only 87° F. (30.55° C.) warmth was applied, and later on she was given an intravenous injection of glucose to combat a blood sugar level of 35 mg. per 100 ml. There were no signs of water retention and the serum sodium was 120 mEq. Cortisone was not given, and she made an uneventful recovery in a few hours.

A few days later a Kepler test was carried out in order to confirm the clinical diagnosis and the patient drank 900 ml. of water. She excreted 23% only of this test dose and gained 0.91 kg. in

weight. No change in the clinical condition was noted until 24 hours later, when she vomited, became lethargic and drowsy, showed mental changes, and then lapsed into coma. The facies appeared bloated. The blood sugar fell to 37 mg. per 100 ml., but she failed to respond to intravenous injections of glucose and remained in coma despite a blood sugar level of 92 mg. per 100 ml. Cortisone was then given by intramuscular injection at a dose of 25 mg. every six hours, and after two days' treatment she recovered consciousness. Some interesting E.E.G. records were obtained during the first attack of coma and it is hoped to report the case more fully. It seems that the first attack of coma was precipitated by hypothermia,¹ the second by water retention, and both were associated with hypoglycaemia.

The response to treatment with intravenous glucose solution varied, and we suggest that in all cases of hypopituitary coma a search should be made for a precipitating cause and appropriate treatment given as well as correcting any hypoglycaemia.—We are, etc.,

First Air Ambulance

SIR.—This is an enlargement of a snapshot taken in Somaliland in January, 1920, and is a photograph of the first ambulance aeroplane ever used.

The ambulance was designed at the request of Air Vice-Marshal Sir William Tyrrell, then Wing-Commander, and principal medical officer of Z Expedition to Somaliland

("Mad Mullah" campaign). The machine, which was a D.H.9, was brought to Berbera in a large crate aboard the aircraft carrier *Ark Royal*, and was assembled on land. The fuselage was converted so that it could accommodate a stretcher and one or two orderlies. It had a hinged as well as a part sliding roof.

I had instructions from the wing-commander to have it tried out at the first opportunity, and the few trial runs we had proved that it would be quite comfortable for the patient. I did not know until afterwards that the pilot had some doubts about its airworthiness. It eventually proved a great success in taking casualties from the front line to the base in a little over two hours—a journey which by camel transport would have taken from 10 to 14 days.—I am, etc.,

London, W.1.

MICHAEL SMYTH.

Experiments on Human Beings

SIR.—In your leading article (*Journal*, February 26, p. 526) you mention the "split" between the "scientist" and the "doctor," now supposed often to reside within the same personality. I take it that it is common ground that there is no more fundamental matter for both doctors and patients

than assurance that the doctor will place the interests of the individual patient before the interests of "all the world." The confidence of the public in its hospitals and in doctors, within and without their walls, must surely demand no compromise with this assurance. Since the split you mention undoubtedly exists, and since advancement in the hospital service is at least closely correlated with the publication of papers, the temptation to allow the scientist to persuade, or overrule, the doctor must be increasingly substantial when the two are indeed but one. This being so, the safeguarding equitable principle that a trustee should, if possible, have no interest which conflicts with his duty (to keep paramount the welfare of the beneficiary) suggests that it is undesirable for any medical officer to experiment on his own patient: thus permission—given with the full knowledge of the nature of the experiment—would first be sought from the patient's doctor (who should not participate in the experiment). The doctor would then attempt to explain to his patient. Any experiment would be on the consenting patient of some (other) consenting doctor. Such a safeguard would allay the present public concern over the recent publicity, and would ensure that consent was valid—that is, with full explanation. Such explanation to non-medical persons alone must often be difficult or merely a mockery.

If "science" be slowed as a result of recognizing the right of the patient in this sense, then, I submit, the slowing must be cheerfully accepted. The principle is vital: any tinkering most dangerous. When the individual patient under consideration is not to benefit, but only possible future patients, the onus on the experimenter is even greater, as you point out. The recent public disclosures must surely demand at least that the profession promptly and authoritatively reaffirm the essential requirement of valid consent. The incriminated paper has not been the sole, regrettable, exception—other papers in the last three years share the opprobrium; this point was made in Parliament.

Finally, may I quote the address of Professor Pulvertaft: "We have inherited a degree of trust more entire than that given to any other group of men." The author shows the consequences of forfeiture of this trust.—I am, etc.,

Sheffield.

JOHN L. EDWARDS.

Isophane Insulin

SIR.—I wish to support Dr. E. B. Kraus in his defence of N.P.H. (isophane) insulin (*Journal*, February 19, p. 478). Through the courtesy of Messrs. Eli Lilly and Co., Ltd., I had the opportunity of using this preparation in 1952 and 1953, before it became available commercially. Although the number of cases (10) in which it was used was small, the trial was a severe one, because it was confined to pregnant diabetics.^{1,2} In such cases, insulin requirement is usually high, so that smooth 24-hour control is difficult to attain by means of a single daily injection. Yet, with N.P.H. insulin alone, good control was maintained throughout all stages of pregnancy in seven cases. In the remaining three cases, hyperglycaemia after breakfast necessitated the addition of soluble insulin which is miscible with N.P.H. The following examples will illustrate the smoothness of control (Case No. 12 had syphilis and active phthisis).

Case No.	Maturity	Dose	Blood Sugars				
			Fasting	11 a.m.	3 p.m.	8 p.m.	11 p.m.
20	36	128 N.P.H.	145	155	170		
19	34	72 "	115	140	95	90	83
16	34	78 "	120	91	83	100	91
12	32	and 28 sol. 52 N.P.H. and 24 sol.	165	150	95	125	140

In no case was there evidence of escape from control during the pre-breakfast period. Published reports³⁻⁵

indicate that the action of N.P.H. continues throughout the full 24-hour period.

It is apparent that the timing of N.P.H. action is far superior to that of globin and P.Z.I. There is considerable similarity between the actions of N.P.H. and "lente." In a proportion of cases N.P.H. needs the boosting effect of soluble insulin just as many cases need a mixture of semilente and lente. The lente group may possess an advantage in the availability of the ultralente preparation to assist in the control of cases which need intensive insulin action during the last four hours of the 24-hour period. However, with N.P.H., few cases seem to escape from control at this phase of the day. The essential difference appears to be the absence from the lente preparation of any protein or peptide material other than insulin itself.—I am, etc.,

Sunderland.

Hydrocortisone Ointment in the Eczemas

SIR.—I was very interested to read Dr. Ronald Church's article (*Journal*, February 26, p. 517) on "Hydrocortisone Ointment in the Eczemas." It seems clear that hydrocortisone ointment is capable of reducing the eczema reaction in most circumstances. In some cases little or no response occurs, and it is obviously important to consider the factors that may influence the effectiveness of the application.

Considering first the preparation itself, Dr. Church is of the opinion that in circumstances where the 1% ointment was ineffective the 2.5% was also ineffective. This has not been my experience, and, in a number of patients with infantile eczema treated on one side with 1% and the other side with 2.5% preparations, improvement has been more marked on the latter side. The base of the ointment seems important so far as the physical characteristics of the application affect the condition treated, but it does not appear to influence the specific effect of the hydrocortisone. The frequency of application may also modify the effect of the ointment. An application once per day may keep a mild eczema under control, but in more severe states four times per day has been found to be more effective than twice per day.

Dr. Church mentions that eczema in certain sites of the body does not respond so readily as in others. He considers that this is related to the thickness of the epidermis affecting penetration, and obviously this must be an important factor. He mentions that there is little response in palmar eczema, and I would agree with this, although I have also noticed that neither the front nor the back of the fingers shows much improvement, suggesting that there may be some other factor in addition to the epidermal thickness. Perhaps penetration occurs more readily in warm, greasy, or moist sites. It is also possible that the hormone has a different quantitative effect on different areas of skin.

In Dr. Church's series weeping stages responded better than lichenified eczema, and again he suggests that this is due to poor penetration. He may well be right, but I think he has been rather unlucky in his results with lichenified eczema and lichen simplex, as a high percentage of such patients I have treated showed improvement. The itching was often relieved very quickly, but, as was expected, the eruption took a long time to clear, since, apart from the thickened skin, many months of an itching and scratching habit had to be counteracted. The severity of the eczema reaction influences the apparent response. The more severe attacks may "swamp" the effect of hydrocortisone. For example, in a patient who showed an improvement of the eczema on one arm treated with hydrocortisone and none on the other arm treated with the inert base, a sudden general exacerbation led to both arms becoming worse, and at this stage no difference in the severity of the rash on the two sides was apparent. Finally, there is, as one would expect, a considerable personal variation in response of the skin to the hormone. Similar patches of

eczema in the same sites show for no apparent reason a difference in response from one patient to another.

I would like to thank Dr. Church for reporting his experiences with hydrocortisone. The hormone is obviously going to have an important place in the treatment of eczema in its various clinical patterns, and it is through such reports that we shall gradually discover the indications, limitations, and best methods of application.—I am, etc.,

Bristol.

ROBERT P. WARIN.

Doctors and the Press

SIR.—In the *Journal* of March 12 (p. 677) is published an intimation that the chairman of the Public Relations Committee has invited representatives of the Press to attend an "exploratory meeting" on March 29 at B.M.A. House to discuss "the relations between the medical profession and the Press, particularly with reference to news from hospitals." This invitation arises from correspondence in *The Times* initiated by a letter over the name of Dr. Robert Forbes, secretary of the Medical Defence Union, wherein he accurately described the legal and ethical obligations that each doctor must observe when he is entrusted with advising and treating a patient at home or in hospital. He stressed the obligation of professional secrecy, of regarding the patients' interests as paramount, and of avoiding unethical advertisement. He also allied himself with Professor Aird in denouncing the unseemly behaviour of certain representatives of the Press when seeking to acquire information concerning the health and treatment of the conjoined Gray twins.

I also have learned of some of the devices which members of our profession were driven to adopt to protect the privacy of the treatment and the interests of the patients. This knowledge justifies me in saying that the castigation of certain representatives of the Press administered by Professor Aird in his letter to the *Observer* is well merited. It was therefore gravely disappointing for me to read a letter in *The Times* by Mr. John Pringle, the Public Relations Officer of the British Medical Association, which seemed to impute that the surgeons concerned bore some responsibility for what occurred through a failure to approach him or to accept his offer of help. He writes: "We could and would have arranged for the orderly issue to the Press of that minimum of news which rightly or wrongly . . . the Press have come to expect on these occasions having due regard all the time to the wellbeing of the patients, the feelings of the relatives and the ethical position of the doctors" (no mention is made of the legal responsibilities of the doctors). Several correspondents have protested vigorously at the unjustifiable invasion of the private lives of citizens when they are often undergoing serious mental stress from some misfortune they have encountered. Sir Linton Andrews in his letter says: "This first question is how far the Press is justified in reporting physical abnormalities that are certain to be a source of distress in the families in which they occur." The cultivation of a public interest in pathological abnormalities and their associated human distress in my view offends against the decencies of life. This is an important professional issue—a crucial issue that cannot be buried. I feel Dr. Forbes more accurately described the feelings of the rank and file of our profession when he wrote: "Every fair-minded person will surely agree that it is wholly improper for representatives of the Press to exploit the medical misfortunes of others and especially when the methods employed to collect information create impossible situations for the medical and nursing staffs of our hospitals."

May I conclude by expressing the hope that our representatives at the forthcoming conference will refuse to capitulate to the importuning of the Press or to compromise on the basic legal and ethical obligations that practitioners must discharge if they are to serve the best interests of their patients and the highest ideals of our profession? I urge our representatives strongly to present the view that the physical and mental misfortunes of our patients do not constitute legitimate "news" for dissemination to the public.—I am, etc.,

London, N.W.4

R. W. COCKSHUT.

Obituary

Sir ALEXANDER FLEMING, M.D., D.Sc.
F.R.C.P., F.R.C.S., F.R.S.

Sir Alexander Fleming, who died suddenly at his home in Chelsea on March 11, will be one of the immortals of medical history for his discovery of penicillin. An element of chance came into the discovery, but Fleming himself, who was something of a philosopher, once said, "Do not wait for fortune to smile on you; prepare yourself with knowledge," and it was a prepared mind which observed one day in 1928 that a culture plate had been contaminated by a stray mould and that around the contaminated culture was a ring of dead bacteria. It was an occurrence that would have meant nothing to many bacteriologists, but to Fleming the observation proved to be as significant as the singing kettle of James Watt or the falling apple of Isaac Newton. Fleming, essentially a humble man, was the first to acknowledge that full success was not possible without the help of others, and it was Sir Howard Florey and Dr. Ernst Chain, with their team at Oxford, who 10 years later took penicillin from the laboratory and brought it to the bedside. "The resuscitation of penicillin as a chemotherapeutic remedy," said Fleming, "is due to the brilliant work of Florey and his colleagues at Oxford."

Behind his taciturn manner and homely speech was a spirit of great modesty. The bacteriologist is almost necessarily a modest man. At his laboratory bench he is largely the "back-room" worker in medicine. The limelight rarely shines upon him. From the discovery of penicillin onwards Fleming had to accept with what composure he could—sometimes perhaps with wry amusement—the role of great man upon whom honours, including the Nobel Laureateship in Medicine (jointly with others), came pouring from many universities and academies. "Reporters, broadcasts, speeches come hard when you are over 60," he said a few months ago when the Duke of Edinburgh made a presentation to Sir Alexander to mark the silver jubilee of the discovery of penicillin. But through it all he remained the Scot, the son of Covenanter stock, greatly embarrassed at having to accept fellowships and doctorates and freedoms and other awards and to be acclaimed as one of the great benefactors of humanity. As Louis Pasteur, whose career in some ways his own resembled, yearned for the smell of his father's tannery in the Jura, so Fleming to the end of his life

never forgot the Ayrshire farm on which he was brought up. "I might have followed in my father's footsteps," he once said, "and have become a farmer, but fate decided otherwise."

Alexander Fleming was born in a humble farm home at Lochfield, near Darvel, in Ayrshire, on August 6, 1881. His father died when Alexander was only 7 years old. The boy went first to a tiny school on the moor, then to the village school at Darvel, from which he passed to Kilmarnock Academy. At the age of 14 he made his way to London, where there lived an elder brother who had already studied medicine at the University of Glasgow. In London he continued his education for two years at the Regent Street Polytechnic, and then, for economic reasons, took up work as a clerk in the office of a shipping company—not the least important part of his training, as he said afterwards.

Savings from his salary as a shipping clerk and a succession of scholarships helped him on his way as a medical student. In 1902 he entered St. Mary's Hospital Medical School. The choice of the school was fortuitous, the reason being that he was a keen swimmer and St. Mary's happened to have an active swimming-club. He won almost all the class prizes, including the senior entrance open scholarship in natural science, and he was described by a contemporary as "the most brilliant examinee ever known." He qualified in medicine in 1906, and two years later took the degrees of M.B., B.S. of the University of London, graduating with honours in physiology, pharmacology, medicine, pathology, forensic medicine and

hygiene, and winning the University Gold Medal. He had a phenomenal memory, which, it was said, made him able to absorb a textbook at a single reading. It was evident that this young man from the land of Burns had a promising future. At the age of 28 he obtained his F.R.C.S. As Sir Zachary Cope has since written, "Surgery might have gained what bacteriology would have lost. Yet surgery gained infinitely more, as things fell out."

Work with Almroth Wright

The turning-point for Fleming was his meeting with one whom he called the greatest of British bacteriologists, the late Sir Almroth Wright, who died in 1947 at the age of 85. With him he worked in close association for 40 years until Wright's death. But for that meeting with Wright, he once told an audience, "it is quite likely that I would not have been a bacteriologist, and if I had not been a bacteriologist I would not have discovered penicillin." It was at St. Mary's that Wright continued his studies of therapeutic inoculation

[Barratt's Photo Press, Ltd.]

after his epoch-making work in the Army with anti-typhoid vaccine, and he gathered round him a band of brilliant men, of whom Fleming was one. For many years Fleming continued to be, so to speak, a planet in Wright's solar system, though he also did work on his own initiative. From 1906 to 1914 onwards he was writing on the opsonic index, on vaccine therapy, and on the Wassermann reaction and salvarsan treatment.

Fleming was assistant bacteriologist at St. Mary's from 1906 to 1919, when he became assistant director of the Inoculation Department. From 1911 to 1919 he was also pathologist to the London Lock Hospitals. In 1920 he was appointed lecturer in bacteriology to the Medical School of St. Mary's, and eight years later he became professor, a chair which he occupied until 1948, when he retired as emeritus.

From 1900 to 1914 Fleming was a private in the London Scottish (T.A.) and was a member of the regimental team which won the *Daily Telegraph* Cup at Bisley in 1908. During the first world war he served in the R.A.M.C., but the association with Wright continued. They worked together at a research laboratory which was housed in the casino at Boulogne. It was here that the saline pack for the treatment of war wounds was introduced. Fleming's wartime publications included papers on the bacteriology of septic wounds, blood transfusion, and influenza; and later he contributed to the *Medical History of the War*. For his war services he was mentioned in dispatches. After the war he returned to St. Mary's. In 1919 and again in 1924 he was Hunterian Professor at the Royal College of Surgeons, and in 1928 he delivered at the Royal College the Arris and Gale lectures on lysozyme, his studies in which began in 1922, when he gave a paper on the subject to the Royal Society. If he had not subsequently discovered penicillin he would have still had a high reputation for his work on this enzyme, an anti-bacterial agent present in many animal fluids and especially in tears. Fleming was now acknowledged to be in the front rank of bacteriologists: it was said that he knew his bacteria—which he usually called microbes—as a shepherd knew his sheep.

For about ten years before he retired in 1946 Sir Almroth Wright was principal of the Institute of Pathology and Research at St. Mary's Hospital Medical School. Because of financial changes after the second world war this institute did not develop as originally planned and eventually lapsed. But the Inoculation Department at St. Mary's was renamed the Wright-Fleming Institute and Fleming was appointed to succeed Wright as its director. He retired from this post at the end of last year, being succeeded by Professor Robert Cruickshank, but he had no intention of giving up research work at the institute, which he visited regularly until the time of his death.

The Discovery of Penicillin

One day in September, 1928, Fleming had been examining an agar plate culture of staphylococci with the plate microscope, which entailed frequent exposure to the air. When, after a few days, he looked at the plate again he found a mould on it, and round the mould the staphylococci were dissolving. This was very unusual, so, as he himself said, "I made some investigations and the more I investigated it the more interesting it became. I found that the mould made a powerful and non-poisonous antiseptic which I christened penicillin. With

the subsequent purification of penicillin I had nothing to do."

Fleming's paper on the subject, published in the *British Journal of Experimental Pathology* in 1929, was "On the Antibacterial Action of Cultures of a Penicillium with Special Reference to their Use in the Isolation of *B. influenzae*."

It was an extraordinary chance whereby the right mould contaminated a culture of the right bacteria, that it was Fleming, and not some uninterested bacteriologist, who observed it, and that Fleming that morning was not preoccupied with other things and did not throw the culture impatiently away. Thus the name penicillin was given to the antiseptic agent which the penicillium mould secreted, and the name is now as familiar as any name in medicine.

Fleming made observations on the inhibitory properties of this new substance against many species of bacteria, and he showed that the unconcentrated culture could, even when diluted some 800 times, inhibit the growth of pathogenic cocci and that it was not toxic to animals. In his summary of this paper he suggested that the new penicillin might be an efficient antiseptic for application to or injection into areas infected with penicillin-sensitive micro-organisms.

But there were many difficulties in the way. It was not at that time recognized by Fleming or anyone else that the new substance could be used to destroy bacteria selectively and harmlessly within the human body. It remained more or less a laboratory curiosity until investigation into its possible therapeutic uses began in the Oxford School of Pathology in 1938. Seven years later the work was recognized by the award of the Nobel Prize for Medicine jointly to the three men most concerned—Alexander Fleming the Scot, Howard Florey the Australian, and Ernst Chain the European refugee. In 1944 Fleming and Florey had received the honour of knighthood.

Honours and Rewards

Upon Fleming himself innumerable honours were conferred. He received the Fellowship of the Royal Society in 1943, of the Royal College of Physicians of London in 1944, and of the Royal College of Physicians of Edinburgh in 1946. The honorary degree of Doctor of Science was conferred on him by three American and six European universities; the honorary degree of Doctor of Medicine by seven European universities; the honorary degree of Doctor of Laws by two Scottish universities. He was made a Fellow of important academies in many countries—Commander of the Legion of Honour in France, a Foreign Associate of the French Academy of Medicine, a Fellow of the Royal Society of Copenhagen. He was Linacre lecturer to the University of Cambridge, Cutter lecturer to Harvard University, Mayo Foundation lecturer to the University of Minnesota, Harben lecturer to the Royal Institute of Public Health and Hygiene, among others. From the last-named institute he received the Harben Medal, the first recipient of which, in 1895, had been Louis Pasteur. He was awarded, jointly with Florey, the Gold Medal of the Royal Society of Medicine in 1947. He had previously been president of the section of pathology and of the section of comparative medicine of the Society, of which he was elected an Honorary Fellow eight months ago. In 1951 he was elected Lord Rector of the University of Edinburgh, in which office

he was succeeded by Sir Sydney Smith in 1954. A Convocation member of the Senate of the University of London from 1950, he was also a member of the Board of the Faculty of Medicine. In 1945 he was president of the Society for General Microbiology, and from 1945 to 1949 he was a member of the Medical Research Council, becoming chairman in 1946 of a committee set up to arrange clinical trials of streptomycin and other antibiotics in non-tuberculous conditions. He was made an Honorary Freeman of the City of Verona in Italy on the occasion of the International Medical Congress in 1949. He was also Honorary Freeman of the burgh of Darvel, where he was born, of Chelsea, where he lived, and of Paddington, where his work was done. In the window of St. James's Church, Sussex Gardens, he is depicted in one of five medallions representing Paddington's life and history.

Fleming had other interests apart from the laboratory bench. These included painting and literature, and he was an honorary member of the Chelsea Arts Club. Rifle shooting, golf, and swimming were his other recreations, and he did much of the work himself in the garden of his country house at Mildenhall, in Suffolk.

He married, first, Sarah Marion McElroy, of County Mayo, by whom he had one son, Dr. Robert Fleming. The first Lady Fleming died in 1949. His second wife was Dr. Amalia Coutouris, a Greek bacteriologist who had come to work on the staff of the Wright-Fleming Institute in 1947, and had returned to Athens in 1952 to become head of the bacteriological department of a hospital there. She had won great respect for her bravery during the war in helping the British and New Zealand soldiers in the Greek campaign, and she was eventually captured and imprisoned by the Germans. Sir Alexander Fleming visited Athens in 1952, when he was presented with the freedom of the city and its gold medal, and he married Dr. Coutouris in the following year.

Although penicillin was given to the world as a therapeutic remedy by the brilliant work of Florey and his colleagues at Oxford, Fleming's name will always be associated with its discovery, and it was the discovery of a man working alone. In an address to students near the end of his life he said, "It is for you to create the free atmosphere which will allow genius full play. . . . Much in the future of humanity depends on the freedom of the researcher to pursue his own line of thought."

We are indebted to Sir HENRY DALE, O.M., for the following appreciation: One is inclined to expect that the opinion of the world at large will be somewhat capricious in its selection of scientific discoveries for general recognition and acclaim, and even in its allotment of credit among those who at different stages, or from different angles, have contributed to the result which has made a discovery famous. Experience suggests that the original discoverer, the man "who fished the murex up," is too often almost forgotten, so that credit comes to be given, not unworthily, but too predominantly, to those who have seen and given effect to its practical potentialities. We may be glad that no such deficiency can be suggested in the recognition which public opinion has everywhere given so spontaneously to the original discovery of penicillin, in 1929, by Alexander Fleming. The world has surely made no mistake in regarding the discovery of penicillin, and its introduction into therapeutics, as providing one of the outstanding landmarks in the progress of medical science and its applications, even in an age in which that progress is

acquiring, in so many directions, so astonishing a speed. For us who were Fleming's friends, still saddened by the thought of his sudden going, but thinking of the great work done so well, this is no time for argument, or for the allotment of credit between the man who first saw the penicillin phenomenon, recognized its interest, and studied it further with the instinct of a bacteriological and medical naturalist, and those others who, a whole decade later, first saw the possibility of what proved to be its immense importance in practical therapeutics—immense, surely, beyond any expectation of theirs—and whose researches carried it through the difficult stages to practical trial and launched it upon its beneficent career of healing.

We should rather rejoice, I think, that, for once in a way, all that penicillin has come to mean directly for the prevention and healing of infections, and even the new and successful quest which it inaugurated for other antibiotics, have become so largely impersonated, in the mind of the world at large, and in the figure of the quiet, devoted, rather dour, but always friendly bacteriologist, working loyally under Sir Almroth's inspiration and by his methods, contributing his own ingenious developments, and showing now and then a gleam of interest in phenomena of a different kind, discovering and investigating lysozyme, and then penicillin, with the eye and the enthusiasm of a naturalist.

The public have fully recognized the romantic features of the story. Those of us who belong to the community of medical research are apt to find more interest in what has seemed something of a puzzle—in the fact that Fleming, having discovered penicillin, having recognized its special properties as an antibacterial agent harmless to leucocytes, and having, apparently, made a tentative observation on the application of the crude medium containing it as an external antiseptic, left the discovery there and took more interest in the value of penicillin as a selective constituent of a culture medium than as, potentially, an internal antiseptic. I think that the main clue, at least, is to be found in the fact that neither the time when the discovery was made, nor, perhaps, the scientific atmosphere of the laboratory in which he worked, was propitious to such further enterprise as its development would have needed. Repeated failure had caused opinion then to harden, almost into a settled conviction, against the possibility of a successful chemotherapy of the common bacterial infections. Sir Almroth Wright himself had no belief in such a possibility. Even when some years later the introduction of sulphanilamide and its derivatives had removed the grounds for such scepticism, Wright, as Dr. Leonard Colebrook tells in his biography, was not impressed by the tremendous change which their coming had produced, even though it helped to prepare the way for Florey and Chain's new investigation, in 1939, of the possibility of preparing penicillin on a larger scale and purifying it sufficiently for practical trial, with the triumphant success that all the world knows.

But, though Fleming had thus put penicillin aside for a time, had almost forgotten it, perhaps, in the interest of the researches on other lines to which he had then returned, it is good to think that he lived not only to see the evidence of its immense practical value, on a scale so far beyond any which could have been predicted, but to receive so full a measure of the gratitude and admiration with which the world has greeted this wonderful gift of research to the health of mankind. His ashes, we learn, are to be buried in St. Paul's, but his name will surely live for evermore.

We are indebted to Professor ROBERT CRICKSHANK, principal of the Wright-Fleming Institute of Microbiology, for the following appreciation: Pasteur has written that in the field of observation chance only favours the mind prepared and that there are no accidents in science. Fleming in his characteristically modest way often spoke about his "lucky chance" in the discovery of penicillin, but his own description of that dramatic happening rather supports Pasteur's dictum:

"A mould spore, coming from I don't know where, dropped on the plate. That didn't excite me, I had often seen such

contamination before. But what I had never seen before was staphylococci undergoing lysis around the contaminating colony. Obviously something extraordinary was happening.

"With the background that I had, this was far more interesting to me than staphylococcal research, so I switched promptly. I am now glad that for years my interest had been directed to antiseptics and that some years before I had found in a somewhat similar manner another naturally occurring antiseptic, lysozyme. But for that previous experience it is likely that I would have thrown the plate away as many bacteriologists must have done before. . . . Instead of casting out the contaminated culture with appropriate language, I made some investigations."

It was his perceptiveness added to his earlier work on antiseptics and lysozyme, with the ingenious techniques he devised for testing their activities, that allowed him to assess and prognosticate so accurately about the value and use of penicillin at the time of its discovery.

Fleming was a born biologist, keenly observant of natural phenomena and intensely curious to know how things work. His apprenticeship with Almroth Wright was a great stimulus and inspiration to him, and perhaps in those early days he was to some extent the technician working under the direction of the master. But it is this early training taught him how to work and think about problems. Fleming soon showed that besides high intellectual ability and superb technical skill he also had originality of mind. Although he carried out a great deal of *ad hoc* research on current problems, his main interest was always the natural defences of the body—the phagocyte, opsonin, lysozyme—and the antibiotics were for him almost an interlude in the study of infection and immunity. He was particularly proud of lysozyme, the body's own antibiotic, and he was very pleased that recent studies were substantiating and amplifying some of his early work on natural immunity.

Phlegmatic Scot that he was in many ways, Fleming had a strong artistic sense. He was a beautifully neat draughtsman with the pen, and most of the diagrams in papers by himself and his colleagues were done by him. He took much pleasure in again preparing a demonstration of chromogenic bacteria growing as colours for the Queen Mother's visit to St. Mary's Hospital Medical School Centenary Exhibition last year, and in the week before his death he was busy preparing lantern slides in his own copperplate handwriting for his projected tour to the Middle East on behalf of the British Council. He willingly undertook many such visits abroad, and, if not a particularly good lecturer, his modest, diffident attitude about his achievements made him one of Britain's best ambassadors. Despite these outside commitments he continued to spend a great deal of time in the laboratory, seeing what was going on and giving useful advice on techniques and problems to all of us. We, his colleagues in the Wright-Fleming Institute, will miss him sorely, and we would express our deepest sympathy for Lady Fleming, who brought him companionship and happiness in these last few years.

We are indebted to Dr. JOHN FREEMAN for the following appreciation: It is hard to sum up the man Alexander Fleming at these close quarters of time and space. As a medical student he had swept all before him and had taken any prize there was to be had; but we never heard much of that, and he arrived in Almroth Wright's research laboratory as a very humble figure, the "little man" as he was affectionately called. He made friends easily, and kept them; but he always seemed a cryptic figure: not a talker, and seldom or never giving himself away. He was fond of card-playing, and at poker he probably never showed a card higher than was strictly necessary. His contribution to any laboratory discussion was usually in the form of Scotch grunts and terse interjections, or he reserved his words till others had talked themselves out; yet in retrospect he was usually seen to have dominated the argument—even in the days of Almroth Wright, who was a great dominator of conversations.

Fleming's chief characteristic was his humility, even under the enormous *réclame* of the public press in late years:

yet he took an impish, almost a schoolboy delight in the honours showered on him by the universities all over the world. Nobody ever found him putting on "side": he was the least pompous of mortals.

Penicillin naturally threw his earlier and preparatory work into the shade both in medical and in popular estimation, yet his laboratory colleagues may consider his beautiful demonstrations of the harmfulness of the common antiseptics when applied to our living tissues to deserve as much praise. He showed that even the slightest trace of an antiseptic in the blood stream did harm. "And yet," he burst out in one of his very rare moments of fervour, "there are at least seven hospitals in London, and Mary's is one of 'em, where they are regularly injecting this or that antiseptic into the blood stream in cases of septicaemia." He didn't get much praise for saying things like that.

The discovery of the powers of penicillin did not occur as a lightning flash of genius, but the way up to it had been built by long years of painstaking observation. He never tired of showing us culture plates showing the action of one colony of microbes in enhancing or retarding the growth of some neighbouring colony. Thus the entry of *Penicillium notatum* on to the stage had been systematically built up. Fleming was, so to speak, waiting for it.

He was, first and last, a man of the laboratory bench. He was very deft and accurate in his hand movements, and there is little doubt that he was the best technician in Wright's team; it used to be a pleasure to watch his controlled speed when handling glass in a blowpipe flame. He told me recently he was glad to be shedding all his responsibilities so that he could "muck about" at the bench once more and do real work again. His going will leave a sad gap in the organization of his beloved laboratories. We shall long miss the steadying influence of that great "little man," Flem.

PETER PATERSON, M.B., F.R.F.P.S.

Professor Peter Paterson, who was the St. Mungo professor of surgery in Glasgow University for eleven years between the two world wars, died at his home at Cove, by Helensburgh, on March 4. He was in his 85th year.

Peter Paterson, who came of farming stock, was born in 1870 and studied medicine at Glasgow University, where he graduated M.B., C.M. in 1891. Two years later, with a surgical career in view, he took the London Conjoint diploma, and in 1907 was elected F.R.F.P.S. After graduation and house appointments he continued his studies in Paris and Berlin, where he met Charles Mayo, with whom he became a lifelong friend. When he returned to Glasgow he became, with Hogarth Pringle, one of the late Sir William MacEwen's hard-driven assistants, being appointed extra dispensary surgeon at Glasgow Royal Infirmary in 1895 and also demonstrator of operative surgery in Glasgow University. He was awarded a Weber-Parkes second medal by the Royal College of Physicians of London in 1897 for his essay on a method of producing immunity against tuberculous infection, and two years later he was awarded the Foulis memorial scholarship for eminence in pathology.

In 1906 Paterson was appointed visiting surgeon to Glasgow Royal Infirmary and in the following year lecturer in surgery at St. Mungo's College, becoming professor at the college in 1910. He vacated the chair at the college some two years before he succeeded the late Professor Robert Kennedy in 1924 in the St. Mungo chair of surgery at Glasgow University. He retired from the university professorship in 1935, when he was appointed professor emeritus. For many years he was

recognized as one of the leading surgeons and teachers of surgery in Glasgow. His wife died three years ago and he is survived by two sons.

J. A. G. B. writes: Peter Paterson did not take long to establish himself in Glasgow as a rapid and safe operator, with a flair for diagnosis. As a teacher he was vivid, dogmatic, and impressive. His main interest in research was cancer. For many years he carried out splenectomy (with oophorectomy in females) in these cases, followed by prolonged injections of various extracts of sheep's spleen. Many of the results were striking, but he firmly refused to publish them.

Socially his manner was rather taciturn, and he disliked "functions" of any sort. To his circle of friends he was an interesting and charming host, and he was at his best entertaining a small tea-party in his picturesque garden on a summer afternoon. Clad in an old shooting-jacket and armed with two boxes of mealworms, he would summon a flock of his bird friends to join the party, and while they hopped around his feet or perched on his knee he would discourse on their habits and character. Peter Paterson must be the last of the "master surgeons" of the early twentieth century.

J. DILL RUSSELL, M.B., F.R.C.S.

Mr. J. Dill Russell, who was well known and highly respected as a general-practitioner surgeon at Finchley before the first world war and as a medical officer under the Ministry of Health for many years after the war, died at Windsor Hospital on February 21. He was 81 years of age.

The youngest son of the Rev. William A. Russell, John Dill Russell was born at Strabane, Co. Tyrone, on August 23, 1873. After receiving his early education in Ireland he went to the City of London School and from there to University College and University College Hospital to study medicine. His undergraduate career was brilliant, for he gained many class medals and in his second year the Filliter exhibition in pathological anatomy and pathology. At the London M.B. examination he was awarded first-class honours, the gold medal in medicine, and honours in forensic medicine. In the same year, 1896, he acquired the London Conjoint diploma and in the following year he took the B.S. degree with honours and the F.R.C.S. by examination. After graduation he held the appointments of demonstrator of anatomy and obstetric assistant at his teaching hospital, and in 1898-9 he was senior surgical officer at the South Devon and East Cornwall Hospital, Plymouth.

Dill Russell's training and bent at first inclined him to a career in pure surgery, but with his warm humanity he was also interested in people. Finally, on leaving Plymouth, he decided to enter general practice at Finchley, where he proved a great success, building up a very large practice. His surgical skill and inclination, however, would not be denied, and in connexion with his general practice he did a good deal of operative surgery, acquiring a considerable local reputation for this work. In those days the general-practitioner surgeon was a well-known feature of the medical world, but was rather rare in areas like London, with its many large teaching hospitals staffed by skilled whole-time surgeons. Dill Russell was immensely popular and beloved because of his great skill as a doctor and his complete devotion to the welfare of his patients. He would be the first to admit that in this work he was greatly helped by his wife, who was equally devoted to the care of his patients

and who loved to help on the administrative side. While in practice he became surgeon to the Metropolitan Police and to the Finchley and Hornsey Cottage Hospital and an examiner and lecturer under the London County Council.

The strain of a large practice induced Dill Russell to accept the post of divisional medical officer under the Ministry of Health in 1920, soon after his return from service in the R.A.M.C. in the first world war. This new work took him to various parts of England; later he became a senior medical officer in Whitehall, from which post he retired shortly before the outbreak of the second world war in 1939. He brought to this work the same high standards that he had held in general practice, and, where deficient, tried to raise the degree of skill and service in panel practice. Dill Russell wrote little and took no active part in medical politics. A member of the British Medical Association for over forty years, he was honorary secretary of the North London area in 1902-3 and of the Hampstead Division in 1904, and a Fellow of the Royal Society of Medicine. In the early days of the second world war he did valuable work on medical boards and in other ways. The outstanding features of his life were his scientific integrity, the thoroughness of his work, and his modesty and humanity. He was a great man, both in his attainments and in his character.

Dill Russell was singularly fortunate and happy in his home life, and he and his wife, a daughter of Dr. Frederick Wimberley, celebrated their golden wedding anniversary three years ago. It was a great tragedy, bravely borne, that two of their five sons were killed in the second world war. Two other sons, Mr. A. Scott Dill-Russell and Dr. Patrick Dill-Russell, have followed their father into medicine. To Mrs. Dill Russell, a devoted wife and mother, to the three surviving sons, and to his daughter we extend our sympathy.—W. G. S.

With the death of Dr. R. D. CAMPBELL at Inverness on February 23 the Highlands has lost one of its best-known and most revered physicians. He was 79 years of age. Ranald Douglas Campbell was born at Innellan, Argyll, on July 20, 1875, and was educated at Kelvinside Academy and at Glasgow University, where he graduated M.B., Ch.B. in 1898. After graduation he held resident posts at the Western Infirmary and the Royal Hospital for Sick Children, Glasgow, and was then resident assistant physician at the Belvidere Infectious Diseases Hospital for two years. In 1904 he left Scotland and settled in practice at Hobart, Tasmania, where he remained until the outbreak of war in 1914, when he sailed in the hospital ship *Kanowna* with the 1st Australian casualty clearing station. He served in Egypt and in the Dardanelles, where, as senior medical officer of his unit, he was the last to embark from Gallipoli at the time of the evacuation. He then came with his unit to England and later went to France, where he commanded the 3rd Australian casualty clearing station. He was awarded the D.S.O. in the 1916 Birthday Honours in recognition of his services during the Dardanelles landings, and while serving in France he received the Croix de Guerre in 1918, by which time he had attained the rank of lieutenant-colonel, and was mentioned in dispatches. After demobilization he acted for a time as deputy superintendent at the Western Infirmary, Glasgow, and then, in 1919, took over the practice of the late Dr. Wilson Black at Inverness, where he remained for the rest of his life. He became an honorary physician and ophthalmologist to the Royal Northern Infirmary, Inverness, and oculist to the Ross and Cromarty

and Nairnshire education authorities. He was chairman of the Inverness Division of the British Medical Association in 1929-30. For nearly 30 years at Inverness his general practice and hospital duties occupied most of his time. When he gave up his hospital work at the end of the second world war and his practice a year or two before the introduction of the National Health Service in 1948, he continued to maintain his connexion with the Royal Northern Infirmary by acting as the hospital's medical librarian. He is survived by a widow, a daughter of Dr. Gregory Sprott, of Hobart, and by two sons, the younger of whom is a consultant ear, nose, and throat specialist.

We are indebted to Mr. A. J. C. HAMILTON for the following appreciation: Ranald Campbell matched very closely one's conception of the ideal family physician. Of handsome appearance, always trim in his dress, a provocative and understanding twinkle in his eye, a shrewd and lively wit which on occasion could be pungent, precise and explicit in his speech, neat, clear, and unhurried in his writing, methodical in all he did—these were a few facets of his impressive personality. Where the welfare of his patients was concerned, irrespective of whether they lived in a mansion or a less pretentious dwelling, nothing was too much trouble, and only the best in treatment was good enough. In return he demanded the patient's trust and loyalty, and this he almost invariably obtained. If he did not, then he and the patient parted company. It was natural that the possessor of such a strong personality should have his detractors, but they were vastly outnumbered by his friends and admirers. Children seemed to trust him instinctively, while the elderly patients longed for his next visit. He kept himself abreast of medical advances by his reading and by the unashamed interrogation of those whose knowledge was more recent or more specialized. As a young man Campbell excelled in many forms of sport. In the Highlands his chief relaxation was fishing, and he knew well most of the beats on the Ness, the Beaulie, the Conon, and the Blackwater.

Medical Notes in Parliament

Genetic Risks of Nuclear Tests

Three questions about the potential dangers to human beings from nuclear bomb tests were put to the Prime Minister on March 10. They asked him to take the initiative in proposing the establishment of a United Nations commission to study and assess these dangers; to propose an international monitoring service to detect test explosions; and to seek the limitation of the number of experiments and thus prevent injury to the human race through worldwide contamination of the atmosphere.

Sir WINSTON CHURCHILL stated that, according to paragraph 40 of the official report issued by the United States Atomic Energy Commission on February 15, the atomic and nuclear tests so far carried out had released only enough radioactive material into the atmosphere to cause an individual living in the United States to receive the same quantity of radiation that he would have received in having his chest x-rayed at a hospital. The experts whose advice was at the disposal of Her Majesty's Government saw, he was informed, no reason to dissent from this opinion. So far as the genetic effects of exposure to varying levels of radiation were concerned, he understood that an extensive programme of research was already in progress in both this country and the United States. In addition, he was informed that the Federation of American Scientists had proposed an immediate United Nations study of the potential genetic risks of nuclear weapons tests. It seemed, however, that they were envisaging dangers from a number of tests greatly in excess of those likely to be carried out in the foreseeable future.

Mr. PHILIP NOEL-BAKER (Derby, South, Lab.) asked the Parliamentary Secretary to the Ministry of Works, as representing the Lord President of the Council, whether he would arrange to publish the information available concerning the genetic effects of the increased radioactivity due to the explosion of nuclear weapons. Mr. J. R. BEVINS stated on March 8 that he should make it clear that, except for an area in the vicinity of the explosion, the increase in the radioactivity of the atmosphere resulting from the explosions of nuclear weapons which had so far taken place was negligible in comparison with the amount already present from natural causes. Investigations were continuing, but the Lord President was advised that these had not reached the stage where any firm conclusions could be drawn from them with regard to the possible genetic effects of radioactivity on human beings.

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) asked what research was being conducted on the problem of the increasing radioactive content of the atmosphere of London, and what evidence there was regarding the association between this increased radioactivity and bronchial disease. Mr. BEVINS replied that there was no evidence that there had been, during recent years, any significant increase in the radioactivity of the atmosphere, which remained mainly due to natural causes. Nor had there so far been any evidence that radioactivity was a contributory factor in the causation of bronchial cancer, but investigations were continuing into this possibility. Measurements of atmospheric radioactivity under different conditions were being undertaken at London and in other centres.

Changing Hospital Needs

Mr. F. TOMNEY (Hammersmith, North, Lab.) asked the Minister of Health why the board of governors of St. Mary's teaching hospital group, Paddington, had decided to convert the Children's Hospital to adult use. Mr. IAN MACLEOD replied on March 7 that he understood the reason was that the board considered there was a surplus of staffed children's beds and not enough adult beds in the hospitals in this group.

Mr. TOMNEY said that the specialized assistance for children would now be more widely dispersed. Paddington, Kensington, and Hammersmith were densely populated areas, with large numbers of children. Would the Minister see if the decision could be reversed? Mr. MACLEOD replied that the decision had not yet been taken. The proposal was put forward because the board considered that on the whole the need for children's beds had diminished, which as a general proposition was true. He added, "We should beware of trying to freeze the pattern of hospital provision as it happened to be in 1948 when the scheme came in. There may well be good reasons for a change of use."

Seconding Nurses

Mr. R. W. SORESENSEN (Leyton, Lab.), in a question about the recruitment of nurses, particularly for mental nursing, on March 7, asked what was being done to divert to other hospitals, where there was a shortage, the services of nurses and student nurses in London teaching hospitals, where there was a disproportionate number. Miss PAT HORNSBY-SMITH said that among other matters the Minister had it in mind to invite teaching hospitals to consider with him whether more might be done to second student nurses to mental hospitals as part of their training.

Tuberculosis Treatment in Switzerland

The MINISTER OF HEALTH told Mr. G. WILLIAMS on March 7 that 140 patients from England and Wales were being treated for tuberculosis in Swiss sanatoria under the Health Service. He said the scheme was reviewed annually, and was due for review in September. The main reason for its introduction was the long waiting-lists, but these had

been dramatically reduced in recent years, so much so that from time to time now it was almost difficult to take up the present allocation.

Fluoridation Tests

Mr. S. P. VIANI (Willesden, West, Lab.) asked the Minister of Health what were the results established by recent work in the United States confirmed by the results of his pilot study into the fluorine content of the urine of adults in connexion with the fluoridation of water supplies; and what were the names of the authors and the dates and places of publication of these researches. Mr. IAIN MACLEOD replied on March 9 that the results showed that it was safe to add one part per million and that it was more practicable to decide the level of fluoridation in the light of dental surveys rather than by urinary examinations. References to all the relevant American work would be found in a recent publication of the American Association for the Advancement of Science, called *Fluoridation as a Public Health Measure*, which was published in Washington and could be obtained in London.

Chewing-gum.—The Food Standards Committee is considering certain aspects of the composition of chewing-gum.

Health Service Chaplains.—At the end of 1953 there were 106 whole-time chaplains employed in the Health Service; 92 were Church of England, 10 Nonconformist, and 4 Roman Catholic.

R.A.F. Standards.—In the medical standards for regular commissions in the R.A.F. (general duties) standards of visual acuity have been slightly raised and the standard of colour perception slightly reduced in the past two years.

Universities and Colleges

UNIVERSITY OF OXFORD

Dr. A. G. M. Weddell has been appointed representative of the University at the sixth International Congress of Anatomy to be held in Paris in July, 1955.

Dr. C. W. Carter has been re-appointed Reader in Biochemistry from October 1, 1955, to September 30, 1962.

The Hon. Mrs. Margaret A. Jennings, D.M., has been re-appointed Demonstrator in Pathology from October 1, 1955, to September 30, 1960.

UNIVERSITY OF CAMBRIDGE

The following degrees were conferred in Congregation on February 4:

M.D.—J. S. Pippard.
M.B.—J. F. Wood (by proxy), A. C. Johansson.

The following candidates have been approved at the examination indicated:

M.Chir.—P. F. Boreham, G. L. Bunton, W. H. Davies, G. R. C. Peatfield, W. R. Probert, J. O. Robinson.

In Congregation on February 19 the degrees of M.B., B.Chir. were conferred, by proxy, on D. M. Surrey Dane and the degree of M.B. on W. S. Ogden, also by proxy.

Dr. R. N. Salaman, F.R.S., has been elected into an Honorary Fellowship of Trinity Hall.

UNIVERSITY OF LONDON

The following degrees were awarded by the Senate on January 26:

M.D.—P. V. Suckling.
M.S.—P. B. Counsell.

UNIVERSITY OF SHEFFIELD

Drs. J. L. A. Dowse and R. S. Sneath, Demonstrators in Anatomy, have resigned their appointments.

ROYAL COLLEGE OF SURGEONS IN IRELAND

The Fellowship of the College was conferred on J. S. R. M. Lavelle and F. X. O'Connell on February 18.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending February 26 (No. 8) and corresponding week 1954.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES In Countries and London	1955					1954

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Vital Statistics

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the nine years 1946-54 (influenza, 1952-4) are shown thus -----. The figures for 1955 thus ———. Except for the curves showing notifications in 1955, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest variations in the trends of the notifications of infectious diseases in England and Wales during the week ending February 26 were increases of 3,724 for measles, from 19,976 to 23,700, and 92 for dysentery, from 1,145 to 1,237, and decreases of 232 for whooping-cough, from 1,910 to 1,678, and 96 for acute pneumonia, from 1,020 to 924.

The largest rises in the incidence of measles were 637 in Yorkshire West Riding, from 2,698 to 3,335; 519 in Warwickshire, from 1,060 to 1,579; 490 in Essex, from 902 to 1,392; 292 in London, from 2,402 to 2,694; 204 in Worcestershire, from 260 to 464; 189 in Nottinghamshire, from 1,086 to 1,275; 184 in Northumberland, from 590 to 774; 177 in Durham, from 843 to 1,020; 155 in Staffordshire, from 420 to 575; 143 in Surrey, from 664 to 807; 140 in Hertfordshire, from 179 to 319; 130 in Buckinghamshire, from 98 to 228; 120 in Middlesex, from 496 to 616. 675 cases of scarlet fever were notified, being 7 fewer than in the preceding week, and there were no large fluctuations in the local trends. The largest falls in the returns of whooping-cough were 41 in Staffordshire, from 92 to 51, and 34 in Kent, from 114 to 80. 13 cases of diphtheria, 3 fewer than in the preceding week, were notified.

10 cases of acute poliomyelitis were notified, and these cases were 4 fewer for paralytic and 7 fewer for non-paralytic cases than in the preceding week. The only area with a multiple case was Birmingham C.B. with 2 notifications.

The largest rises in the incidence of dysentery were 83 in Northumberland and 58 in Lancashire. The largest centres of infection during the week were Lancashire 503 (Blackpool C.B. 135, Oldham C.B. 109, Manchester C.B. 73, Blackburn C.B. 48, Lytham St. Annes M.B. 21, Liverpool C.B. 16, Darwen M.B. 16, Middleton M.B. 10, Royton U.D. 10), Northumberland 128 (Whitley Bay M.B. 28, Morpeth M.B. 27, Ashington U.D. 26, Newcastle-upon-Tyne C.B. 24), Durham 72 (Easington R.D. 15, South Shields C.B. 13, Durham R.D. 11), Yorkshire West Riding 61 (Huddersfield C.B. 20, Barnsley C.B. 11, Leeds C.B. 11), Glamorgan-shire 59 (Cardiff C.B. 28, Swansea C.B. 13, Llantrisant and Llantwitfardre R.D. 11), Leicestershire 57 (Leicester C.B. 27, Wigston U.D. 21), Northamptonshire 57 (Northampton C.B. 41), London 51 (Camberwell 10), Norfolk 31 (Norwich C.B. 13), Staffordshire 22 (Newcastle-under-Lyme M.B. 10), Yorkshire North Riding 21 (Middlesbrough C.B. 21), and Middlesex 20 (Edmonton M.B. 10).

Week Ending March 5

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 648, whooping-cough 1,834, diphtheria 17, measles 26,453, acute pneumonia 954, acute poliomyelitis 14, dysentery 1,265, paratyphoid fever 5, and typhoid fever 3.

Medical News

Medical Society of London.—The DUKE OF GLOUCESTER was the principal guest at the 175th anniversary dinner of the Medical Society of London held on March 8 in the Hall of the Royal College of Surgeons. Sir HORACE EVANS, the President of the Society, was in the chair. In proposing the health of the Society the Duke of Gloucester said that as an honorary F.R.C.S. he felt he was speaking on his own ground. Doctoring, he thought, must be a pretty hard life. The medical man had to keep abreast of things and be always ready for emergencies. Sir Horace Evans in reply referred to the Duke of Gloucester's close association with King Edward's Hospital Fund and many other medical institutions. He took the opportunity of thanking Dr. HOPE GOSSE and Dr. CUTHBERT DUKES for the work they had done for the Society, and also the honorary secretaries, Colonel R. DREW and Dr. E. C. SEWARD, and the registrar, Mr. PERCY MINTER.

Hunterian Link.—At a little ceremony held on March 10 at the Royal College of Surgeons Dr. W. S. C. COPEMAN, President of the Hunterian Society, presented to the council of the College John Hunter's coat of arms. The device, bearing the name of John Hunter, is fixed to the gallery of the great hall in the College's new wing; Lister's arms are at the other end of the gallery. Dr. Copeman, begging the President of the College to accept "this small tribute" from the Hunterian Society, recalled that in fact John Hunter had no arms; these were the arms of his brother William. In response Sir HARRY PLATT, P.R.C.S., said the council of the College accepted the gift with great joy. In the history of the College John Hunter had remained their great inspiration, and the presentation would form a link between the societies which revered John Hunter.

Royal Institute of Public Health and Hygiene.—The council announces the award of the Harben Medal, "for eminent services rendered to the public health," to LORD ADRIAN, O.M., P.R.S., and of the Smith Award, given to a medical officer of health "recognized as having done the most noteworthy work in the discharge of his official duties," to Dr. KENNETH COWAN. Both these are triennial awards. The presentations will be made at a social function at the Institute on July 20.

Fellows of University College, London.—Among the new Fellows are Professor A. BRADFORD HILL, F.R.S., professor of medical statistics at the London School of Hygiene and Tropical Medicine, Dr. A. J. MORLAND, physician at University College Hospital, and Professor SOLLY ZUCKERMAN, F.R.S., professor of anatomy at Birmingham.

Arsenic in Food.—Revised recommendations for the limits for arsenic in food have been issued by the Minister of Food in a pamphlet entitled "Food Standards Committee: Report on Arsenic" (H.M.S.O., price 4d.). Earlier reports on this subject were published in 1950 and 1951 (see *British Medical Journal*, 1950, 1, 657). Water and milk, says the new report, should not normally contain arsenic, but a content of up to 0.1 part per million would be allowable. The following limits for other nutrients are proposed: cider, 0.2 p.p.m.; "black beer," concentrated soft drinks, ice-creams, and iced lollies, 0.5 p.p.m.; certain other foods and condiments such as dried onions, edible gelatin, chicory, and spices, limits varying from 2 to 5 p.p.m. The report states that there should be no difficulty in attaining these limits under good commercial practice, and it is recommended that statutory effect should be given to them.

Advice on Head Injuries.—A six-page clinical memorandum on the early treatment of head injuries has been prepared for the North-East Metropolitan Regional Hospital Board by its advisory committee in neurology and neurosurgery. The intention is to issue the memorandum to junior hospital medical staff in the region.

Royal College of Surgeons.—At the Council meeting on March 10 it was reported that Sir GORDON GORDON-TAYLOR had been elected a Trustee of the Hunterian Collection in place of the late Sir Arthur Keith. Sir GEOFFREY MARSHALL has been awarded the Tudor Edwards Lectureship for 1955.

Professor P. B. Medawar, F.R.S., Jodrell professor of zoology and comparative anatomy at University College, London, has been appointed to the University Grants Committee. His appointment is until December 31, 1959.

Dr. Ian MacGillivray, lecturer in obstetrics and gynaecology at Bristol, has been appointed lecturer in midwifery and gynaecology at Aberdeen.

Ladies Medical Golfing Society.—This year the society's course is Wentworth. Lady doctors and close relatives of doctors are eligible for membership. The subscription is 10s. per annum. The spring and autumn meetings will be held respectively on April 25 and September 26 at Wentworth, and there will also be matches against other clubs.

Professor L. J. Witts, Nuffield professor of clinical medicine at Oxford, will receive the honorary D.Sc. of Dublin University at Trinity College, Dublin, on July 5.

Sir Henry Cohen is to receive the honorary D.Sc. of Nottingham University at a congregation on April 22, when the DUKE OF PORTLAND is to be installed as chancellor.

COMING EVENTS

American Trudeau Society.—The 50th anniversary meeting will be held at Milwaukee, Wisconsin, from May 23 to 27. There will be papers, panel discussions, and lectures on tuberculosis and other pulmonary diseases. Details of the programme from National Tuberculosis Association, 1790, Broadway, New York, 19, U.S.A.

International Congress of Comparative Pathology.—The seventh international congress will be held at Lausanne from May 26 to 31. Among the subjects for discussion are viral diseases transmitted to man by animals, atmospheric pollution, and growth disturbances. Details from the general secretariat, 19, rue César Roux, Lausanne.

NEW ISSUES

Journal of Neurology, Neurosurgery, and Psychiatry.—The new issue (Vol. 18, No. 1) is now available. The contents include:

VARIATIONS IN THE BASOPHILIA OF NERVE CELLS ASSOCIATED WITH INCREASED CELL ACTIVITY AND FUNCTIONAL STRESS. LÄRUS EINARSON and Erik Krogh.
ARGYROPHILE BODIES IN THE HUMAN SPINAL CORD. Marion C. Smith.
MORPHOLOGICAL NERVOUS CHANGES IN SURVIVORS OF SEVERE JAUNDICE OF THE NEWBORN. L. Crome.
UNUSUALLY SEVERE LESIONS IN THE BRAIN FOLLOWING STATUS EPILEPTICUS. A. Meyer, E. Beck, and M. Shepherd.
PREFRONTAL LEUCOTOMY AND THE ANTICIPATION OF PAIN. Alice Elithorn, Malcolm F. Piercy, and Margaret A. Crosskey.
INTELLECTUAL CHANGES FOLLOWING TEMPORAL LOBECTOMY FOR PSYCHOMOTOR EPILEPSY. Victor Meyer and Aubrey J. Yates.
VISUAL HALLUCINATIONS OF THE SELF IN ORGANIC DISEASE. Kenneth Dewhurst and John Pearson.
BASILAR IMPRESSION. D. G. Phillips.
SOME OBSERVATIONS ON THE ELECTROENCEPHALOGRAM IN CEREBRAL TUMOURS. J. H. D. Millar.
ALZHEIMER'S DISEASE WITH ACNE ROSACEA IN ONE OF IDENTICAL TWINS. Esther A. Davidson and E. Elizabeth Robertson.

Issued quarterly; annual subscription £2 2s.; single copy (2s. 6d.); obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, March 21

●BRITISH ASSOCIATION OF SPORT AND MEDICINE.—At Wright-Fleming Theatre, St. Mary's Hospital Medical School, 5 p.m., Dr. Roger Bannister: Athletics and Physiology.
●HUNTERIAN SOCIETY.—At the Talbot Restaurant, London Wall, E.C.4, 7 for 7.30 p.m., third dinner meeting. 8.30 p.m., discussion: An Assessment of Some New Drugs. To be opened by Sir Daniel Davies and Dr. Donald Reid. Dr. F. H. K. Green will sum up.

Tuesday, March 22

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. G. C. Wells: Pigmented Tumours.
LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., special university lecture by Professor Lester Cahn (Columbia): Oral Medicine.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Diagnostic Curettage in Suspected Uterine Cancer

Q.—What is the danger of a diagnostic curettage spreading cancer cells in a patient with suspected cancer of the uterus?

A.—Diagnostic curettage, by exposing vascular channels to malignant cells, must on theoretical grounds be accepted as involving some risk of disseminating carcinoma of the body of the uterus, although no more than the performance of biopsy on a suspicious lesion anywhere else in the body. There is nothing to show how great is the risk, but practical experience suggests it is small, since distant metastases are rare even when carcinoma recurs after curettage and hysterectomy. Vaginal metastases are now regarded as being the result of spread via the blood or lymph stream rather than by cellular spill through the cervix, and again there is no evidence to show that they are more frequent in cases subjected to diagnostic curettage before hysterectomy.

The alternative to diagnostic curettage would be to carry out total hysterectomy on every woman with symptoms at all suggestive of carcinoma, and most authorities would regard the risk of an unnecessary hysterectomy as being greater than that of disseminating a possible growth by curettage. Cytological studies carried out on smears of upper vaginal debris are not by themselves a sufficiently reliable method of diagnosis, so, for the present, curettage remains a proper procedure to exclude or diagnose carcinoma of the body of the uterus. Nevertheless, if the clinical features are such as to make the diagnosis practically certain, many gynaecologists would proceed to total hysterectomy without preliminary curettage. Others believe that if the curettings show naked-eye evidence of malignancy then there is less risk of growth becoming disseminated if hysterectomy is carried out at once rather than deferred for a few days pending microscopic examination and report.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Gray.—On March 10, 1955, at St. David's Hospital, Cardiff, to Marion (formerly Muir), wife of Dr. Peter Gray, a daughter.
Laidlaw.—On March 11, 1955, at Rookwood Hospital, Worcester, to Greta (formerly Muir), wife of Dr. Allan J. Laidlaw, a brother for Fiona—Alistair Malcolm Lawrie.
Nathanson.—On March 9, 1955, to Margaret (formerly Milman), wife of Dr. N. E. Nathanson, a daughter.
Summers.—On March 8, 1955, at Brixworth, Northants, to Mary, wife of Dr. H. A. Hamilton Summers, a son.

MARRIAGES

Alexander—Munro.—On March 12, 1955, at Egremont, Cumberland, Conel Patrick Alexander, M.B., B.S., M.R.C.P., of the Royal Free Hospital, London, W.C.2, to Susan Lilias Munro, M.B., B.S., of Egremont.
Baskin—Gibbins.—On March 3, 1955, in London, Dr. Michael Baskin, of Seapoint, Capetown, South Africa, to Miss Thelma R. K. Gibbins, of Surbiton, Surrey.
Stone—Dana.—On March 12, 1955, at Christ Church, Sutton, Surrey, Arthur Richard Stone, M.B., Ch.B., M.R.C.P., of Wellington, New Zealand, to Barbara Mary Dana, M.B., B.S., of Sutton, Surrey.

DEATHS

Clark.—On February 24, 1955, at her home, 4, Overleigh, Street, Somerset, Hilda Clark, M.B., B.S., aged 74.
Covey.—On February 17, 1955, at Barnwood House, Gloucester, Reginald Vionnée Covey, D.S.O., L.S.A., Lieutenant-Colonel, R.A.M.C., retired, aged 81.
Densham.—On February 23, 1955, at his home, 29, The Plantation, Worthing, Alec Densham, M.B., aged 79.
Du Boulay.—On March 1, 1955, at "Chesil," Chandler's Ford, Eastleigh, Hants, Hubert Houssemayne Du Boulay, M.R.C.S., L.R.C.P., aged 94.
Garfit.—On February 23, 1955, Charles Corringham Garfit, M.B., Ch.B., of Kirby Muxloe, Leics, aged 84.
Goddard.—On February 22, 1955, at Washington, U.S.A., Calvin Hooker Goddard, M.D., aged 63.

patients recover with little or no residual discomfort. One assumes that the zoster is not symptomatic—that is, there is no pre-existent structural nervous disease.

The Evening Rise of Temperature

Q.—Why, in most pyrexial illnesses, does the temperature rise take place in the evening?

A.—Normal body temperature measured either in the mouth or in the rectum shows a diurnal rhythm with the lowest temperature recorded in the early morning, rising steadily to reach a maximum usually about 4 p.m., and thereafter declining again. The normal difference between the morning and evening temperature is of the order of 1.2–1.5° F. (0.7–0.85° C.). In pyrexia this diurnal rhythm is in most cases still present although considerably accentuated; so the highest temperature recorded is in the late afternoon and the evening.

There are many other diurnal rhythms apart from body temperature: for instance, the rate of urine secretion rises during the day and falls in the night, and there is a diurnal rhythm in the excretion of corticosteroids. The diurnal rhythms are found in animals and plants. All these rhythms are associated with the local environment. In the case of man the day-night rhythm is imposed from early childhood, but the rhythms can be extremely persistent, even when the pattern of activity is completely altered, so a change from a day to a night shift means that the peak of temperature is reached during sleep and the nadir after several hours of work. It may take many days, or even weeks in some individuals, for any particular rhythm to change to the new pattern. The final cause of diurnal rhythms can be reasonably concluded to be the pattern of activity of the individual, but the intermediate factors are unknown. The physiology of these rhythms provides a long and fascinating chapter of ignorance. Staying in bed does not suppress the diurnal temperature rhythm, and this has been shown by many observers. It is not surprising, therefore, that pyrexial temperatures follow the normal diurnal rhythms, although set at a much higher level.

Histamine Treatment of Migraine

Q.—Can you please give me some information about the treatment of migraine with histamine?

A.—Although there have been reports from the United States which suggest that the treatment of migraine with histamine is sometimes helpful, one's personal experience has been that it is of no value.

Treatment of Mongolism

Q.—The third child of one of my patients is a mongol with all the stigmata of mongolism. He is a boy aged 9 years. What is the latest treatment of mongolism? Is glutamic acid helpful?

A.—No satisfactory specific treatment for mongolism has yet been discovered. There is no evidence that glutamic acid has any specific role in this disorder. A satisfactory diet with adequate protein includes all the amino-acids necessary. The prognosis depends on the degree of the mongolism. Occasionally a case is described in which all the physical signs are present but the individual is of normal intelligence. On the other hand, these children are sometimes low-grade idiots. Most of them are imbecile and can learn to be useful but not economically independent. They usually do better if it is possible to keep them at home rather than putting them in a special institution. This will depend on the position in regard to the other members of the family. Attempts at education should be adjusted to the apparent mental level, though a few cases of mongolism have been able to learn to read and write and profit by more formal instruction.

Bladder Training

Q.—At what age should a child be expected to be dry in bed? A professional couple are worried because their boy of 3½ years wets his bed every night and shows no signs of becoming dry. The parents remove the wet napkin when they go to bed, put the boy, and he then remains dry until the morning. What preventive measures, if any, should be instituted? So far, I have just done my best to reassure the parents that there is nothing to worry about, and that treatment would be a mistake.

A.—Most children have acquired bladder control by the age of 3½ years, but failure to do so does not imply that nocturnal enuresis will be permanent. Not infrequently there is a history in the family of delay in acquiring control, and the history may give an indication of when improvement in the boy may be expected. Routine examination of the urine is desirable to eliminate the unlikely presence of a renal condition. Other investigations are not indicated. Over-zealous "training" should be discouraged. A trial should be given to advancing the hour at which the boy is potted, and to encouraging confidence by not replacing the napkin.

Failure to Ejaculate

Q.—My patient is a married man aged 36, strong and vigorous. He has been married about four months. His wife is aged 26. He complains that he cannot get an orgasm. There is no difficulty in the marital act. His wife seems to be completely satisfied by the act. They have intercourse four or five times a week. He is in good physical health. By occupation he is a farmer, and has no mental inhibitions or complicated ideas. In short, he is a normal, healthy, hardworking outdoor man. Please suggest a line of treatment.

A.—These cases of failure to ejaculate are far commoner than was formerly believed. They are not due to any physical defect, for such patients are able to ejaculate in their sleep, and often have one of these spontaneous emissions in sleep on the same night as they have sexual intercourse or on the following night. As a rule the patient is unable to produce semen by masturbation, and for this reason artificial insemination with the husband's semen cannot be used as a means of satisfying the wife's desire for a child.

Despite the questioner's assurance that this particular patient has "no mental inhibitions," it is in this region of the mind that the explanation of his condition lies. Unfortunately these cases of failure to ejaculate usually prove more resistant to psychotherapy than do cases of failure to obtain an erection, but psychotherapy is the right line of treatment. It might be worth while making a trial of giving him some octyl nitrite to inhale at the time of intercourse. This has helped a few patients, but too much should not be expected of it.

Books of "Any Questions?"—The second and third volumes of "Any Questions?" are available, price each 7s. 6d. (postage 6d.), from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller. Each contains some 200 selected expert answers, and the third volume a cumulative index to the three published books.

ENVIRONMENTAL FACTORS IN CERVICAL CANCER

AN APPROACH TO ITS PREVENTION*

BY

ERNEST L. WYNDER, M.D.

Head, Section of Epidemiology, Sloan-Kettering Institute, New York; Assistant Professor of Preventive Medicine, Sloan-Kettering Division, Cornell University Medical College, New York

Though preventive measures against disease have long been the basic goal of medical research, their possibility has never been fully appreciated in the field of neoplastic disease. This is true in spite of the fact that such an approach has appeared to be practical since Pott's classical observation on scrotal cancer in chimney-sweeps. In a few instances only, involving primarily industrial cancers, have such measures been advanced. Then recent clinical statistical studies on lung cancer, both historical and prospective, demonstrated that environmental factors play a significant part in the production of this major type of cancer. The results of these surveys have led to a continuation of efforts to search for environmental factors that might influence other types of human cancer.

Our initial environmental cancer studies concentrated on those neoplasms whose incidence data suggested significant differences between population groups. We, furthermore, first investigated epidermoid cancers because these types seem particularly dependent on extrinsic factors. Cancer of the cervix belongs to these groups of cancer. It is predominantly an epidermoid cancer and varies significantly among different population groups. Unless such variations can be accounted for by racial factors, they must be explained by differences in environmental patterns. The present communication serves to summarize the findings which may account for the observed rates of cervical cancer recently reported in greater detail (Wynder *et al.*, 1954).

Rates of Cervical Cancer

For statistically significant variables, which epidemiological cancer studies may reveal, to be regarded also as causatively significant, they must at least in part account for such differences in rates. In Table I are shown the relative rates of cervical cancer which have been reported among different population groups. Not all of the data are available as incidence data. Indian data are available only as frequency rates from Indian hospitals. The following rates are of particular interest:

(a) In the United States the incidence of cancer of the cervix among Negroes is 60% higher than among whites, and among the latter it is more common among the lower-income groups (Wynder *et al.*, 1954).

*This paper was presented in part before the Annual Meeting of the American Cancer Society, October 18, 1954, New York.

(b) The rate of cervical cancer among Jews is only one-fifth to one-tenth of that of the non-Jewish women in the United States, and the difference appears to be even greater if one takes the Jewish rate as observed in Israel (A. Symeonidis, personal communication).

(c) A recent report from Denmark by Rojel (1953) shows the rate of cervical cancer among prostitutes to be four times greater than that of non-prostitutes of similar social class.

(d) In most Asiatic and South American countries cancer of the cervix is the most common female cancer.

(e) Gagnon (1950) found no cancer of the cervix among a large group of nuns studied in Canada. A similar finding was recently shown by Schömig (1953) among German nuns.

(f) Cancer of the cervix rarely occurs in women under the age of 20; and in the majority of cases, as reviewed by Pollack and Taylor (1947), before this age, a glandular type of cervical cancer was found.

(g) The relative frequency of cancer of the cervix among Hindu women is about 45%, while it is 29% for the Indian Christians, 18% for the Moslems, and 16% for Parsees as based upon extensive records from the Tata Memorial Hospital in Bombay (Khanolkar, 1950).

These incidence and frequency rates of cervical cancer thus show a marked variation. It has been the purpose

TABLE I.—Relative Frequency Rates of Cervical Cancer Among Some Different Population Groups

Population Group	Relative Rate
Hindus	Very high
Christians (India)	High
Negroes	Low
Parsees	Low
Moslems	Low
Jews	Very low

TABLE II.—Factors which Previous Groups of Investigators Have Suspected to be of Significance in the Production of Cancer of the Cervix

1. Pregnancy and rate of pregnancy
2. Marriage and age of first marriage
3. Cervical laceration
4. Chronic cervicitis
5. Diet
6. Lack of circumcision (poor penile hygiene)
7. Vaginal discharge
8. Hormonal imbalance
9. Coal-tar douching
10. "Racial" factors

of this investigation to uncover the reason or reasons for these differences. In Table II are listed the factors which previous investigators have suspected to be associated with the production of cervical cancer.

Methodology of Study

The significance of environmental cancer surveys rises and falls with the methodology employed. It is paramount that the study is based upon a representative sample of the types of cancer one wants to study, and it is equally important that a proper comparison group is analysed in identical detail.

The cervical cancer patients were interviewed by specially trained interviewers in nine different hospitals in the United States, with the largest single group being interrogated at the Memorial Center, New York. As controls we selected patients with other pelvic disorders. The control group was age- and hospital-standardized in accord with the cervical cancer group. The analyses were based entirely on epidermoid cancer of the cervix. Microscopical diagnosis was obtained in every case. The Indian cancer cases were interviewed by Dr. P. D. Shroff at the Tata Memorial Hospital in Bombay. The same questionnaire was used for the American and Indian studies. The questionnaire attempted to include all of the factors suggested or suspected of playing a part in the development of cervical cancer that could be determined by clinical interrogation.

In part, the interview attempted to obtain information about rather personal matters. It is realized, of course, that not every patient may have told the truth about the age of her first sexual experience. It is also understood that not every patient was certain about the circumcision status of her partner. However, by careful and private interview we have tried to keep such inherent errors to a minimum. Furthermore, the control patients were questioned in the identical manner. It may thus be assumed that some of the inherent interview errors may be balanced out and that actual differences found between the cancer and control groups studied are of real rather than of apparent significance. Upon completion of the interview, the form was edited to assure complete answers to all of the questions, and then the information was coded and punched on special cards. All of the statistical analyses were carried out by Jerome Cornfield, of the Section of Biometry of the National Institutes of Health. Table III shows the number of patients on which this study is based, divided into the respective population groups studied separately.

TABLE III.—Number of Cervical Cancer and Control Patients Included in Study

	Cervical Cancer	Controls
U.S.A.:		
White (non-Jewish)	354	594
" (Jewish)	20	326
Negroes	215	391
Total	589	1,311
India:		
Hindu	255	238
Moslem	26	135
Christian	22	80
Parsee	—	62
Total	303	515

If a given variable was found to be significantly different between cancer and control groups, tests were made to determine whether the variable was independently significant or whether it simply depended on some difference in another variable. The pertinent parts of the study are summarized below.

Results

Only along two broad lines did we find significant differences between the cancer and control groups. These referred to the factors of marriage and circumcision. Two negative factors must be stressed because previous investigators had placed much emphasis on these variables. These four factors are discussed in some detail.

Marriage Factor

As in previous studies, we found fewer single women among patients with cancer of the cervix as compared with the controls. Nine per cent. of the controls had never been married, compared with only 2% in the non-Jewish cervix cases. Respective data for the Negro group

Fig. 1.—Percentage of cervix cancer and control groups in American Hospitals having first coitus at age 16 or before.

Fig. 2.—Percentage of control groups at the Tata Memorial Hospital in Bombay, India, having first coitus at 16 or before.

were 10% and 4%. The single women were of course further questioned for sexual relationship, and in only three instances out of the total white and Negro cases studied was cervical cancer found in a woman who claimed to be virginal.

Cervical cancer patients were found to marry more frequently than control patients. Of the non-Jewish white patients with cervical cancer, 30% had married more than once, in contrast to 14% of the controls. The respective figures for the Negro group were 35% and 23%.

It was a striking fact that the cervical cancer group married significantly earlier than the control group, as has been previously noted by Lombard and Potter (1950). Marriage at the age of 16 or under, for example, for the white cervical cancer group gave 14%, compared with 8% for the controls. The respective data for the Negro group were 32% and 19%, whereas it was 4% for the Jewish controls. Negroes marry at an earlier age than the non-Jewish whites, who in turn do so earlier than Jewish patients. These data are magnified and certainly of greater importance, though perhaps less reliable, if we note the age of first coitus. For the non-Jewish white cervical cancer group it was 19% before the age of 16 and for the controls 10%. Respective data for the Negroes were 55% and 36%, and for the Jewish group 15% and 4% (Fig. 1).

The Indian data showed a significantly earlier onset of first coitus among Hindus and Moslems as compared with Indian Christians and Parsees (Fig. 2). In India the age of first marriage does not necessarily reflect early intercourse, because of childhood marriages. The age of first coitus data among Hindu controls showed 83% to have had intercourse prior to age 16, whereas 76% of Moslems and only 15% of the Indian Christians, and none of the Parsees interviewed, had sexual relations prior to that age.

The data agree with the concept that those population groups with a high incidence or frequency of cervical cancer have uniformly an early onset of first sexual relationship.

Circumcision

In view of the fact that some degree of circumcision has been practised in the United States for the past 60 years and that among non-Jewish males the rate of circumcised men in the age group of 40 to 70 was shown to be 20%, this factor could be studied among the non-Jewish population groups (Wynder *et al.*, 1954). For the white non-Jewish group 5% of the cases reported exposure only to circumcised males, as compared with 14% of the controls. For Negroes the respective percentages were 0.5% and 9%. Among the

Fig. 3.—Percentage of cervix cancer and control groups at American hospitals exposed only to a circumcised sexual partner.

Jewish controls 95% were exposed only to circumcised sexual partners, in contrast to only 55% among 20 Jewish patients with cancer of the cervix (Fig. 3). Among 20 Jewish patients with cervical cancer, three had been married to uncircumcised non-Jews and six admitted to extensive relationships with uncircumcised partners. The age of circumcision does not seem of importance so long as it occurs before marriage. In India only the Moslems practise circumcision. Moslem boys are circumcised between the ages of 6 and 9. The factor of circumcision was cross-analysed and found to be independently significant.

The most desirable way to study the possible effect of penile hygiene would have been to examine the husbands of the patients studied. Because of the obvious difficulty of such a procedure, we examined males from the general hospital population, dividing them into different economic,

TABLE IV.—Percentage Distribution of "Smegma Formation" Among American and Indian Males

	No. of Cases	None	Moderate	Marked
American:				
Non-Jewish white (private)	580	92	7	1
" (clinic)	125	70	24	6
Jewish	980	99.4	0.6	0
Negro	100	44	48	8
India (Bombay):				
Hindu	130	56	28	16
Christian	50	56	30	14
Parsee	50	94	4	2
Moslem	130	100	0	0
India (Madras):				
Hindu	61	16	66	18
Christian	48	27	63	10
Moslem	31	58	42 (slight)	0

racial, and religious groups. The data show that those male groups have the highest degree of poor penile hygiene whose females also have the highest rates of cervical cancer (Table IV). This holds true for the American as well as for the Indian data. It is of interest to note, as judged from the Madras data, that not all circumcisions done on Moslems are complete.

Pregnancy

Several authors have found more pregnancies among patients with cancer of the cervix than among controls, as was indeed also found in this study. For example, in the non-Jewish white group 20% of the cancer group had more than six children, in contrast to 11% among the controls. The respective figures for the Negro cases were 15%

Fig. 4.—Pregnancy rate of cervix cancer and control groups for white non-Jewish women standardized to age of first marriage.

Fig. 5.—Pregnancy rate of cervix cancer and control groups for Negro women standardized to age of first marriage.

and 13%, showing no essential difference. The nulliparous rates for the white non-Jewish group were 9% and 12%, and for the Negroes 11% and 19%. In cross-analysing the data we standardized the number of pregnancies against the age of first marriage, since it was clear from recent studies by the Milbank Foundation that the age of marriage has a significant influence on the number of pregnancies (Kiser and Whelpton, 1944). In Figs. 4 and 5 we present the number of pregnancies standardized to the age of marriage separately for non-Jewish white and Negro cases, and find that there are indeed no significant differences in the rate of pregnancy between cervical cancer and control groups.

Abstinence after Menses

Abstinence from coitus for seven days after the last day of menses, as prescribed by Talmudian law, has often been thought to account for the low rate of cancer of the cervix among Jews (Kennaway, 1948). It was also thought to account for the low rate of cervical cancer among the Parsees. The following points seem to rule out this factor as one of great significance in preventing cervical cancer:

(a) Though the law is practised to some extent in the older Jewish age groups, it is generally not practised at all in the younger age groups. Among Jewish controls 30% reported no abstinence after menses. Among those who abstained, 40% did so for a full seven days. Of those who abstained over the age of 50, 50% abstained for seven days. The comparative figure for those under 50 was 28%. Very few Jewish women under 40 abstained for the seven-day period. Thus, cervical cancer should begin to increase in frequency in Jewish women if this factor were indeed of great significance.

(b) Twenty Jewish cervical cancer cases do not suffice for statistical comparison, but they seem to be in line with the controls. Five of the 20 patients in this group did not abstain after menses.

(c) None of the Parsees studied abstained for one week after menses.

Miscellaneous Factors

Other negative factors included douching, hormone therapy, and vaginal discharge. Negative factors found also include onset and regularity of menses, and number of miscarriages and abortions.

There was some difference in the rate of syphilis; however, the data indicated this to be a result of the earlier age of first intercourse among the patients with cancer of the cervix. The role of contraception remains questionable because no reliable data could be obtained on the frequency of the use of contraceptives, though the data suggested that the use of condoms was somewhat greater among the control group. We did question our patients on the frequency of sexual relations in the early part of their sexual lives. We felt, however, that the patient's memory in respect to these data was too hazy to give information which would be useful for statistical analysis.

The presence of cervical laceration could not be studied with any degree of reliability by personal interview, but, in view of the fact that there was no difference in the number of pregnancies, some doubt must be placed on the role of this factor. Chronic cervicitis was as often diagnosed among the Jewish patients as among the non-Jewish patients studied.

The study also included 32 cases of adenocarcinoma and 34 cases of carcinoma *in situ*. These are not sufficient to afford statistical analysis. In general the *in situ* cancer cases tended to be in line with the epidermoid cancer cases, while the adenocarcinoma cases went in the direction of the controls.

Discussion

For statistical association to have also causative significance the association must at least in part explain differences in incidence and frequency patterns. Table V presents

TABLE V

Population Group	Rate of Cervical Cancer	Age of First Coitus	Circumcision State and Penile Hygiene
Hindus (India) ..	Very high	Very early	Very poor
Negroes (U.S.A.) ..	High	Early	Poor
Christians (India) ..	Low	Very early	Good
Moslems (India) ..	Low	Very early	Good
Parsees (India) ..	Low	Late	Very good
Jews (U.S.A.) ..	Very low	Late	Very good

evidence suggesting that the factors of age at first coitus and lack of circumcision may account for the differences in rates of cervical cancer. In respect to circumcision, it may well be that good penile hygiene may achieve the same end.

The data suggest that virgins have the least risk of developing cancer of the cervix, whereas those groups practising early relationships and whose males have poor penile hygiene have the highest risks of cervical cancer. These two factors can, in our opinion, account for the observed differences in frequency rates. For example, Negroes tend to have early sexual relations and relatively poor penile

hygiene, and have a high rate of cervical cancer. Hindus have an even earlier rate of first intercourse and more extensive bad hygiene, and have the highest rate of cervical cancer. Jewish women have a relatively late age of first marriage, the males practise excellent penile hygiene due to circumcision, and have a low incidence of cervical cancer. Moslems marry quite early yet have only one-third of the rate of cervical cancer as compared with the Hindus. No other differences could be determined between the Hindu and Moslem data except for the circumcision variable. Parsees, with a relatively low incidence of cervical cancer, marry late, and, though they do not practise circumcision, have good penile hygiene. Cancer of the cervix is rare among women without sexual relations, and is quite frequent among prostitutes.

It does not lie within the confines of this communication to speculate upon the mechanisms by which lack of circumcision and early sexual relationships may influence the development of cervical cancer. It may be theorized that under the male foreskin exists a carcinogenic agent. This hypothesis is emphasized by the infrequency of penile cancer among circumcised males and by the fact that horse smegma has been found to be carcinogenic to mouse skin (Plaut and Kohn-Speyer, 1947). Recently, H. R. Pratt-Thomas (personal communication) induced a significant number of cervical cancers in mice with human smegma. It is of interest, too, in this respect that population groups with a high rate of penile cancer also have a high rate of cervical cancer. The fact that the latter is more common than the former may be due to the much greater tissue susceptibility of cervical epithelium to cancer formation.

The earlier onset of intercourse among patients with cancer of the cervix could be explained on the basis of special hormonal patterns or merely as a result of the socio-economic mores of a given population group. We believe it to be primarily due to the latter factor, since early coitus seems to be a consequence of socio-economic and conventional standards rather than due to a special hormonal status. It can only be speculated why early intercourse leads to more cervical cancer. It may be due to greater susceptibility of young cervical tissue. It may be because of a more active sexual life in women who marry early. It may be due to a greater variety of sexual partners in women who marry early—a factor which we were not able to study in detail. The fact that cancer of the cervix occurs more frequently, for example, in women who have been married more than once might be on the basis that these women have had two active sex lives, or on the basis that such a woman is more likely to be exposed to a "carcinogenic" male than one who has had only one marriage.

The lack of correlation of pregnancy with the development of cervical cancer is of academic as well as of statistical interest. It demonstrates the importance of properly controlled and analysed environmental studies. It is suggested that if previous investigators had standardized their data to age of first marriage the pregnancy rate of their controls would also have been similar to those of the cervical cancer patients.

Since pregnancy rate, including that of miscarriage and abortion, was demonstrated to be a negative variable, it may be proposed that factors associated with pregnancy, such as cervical laceration and poor prenatal care, may also not be significant in the development of cervical cancer.

Epidermoid Carcinogenesis

The results of this study re-emphasize the data of Pott, other industrial cancer investigators, and recent lung cancer surveys that epidermoid cancer but rarely arises in sites not exposed to extrinsic factors of irritation. The human evidence in this respect is supported by animal data. Spontaneous epidermoid cancers in laboratory animals are quite uncommon. In a large necropsy series (Wells, Slye, and Holmes, 1941) they could find only a few epidermoid lung cancers. Spontaneous skin cancer in mice is very uncommon, though this area is quite susceptible to carcinogens.

From the point of view of practical significance it makes little difference what concept one holds regarding the mechanism which transforms a normal cell into a neoplastic one. It might well be, as Warburg (1954) suggests, that extrinsic factors interfere with the oxidation mechanism of the cells and thus initiate neoplasia. Perhaps at some future date we may uncover the specific mechanism by which certain extrinsic factors may initiate cancer. From the present point of view, however, it is most important to recognize that in the absence of these factors the incidence of some cancers is greatly reduced, and that by their control we are advancing an effective means of cancer prevention.

Epidemiological Considerations

Recent epidemiological surveys on cancer have re-emphasized the significance of properly controlled and conducted clinical studies which, we believe, can add more information about the effect of environmental factors on human cancer than could be obtained from any laboratory experiment. It is a method which requires a close co-operation of qualified statisticians, clinicians, and trained interviewers. Such a team can establish data which can be regarded as experimental as any laboratory work, and thus do not represent "just some statistics." If the data obtained by such an investigation are compatible with the incidence pattern of the cancer, with its geographic distribution, and with its time trends, then, it seems, we are dealing with factors that are not only of statistical but also of causative significance.

Practical Considerations

In environmental cancer work we have to separate data into those of academic and those of practical importance. The factor of age of first intercourse is primarily of the former, whereas those referring to circumcision and penile hygiene are of the latter. The data suggest, though they do not prove, that good penile hygiene may be as effective as circumcision and that this may account for the relatively low frequency of cervical cancer among the high-income groups, a fact which of course may also be influenced by the later onset of marriage as compared with the low-income group (Wynder *et al.*, 1954). The best and most practical measure for obtaining good penile hygiene is universal circumcision. For the past ten years a high degree of circumcision has indeed been practised in the United States. In a recent study based upon reports from 84 hospitals throughout the United States, 85% of all non-Jewish male babies born in the semi-private or private class were circumcised at birth (E. L. Wynder, unpublished data). The circumcision rate was equally high among Protestant and Catholic births. Thus, if it is indeed true that circumcision acts as a preventive measure against cancer of the cervix, a marked lowering should be noted in this type of cancer in the coming generation.

In summary, this study again showed that in the development of epidermoid cancer extrinsic factors are of significance. It was demonstrated that clinical-statistical investigation, provided that it considers all of the environmental factors, can separate those that are independently and those that are only dependently significant. It was shown that factors can thus be determined which can account for marked differences in frequency patterns found among different population groups which previously had been supposed to be on the basis of racial factors. The two most important factors were those of the age of first sexual relations and the lack of circumcision, or the associated poor penile hygiene. Of these two factors, the latter has the greatest practical significance. Even these two factors, of course, represent only a link in the total chain of cancer development, and undoubtedly other factors must be present, though so far they remain unknown to us. However, if by removing a link we can interrupt a chain of development we have succeeded in preventing the chain from undergoing completion. It is along this line that environmental cancer research has its greatest purpose.

Summary and Conclusions

A study of the role of environmental factors in cervical cancer indicates that differences in age of first coitus and circumcision status or lack of good penile hygiene can explain variant incidence data of cervical cancer among different population groups.

There is no statistical evidence that pregnancy rate plays a part in the production of cervical cancer. The data on pregnancy demonstrate the significance of careful statistical analysis in separating the dependent from the independent variables. They clearly emphasize the importance of trained statistical aid in these investigations.

The abstinence period practised by orthodox Jewish women after the end of menses is not believed to be the basic factor accounting for the low incidence of cervical cancer among Jewish women.

The data emphasize that exogenous factors play a major part in the development of epidermoid cancer.

The results underline the importance of international co-operation, which can achieve more conclusive results than can be obtained from any one country alone.

The findings suggest that universal circumcision may be a practical preventive step, significantly reducing the incidence of cervical cancer.

The downward trend in the total volume of crime in England and Wales, first noted in 1952, continued throughout 1953, according to statistics in the *Report of Her Majesty's Inspectors of Constabulary for the Year ended September 30, 1954*. Offences against property without violence decreased by 8.9%, and offences with violence by 9.5%, including 6,512 fewer crimes of shopbreaking and 1,619 fewer of housebreaking. An encouraging decrease was also shown in the number of boys under 14 and youths under 17 found guilty of indictable offences. Though the figures are still high, 20,774 and 14,549 respectively, compared with those for 1938, it is believed that the post-war wave of juvenile delinquency has at last been checked. The most disquieting feature of the report was the record of continued increase in sexual crimes; sexual offences increased by 9% and offences of violence against the person by 14% over the previous year. The public's response to the police drive to make them "crime prevention conscious" is one of the main reasons given for the reduction in the total. It is also thought that the building-up of the uniformed branches of the police, the advantage of basic training for young officers, and the still increasing assistance given by the forensic laboratories have proved a deterrent. The preliminary figures for the first nine months of 1954 show that the improvement continues. Of the non-indictable offences, traffic offences decreased by 6%, but gaming and betting offences increased by 7%. There was little change in the number of persons found guilty of drunkenness.

PSYCHICAL PHENOMENA IN TEMPORAL LOBE EPILEPSY AND THE PSYCHOSES*

BY

SHAFICA KARAGULLA, M.D., M.R.C.P.E.

University and Montreal Neurological Institute

AND

E. ELIZABETH ROBERTSON, M.B., F.R.C.P.E.
D.P.M.

Royal Edinburgh Hospital for Mental and Nervous
Disorders

The psychical phenomena which form part of the seizure pattern in certain cases of epilepsy may be said to represent a mental disorder in miniature, and for this reason their study may help us to understand the more complex and global mental disturbances found in the psychoses. We claim no originality for this suggestion, for it was made by Hughlings Jackson in 1875. And the Jacksonian epithet, "dreamy state," serves to remind us that Hughlings Jackson was one of the first to stress that psychical phenomena are just as much a manifestation of epileptic discharge as the more spectacular tonic and clonic contractions. Moreover, he was able to correlate such mental concomitants of epilepsy with a structural lesion—since in his famous case of Dr. Z, who suffered from "dreamy states," he and Colman (1898) demonstrated at necropsy a softening in the uncus of the left temporal lobe. These were some of the first stages in a long pathway which has led to present-day investigations into the psychical phenomena in temporal lobe epilepsy—investigations which will always be associated with the name of Dr. Wilder Penfield, of the Montreal Neurological Institute.

Hughlings Jackson and his contemporaries obtained their knowledge from clinical observation and interrogation of the patient during or after the seizure. This must always remain an essential preliminary to any investigation. The proof, however, that such abnormal mental experience is the product of epileptic discharge in the temporal lobe has come from electrical stimulation of the temporal lobe cortex in conscious patients. In particular it has come from the accumulated, carefully controlled, and correlated stimulations carried out in the last 30 years by Penfield and his associates (1941, 1950, 1954) during their operative procedures for the relief of epilepsy. These electrical stimulations are an essential part of the operative technique, their purpose being to delineate the epileptogenic focus, but probably no other routine operative technique arouses such strained suspense in the observer, who knows that at any moment the electrode may elicit from the patient a description of some sudden and compelling mental experience which cuts across his normal stream of consciousness. Thus, for the first time in history, man has been made to see visions and hear voices by means of the stimulating electrode and at the will of the surgeon.

The psychical phenomena which are produced by epileptic discharge in the temporal lobe or by cortical stimulation are many, and include hallucinations of vision, hearing, smell, taste, touch; illusions of distance, size, form, colour, motion, speed of sound and time;

*Delivered at an open meeting of the Royal Medico-Psychological Association at the Royal Society of Medicine on November 3, 1954.

disturbances in equilibrium and body image; alteration in thought and affect; disorientation for time, place, and person; disturbances in speech and automatism, the latter with its accompanying memory defects.

From all this bewildering variety we have had perforce to make a selection, and here we propose to illustrate but three, which have a special bearing on the psychoses, in particular on the disturbance in thinking found in schizophrenia.

Material

The cases of temporal lobe epilepsy presented here have been selected from the first 105 cases of a series studied by one of us (S.K.) under the direction of Dr. Wilder Penfield at the Montreal Neurological Institute since September, 1952. Sixty-eight had undergone one or more craniotomies. Nine of the total were tumours, two were cysts, and the remaining 94 were atrophic lesions of the temporal lobes.

The cases of psychoses were studied at the Royal Edinburgh Hospital for Mental and Nervous Disorders, between the years 1946 and 1954, under the direction of Professor Sir David K. Henderson.

The experiences which we describe and illustrate may be stated thus: (1) The experiencing of "thoughts"—such thoughts being either indefinite or formulated. (2) The hearing of "voices" within the mind or body or from a point external to the self. (3) The seeing of persons, objects, or scenes, which, again, may be perceived within the mind or at some point external to the self.

We later present the hypothesis that all these three are but variants of the same phenomenon—that they all represent abnormal derivatives of thought.

1. Evocation of "Thoughts" in Temporal Lobe Epilepsy

We first illustrate these experiences from cases of temporal lobe epilepsy. The first case is one in which "thoughts" occurred as part of the seizure pattern and were also reproduced on cortical stimulation. The "thoughts" so induced were not clearly formulated—they may be called "amorphous" thoughts.

Case 1

A.D. was a young man of 20 who had suffered from both major and minor epileptic seizures since the age of 16. E.E.G. examination revealed an extensive epileptic abnormality in the right temporo-parietal lobes. Before operation he described what he experienced during his seizures as "two thoughts coming together." He explained it thus, "It is something whatever I may be occupied with at present is overlapped or overjoined by another thought. This thought comes along, hits me and goes back, a reminder, but I cannot give a picture of what it reminds me. Something hits me and reminds me of something which hit me before; maybe that is why I think it is two thoughts." This mental experience was followed by a squeamish feeling in his stomach. He remained able to speak and understand throughout the minor seizures.

When, during operation, cortical stimulation was made at a point 6 cm. from the tip of the right temporal pole in the second temporal convolution, at a depth of 1 cm., the patient said, "My thoughts sort of bounced together for a second," but he added that this was not exactly similar to his experience during an attack. Three later stimulations, carried out at variable intervals at a depth of 2 cm. slightly anterior, reproduced, however, a change in thought identical with that which occurred during his attacks. During the first stimulation he said "the same two thoughts which come together"; and when the electrode was withdrawn he explained that one of those thoughts was concerned with what was happening at the present time, and the second thought was of something different, but what it was he could not recall. Stimulated a second time, he said, "This is it," and crossed his index finger over his third in an attempt to illustrate what he meant. When the electrode was withdrawn he was asked whether what he experienced was a memory; he said definitely, "No, it is the thought that crosses." Stimulated a third time, he said, "It comes again," and moved his fingers in

illustration, saying, "They mixed the thought." This was followed by a feeling in the stomach. This experience of "thoughts" identical to that which formed part of his seizure pattern was reproduced no fewer than three times by cortical stimulation. These evoked "thoughts" forced themselves on consciousness as something separate and distinct from the normal stream of thought of the patient, and were recognized by him as not clearly formulated.

In a second case, both epileptic discharge and cortical stimulation induced the experience of "rhythmic thoughts," which to the patient appeared at the time of their experiencing as fully formulated, although he could not later recall their content.

Case 2

W.S. was an intelligent man of 30 with a left temporal focus. His seizures were ushered in by a sensation in the left chest, and immediately thereafter he was aware that the sounds in his environment—for example, the machinery in his factory—became louder and faster. Human voices, however, did not change. At the same time he experienced "thoughts" coming into his mind—which he described as "rhythmic thoughts—as though I were thinking of something, maybe the rhythm of poetry or music: the rhythm is always the same. It feels familiar to me during the seizure, yet I cannot recall it afterwards." When asked if they were memories, he said, "No, they were like words or combinations of words." On another occasion he added that it was like thinking two things at once. At operation, the pattern of his seizure was best reproduced by stimulation at a point 1 cm. from the tip of the left temporal pole on the second temporal convolution. He was unable to speak during the actual moment of stimulation, but when the electrode was withdrawn he said, "That was something like an attack," and described the sensation in the left chest, and his awareness of "thoughts" entering his mind, the content of which he was unable to recall.

The clinical findings in this case are almost identical with those of a case reported as far back as 1876 by Dr. Coats, of Glasgow, in which the patient's fit was preceded by giddiness and a "peculiar thought." To quote Dr. Coats: the patient "cannot tell what the 'thought' is, yet is confident that it is always the same. He always recognizes it at once when it occurs, and he tries to fix it in his memory, but he invariably forgets when the fit is over."

This induction of thoughts into the mind by cortical stimulation has occurred in other cases, and the stimulation points tend to be grouped around the second and inferior temporal gyri.

It is worthy of emphasis that these patients have difficulty in describing both the content of their induced thoughts and the manner in which they are experienced. This difficulty was well expressed by one intelligent patient, who tried in vain to describe the manner in which thoughts rushed into his mind during his seizures, and finally, in desperation, exclaimed, "It is like asking an artist to paint a picture of what roast beef smells like and he cannot do it." It seems only too probable that what we are asking of them is comparable to the impossible task of describing one sensation in terms of another.

How can we categorize this experience? In what group of abnormal mental phenomena can it be placed? We have of necessity to make use of such concepts as are at present available—although these are less than ideal—and so we would designate these intruding "thoughts" as hallucinations. There is no other word extant—although we hope in future that more precise terms will be formulated—which can cover this experience, whereby a thought, evoked either by epileptic discharge or cortical stimulation, apparently assumes a separate existence alongside the patient's own current of thought. Such separate existence would appear to be proved by the patient's ability to bring his powers of introspection to bear on it, and to describe it, however inadequately, during or after its occurrence.

Definition of Hallucination

According to the Oxford Dictionary, a hallucination is defined as "the apparent perception of an external object when no such object is present," and this placing of the hallucinatory experience outside the self is usually implied in the general usage of the term. It is a finding in psychia-

try, however, that when a patient says he "hears" certain words or phrases, that he "sees" certain objects or scenes, what he "sees" and "hears" has for him no external location, but is "heard" and "seen" in the mind. There exists to-day a disinclination to apply the term "hallucination" to these abnormal "internal" perceptions, yet the older French writers showed no such hesitation. Baillarger (1890) entitled them "psychical hallucinations" using the contrasting term "psychosensory hallucinations" to designate these abnormal external perceptions, which then, as now, were more generally accepted as constituting true hallucinations. Under this title "psychical hallucinations" Baillarger included not only these "alien" ideas which "come to" the psychotic patient in the form of "thoughts," but "voices" which he locates in the head or epigastrium. Séglas (1892) cites, with approval, this category of "psychical hallucinations" first demarcated by Baillarger, emphasizing its clinical authenticity. He himself coined the term "psychomotor hallucinations" to denote the "inner voices" experienced by psychotic patients—believing, in terms of the strict cerebral localization theories popular in his time, that such internal auditory hallucinations resulted from an excitation of the motor centre for speech. Older theories of causation need not concern us here—what is important is that these older writers clearly realized from their detailed clinical examinations that there were varying gradations in the patient's mode of experiencing hallucinations—particularly the so-called auditory hallucinations.

2. "Auditory" Hallucinations in Temporal Lobe Epilepsy

The following case illustrates the hearing of an inner voice within the head.

Case 3

W.D. was a youth of 18 who had had seizures for eight years. E.E.G. showed a shifting focus in both temporal lobes. He was bilingual, Afrikaans being his mother's tongue. His seizure pattern was a sensation in his head accompanied by a voice which spoke in Afrikaans, commanding or threatening him. He had a feeling of intense fear and finally lost consciousness. Asked where the voice came from, he said, "It was just in my head." The patient was aware that he could not speak while hearing this voice and felt that his tongue was stiff (a finding common among others who heard voices within the head). He said, "If I heard the voice I used to point to my head so that my parents would know I was going to have an attack." The voice spoke in short sentences which were accusatory or threatening, telling him "You do this" or "You do that," "You did something wrong." "Things," the patient added, "that I did not do wrong."

The next case illustrates the hearing of voices within the stomach.

Case 4

M.S. was a little boy of 7, with an eight-months history of epileptic seizures. E.E.G. showed a shifting focus in both temporal lobes. This boy described his experience during the seizure as "I have 'bumps' in my tummy, and I hear 'Do this, do that.'" Asked "Who says 'Do this, do that'?" he replied, "My stomach—I feel something talks in my stomach." On further questioning he said it sounded like a man's voice, but he did not recognize it as the voice of anyone he knew, and that he heard it only in his stomach. Asked whether he ever obeyed this voice, he replied, "I don't do what he says, I do what Mummy says." To the question, "Do you think there is a voice in your tummy?" he answered, "Yes—I don't know how he gets in there." The commands "Do this, do that," were repeated a few times and were followed by automatism and loss of consciousness. This boy never heard the voice in the intervals between seizures.

This hearing of an inner voice giving unacceptable commands is, of course, typical of schizophrenia, but in both these cases this was a momentary experience, whereas in schizophrenia it tends to be a continuous process. We shall return to this later.

The fifth case illustrates the hearing of an external voice—that is, the experience comes within the commonly accepted definition of auditory hallucinations. (This case has already been reported by Penfield and Jasper (1954).)

Case 5

S. B. was a man whose seizures began at the age of 18, and E.E.G. showed a right temporal focus. The attacks first took the form of vertigo, but a year after their onset the patient, in addition to the vertigo, heard a voice calling his name, "Sylvere, Sylvere," and this was sometimes followed by loss of consciousness. Two years later the pattern again changed, and the aura consisted mainly of a feeling of nausea behind the mid-sternum. At operation, performed six years after the onset of seizures, and four years after the voice calling his name had ceased to be part of his seizure, cortical stimulation reproduced the following:

On stimulation at a point 5 cm. from tip of the right temporal lobe, in the first temporal convolution, the patient said, "Just like someone whispering or something in my left ear—it sounded something like a crowd." Warning without stimulation produced "nothing." When stimulation was made at a point 1 cm. posterior, he said, "Again someone trying to speak to me, a single person." When asked, he added, "Oh, a man's voice—I could not understand what he said." On stimulation at a point 5 cm. from tip of the right temporal lobe on the second temporal convolution, he said, "Someone calling me in my left ear 'Sylvere, Sylvere'—it could have been my brother."

Interesting features of this case are: (1) the hearing of a voice from the side opposite to the stimulation—that is, the phenomenon of lateralization; and (2) the reproduction, by cortical stimulation, of a certain auditory hallucination—to wit, the hearing of a voice calling the patient's name—four years after it had disappeared from the pattern of his seizures.

Penfield and Jasper (1954) have reported the reproduction of auditory hallucinations by cortical stimulation in many cases, and the stimulation points are found to be concentrated around the first temporal gyrus.

These five cases have been selected from many for this one reason—that the five represent a continuous gradation or a spectrum. The epileptic discharge has evoked successively "amorphous" thoughts, formulated or "crystallized" thought, an inner audible voice located in the head, a similar audible voice with an apparent location in the abdomen, and, finally, voices seeming to emanate from the external environment. Cortical stimulation reproduced both the experiencing of thoughts and the hearing of external voices.

Hallucinations in Schizophrenia

We believe that a more complex and less well defined gradation or spectrum can be illustrated in the hallucinations of schizophrenic patients. Here interrogation of the patients presents much more difficulty, for we have to probe beneath a superstructure of delusional misinterpretations and rationalizations to discover the patient's mode of perceiving such hallucinations.

Schizophrenic Thinking

In schizophrenia the patient is continually troubled by ideas which are presented to him independent of his volition. Some appear to him as though emanating from voices in his external environment. These, the commonly accepted auditory hallucinations, represent in our opinion but one gradation of this experience. The term "auditory hallucinations" cannot be made to cover all the modes of perception of this phenomenon, nor does it sufficiently stress its intricate nature, the intimate relationship which exists between it and the patient's own thought. We may illustrate briefly the range of qualitative difference seen in such hallucinations.

In some patients these alien ideas appear as "thoughts" differing only slightly in quality from the silent imperceptible flow of normal thinking. Secondly, they may erupt in consciousness as a formulated word or phrase, with or without some extrinsic quality which the patient describes in terms of known sensations. Patient S. F. said that she experienced "strong thoughts" or "thought forms" which she described as vibrating through her head. She added that the content of these strong thoughts was quite different from what she was thinking at the moment of their appear-

ance—for implicit in this and subsequent modes of experience is the rejection by the patient of these thoughts as his own.

The next gradation occurs when the hallucinatory words and phrases exhibit some kinaesthetic—or verbal—quality which enables the patient to experience them as soundless speech within the mind. I. H., an intelligent nurse of 30, described her mode of perceiving two voices within her mind as follows: "If I compared it to lip-reading, the formation of words without the sound, that is the clearest I can describe it." (There must surely be only a minimal difference in the experiencing of "strong thoughts" and "soundless voices." This is borne out in a famous case, cited by Ségla, of a woman who said that what she heard in her mind was a "voice," and then corrected herself, adding, "No, I am explaining it badly; it is not a voice, it is a suggestion, it is a thought without sound, it is an internal voice which flesh and blood cannot understand—it is a mute voice.")

A further gradation is reached when the patient describes voices, still experienced within the mind, which have super-added to them some subtle quality of sound. W. F. described his experiencing of a voice within his head thus: "I don't actually hear it with the ear—it is not heard outside the head, but it has some sound quality within the head." (It was from this patient's spontaneous description that we borrowed the term "sound quality.") He could not further elaborate it. What seems reasonably certain is that this sound quality does not partake of the tone and timbre of the human voice. A. W. spoke of a "whisper in my head that goes on and on. I don't know where it gets the stamina." This internal voice with a quality of sound may also be experienced in other parts of the body—in the chest or abdomen, as is illustrated by the case of Y. Z., who was suffering from schizophrenia and believed that a certain Dr. T. was in her abdomen. When asked how she knew that, she replied, "I hear him speak and I feel him move." She gave as an illustration that while having a tub bath she heard Dr. T. cry out, "I am drowning." She told him "move up" and he did! This case is almost identical with that of the little boy (Case 4) who heard voices in his stomach as part of his seizure pattern.

The final stage is illustrated in the experiencing of voices which appear to the patient to emanate from his external environment. Some patients unhesitatingly liken these to actual human voices. But others do not display this certainty. They describe a far-away quality—a voice coming from a distance; or, conversely, if near at hand, they use qualifying phrases, such as "like a voice heard through a megaphone." It seems, therefore, that if an auditory component is present it does not always, even in external auditory hallucinations, simulate the tone and timbre of the human voice.

Schizophrenic patients, if carefully interrogated, may admit to experiencing not merely one but two or three of the several gradations above described. There are still further modifications of this phenomenon—for instance, all the patient's thoughts may become verbalized and appear to resound in his external environment—the so-called "echo de la pensée." This necessarily abbreviated account is nevertheless sufficient to indicate the close resemblance which exists between such hallucinations and those found in temporal lobe epilepsy. The "thoughts," the internal and external "voices," which form part of the seizure pattern in the above five cases of temporal lobe epilepsy find their counterparts among the admittedly more numerous and complex modes of abnormal perception illustrated for schizophrenia.

Syntax of "Auditory" Hallucinations

The form of syntax of hallucinations of thought and speech in schizophrenia is difficult, and often impossible, to elicit. It is common but not invariable for patients to describe them as consisting of brief phrases, commencing with pronouns of the second or third person—for example,

"You are," "He or she is," "You did," "Do it." We find striking analogues of these in two of the cases of temporal lobe epilepsy. Case 4 heard a voice in his stomach saying "Do this," "Do that." Case 3 heard a voice in his head saying "You do this," "You do that," "You did something wrong." "Things," the patient added, "that I did not do wrong." This case is of surpassing interest, since not only the syntax, but the content of the patient's hallucinations closely simulates that found in schizophrenia. Here we see evoked by epileptic discharge that specific quality of schizophrenic thinking to which later French writers have applied the term "bipolarity." The content of the hallucinations in schizophrenia tends to consist of ideas that are repugnant or terrifying to the patient, that are the polar opposite of what he himself would wish to think and do. Wherefore he feels constrained to counter them by denial or refusal, and only finally, when their continuous reiteration exhausts him, by acceptance. But acceptance does not terminate this intense mental argument, for new commands and incompatible ideas are evoked, which in their turn engender fresh tension. The patient with temporal lobe epilepsy (Case 3) experienced in episodic form a phenomenon which in schizophrenia may go on every minute, every hour, of waking life, rendering impossible single-minded concentration on all other subjects.

3. Visual Hallucinations

It has been shown that so-called "auditory" hallucinations may be experienced either within the mind or as emanating from the external environment. Visual hallucinations may likewise take the form of internal or external perceptions.

(a) In Temporal Lobe Epilepsy

The first gradation of abnormal visual experiencing is illustrated in what patients tend to describe as "flash-backs."

Case A (M. M.) has been reported by Penfield and Jasper (1954). The patient described what she experienced in some of her attacks thus: "Suddenly something flashes through my mind—it is a memory of something past; the experience may last only a few seconds, yet I feel close to that event in my life after it had occurred." She stressed the sudden appearance, brief duration, and extraordinary vividness of this mental image, which was quite different in quality from the ordinary mental pictures which are part of everyone's thinking. Here we have a visual hallucination experienced within the mind.

Case B also illustrates a vivid internal visual experience, with the additional interest of reflecting the patient's immediate interests.

A. R. (Case B) an Englishwoman of 29, was married to a Canadian butcher. She had recently received a photograph of her brother's grave in a military cemetery in Holland. During her seizures she saw, vividly etched on her mind, series of gravestones, rows of tulips, lines of lamb carcasses. She described her manner of experiencing these hallucinations thus: "They were inside my forehead. It was not as though outside on a screen. I did not actually see it in the room; it must have been a mental picture—it came to me without my own powers of direction . . . and it came suddenly." This patient had had seizures since the age of 8, but the induced visual imagery of graves, tulips, and lamb carcasses had only recently appeared as part of her seizure pattern. Her mental preoccupations dictated the content of her visual hallucinations although they played no part in their causation.

Cases C and D experienced visual hallucinations which conform to the accepted definition of hallucinations in that they were apprehended by the patient as though located in his external environment.

Case C is unusual in that it illustrates the transformation of thought into visual hallucinations at the moment of epileptic discharge. There exists a certain analogy between this experience and the "echo de la pensée" of schizophrenic patients, who say they hear their own thoughts. This patient saw his own thoughts.

D. C. (Case C), aged 16, had an extensive atrophy involving the temporal, parietal, and occipital lobes of the left hemisphere,

necessitating their complete resection. Since the age of 8 he had had frequent seizures without loss of consciousness. In the year preceding operation he had three major convulsions. He described what he experienced in these major attacks before losing consciousness. He fell down during the attack and tried to overcome it by mental effort, whereupon he was aware of all his thoughts transforming themselves into vivid external visual images. He was so terrified by this that he kept changing his thoughts, but each thought continued to transform itself into a visual image. For instance, he thought of fire-crackers, and suddenly these were seen in sunset colours of blue and mauve in front of his eyes located "about a block away," seeming to tumble down through the sky but never reaching him. Then he thought of a space ship, and it appeared as a pinkish-blue object, moving towards him, becoming smaller as it did so. He thought of maple trees in the playground, and saw them as though "upside down." (This curious anti-gravity positioning also occurred with a leptazol-induced seizure when he reported seeing the technician as though walking on the ceiling.) Finally, he thought of himself lying on the ground, and immediately saw an external pictorial image of himself, described thus: "The way I felt on the ground was the way I looked in the picture, but people were not around me. I was in different forms; I thought of something, then I saw it. I thought of myself, and then I saw myself the way I was thinking of myself." This occurred with his eyes closed, and the phenomenon disappeared when he opened his eyes, but he said that it was difficult and "unpleasant" to keep his eyes open.

The following case has been reported by Penfield and Jasper (1954).

A. B. (Case D), aged 32, an artist's daughter, had a right temporo-occipital focus. Both simple and complex visual hallucinations occurred as part of her seizure pattern. These included: (a) flickering lights seen in the left visual field. (b) Representations of famous paintings—Rembrandt's "Night Watch" and "Self Portrait." She also saw, as though in a picture, "Christ coming down from the sky." All these were two-dimensional and were seen in the left visual field, as if superimposed on the existing external environment. (c) A kitchen in the country, and she felt—although she did not see—herself there, with two boys running towards her. The kitchen and the boys appeared in three-dimensional form. Unlike a and b, this image was seen in both visual fields, and during its appearance the patient was blind to all else in her external environment.

(b) In Schizophrenia

Only brief reference can be made to visual hallucinations in schizophrenia. Generally accepted as being a less constant symptom than "auditory" hallucinations, they can on occasion assume predominance. All the visual phenomena described in temporal lobe epilepsy have been found in schizophrenia. There may occur in the latter disease many more varied and complex visual hallucinations. Bizarre hallucinations of parts of the human body are frequent. The patient may have a vision of the self—that is, autoscopic hallucination—but a somewhat similar phenomenon has been elicited in temporal lobe epilepsy (Case C). In temporal lobe epilepsy such hallucinations are an episodic occurrence, whereas in schizophrenia they are a constantly recurring experience; but in both they are of brief duration—"they come and go in a flash"—and in both they may be "seen" in the mind or in the external environment.

Basis and Unitary Nature of the Hallucinations Described

These psychical phenomena—or hallucinations—may be illustrated in the form of a spectrum at one end of which the hallucinatory experience is apprehended as "thoughts," and at the other end as visual or auditory images with an apparent location in the external environment. Intermediate are these visual and auditory abnormal perceptions—or hallucinations—which the subject experiences within his mind. The similarity which exists between these hallucinations in temporal lobe epilepsy and schizophrenia makes it difficult to avoid the inference that the latter disease is also based on some neurophysiological change, the nature of which is yet unknown.

We also submit that all these abnormal experiences are based on a single phenomenon, showing gradations in its mode of perception by the subject; or, in other words, that they all represent but different modes of perceiving abnormal derivations of thought. How, then, can we explain the various gradations? We think it is possible to do so by considering, in its simplest terms, the process of normal thinking.

Some part—the greater part—of normal thinking consists in the intangible, imperceptible linkage of elements which cannot be described in terms of known sensations. But there are superadded qualities in thinking which can be termed kinaesthetic and visual. Part of our thinking consists in the evocation of words and visual images. This is illustrated in the division of human beings into “verbalizers” and “visualizers.” It seems permissible, therefore, to assume that when some physical stimulus acts on certain areas of the brain to produce an abnormal thought—a hallucination of thought—such hallucination may present (a) as a thought—which forces itself on the attention of the subject, cannot be banished or superseded at will as in the manner of normal thought, but is nevertheless incapable of description in other terms than that of “thought”; or (b) as a visual or verbal image—of varying degrees of intensity, which the subject describes in terms of vision or hearing.

Summary

A comparison is made between certain hallucinatory phenomena or, more properly, the patient's mode of perceiving certain hallucinatory phenomena—in temporal lobe epilepsy and schizophrenia. The current popular definition of a hallucination, which implies the location of the abnormal perception external to the self, is criticized, and it is submitted that abnormal internal perceptions can also be included under the designation of hallucination. This designation, however, lacks precision, and it is hoped that in future more precise terms will be formulated to cover the many varieties of abnormal perception here illustrated.

Five cases of temporal lobe epilepsy are described in which epileptic discharge evoked respectively (a) ill-defined or “amorphous” thoughts, (b) formulated or “crystallized” thoughts, (c) a voice located in the head, (d) a voice located in the abdomen, and (e) a voice heard in the external environment. Cortical stimulation reproduced a, b, and e. Similar gradations in this type of hallucinatory experience, elicited from interrogation of patients suffering from schizophrenia, are briefly tabulated.

Four cases of visual hallucinations in temporal lobe epilepsy are described. In two of these the visual experience was apprehended within the mind of the patient, and in the third as superimposed on the external environment. (This last was reproduced by cortical stimulation.) In a fourth case the patient experienced the transformation of all his thoughts into vivid external images—“What he thought, he saw.” This bears a certain analogy to the phenomenon known as “echo de la pensée” found in schizophrenia.

It is submitted that these various gradations from “thoughts” to external auditory and visual hallucinations represent but different modes of perceiving abnormal derivatives of thought or hallucinations of thought. Since some part of normal thinking consists in the evocation of visual images and words, it is argued that a hallucination of thought may present either as a “thought” or as a visual or verbal image of varying degrees of intensity.

The finding that epileptic discharge and cortical stimulation can evoke gradations in hallucinatory experience

similar to those found in schizophrenia suggests that the latter disease may also have a neuro-physiological basis.

CHRONIC PAIN IN THE RIGHT ILIAC FOSSA*

BY

S. H. WASS, M.S., F.R.C.S.
Surgeon, Guy's Hospital

Chronic pain in the right iliac fossa constitutes a common problem in all branches of medical practice. The correct management of the disorder depends upon careful clinical evaluation, and mistakes are easy to make. One common mistake is the tendency among many people to rush into the much abused diagnosis of a “chronic appendix” or, as the only alternative, to treat the patient as a “neurotic.” Either of these assumptions may lead to disastrous consequences, and to avoid such obvious pitfalls it is my practice to approach the problem of diagnosis by seeking the answers to three questions: (1) Is there an organic cause for the pain apart from the appendix? If not, (2) Is the appendix genuinely at fault? Or, (3) Is the pain of functional origin? This order of questioning has been chosen deliberately, because it often happens that the appendix is removed when some other cause for the pain is present, and because it too often happens that the appendix is removed without reasonable evidence that it is diseased. Functional affections, however, should always be considered last, because there can be no greater error than to stigmatize a patient “neurotic” when in fact organic disease is present.

1. Causes of Pain Apart from the Appendix

Let us first consider those organic causes of chronic pain in the right iliac fossa which are unconnected with appendicular disease. So that nothing of importance shall be omitted, it will be convenient to classify them on an anatomical basis.

(a) *The Caecum*.—There is no doubt that chronic pain in the right iliac fossa can arise in the caecum. It may be due to gaseous distension, when the area is tympanitic, gurgling is present on palpation, and excessive borborygmi are heard on auscultation of the abdomen. In older patients it must always be borne in mind that caecal distension may signify chronic intestinal obstruction due to a carcinoma of the pelvic colon, and every effort must be made to exclude this serious disease. Loading of the caecum with soft faeces, in association with constipation, may also cause chronic pain in the right iliac fossa; in these cases a characteristic doughy feeling is detected on palpation. Pain may also arise from caecal spasm accompanying general

*A lecture delivered to the Hendon Division of the British Medical Association on February 8, 1955.

colospasm; tenderness is present over the caecum and often over a rigid pelvic colon in the left iliac fossa. In such cases propantheline (“pro-banthine”), a recently developed ganglion-blocking agent, is of great diagnostic and therapeutic value. Malignant disease of the caecum seldom causes pain as its first symptom.

(b) *The Terminal Ileum*.—Chronic pain in the right iliac fossa is rarely due to disease of the terminal ileum. Crohn's disease (regional ileitis) may give rise to an attack of acute or subacute pain closely resembling appendicitis, but in its chronic form it produces the symptoms of chronic small-intestinal obstruction with recurrent attacks of colicky pain in the right iliac fossa. Young adults are usually affected, and loss of weight is common. The thickened terminal ileum is usually palpable as a tumour in the iliac fossa. A similar history of recurrent bouts of colic occurs with localized tuberculous enteritis, but here no tumour is palpable. Both these diseases are rare, but they should be considered in the differential diagnosis of difficult cases.

(c) *Mesenteric Glands*.—Enlargement of the ileo-caecal glands is a common cause of pain in the right iliac fossa in children. Pain arising in these glands is due to inflammatory disease and may be tuberculous or non-specific. In non-specific mesenteric adenitis pain may be felt in the iliac fossa or in the umbilical region, and may be colicky in nature; there is no shifting of the pain as in appendicitis, and vomiting is rare. Tenderness and muscular guarding are present, but there is no true muscular rigidity. The glandular infection often follows a sore throat and there is usually evidence of chronically infected tonsils. Tuberculous adenitis is more difficult to diagnose with accuracy, although a positive Mantoux reaction in young children is suggestive. Radiography is of little use in diagnosis because calcified (healed) glands produce no symptoms. A pale fatty stool due to blockage of lymphatic vessels (tabes mesenterica) is evidence of gross tuberculous disease.

(d) *The Urinary Tract*.—Chronic pyelitis, stone in the ureter, and hydronephrosis may all cause pain in the right iliac fossa. Frequency of micturition almost invariably accompanies chronic pyelitis, and pus cells and organisms are present in the urine. Pain arising from a ureteric calculus usually radiates from the loin to the groin, but when a stone becomes impacted in the ureter the pain may be localized to the iliac fossa. In such cases a previous history of ureteric colic is of the utmost importance and the urine should be searched for red blood cells. Chronic or intermittent hydronephrosis may cause great difficulty in diagnosis when the pain is not felt in the loin, because associated urinary symptoms are usually absent. Careful bimanual palpation of the loin must be carried out, and in all doubtful cases the urinary tract must be investigated completely.

(e) *Female Pelvic Organs*.—Gynaecological conditions are a fairly common cause of pain in the iliac fossa, but the differential diagnosis of these conditions must rest with the specialist. The classical ovarian pain of “Mittelschmerz,” spasmodic and congestive dysmenorrhoea, uterine fibroids, pyosalpinx, small ovarian cysts, and prolapse of the ovary come readily to mind. As a generalization it can be said that gynaecological causes of pain in the right iliac fossa should be considered only if the attacks of pain bear a definite relationship to the menstrual cycle, if there is some associated disorder of menstruation, or if a swelling in the pelvis is detected on rectal or vaginal examination. Pain in the iliac fossa associated with a vaginal discharge does not justify a diagnosis of salpingitis.

(f) *The Spine*.—Chronic pain in the iliac fossa may also arise from affections of the spine. A psoas (tuberculous) abscess will cause pain in the lower quadrant of the abdomen and will be associated with a palpable swelling, but backache is usually the first symptom and the lumbar spine will be rigid when movements are tested. Congenital or acquired deformities and arthritis of the spine may give rise to pain radiating to the iliac fossa, but a careful analysis of the pain will reveal its radiating character and direct attention to an examination of the spine.

A formidable number of causes of chronic pain in the right iliac fossa have now been discussed, but they must all be given careful consideration in the diagnosis of this symptom. Investigation must always include a detailed and accurate history, careful inspection and palpation of the abdomen, the performance of rectal and vaginal examinations, examination of the spine, and testing of the urine, both chemically and in the laboratory. If all these investigations are negative the next question must be posed—is the appendix genuinely at fault?

2. The “Chronic Appendix”

The term “chronic appendicitis” is misleading and is often used without any serious consideration of its meaning. Some people believe that chronic appendicitis is a clinical entity of common occurrence, others that there is no such disease. A well-known teacher has said that an honest surgeon up to the age of 35 would refuse to believe in the existence of chronic appendicitis; that between the ages of 35 and 40 he would wonder if it occurred but refuse to accept a fee for removing the appendix; and that over the age of 40 he would be convinced that it was indeed a clinical entity.

To try to understand the meaning of the terms “chronic appendix” and “chronic appendicitis” let us consider the common clinical syndromes which occur in appendicular disease. Apart from acute appendicitis, which we are not considering in this discussion, two definite clinical syndromes can be recognized—recurrent subacute appendicitis and recurrent appendicular colic. By recurrent subacute appendicitis we mean recurring mild inflammation. In the earlier of these attacks the pain begins in the epigastric or umbilical regions and settles down in the right iliac fossa; in later attacks this shifting character is often absent and the pain is felt in the iliac fossa from the beginning. Fever is slight or absent, but the tongue may be furred and the appetite lost; vomiting is uncommon. Examination of the abdomen during an attack will show tenderness and guarding in the iliac fossa, but no rigidity. Such mild attacks usually last for 12 to 36 hours and then subside, leaving the patient free of symptoms for many months or even years. With recurrent appendicular colic the pain is felt around the umbilicus, but tenderness and guarding are present in the right iliac fossa. The pain is spasmodic in character, often more severe than the inflammatory pain of mild appendicitis, and vomiting is common. There is no fever and the tongue is clean. The bouts of colic may last for a few days at a time, and the intervals of freedom between attacks are usually shorter than those between attacks of inflammatory disease.

In the intervals between recurrent bouts of appendicular inflammation or colic the patient may show no abnormal physical signs whatever. The diagnosis depends upon an accurate history and upon observations made by the practitioner during one or more of the attacks; the importance of such observations cannot be overemphasized, and without them the consultant may have great difficulty in deciding the nature of the attacks.

Recurrent subacute appendicitis and recurrent appendicular colic may be considered to represent two types of “chronic appendix,” inasmuch as the appendix is repeatedly giving rise to trouble or “grumbling”; but cannot truly be called “chronic appendicitis” because this term implies persistent chronic inflammation of the appendix. It sometimes happens, however, that after repeated bouts of mild inflammation or colic there may be persistent pain and tenderness in the iliac fossa between the main attacks. To this state of affairs the term “chronic appendicitis” might reasonably be applied.

Lastly, we must consider those patients who complain of chronic pain in the right iliac fossa without any definite preceding “attacks” to suggest recurrent inflammation or colic. The pain of which they complain may show occasional remissions, but often it persists for weeks on end,

though sometimes occurring for only short periods during a day. Such patients may show localized tenderness in the region of the appendix but no other abnormal physical signs. Can they be said to be suffering from "chronic appendicitis"? These cases are certainly the most difficult to assess, but increasing experience soon tends to dispel any scepticism about the existence of this type of appendicular disease. We have all had our share of surprises in this field. Patients about whom we were extremely doubtful before operation have shown unexpected pathological changes in the appendix; others who have had an apparently normal appendix removed have been magically cured of their symptoms. In all such patients the history is usually vague and inconclusive. Diagnosis depends upon the single physical sign of persistent localized tenderness and upon our assessment of the type of patient with whom we are dealing; here again the general practitioner can be of enormous help to the consultant with his knowledge of the domestic and personal background of his patient. Clinical impressions of this type assume great importance when we consider that accessory aids to diagnosis are often of little value. Radiographic examination of the appendix is uncertain and its results are often equivocal.

From this discussion the position with regard to the various types of "chronic appendix" may be summarized as follows: (a) With a history suggesting *recurrent subacute appendicitis* or *recurrent appendicular colic* we are on safe ground in advising removal of the appendix. (b) A similar history followed by the development of persistent pain and tenderness in the right iliac fossa may reasonably be called *chronic appendicitis*, and here again appendectomy can be safely advised. (c) *Chronic appendicitis* without a previous history of recurrent "attacks" of pain is a more difficult problem. Children should always be given the benefit of any doubt, but in adults the decision to advise removal of the appendix will rest largely upon the general practitioner's knowledge of his patient's character and his interpretation of the nature of the symptoms.

3. Functional Pain

Last of all we come to those patients with no evidence of organic disease apart from the appendix and in whom we are not satisfied that the appendix itself is genuinely responsible for their symptoms. Few patients with pain in the right iliac fossa are true malingerers, and if we are correct in assuming that there is no organic cause for their pain we are dealing with examples of the *anxiety state*.

These patients have genuine symptoms and need help, but great patience and tact are required if that help is to be given. It is surprising how often a sympathetic attitude will reveal a psychological basis for the symptoms, and sometimes the mere unburdening of his troubles will help the patient enormously. Some people are quickly assured if they are satisfied that we have made a thorough and complete examination and can convince them that there is no evidence of serious disease. Others are more difficult to manage and do not readily accept the idea that their pain is nervous in origin in spite of a completely negative examination and a series of negative investigations. The psychiatrist cannot help if the patient is uncooperative, and if our common-sense approach to the mental problem does not produce conviction we are likely to have a dissatisfied patient. But at all costs we must avoid advising appendectomy in someone we know to be a true neurotic.

All too often such patients will continue to seek further opinions until they find someone who will remove the appendix, but we must not be responsible for such action if we consider it ill advised. It is better to lose a disgruntled patient than to have him return with the same pain after an operation to which we have agreed against our own judgment. It is also better to lose such a patient than to be responsible for that dreadful sequence of events which culminates in subsequent operations for adhesions or other mythical maladies and leads to the creation of a confirmed hypochondriac.

GENERALIZED HYPERTROPHIC OSTEOARTHROPATHY IN ASSOCIATION WITH BRONCHIAL CARCINOMA

A REVIEW, BASED ON 24 CASES

BY

THOMAS SEMPLE, M.D., B.Sc., F.R.C.P.Ed.
M.R.C.P.

AND

R. A. McCLUSKIE, M.B., F.R.C.S.Ed.

From the Victoria Infirmary, Glasgow, and Hairmyres Hospital, Lanarkshire

During the past seven years we have encountered in the West of Scotland no fewer than 24 examples of generalized hypertrophic osteoarthropathy in association with bronchial carcinoma. As it would appear to be the largest reported collection of patients suffering from this fascinating syndrome, and because modern surgery may handsomely reward early clinical recognition, it seems to be an opportune time to review the known facts and some theories of pathogenesis.

While the literature on the subject of generalized osteoarthropathy continues to grow, there has been little increase in our knowledge of the cause and real nature of the pathological changes of this condition since the first known description by von Bamberger in 1889. Marie (1890) named the syndrome "hypertrophic pulmonary osteoarthropathy" and defined it as a "symmetrical osteitis of the four limbs chiefly localized to the phalanges and terminal epiphyses of the long bones of the forearm and leg, sometimes extending to the roots of the limb and flat bones and accompanied by a dorsal kyphosis and some affection of the joints." This description requires little alteration to-day.

Although Hippocrates (1923), as early as the fifth century B.C., had described clubbing of the finger-nails, it was not until late in the nineteenth century that von Bamberger and Marie drew attention to the changes in the extremities associated with certain diseases. The confusion existing prior to Marie's description is illustrated by a case described by Saundby (1889) as one of acromegaly: a man aged 37 with thickening of the hands and joints died after five months, and necropsy showed "a sarcoma of the left lung with caseating pneumonia, a discovery which could only be coincidental." His illustrations put beyond doubt that he had unwittingly dealt with a case of osteoarthropathy.

Numerous reports have appeared dealing with the association of arthropathy with a variety of internal diseases. These diseases have most frequently affected the respiratory tract. Chronic lung abscess, putrid bronchiectasis, and empyema, all now fortunately rare, predominated. Brooks (1913) and Locke (1915) pointed out that at least a proportion of cases of osteoarthropathy had a malignant chest lesion. We have found it in a patient with metastatic lung tumours, and it has been reported in association with such intrathoracic lesions as arteriovenous aneurysm of the lung (Adams *et al.*, 1944), fibroma of the visceral pleura (Price-Thomas and Drew, 1953), and benign tumours of the lung and chest wall (Van Hazel, 1940).

It is interesting to note that osteoarthropathy has been described in a dog with a bronchial carcinoma (Wissing and Weisz, 1943) and in rats (Sutro and Pomerantz, 1939), a horse (Liénaux, 1909), and even a lion (Ball and Lombard, 1926).

It has been witnessed in many apparently unrelated diseases such as carcinoma of the nasopharynx, myeloid leukaemia, colitis, and steatorrhoea. Although a few cases of idiopathic osteoarthropathy have been recorded (Freund, 1938; Camp and Scanlan, 1948) one should hesitate in making such a diagnosis until a primary disease has been excluded. The fickleness of the syndrome is well illustrated by Locke's account of a patient who had osteoarthropathy for five years before a lung tumour became obvious. Such an experience was repeated in one of our series (Case 14); it was nine

months before there was radiological evidence of a lung tumour.

Craig (1937), Rottjer *et al.* (1946), Temple and Jaspin (1948), Pattison *et al.* (1951), and Ellman (1953) have all reported a small series of cases of bronchial carcinoma having joint symptoms as the presenting feature. The syndrome is seldom encountered by general physicians, and a possible reason is that the rapidly growing or oat-celled growth, common in the medical wards, does not produce osteoarthropathy. Conversely, in chest-unit patients the more chronic epidermoid variety predominates, and so it is difficult to estimate the frequency of the syndrome in all cases of lung cancer. Jack (1952) found three fully developed cases in 668 patients with bronchial carcinoma. Wierman *et al.* (1954) report an incidence of 5% in 481 resections for malignant lung

Summary of 24 Patients having Joint Symptoms Related to Lung Cancer and showing Clinical and Radiological Evidence of Hypertrophic Pulmonary Osteoarthropathy

Case No.	Age	Tumour Site	Histological Type of Tumour	Initial Symptoms and Signs	Duration of Joint Symptoms Before Correct Diagnosis Made	Treatment	Result (To November, 1954)
1	45	R.U.L.	Adenocarcinoma	Radiological shadow for 18 months	5 months	Pneumectomy, 1947	Operation death
2	51	L.L.L.	Epidermoid	"Rheumatic fever"	7 "	Pneumectomy, 1948	" "
3	47	R.U.L.	—	Stiffness and swelling of ankles and knees	5 "	Radiotherapy	Gold therapy produced a remission of joint symptoms. Died with metastases 4 months after start of treatment
4	64	R.L.L.	—	Stiffness, swelling, and pain in ankles and knees	5 "	"	No relief of joint symptoms. Died with metastases 3 months after start of treatment
5	47	R.L.L.	Epidermoid	Stiffness and pain both legs. Also haemoptysis	4 "	Pneumectomy, 1949	Complete and immediate relief of joint symptoms. Died 3 months after operation with cerebral metastases
6	56	L.U.L.	Adenocarcinoma	Haemoptysis	3 "	Pneumectomy, 1950	Complete relief of joint symptoms. Died 7 months after operation with cerebral metastases
7	53	R.L.L.	"	Pain and stiffness of knees	3 "	Lobectomy, 1949	Immediate relief of joint symptoms which, however, recurred with the appearance of osseous metastases. Died 8 months after operation
8	52	R.L.L.	Epidermoid	Pain and swelling of wrists, feet, and ankles	10 "	Pneumectomy, 1949	Immediate and permanent relief of joint symptoms. Died 6 months after operation with local recurrence of tumour
9	59	R.L.L.	Adenocarcinoma	Haemoptysis	4 weeks	Pneumectomy, May, 1951	Immediate relief of joint symptoms. Some residual stiffness of left shoulder and slight deformity of fingers. Has remained well since operation
10	59	R.L.L.	Epidermoid	Pains in legs and swelling of ankles and knees	5 months	Pneumectomy, Sept., 1947	Has remained symptom-free since operation
11	38	L.U.L.	"	Stiffness of ankles and knees	6 "	Pneumectomy, Jan., 1952	Immediate disappearance of joint symptoms. Died October, 1952, with local tumour recurrence
12	52	R.L.L.	"	Stiffness of arms and legs	2 years	Symptomatic	Died 2 months after first seen and diagnosed
13	41	R.U.L.	"	Stiffness, pain, and weakness of knees and ankle	5 months	Radiotherapy	Partial remission of joint symptoms and of chest pain. Died with cerebral metastases 12 months after diagnosis made
14	46	R.L.L.	"	Stiffness and swelling of knees	10 "	Pneumectomy, April, 1952	Relief of stiffness and pain. "Weak joints" remained after operation. Ultimate complete rehabilitation. Died December, 1953, with cerebral metastases
15	54	L.U.L.	—	Left shoulder pain	3 weeks	Radiotherapy	Partial relief of joint symptoms with corticotrophin. Complete and permanent relief after radiotherapy. Died with local tumour extension 9 months after diagnosis made
16	50	R.U.L.	Epidermoid	Lassitude and weight loss	4 months	Symptomatic	Died 2 months after diagnosis made
17	48	R.L.L.	"	Haemoptysis	4 "	Lobectomy, Sept., 1952	Immediate relief of joint symptoms. Died with generalized metastases December, 1953. No recurrence of rheumatism
18	56	R.U.L.	"	Pain and stiffness left shoulder and cough	12 "	Thoracotomy, Oct., 1952	Partial spontaneous remission of joint symptoms before operation, and continued improvement after thoracotomy. Died April, 1953, with metastases
19	52	R.L.L.	"	Cough and chest pain	5 "	Thoracotomy, Feb., 1953	Spontaneous remission of joint symptoms preceded operation. No recurrence before death from metastases January, 1954
20	49	L.L.L.	"	Stiffness and pain in hips, knees, and wrists	6 weeks	Lobectomy, May, 1953	Immediate complete relief of joint symptoms. Has remained well to date
21	55	L.U.L.	"	Swelling and stiffness of ankles	6 months	Pneumectomy, July, 1953	Relief of polyarthritides symptoms. Myocardial infarction with congestive failure during convalescence. Died with cerebral metastases March, 1954
22	57	L.L.L.	"	"Arthritis" left knee	16 "	Symptomatic	Admitted to hospital in terminal stages of illness with massive left pleural effusion. Died after 2 months' observation
23	62	R.U.L.	"	Generalized joint stiffness	3 "	Pneumectomy, July, 1953	Immediate disappearance of joint symptoms. Died with metastases April, 1954
24	57	L.L.L.	"	Swelling of knees	3 "	Lobectomy, Nov., 1953	Had usual relief of "rheumatism" and has remained well to date

lesions, but these included patients with so-called "local osteoarthropathy" or simple clubbing. It is our impression that the frequency of the generalized form is in the region of 1-2%.

Clinical Manifestations of Osteoarthropathy

From the Table it will be seen that 16 patients had joint disability as the first evidence of disease. Case 12, for instance, had stiffness for a year before the first symptoms directly related to the lung tumour appeared. All 24 patients had experienced such "rheumatic" symptoms for an interval, varying from 3 weeks to 16 months, before the presence of a tumour was suspected. Stiffness and swelling of the large and small joints of the limbs were the usual complaints; pain may be severe or be present only with joint

may occur in certain types of chronic lung and congenital heart disease without evidence of periosteal reaction or joint disability. Clubbing therefore should not be considered synonymous with osteoarthropathy, nor even necessarily the earliest stage of it (Hansen, 1954).

There may be a low-grade pyrexia, and a raised erythrocyte sedimentation rate is invariable, but these, and especially the latter, are common findings with bronchial carcinoma. Swelling of the nipples occurred in two of our patients. Stephens (1928) reported an incidence of 7% with gynecomastia in a series of 156 cases of bronchial carcinoma.

Response to Treatment

Remission of joint symptoms may occur spontaneously (Cases 18 and 19), and some relief may be obtained from nitrogen mustard (Case 8), gold therapy (Case 3), and corticotrophin (Cases 14 and 15). Some patients treated by deep x-ray therapy had partial or complete relief of "rheumatism," but the objective signs of osteoarthropathy were little altered.

The most dramatic, immediate, and complete relief of joint symptoms is produced by operative removal of the lung tumour. In all 13 patients who survived tumour resection, joint mobility was increased within hours of the operation, and the patients who had been bedridden with "arthritis" for weeks or months were walking normally within a few days. It is no exaggeration to state that these patients were dumbfounded at the relief, and more than once we found them the morning after operation studying the increased mobility of their fingers and arms in utter amazement. Just as rapidly,

they remarked that their hands and feet felt more cool, and objectively we could no longer find evidence of increased peripheral blood flow. Joint swelling subsided in a matter of days; in a few weeks, thickening of the skin of the face and around the joints had disappeared and clubbing subsided (Figs. 1 and 2). After a few months, radiological examination showed absorption of subperiosteal new bone (Fig. 3) and disappearance of osteoporosis in the wrist bones.

FIG. 1.—Clinical photographs of Case 14, illustrating (left) the furrowed and coarse features sometimes seen with osteoarthropathy, and (right) the same patient four months after right pneumonectomy.

movement, or it may be absent. Four of the patients were completely crippled and confined to bed. Sensations of warmth or burning and increased moisture of the hands and feet were sometimes volunteered.

Skin around the affected joints may show thickening and brawny oedema. A similar change is sometimes found on the face, producing rather a characteristic coarse, furrowed appearance (Fig. 1), already observed by Fried (1943).

The hands may have a rheumatoid appearance or be spade-like as in acromegaly (Fig. 2). Hands and feet are warm and moist, and pulsation may be felt in the palms and fingers and heard with a stethoscope on the brachial or femoral artery. Capillary pulsation, however, is not a feature.

Finger-clubbing is almost invariably associated with osteoarthropathy, and occasionally is the most obvious feature clinically; on the other hand, it may be very mild in degree. Conversely, it is known that advanced clubbing

FIG. 2.—Case 14. Patient's right hand (A) before operation, showing the spade-like deformity, with clubbing and thickening around the wrist- and finger-joints. Same hand (B) seven months after pneumonectomy.

FIG. 3.—Case 10. Right radius and ulna before operation (A): note the marked subperiosteal proliferation. Film (B) three months after pneumonectomy shows considerable absorption of this new bone.

One patient (Case 7), who had obtained the usual relief from lung resection, had a relapse of "arthritis" associated with the appearance of metastases; however, this was an exception, as other patients who died from local tumour recurrence or from metastases had no such relapse before death.

Death was invariably related to tumour spread and there was little evidence that these tumours behaved differently from the more usual case of slowly growing epidermoid carcinoma. Indeed, operative results have been disappointing, only 4 out of 15 patients treated by resection being alive.

Biochemical Findings

In common with previous observers, we have found essentially normal results in most estimations carried out for the study of metabolic bone disease. An exception was the serum phosphorus level, which was found elevated in four severe cases studied. Excretion of F.S.H. (follicle-stimulating hormone) was normal, but this test brought to light a finding which may be of practical importance: in two cases the patient's urine, extracted for the hormone, appeared to contain an unidentified substance which was lethal to laboratory mice.

Arteriovenous oxygen difference was found to be very low in two patients, and in one other the figure rose abruptly after operation. This finding and increased peripheral blood flow, along with absent capillary pulsation, suggest the presence of arteriovenous shunts by-passing the capillary bed.

Skeletal and Articular Changes

The bone changes of osteoarthropathy have been adequately described by past observers (Compere *et al.*, 1935; Gall *et al.*, 1951). There is a proliferative periostitis, characterized by lymphocytic and plasma-cell infiltration, subperiosteal new bone formation, and the production of a pseudo-cortex, 1 to 5 mm. thick, which ultimately fuses with and expands the cortex. It particularly affects the lower ends of the forearm and leg bones, metacarpals, and metatarsals. In extreme cases, clavicles, ribs, pelvic bones, scapulae, and malar bones may be involved. Radiologically (Fig. 3) the picture is quite characteristic, and is perhaps most like a yaws periostitis, showing an irregular but symmetrical osteoid sheathing of the long bones. Joints in involved extremities show extra-articular thickening, but may be the seat of mild to moderately severe chronic synovitis, associated with non-specific degenerative changes in the articular cartilages. In advanced cases, deformities and even subluxations may occur. Changes in the carpus and tarsus are of an osteoporotic character.

Lung Tumour Features

Most of our patients had bulky, circumscribed peripheral neoplasms. Of these studied histologically, 17 were of epidermoid type and four were adenocarcinoma. Central necrosis was a feature in all operation and necropsy specimens. The tumours were present in the right upper lobe (6), right lower lobe (10), left upper lobe (4), and left lower lobe (4). As this type of neoplasm rarely produces atelectasis or invasion of neighbouring structures in the earlier stages, clinical silence is the rule, and yet the patient may be a helpless cripple from his associated arthropathy.

Illustrative Case Histories

Case 7.—An electrical engineer aged 53 was admitted to hospital in January, 1949, complaining of pain in his left chest for a month, pain and stiffness of his knees and swelling of the finger ends for three months, and swelling of the ankles and feet for one month. X-ray examination showed a circumscribed dense homogeneous shadow in the posterior basal segment of the right lower lobe and the changes of osteoarthropathy in the long bones. There was marked clubbing of the fingers and toes and tender extra-articular thickening around both knee-joints. Bronchoscopy showed tumour tissue in the orifice of the right posterior basic

segment orifice (histologically adenocarcinoma). He had a right lower lobectomy on March 1, 1949, and the following day his knees and ankles were much less stiff. Convalescence was uneventful and the joint symptoms disappeared completely. Six months later, however, he developed pain in his left elbow, and x-ray examination showed a metastasis in the lower end of the humerus. From then until his death in November he had a marked exacerbation of the joint symptoms. Two weeks before death he was almost unable to move his arms and legs because of joint swelling, pain, and stiffness.

Case 8.—A married woman (the only female in the series), an accountant aged 52, developed pain and swelling of the feet and ankles in November, 1948. A month later her knees became swollen and stiff, and in January, 1949, she noticed that the ends of her fingers were swollen. Five months later she had to stop work because of pain and stiffness in her hands, wrists, and elbows. The only other symptoms at this time were listlessness and "catarrh." In August, 1949, she was admitted to hospital with gastroenteritis. Generalized osteoarthropathy roused interest, and an x-ray film of the chest showed a large circumscribed shadow in the right mid-zone. She was transferred to a thoracic unit in October. By this time she was in poor general condition. She looked old and wizened, with deep facial furrows, marked swelling of joints, and clubbing of fingers and toes. X-ray examination showed a massive shadow in the right lower chest and radiological signs of advanced osteoarthropathy. In November she was given a four-day course of nitrogen mustard (total 19 mg.), which produced some relief of joint stiffness. On December 6, as her general condition had improved, a right pneumonectomy was performed with dramatic and immediate relief of her joint pains. Histology of the tumour showed an epidermoid carcinoma. She died six months later with local recurrence of the tumour, but without recurrence of joint symptoms.

Case 10.—A blacksmith aged 59 (the longest survivor) began to have pains in his legs with swelling of the ankles and knees in March, 1947. The following month he could not get out of bed because of joint stiffness. When admitted to hospital in August he had lost 2½ st. (15.9 kg.) in weight. He was investigated as a case of infective rheumatism. The blood sedimentation rate was 65 mm. in the first hour (Westergren). Clubbing of his fingers was noted, and an x-ray film showed a round shadow in the apex of the right lower lobe. Bronchoscopy confirmed the presence of an epidermoid carcinoma protruding from the apical segment orifice. He had a right pneumonectomy in September, some six months after the onset of his joint symptoms. The day after operation he was surprised at the relief of pain and joint stiffness and the improvement was progressive. Three weeks after the operation he was walking well. Four months later, x-ray examination showed marked diminution in periosteal new bone formation round the radius and ulna (Fig. 3). His progress was uneventful, and he is alive and working more than seven years after the beginning of his symptoms.

Discussion

Although simple clubbing of the fingers is a common phenomenon, true osteoarthropathy is relatively rare, and in this seven-year period we have not witnessed a case related to disease other than lung cancer. As stated recently (British Medical Journal, 1954), bronchial carcinoma would seem now to predominate as the chief cause, although Price-Thomas (1953) has stated that no condition is associated with osteoarthropathy as constantly as fibroma of the visceral pleura. This, however, is a rare tumour. It seems possible that many cases of arthropathy previously reported as associated with empyema and lung abscess were suffering from carcinomatous lung abscess or empyema secondary to unrecognized lung cancer.

Mendlowitz (1942), reviewing the "welter of hypotheses" advanced to explain the phenomenon, found them unconvincing. These included the theories of toxæmia, anoxæmia,

capillary stasis, lymph stasis, endocrine disturbance, and autonomic nervous upset. He concluded, however, that increased blood supply must form the cornerstone of any theory of production of osteoarthropathy, and certainly we have found increased peripheral blood flow a constant feature and one which disappears within two or three hours after removal of the lung tumour.

Hypertrophy and hyperplasia from circulatory changes can be observed in arteriovenous fistulae in the limbs. The increased growth of the limb was thought by Sir Thomas Lewis to result from the more rapid flow of blood distal to the arteriovenous shunt. Cross and Wilson (1952) record a case of axillary arteriovenous aneurysm with unilateral clubbing in which increased blood flow to the hand was the only demonstrable circulatory abnormality. Increased peripheral circulation was regarded by Wilson (1952) as an essential feature in acquired clubbing. He demonstrated that blood flow through clubbed fingers was greater than normal, and showed that vasomotor nerves were probably not responsible for this. Lovell (1950) found an excess of fibrous tissue in the distal segments and increase in the calibre of the digital arteries in clubbed fingers. There were abundant characteristic local arteriovenous anastomoses in the distal finger segments, near the junction of the dermis and subcutaneous tissue. He thought that the excess of blood reaching the finger-tip was mainly through these anastomoses and that the by-pass of blood away from the capillary bed might be responsible for the proliferative changes. Mauer (1947), attempting to explain the aetiology of clubbing in both cyanotic and hypervascular states, elaborated this theme. He introduced the interesting concept of peripheral tissue anoxia produced by combination of accelerated peripheral blood flow and raised erythrocyte sedimentation rate; thus erythrocytes, moving rapidly in rouleaux formation through capillaries or arteriovenous shunts, do not have an opportunity for adequate gaseous exchange. It is worthy of note that in our patients both hyperaemia and raised E.S.R. approached normal limits immediately following tumour resection.

The exact mechanism by which increased blood flow produces hypertrophy is unexplained, but from the postulations of Leriche and Policarde (1928) and of Greig (1931) it seems just possible that hyperaemia alone may be the responsible factor in osteoarthropathy. It is acknowledged that new bone is normally restrained by the periosteum, and that a bone cannot exceed its normal limits unless this membrane be removed or raised. Possibly, in this disease, subperiosteal new bone may be deposited as a result of raising of the membrane by serous effusion, an invariable accompaniment of the oedema and cellular proliferation of periosteal hyperaemia. Similar vascular changes may explain the associated subcutaneous tissue and joint involvement. Increase of periarticular circulation modifies synovial fluid both in quantity and in quality and stimulates proliferation of all connective-tissue cells.

Before considering any theory on the mode of production of osteoarthropathy by bronchial carcinoma we must bear in mind the following facts. Osteoarthropathy is produced by only a small proportion of bronchial cancers, most of which are peripheral, grow slowly and concentrically, and show marked central necrosis. There is invariable and immediate relief when such a tumour is resected. Similar relief has been reported to follow ligation of the pulmonary artery on the side of the tumour (Wyburn-Mason 1948) and also denervation of the lung hilum when the tumour could not be removed (Brea, 1948). We have witnessed remission of symptoms occurring spontaneously, following certain drugs, and also after thoracotomy. It must also be remembered that osteoarthropathy can be produced by many other tumours both within and without the thorax. Three hypotheses might be considered.

1. *Tumour affects indirectly the endocrine balance.*—Such a theory is supported slenderly by the production of bone growth and soft-tissue changes in acromegaly and by Selye's

work showing that D.C.A. can produce polyarthritis in adrenalectomized animals (Selye *et al.*, 1944). Thomas (1933) described osteoarthropathy occurring after subtotal thyroidectomy. Bariéty and Coury (1950) obtained relief of arthralgia by giving synthetic oestrogen to a patient with inoperable lung cancer. Fried (1943) reported four cases with bronchial carcinoma and osteoarthropathy, all of which showed variable clinical and pathological evidence of endocrine upset. (These changes included an acromegalic appearance, tufting of terminal phalanges, testicular atrophy, hirsutism, macroglossia, and gynaecomastia.) We have already commented on the reversible coarse facial features, and would point out that gynaecomastia (present in two of our patients) must not be accepted as certain evidence of an endocrine aetiology; it has been described in severe starvation and in hepatic cirrhosis, and we have noted it occasionally with bronchial carcinoma in the absence of arthropathy. We have not found testicular atrophy, hirsutism, or macroglossia in our patients. We have not detected any pituitary cortical or thyroid adenomatous changes in the course of three necropsies. Our biochemical investigations lend little support to this endocrine theory, and the dramatic response to removal of the tumour suggests to us a much more direct connexion between the neoplasm and the osteoarthropathy.

2. *Tumour secretes a specific chemical substance, responsible for the change.*—The rapid disappearance of symptoms and signs of osteoarthropathy after tumour resection favours such a theory and also suggests that this substance, possibly of hormonal nature, is destroyed or excreted rapidly. It seems just possible that, excreted in the urine of patients, it might even account for the severe reaction in mice found during our F.S.H. studies. Its effect could be an indirect one through the medium of hyperaemia. On the other hand, the tumour has no special cytological features which would single it out for such a secretory role. A toxic product of tumour necrosis, however, might be absorbed into the blood stream and produce such an effect. While such a theory could explain the relief following pulmonary artery ligation it could not account for the relief after hilar denervation, nor for the occurrence of osteoarthropathy in conditions other than neoplasm.

3. *Theory of an autonomic pulmonary-systemic vascular reflex.*—Cudkowicz and Armstrong (1953a, 1953b) have found precapillary broncho-pulmonary anastomoses in the lungs of patients with variable degrees of finger-clubbing and osteoarthropathy. They were unable to demonstrate such anastomoses in normal lungs or in cases of bronchial carcinoma in which no clubbing was present. The anastomoses in cases of tumour, bronchiectasis, and emphysema were seen only in the affected lobes, and there was occlusion of the pulmonary artery proximal to the anastomoses with a variable degree of recanalization. Cockett and Vass (1951) suggest that thrombosis of a pulmonary artery branch may be a stimulus to the development of these anastomoses. Gilroy *et al.* (1951) found arterial blood in the pulmonary arteries of collapsed lobes at operation, strongly suggesting the presence of bronchial arterial blood in the pulmonary circulation. Accompanying this diversion of bronchial artery blood, Cudkowicz and Armstrong demonstrated hyperplasia of the walls and narrowing of the lumina of the smaller peripheral bronchial artery branches, suggesting a state of spasm and reduced function. They suggest that impulses from the peripheral nerve fibres of the lung, rendered ischaemic by the deviation of bronchial arterial blood flow, reflexly influence the formation of the systemic arteriovenous anastomoses in the limbs, described by Lovell. Such an autonomic reflex theory could explain the occurrence of osteoarthropathy in a variety of thoracic lesions, its absence in most lung tumours, and the relief given by tumour removal, pulmonary artery ligation, hilum denervation, and vagus resection (Hansen, 1954).

All three theories have defects, but their further study will probably furnish a conclusive explanation of the syndrome. Investigations by inoculation of animals with

tumour and urine extracts, vascular studies of resected lungs, and autonomic block are all possible keys to the solution of this fascinating problem.

Summary

Bronchial carcinoma may now be regarded as the chief cause of generalized hypertrophic pulmonary osteoarthropathy. A review of 24 patients with this syndrome encountered during the past seven years is presented.

The pathogenesis of osteoarthropathy has been reviewed in the light of our clinical studies, past experimental work, and the dramatic and invariable "cure" effected by tumour removal.

Such patients are often treated for rheumatism or rheumatoid arthritis for many months, and may become bedridden cripples before the presence of a silent lung tumour is suspected.

Fifteen of the patients were submitted to lung resection. Only four are alive. Operative results in this type of tumour might be expected to improve when the significance of such joint symptoms becomes more generally appreciated.

We wish to thank Mr. Bruce Dick for his ever-helpful co-operation and stimulation; Dr. Angus Scott (Cases 3, 4, and 15) and Professor Sir John McNee (Case 16) for permission to record their respective patients; Mr. R. S. Barclay and Mr. Kenneth Fraser for surgical assistance and advice; and Dr. Ian Anderson for biochemical determinations. For the photographic reproduction we are indebted to Mr. H. C. Gray, of the clinical photographic department, Victoria Infirmary, Glasgow.

CARCINOMA OF BRONCHUS IN ASSOCIATION WITH ACTIVE PULMONARY TUBERCULOSIS

BY

A. SAKULA, M.D., M.R.C.P.

Assistant Physician, Kingston Chest Clinic, Surrey

Both pulmonary tuberculosis and carcinoma of the bronchus are common diseases, and it is not a matter of surprise that the two conditions should at times be encountered together. It is generally accepted that there has been, in recent years, an absolute increase in the incidence of bronchial carcinoma, a disease more common in middle-aged and elderly males. With modern methods of treatment, the mortality from pulmonary tuberculosis has shown a dramatic fall, and this implies that more tuberculous patients are surviving into the cancer age. In addition, more cases of active pulmonary tuberculosis are being found in the older men. It is to be expected, therefore, that the two diseases will be encountered more and more in association. For this reason it is of interest to describe the following six cases with the dual pathology. They were all seen during the past three years, the diagnosis being made during life and confirmed at necropsy. They demonstrate the various problems which arise in the diagnosis of these conditions when associated, and their possible interrelationship.

Case 1

A plasterer aged 50 was found, in 1935, to be suffering from bilateral fibrocavernous tuberculosis, the left upper lobe being chiefly affected. He spent two years in a sanatorium, at the end of which time his sputum still contained tubercle bacilli, but his condition was improved. He remained well and at work for the next 10 years in a stable chronic condition. When seen in 1950 he was bothered by a wheezy bronchitis, but for two years there had been no change in the radiological appearances of his lungs, which showed many calcified foci on the right side, while on the left there was some fibrotic disease of the upper lobe.

In October, 1951, he began to deteriorate. There was some staining of the phlegm, he became easily fatigued, but there was little loss of weight. He was forced to give up his work. Radiologically there was a coalescence of the opacities present in the left upper lobe. In February, 1952, streptomycin and P.A.S. were administered to him at home, with little benefit, and in May it was necessary to admit him to hospital. Tomograms of the left upper lung showed a number of large cavities, those lying posteriorly having a fairly regular outline, but there was one anteriorly which had a very irregular wall. This appearance suggested the possibility of a carcinoma having supervened on his chronic pulmonary tuberculosis. He was too ill for bronchoscopy. Despite the administration of further streptomycin, together with isoniazid, his condition deteriorated. In October the sputum still contained tubercle bacilli, but thereafter all sputa were reported as negative for tubercle bacilli on direct smear. Radiologically there was the gradual development of a large dense opacity in the left upper lung, and the left hemidiaphragm became paralysed. No radical therapy was possible, and in March, 1953, he died.

Necropsy revealed the presence of chronic fibrosis and cavity formation of a tuberculous nature in the apices of both lungs, but in the left lung there was also a round necrotic mass (7.5 cm. in diameter), macroscopically a carcinoma, lying mainly in the upper lobe, against the hilum and the aorta.

Histology showed the carcinoma to be of the epidermoid type, arranged in solid masses, with a little differentiation

into squamous cells. The cell type was relatively polymorphic, and the mitotic frequency relatively high. Tubercles were seen in sections from the adjacent portions of the lung.

Case 2

A railway clerk aged 60 was discovered by mass radiography in 1946 to have quiescent tuberculous lesions in both upper lobes. In 1949, however, he developed a cough, and radiographs showed some slight apical fibrosis on the right side, but on the left side there was infiltration in the upper and mid-zones not previously present in 1946. Examinations of the sputum were negative, but Löwenstein culture of one laryngeal swab in October, 1949, revealed a scanty growth of tubercle bacilli. In 1950 tomograms demonstrated a small thick-walled cavity in the left upper lobe. Apart from three months of bed rest, he did not receive any specific treatment, but continued at work feeling fairly well, although he did complain of undue fatigue. In April, 1952, radiographs showed his condition to be stable.

In July he developed a bad "cold," which was followed by stabbing pains in the right axilla, spreading towards the back of the right chest. At this time he had already retired from his work, but he still was very fatigued. He was bothered by considerable dyspepsia, and was losing weight. Radiologically he was found to have developed a new circumscribed homogeneous opacity in the right upper zone. Tomograms showed a well-defined opacity, but there was no central excavation. Sputum tests were negative for tubercle bacilli.

Bronchoscopy was performed, but with negative result. Nevertheless, the presence of a carcinoma was strongly suspected on radiological grounds, but treatment, either by surgery or radiotherapy, was not thought advisable. In January, 1953, he had considerable pain in the right chest and arm and he developed severe headache and vomiting. It was thought that he now had a cerebral metastasis. In April he had to be admitted to hospital. Radiologically the opacity in the right upper lobe had steadily increased in size, but sputum examinations for tubercle bacilli were negative. Later his liver enlarged, he became jaundiced, and he died in August, 1953.

Necropsy revealed an extensive lesion of the right upper lobe, consisting of areas of carcinoma round one division of the right upper lobe bronchus, and a firm plaque of similar appearance under the pleura, both layers of which were firmly adherent. The rest of the right upper lobe was necrotic, with areas suggestive of tuberculosis. The left upper lobe contained fibrocaseous tuberculous disease, with cavitation. There were also scattered firm nodules in both lungs, due to metastases. The liver was enlarged and showed fatty infiltration but no metastases, and examination of the brain failed to show any evidence of secondary deposits.

Histology showed the carcinoma to be of undifferentiated anaplastic type, and there were some foci of tuberculosis adjacent.

Case 3

A painter aged 53 developed in October, 1951, a cough with sputum, associated with fever and loss of weight. When seen in January, 1952, he was found to be in very poor condition, 1½ st. (10 kg.) underweight, with a marked kyphosis and an emphysematous chest. A chest radiograph revealed evidence of tuberculous infiltration and fibrosis in the left upper zone, the right lung being quite clear. Sputum tests were negative for tubercle bacilli. It was significant that a chest radiograph in 1948 had been normal. He spent six weeks in a sanatorium, which he left prematurely at his own request. He was then treated at home with rest and P.A.S. for four months, but with little benefit.

In May, 1952, a new small opacity appeared in the peripheral portion of the right first intercostal space. During the course of the next two years his general condition and the radiological appearance of the lesions in the left apex did not seem to alter, but the opacity in the right upper

zone showed a steady increase in size, becoming a large, rounded mass. Sputum tests were negative for tubercle bacilli. The blood Wassermann reaction was negative. His haemoglobin was 87%, and white blood count 13,100 (87% polymorphs).

In June, 1954, his clinical condition deteriorated, and he became more easily dyspnoeic. Bronchoscopy was not attempted, as it was not thought likely that any abnormality would be visible, since the growth, if present, was peripheral. Nevertheless, on clinical and radiological grounds, he was believed to have a carcinoma of the right lung in addition to the quiescent pulmonary tuberculosis in the left lung. Radical therapy was not regarded as being indicated.

In August he developed severe headaches and became mentally confused. He was admitted to hospital, where he was found to have papilloedema, and a cerebral metastasis was suspected. There were now also some subcutaneous nodules under the skin of the right forearm which had not been previously present. He became comatose, and soon died.

Necropsy revealed fibrotic tuberculous lesions in the left apex, adherent to the chest wall, while in the right upper lobe there was a large rounded solid mass of carcinoma (10 cm. in diameter) replacing most of the lobe. The nodules under the skin of the right forearm were confirmed to be secondary deposits. The right cerebellum contained one large metastasis (5 cm. in diameter).

Histology revealed the carcinoma to be of the undifferentiated, polymorphic, large-celled variety. Sections of the left apex showed evidence of fibroid tuberculosis.

Case 4

An unskilled labourer aged 64 developed in January, 1953, a cough associated with undue dyspnoea on effort. He also lost his appetite, had considerable abdominal pain after meals, and was losing weight. In March, 1953, his doctor referred him for a barium-meal examination, but no abnormality was discovered in his alimentary tract. One month later the cough was worse, there was a great deal of offensive yellow sputum, and his voice became husky. He was referred for a chest radiograph, and this revealed a dense opacity in the base of the left upper lobe with central excavation. There was pleural thickening over the left chest wall laterally. In the left lower lobe were miliary changes suggestive of tuberculous disease. He was then admitted to hospital, and the following facts were ascertained regarding his previous history. His mother had died of pulmonary tuberculosis. He himself had had three attacks of "pneumonia" before the age of 35. He had been a regular smoker of 10 cigarettes daily for most of his life.

Examination revealed him to be a very ill wasted man, with marked clubbing of the fingers. There were dullness and bronchial breath sounds, with many rales and rhonchi, on the left side of his chest, and the liver was enlarged. His haemoglobin was 72% and white blood count 16,800 (82% polymorphs). Sputum examinations revealed the presence of tubercle bacilli on direct smear. Pulmonary tuberculosis was diagnosed, but the dense opacity in the base of the left upper lobe made one suspicious of the presence of a carcinoma in addition. Any radical therapy for a carcinoma was, however, quite out of the question. Streptomycin and P.A.S. were administered, but his condition rapidly deteriorated, and he died a fortnight after admission to hospital.

Necropsy revealed the left upper lobe to be a solid mass of carcinoma and cavitation. There was one small focus of carcinoma in the right upper lobe near a bronchus. The left lower lobe presented the appearance of a localized miliary tuberculosis. The liver contained four large metastases (5-7.5 cm. in diameter). On the left side of the neck there was a large mass of glands, and smaller masses were in the anterior mediastinum and around the tail of the pancreas. There was a subcutaneous nodule at the

umbilicus, and scattered enlarged glands in the mesentery, the para-aortic area, and the pelvis.

Histology showed the carcinoma to be small-celled, poorly differentiated to an epithelial character. The cell type was moderately polymorphic, and the mitotic frequency relatively moderate. There were also tubercles distributed throughout the left lower lobe.

Case 5

A bookmaker's clerk aged 45 was seen in January, 1953, with a history of cough and sputum of six months' duration. He had regularly smoked 20 cigarettes daily. For three months he had been feeling increasingly fatigued, and had been running an evening pyrexia—to 99.4° F. (37.4° C.)—and had lost 1½ st. (10 kg.) in weight. His father had died of pulmonary tuberculosis.

On examination he was seen to be very ill, and was mentally confused. There was early clubbing of the fingers, and numerous crepitations could be heard in the left upper lung. A chest radiograph revealed a large cavity in the left upper zone, with infiltration in the left upper and mid-zones. The right lung was normal. It was of interest that a chest radiograph, taken when he was demobilized from the Royal Navy in 1944, was normal. Examination of the sputum revealed tubercle bacilli on direct smear. A diagnosis of active pulmonary tuberculosis was made, and he was admitted to hospital. Treatment with streptomycin and P.A.S. was begun at once, but despite this his condition deteriorated. In May he was bronchoscoped, but, owing to gross upward displacement, the orifice of the left upper lobe bronchus could not be seen. A biopsy was carried out on an enlarged gland in the neck, and histological examination showed the gland to be extensively replaced by an undifferentiated carcinoma, probably squamous-celled. It was now realized that a carcinoma of the lung was present, complicated by pulmonary tuberculosis, but no radical therapy for the carcinoma was feasible.

His condition deteriorated rapidly. He soon became cachectic, and clubbing was more pronounced. Radiologically there was now a larger dense mass in the left upper lung, in which there was a cavity (with fluid levels), the walls of which were very irregular, and in which one could distinguish several nodules of growth. His haemoglobin was 58%, and white blood count 15,200 (87% polymorphs). A right hemiplegia developed, and several epileptiform fits occurred, followed by marked impairment of speech. A skull x-ray film showed a small area of thinning of bone in the left frontal area, and it was thought that a cerebral metastasis was present. In July, 1953, he died.

Necropsy revealed a bronchial carcinoma involving and surrounding the left upper and lower bronchi. Distal to this in the lung was a large pus-filled abscess cavity (5 cm. in diameter). There were secondary involved glands in the mediastinum and both sides of the neck, as well as one plaque on the anterior surface of the liver and an enlarged para-aortic gland on the left side. In the brain there was a large cystic area in the left parietal region, the pathology of which was obscure.

Histology showed the lung substance to be infiltrated by cells of a poorly differentiated carcinoma of the bronchus. There were also tuberculous giant cells and endothelial cells.

Case 6

A retired welfare officer aged 69 was seen for the first time in January, 1953. He had suffered from bronchitis for many years, and in 1950 had had a brief attack of left-sided "pleurisy." He had smoked 20 cigarettes daily for most of his life. He had lost weight during the previous three months, and for one month had been having pains in the left chest associated with undue shortness of breath. His cough had become worse, and the phlegm was streaked with blood.

On examination his general condition was very poor and he was markedly dyspnoeic at rest. There was no clubbing of the fingers, but wheezy rhonchi could be heard in both lungs. A chest radiograph revealed some scattered opacities

in the right lung, and on the left side there was a dense opacity arising from the hilum and radiating upwards and outwards into the left upper lobe. Examination of the sputum was negative for tubercle bacilli, and the E.S.R. was 56 mm. in the first hour (Westergren). A diagnosis of carcinoma of the bronchus was made, but further investigation by bronchoscopy was not carried out, in view of his age and very poor condition.

In March he was admitted to hospital. He was cachectic, with an irregular pyrexia—to 102° F. (38.9° C.)—and had now developed clubbing of the fingers. Examination of the chest revealed diminished movement and air entry on the left side, and the coin test was positive. A radiograph revealed that a spontaneous pyopneumothorax had taken place on the left side. The sputum contained scanty tubercle bacilli on direct smear. The haemoglobin was 70%, and the white blood count 17,300 (81% polymorphs). The left chest was aspirated and turbid yellowish-green fluid withdrawn. This was lymphocytic and no tubercle bacilli were seen on direct smear, but Löwenstein culture proved positive. It was realized that the carcinoma was now accompanied by a tuberculous pyopneumothorax, but no radical therapy would avail. He deteriorated rapidly, and died in May, 1953.

Necropsy revealed the left lung to be a solid mass of cancer and abscesses, and perhaps tubercle, too. The left hilar glands were replaced by cancer. The neoplastic left lung had spread over the mediastinum, but the glands themselves were not obviously invaded, apart from the hilar ones. The left pleural cavity contained some purulent fluid, and the right upper lobe showed miliary tuberculosis.

Histology showed a bronchogenic carcinoma with solid epithelial alveoli but no further epidermoid differentiation. The cell type was fairly regular and the mitotic frequency relatively low. There were also scanty tuberculous follicles.

Discussion

It is now nearly 150 years since Bayle (1810), the great teacher of Laennec, described the "phthisies cancéreuses," but he used the term "phthisis" to include the wasting which might ensue from any pulmonary disease, and it is doubtful whether he was in fact describing tuberculosis and carcinoma occurring together in the lungs. Credit for the first description of the two diseases coexisting must be given to Penard (1846). In recent years it has become increasingly recognized that carcinoma and tuberculosis may occur together in the lungs, and reports have been published on the subject (Fried, 1935; Cohen, 1949; Blasi, 1950; Shefts and Hentel, 1950; Coutts, 1951; Helm and Moon, 1952; Nuessle, 1953).

Incidence

The incidence of the association of the two diseases at necropsy has varied greatly in the large series published by different authorities, and is shown in Tables I and II. Among live patients, Källquist (1952) has described a series of 5,527 cases of pulmonary tuberculosis, of which 11 (0.2%) had carcinoma of the bronchus as well; and Seyfarth (1952), in a series of 1,103 cases of carcinoma of the lung, found 11.42% to have evidence of tuberculosis also.

The discrepancies between these different series may partly be explained by the varied interpretations adopted

TABLE I

Authority	Necropsies on Pulmonary Tuberculosis	Coincident Carcinoma
Gerstl <i>et al.</i> (1946)	1,600	0.44%
Drymalski and Sweeney (1948)	2,000	0.75%

TABLE II

Authority	Necropsies on Carcinoma of Lung	Coincident Active Tuberculosis
Farber <i>et al.</i> (1949)	266	3.8%
Bryson and Spencer (1951)	866	1.8%
Gloyne (1951)	648	5.5%

by the different workers regarding what constituted tuberculous disease. Thus Bryson and Spencer's (1951) low figures included only those with chronic active pulmonary tuberculosis, as distinct from mere microscopical evidence of old chronic tuberculous lesions.

It may be concluded that the incidence of active tuberculous changes in patients suffering from cancer of the lung (as exemplified in Cases 4, 5, and 6) are not rare, while patients with pulmonary tuberculosis developing a new growth (as in Cases 1, 2, and 3) are less common.

Problems of Diagnosis

When a carcinoma of the bronchus develops insidiously in a known case of chronic pulmonary tuberculosis (as in Cases 1, 2, and 3), the diagnosis of the dual pathology is likely to be more difficult than when a diagnosed case of carcinoma of the bronchus is complicated by the finding of tubercle bacilli in the sputum (as in Cases 4, 5, and 6).

Clinically, carcinoma of the bronchus should be suspected in a man over the age of 40, usually a smoker, and known to have chronic pulmonary tuberculosis, who appears to be more ill than his tuberculous condition alone warrants, or if he is unusually dyspnoeic or has a pain in the chest which is persistent. It is of interest that in the six cases described above, haemoptysis was not a conspicuous feature. Another suspicious feature is the failure to respond to specific antituberculous chemotherapy. There may, of course, be many reasons for this, but one of them may be the complication of a carcinoma of the bronchus. Similarly, excessive anaemia and a polymorphonuclear leucocytosis (as in Cases 3, 4, 5, and 6) may indicate the presence of a carcinoma superimposed on the tubercle.

The radiological features suggestive of carcinoma are the superimposition on the tuberculous changes of a dense opacity, especially near the hilum. Enlargement of hilar glands, paralysis of a hemidiaphragm, and erosion of a rib are also helpful diagnostic signs. Where there is a thick-walled cavity with a very coarse irregular lining (often best seen in tomograms), it may merely mean a breaking-down neoplasm, but it may also indicate a cancerous development in a tuberculous cavity (as in Case 1).

Bronchoscopy (which was possible only in Cases 2 and 5) did not prove at all helpful. The diagnosis of a cerebral secondary deposit, or the biopsy of an enlarged gland (as in Case 5) or of a subcutaneous nodule (as in Case 3), may be conclusive, but it indicates that such a metastasis precludes any hope of a radical cure.

So long as it is remembered that carcinoma and tubercle in the lung do not exclude one another, it is very unlikely that the diagnosis of the two conditions occurring together will prove difficult or be unduly delayed. In a known case of pulmonary tuberculosis the early diagnosis of a superimposed carcinoma is of great importance, since otherwise it may prove too late to treat. Although the six cases described here were diagnosed correctly during life, the carcinoma was too advanced in all of them to allow any radical therapy to be considered. It should be remembered that the finding of tubercle bacilli in a case of carcinoma of the bronchus may be of minor importance so far as the practical management of the case is concerned. The treatment of the cancer takes precedence.

Relationship of the Two Diseases

The association of tuberculosis and carcinoma of the lung may be considered in various ways.

1. *The Two Diseases Exert a Mutual Antagonism.*—Rokitansky (1854), as a result of his famous morbid anatomical studies, first propounded the theory that there was an antagonism between cancer and tuberculosis, and this was supported by Raymond Pearl (1929) in his statistical studies based on the records of the Johns Hopkins Hospital. Cooper (1932), however, in his comprehensive study of the association of the two diseases, showed conclusively that the two diseases were not antagonistic.

2. *Tuberculosis (active or healed) is a Factor in the Production of Carcinoma.*—Cherry (1931), as a result of experiments on mice and his statistical studies, believed that cancer was predisposed to by previous tuberculous disease. Woodruff and Nahas (1951), analysing 23 cases of carcinoma of the bronchus, found 12 which were squamous-celled, and these were associated with large calcified foci in the same lobe or adjacent tracheo-bronchial lymph node, but not with active tuberculous disease. They suggested that it was healed tuberculosis which, leading to calcification and bronchiectasis (usually saccular, in the upper lobes), predisposed to the development of cancer, since smoking tended to produce an accumulation of tobacco products in the saccules. It has been thought by many that chronic irritation and atypical regeneration of epithelial tissues in old tuberculous cavities may lead to neoplastic changes. Bryson and Spencer (1951), however, found in the 866 cases of cancer of the lung they studied *post mortem* only four examples where the cancer arose in the wall of a bronchiectatic cavity.

3. *Cancer Activates Pre-existing Tuberculous Disease.*—When one considers the frequency of healed tuberculous foci in the lungs it is not surprising that carcinomatous infiltration into the lung, as well as the debility produced by the cancer, should lead to erosion of the tuberculous foci, with proliferation of the tubercle bacilli and reactivation of the tuberculous disease. Thus Pagel (1934) showed that a cancer nodule in the lung may be seen to be encircled by recent macroscopic tuberculous foci. Even if a very small lesion is eroded by growth, some tubercle bacilli may be found in the sputum, but this may be of minor importance (Gloyne, 1951).

It is very likely that either of the points of view described in (2) and (3) above may operate in different circumstances. It is also true, however, that in many cases the two diseases arise quite independently, running their separate courses with little effect on each other.

Summary

Six cases in which carcinoma of the bronchus and active pulmonary tuberculosis were associated in male patients over the age of 40 are described. In three a carcinoma developed insidiously in known cases of chronic pulmonary tuberculosis. In the other three, carcinoma of the bronchus was complicated by the presence of active pulmonary tuberculosis.

The interrelationship of the two diseases and the problems of their diagnosis are discussed.

The incidence of the two diseases occurring together is presented, and it is suggested that possibly this association will now be encountered more frequently.

I should like to thank Dr. C. O. Edwards for allowing me to quote Case 2, and Dr. J. C. Lees for giving me access to his necropsy records.

ACQUIRED ICHTHYOSIS IN HODGKIN'S DISEASE

BY

I. B. SNEDDON, M.B., Ch.B., M.R.C.P.

Involvement of the skin by either specific or non-specific lesions is a common finding in Hodgkin's disease. In a study of 156 cases Epstein and MacEachern (1937) found that 53.2% showed skin changes. A rare and interesting change is that of acquired ichthyosiform atrophy. It simulates congenital xeroderma so closely that it can be overlooked unless it is appreciated that the eruption has not been present since infancy. Ronchese (1943) first described the onset of an ichthyosiform atrophy of the skin in a patient with Hodgkin's disease eleven months before the patient's death and while he was apparently in good health. Since then Glazebrook and Tomaszewski (1944, 1947) have reported the skin change in association with cases of Hodgkin's disease and lymphosarcoma, Welch and Epstein (1952) in a case of Hodgkin's disease, and Forman (1953) in a case of reticulosarcoma. It is probable that the complication occurs more frequently than the scanty reports suggest, as it was present in the four following cases.

Case 1

A man aged 48, a steelworks gas-producer, some five months before admission began to feel weak and ill, and complained of a pain in the right loin which spread round to the abdomen. He vomited occasionally and was troubled with morning diarrhoea, sometimes three to four loose stools after rising. There had been a weight loss of several stones in the preceding year. On several occasions in the preceding months he had been confined to bed with attacks of so-called "flu." For two months before admission to hospital he noticed that his skin had become dry and scaly (Fig. 1) but not irritable. He was adamant that he had never had a skin abnormality before this.

On examination he appeared wasted, and the skin of the whole body and face showed a dry ichthyotic change. The ichthyosis was indistinguishable from a congenital ichthyosis, though at the time no special attention was paid to whether it spared the flexures. Enlarged glands were detected in the left supraclavicular region and in the left axilla. The spleen was enlarged a handbreadth below the costal margin. Gland biopsy showed Hodgkin's disease.

Histological examination of the skin showed only hyperkeratosis and atrophy. There was no sign of an infiltrate. Dark-adaptation tests gave results within normal limits.

The patient was included in the M.R.C. trial of R.48 and at first seemed to benefit from treatment, the glands and spleen diminishing in size. Coincident with this improvement the ichthyosis became less pronounced.

FIG. 1.—Case 1. Showing well-marked ichthyosiform change in the skin of the arm.

Five months later he was readmitted for transfusion, and his ichthyosis was then worse than it had been originally. He was readmitted on several occasions in the next two years, but contact with him was eventually lost. He is presumed to be dead.

Case 2

In August, 1953, I was asked to see a 52-year-old man in the Sheffield Royal Hospital, under the care of Dr. T. E. Gumpert. He had been admitted six days previously with a five-weeks history of severe diarrhoea, which had come on suddenly when on holiday in Germany and which had not been controlled with sulphaguanidine. For several weeks previous to the onset of diarrhoea he had felt listless and tired. Soon after the start of the diarrhoea the skin of his face felt tight and drawn and the skin of his body became dry and scaly.

On examination the skin of the chest and trunk was dry, was slightly erythematous, and showed large leafy scales; the facial skin seemed to be tightly stretched and was desquamating. On the limbs the appearance was identical with a moderate degree of congenital ichthyosis, though there was no sparing of the flexures. No enlarged lymphatic glands were found, or any abnormality on palpation of the abdomen.

At this stage the tentative diagnosis was a chronic dysenteric infection, and the skin change was ascribed to dehydration. Culture of stools, however, revealed no pathogens, and agglutinations were negative for salmonella. Sigmoidoscopy revealed only inflamed and oedematous mucosa, and a barium enema gave normal results. A blood count showed: Hb, 68%; red cells, 3,200,000; white cells, 4,400 (normal differential); platelets, 32,000. Marrow examination was inconclusive. The only other really positive finding was some enlargement of the hilar glands seen on a chest x-ray film and tomogram.

The course of the illness was one of uninterrupted deterioration. The haemoglobin and platelets fell, and extensive purpura developed shortly before the patient died, one month after admission. A tentative diagnosis of Hodgkin's disease, based on the ichthyotic skin change, the discovery of the enlarged hilar glands, and the course of the illness, was reached before his death.

Necropsy.—The relevant findings were enlargement of the glands at the base of the neck and in the mediastinum. These showed a grey uniform cut surface and were rather soft. The lungs and bronchi were not involved. Many whitish nodules were present in the omentum, which was almost devoid of fat; in the wall of the jejunum and in the wall of the ileum were firm masses made up of nodules aggregated together. They were firmer and more rubbery than the mediastinal glands. The aortic glands, and particularly those in the portal fissure and around the pancreas, were enlarged and firm. The liver showed a whitish mottling and at one point appeared to be infiltrated. The spleen was small and fibrotic. On macroscopic examination there was still some doubt about the nature of the nodules in the jejunum and ileum, which resembled carcinomata. Histological examination showed that there were deposits of sclerosing Hodgkin's disease in all coats of the bowel. The lymph nodes from the portal fissure, and the liver and spleen, showed recognizable Hodgkin's disease. The mediastinal nodes were less characteristic, and in some areas resembled an undifferentiated malignant neoplasm. The pathologist, Dr. J. I. Edwards, was confident, however, that only one pathological condition was present—Hodgkin's disease. Section of the skin showed similar findings to the first case—hyperkeratosis, with atrophy of the remainder of the skin elements and no evidence of infiltration in the dermis.

Case 3

An old-age pensioner of 67 had suffered for two years from an eczematous eruption on the feet and ankles. Some four months before he attended hospital he had developed hard painless lumps on the skin of the shoulders and chest. He had not lost weight nor did he feel unwell.

On examination a well-marked ichthyosiform change was present on the skin of the face, trunk, and limbs. This did not spare the flexures. He was uncertain how long the dry scalliness had been present, but was sure it was of recent onset. Multiple skin tumours of firm consistency and a reddish-purple colour, varying in size from a pea to a golf

FIG. 2.—Case 3. Showing multiple skin tumours on the trunk.

ball, were present over the shoulders, chest, upper abdomen, and thighs. Enlarged glands were found in the neck and the supraclavicular axillary and inguinal regions. The liver and spleen were not palpable. Skiagrams of the chest showed no mediastinal glands. Marrow puncture and blood count revealed no abnormality.

In view of the ichthyotic change, the nodules were presumed to be due to Hodgkin's disease rather than

secondary carcinomata, and this was substantiated by the histological findings of a reticulosarcoma of Hodgkin's type.

Case 4

An 85-year-old woman complained of painless lumps appearing on the back of her neck some two months previously. After discovering those lumps she had noticed others on the trunk.

Examination showed a dusky-red nodular tumour on the back of her neck and another below her left ear. Less obvious smaller nodules were present over the left parotid region and the trunk. No enlarged lymph nodes were found, nor was there demonstrable enlargement of liver and spleen. On the trunk was a mild generalized ichthyosis which she said was of recent onset. The nodules were obviously either secondary carcinomatous deposits or some form of reticulosis. The presence of the ichthyosis suggested the likelihood of the latter, and histological examination of a neck nodule showed a reticulosis of mycosis fungoides type. The nodules failed to respond to radiotherapy or triethylene melamine, and she died two months after admission to hospital.

The significant findings at necropsy were nodular plaques of greyish-white tissue on the lateral thoracic wall and on the lung beneath the pleura. The mediastinal lymph nodes were enlarged. More neoplastic nodules were present on the peritoneal surface of the small and large intestine and in the tail of the pancreas, and the mesenteric lymph nodes were massed together and enlarged. Another greyish-white mass was seen to surround the pelvis, ureter, and inferior pole of the right kidney, and more were present on the posterior wall of the uterus and in the broad ligaments. The liver and spleen showed no macroscopic change. Sections from the affected organs showed deposits of large pleomorphic neoplastic cells characteristic of a reticulosarcoma.

Discussion

In the present series of cases no light has been thrown on the mechanism of production of this curious skin change, but it seems probable that it falls into the group of non-specific skin changes, a great variety of which are known to occur in Hodgkin's disease and allied reticuloses.

In Case 1 the ichthyosis did improve during a remission of the Hodgkin's disease whilst under treatment with R.48, and

this suggests a close association between the presence of Hodgkin's tissue and the skin change. Similar improvement was reported by Welch and Epstein when their patient was given x-ray therapy. Vitamin A was being given at the same time, so there is also a possibility that this played some part in the improvement. A disorder of vitamin A metabolism due to liver damage was suggested by Glazebrook and Tomaszewski as the cause of ichthyosis, but in Forman's case blood vitamin A studies were normal, and in my Case 1 dark-adaptation tests were normal.

If the ichthyotic change were due to liver damage alone one would expect to find it in other types of severe liver disease, and such is not the case. Also, it does not occur in association with secondary carcinomatous damage to the liver.

The onset of the ichthyotic change occurs early in the course of the disease and before there has been any appreciable wasting, so that mere inanition is not the cause.

From a practical point of view acquired ichthyosiform atrophy is a rare change, but it may be of value when the diagnosis of Hodgkin's disease is in doubt, as in Case 2. It is not easily differentiated from congenital ichthyosis, though my impression is that the acquired type affects the trunk and face more than the limbs, and, also, it does sometimes involve the flexures, which are usually spared in the congenital variety. Histologically there is no difference.

The onset of an ichthyotic eruption in an adult should certainly initiate a search for an underlying lymphoblastoma.

Summary

Four cases of an acquired ichthyosis associated with Hodgkin's disease and reticulosarcoma are described. The importance of investigating cases of acquired ichthyosis for underlying Hodgkin's disease or lymphoblastoma is stressed.

I should like to thank Professor C. H. Stuart-Harris and Dr. T. E. Gumpert for allowing me to report their cases, Drs. J. L. Edwards and L. C. D. Hermitte for the post-mortem reports and histological findings, and Mr. Brookes for the photographs.

The Victoria Cross awarded to Surgeon-Major Edmund Baron Hartley in 1879 was acquired for the record sum of £300 by the Royal Army Medical Corps when it came up for auction in London on March 17. Hartley, the son of a Devonshire doctor, was born in 1847 and qualified from St. George's Hospital in 1874. He then became district surgeon in Basutoland. In 1877 he joined the Cape Mounted Rifles as surgeon, becoming principal medical officer in the following year, and subsequently colonel in command of the Cape Medical Corps. He served in several campaigns during the Zulu war of 1877-9, and in the Boer War. He was decorated with the Victoria Cross for the conspicuous gallantry he displayed on June 5, 1879, in attending the wounded under fire at the unsuccessful attack on Morosi's Mountain, Basutoland. Other awards to Hartley included in the sale were the Cape General Service Medal with three bars (only thirteen other recipients of this medal and three bars are known), the Queen's South Africa Medal with three bars, and the King's South Africa Medal with two bars. He was appointed C.M.G. in 1900; he died on March 20, 1919, in his seventy-second year.

FOETAL FIBROELASTOSIS

BY

J. F. HORLEY, M.B., B.S.

Assistant Pathologist, Group Laboratory, Royal Sussex County Hospital, Brighton

Interest has been aroused from time to time in a cardiac lesion found in infants, the main features of which are thickening and opacity of the lining of the left chambers of the heart. First described as foetal endocarditis in the nineteenth century, it has subsequently been called congenital endocardial sclerosis (Craig, 1949), endocardial dysplasia (Prior and Wyatt, 1950), and endocardial sclerosis (Bonham-Carter *et al.*, 1952), and is now most generally known as fibroelastosis (Weinberg and Himelfarb, 1943). These titles reflect to some extent the changing conceptions of an aetiology which, however, has never been satisfactorily settled.

Recently a disease similar, superficially at least, to fibroelastosis in infancy has been described by several authors, including Bedford and Konstam (1946), Ball *et al.* (1954), and O'Brien (1954). This has occurred predominantly in natives of the Middle East area, and is characterized *post mortem* by cardiac enlargement and sclerosis of the endocardium; the possibility that the one may be a late stage of the other has naturally been raised. Already cases previously known as idiopathic cardiac hypertrophy of infancy, in which endocardial thickening may occur, have been linked with fibroelastosis, and this attempt to widen the scope of the disease to embrace all cases showing endocardial sclerosis is attractive. The examination of this problem has been prompted by the occurrence in the last two years in the Brighton Group of Hospitals of three examples of congenital aortic stenosis accompanied by fibroelastosis of the endocardium.

Case 1

Maternal History.—Aged 27 and in good health; W.R. negative; Group O, Rh positive. She had two healthy children, aged 4 and 7 years; there have been no abortions. Study of the antenatal records and retrospective questioning revealed no illness during the pregnancy; the parents were not blood relations.

The infant, a male, weighed 8 lb. 10 oz. (3.9 kg.) at birth. Labour was spontaneous and easy, and his immediate

FIG. 1.—Horizontal section through the ventricles. Case 1.

recovery was good. On the first day he was observed to be somewhat cyanotic at times, and subsequently respiration became laboured and rapid with frequent cyanotic attacks, in one of which, on the fourth day, he died. No abnormal physical signs had been found during life.

Necropsy.—Complete examination revealed severe venous congestion; apart from the changes in the heart no developmental or pathological lesion was found.

Heart (Fig. 1).—Weight 25.5 g. Size, apex to base, 4.5 cm.; side to side, 5 cm.; antero-posterior, 3.5 cm. The interventricular groove on the anterior surface ended 0.5 cm. above the apex, which was thus formed from the myocardium of the right ventricle. The right atrium and ventricle were dilated and the latter was also hypertrophied (wall 0.5 cm. thick). The left atrium was normal in size and the left ventricle small. The inner lining of the left ventricle was yellow, tough, and opaque; it measured 0.5 cm. over the interventricular septum and 0.4 cm. elsewhere. The foramen ovale was patent but capable of being closed by a flap-like valve of endocardium. The ductus arteriosus was widely patent and slightly larger than the aorta in diameter. The mitral, tricuspid, and pulmonary valves were natural. The aortic valve was stenosed by fusion of the contiguous borders of the valve cusps, except for a narrow slit between the anterior and left posterior ones.

Case 2

Maternal History.—Aged 27 and in good health; W.R. negative; Group O, Rh positive; no immune antibodies in the serum. She had one child, aged 3½ years, who was healthy, and there had been no abortions. Study of the antenatal records and retrospective questioning revealed no illness during the pregnancy. The parents were not blood relations.

The infant was female and weighed 5 lb. 7 oz. (2.5 kg.) at birth. Born spontaneously, she appeared well until 2 days old, when she became temporarily dusky in colour and thenceforward suffered from cyanotic attacks; in one of these, on the fifth day, she died. No abnormal physical signs had been detected during life.

Necropsy.—There was extreme generalized venous congestion; apart from this, complete examination revealed no congenital or pathological lesion except in the heart.

Heart.—Weight 22.5 g. Size, apex to base, 4.5 cm.; side to side, 4 cm.; antero-posterior, 3.5 cm. The interventricular groove on the anterior surface of the heart ended 1.5 cm. above the apex of the heart, which was thus formed by the myocardium of the right ventricle. The right atrium was dilated, the right ventricle dilated and hypertrophied (wall 4 mm. thick); the left atrium was small and the left ventricle vestigial. The endocardium of the left ventricle was tough, yellow, and thickened, especially over the interventricular septum, where it varied from 2 to 3 mm. in thickness. The ductus arteriosus was widely patent and a little larger than the arch of the aorta in diameter. The foramen ovale was patent, but could be closed by an efficient valve-like fold of endocardium. The tricuspid, pulmonary, and mitral valves were natural. The aortic valve was stenosed by fusion of the contiguous borders of the valve cusps, except for a narrow slit between the anterior and left posterior ones; there was no fibrosis or distortion of the cusps, which remained thin and pliable. The coronary arteries were normal in origin, structure, and distribution.

Case 3

Maternal History.—Aged 20 and in good health; W.R. negative; Group O, Rh negative, with no immune antibodies in the serum. She had had no previous children, abortions, or blood transfusions. Retrospective questioning and perusal of the antenatal records revealed no illness during the pregnancy. The parents were not blood relations.

The infant, a male, weighed 5 lb. 12 oz. (2.6 kg.) at birth; blood Group O, Rh positive. Hb at birth 16.3 g. per 100 ml., direct Race-Coombs test negative. The day after birth he was observed to be dusky-coloured at times.

Cyanotic attacks thereafter became frequent, and on the eighth day he died in one of them. No abnormal physical signs had been detected during life.

Necropsy.—There was severe systemic venous congestion, but apart from this no congenital or pathological lesion was found other than that of the heart.

Heart.—Weight 17.3 g. Size, apex to base, 4.4 cm.; side to side, 4 cm.; antero-posterior, 3.4 cm. The interventricular groove on the anterior surface ended 1.6 cm. from the apex of the heart, which was formed by the myocardium of the right ventricle. The right atrium was dilated, the right ventricle dilated and hypertrophied (wall 4 mm. thick). The left atrium was small and the left ventricle vestigial. The lining of the left ventricle was opaque, tough, and yellow-white, especially over the interventricular septum, where it was 3 mm. thick. The columnae

FIG. 2.—Arrangement of the great vessels in Case 3.

carneae were absent. The foramen ovale was widely patent, but could be closed by a flap-like valve of endocardium. The arrangement of the great vessels is shown in Fig. 2. The ductus arteriosus was patent, 6 mm. in diameter, and the same size as the arch of the aorta. The ascending aorta was 2 mm. only in diameter and there was no communication between it and the left ventricle. The aortic valve was closed by complete fusion of the valve-cusp borders. It was 2 mm. in diameter, and when viewed from the aortic side presented three distinct pits defined by three ridges meeting at the centre and corresponding to the edges of the aortic valve cusps. The coronary arteries arose opposite the anterior and left posterior depressions and were distributed normally; they were fed by retrograde blood-flow down the ascending aorta, which served no other purpose. The tricuspid and pulmonary valves were natural, the mitral small but not stenosed.

Microscopy

Sections were taken from the myocardium, opaque endocardium, aortic valve cusps, and coronary arteries in each case: the microscopical appearances were similar in all, so that their description may be combined.

FIG. 3.—Section at point of fusion of an aortic valve cusp. (x95.)

Section of the coronary arteries taken at 0.5-mm. intervals revealed no constriction of lumen or abnormality of the wall. The aortic valve cusps showed some increase in volume, made up by interlacing bundles of collagen undergoing oedematous change. In no case was there inflammatory cell infiltration; in particular, section at the point of fusion of valve cusps (Fig. 3) showed no scar tissue.

The myocardium was normal, with no inflammatory cell aggregates or fibrosis. The junction between the myocardium and the opaque endocardium was irregular and ill-defined, and in places islands of myocardial fibres were surrounded by tongues of fibrous tissue (Fig. 4). Many of the myocardial fibres were degenerate in the junctional layer and were being replaced by fibroblasts. The bulk of the opaque endocardium was composed of normal collagen fibres, but

FIG. 4.—Section at point of junction between the myocardium and the endocardium. (x55.)

when stained with orcein and eosin a high proportion of elastic fibres were found. A feature of the junctional layer was a large number of thin-walled dilated blood vessels.

Discussion

Aortic atresia is a rare condition. Canton (1948-9) appears to have been the first to report a case, and since then 20 others have been traced—those of Shattock (1881), Summons (1906), Gauss (1916), Fraser (1921), Mueller (1924), Abbott (*Loose-Leaf Medicine*), Schrader (1928), Philpott (1928), Willer and Beck (1932) two cases, Bellet and Gouley (1932), Farber and Hubbard (1933), Wesson and Beaver (1935), Roberts (1936), Rossman (1942), Craig (1949) four cases, and Halliday (1954). Case 3 reported here is thus the 22nd recorded example. In addition to aortic atresia, all showed a hypoplastic left ventricle lined by an opaque, white, thickened endocardium with an intact interventricular septum. The appearance of the aortic atresia is striking, and descriptions exactly similar to that given in Case 3 are repeatedly encountered. It is evident that the valve cusps have developed regularly and then fused along their borders, for, macroscopically, there is usually no distortion of pattern and microscopically no evidence of fibrosis. Incomplete aortic stenosis such as was found in Cases 1 and 2 differs from that of complete atresia in degree but not in essential nature. Fusion of valve cusps occurs as in atresia, except that a slit may be left between one pair, while endocardial sclerosis is constant and hypoplasia of the left ventricle is usually found. It seems likely that atresia and stenosis are both the end-result of the same disease process.

The clinical pattern of aortic atresia is very constant. The infant recovers satisfactorily from the immediate stress of parturition and then suffers from cyanosis and difficult respiration 12-36 hours after birth. Usually no abnormal physical signs are elicited and death occurs at about 5 days old. Out of the 22 recorded examples, 14 died in less than 6 days, while, of the remainder in which the age at death was given, only 3 lived more than 15 days.

Cases of aortic stenosis pursue a very similar clinical course, and it is exceptional for an infant to live more than 14 days. The cases of Farber and Hubbard (1933) and of Du Shane and Edwards (1954), in which the patients lived for 9 weeks and 2½ years respectively, are very exceptional, but both appeared to have had typically fused valve cusps.

Recent literature on fibroelastosis gives the impression that this change may occur at any age from birth to 5-6 years of age, and that valvular stenosis may or may not be associated in any particular example. However, study of available case reports and photographs shows that the occurrence of aortic stenosis is by no means haphazard. The heart weights and times of death when stated in all the patients under 9 months old accepted by Gowing (1953) in a recent review of the subject are arranged in Fig. 5; added to these are

FIG. 5.—Cases of foetal and infantile fibroelastosis contrasted.

all cases of aortic stenosis or atresia which could be traced. It is apparent from this that fibroelastosis in infancy is capable of division into two groups which are in many ways contrasted.

One group, which is referred to as foetal fibroelastosis and which is represented by the three cases described in this paper, is characterized by aortic stenosis (sometimes accompanied by mitral stenosis), early death, and relative or absolute hypoplasia of the left ventricle; the heart weight is only moderately increased and is accounted for by right ventricular hypertrophy. The other group, many cases of which had been described previously as idiopathic cardiac hypertrophy of infancy, is without valvular lesions and is referred to as infantile fibroelastosis. The left ventricle is grossly hypertrophied and usually dilated, and it accounts for heart weights three to five times the normal; death is uncommon under 3 months old, and it is interesting that fibroelastosis without valvular stenosis has not been recorded at birth except in the case described by Prior and Wyatt (1950). The latter would be an interesting exception, but, since it is given no separate description and there is no photograph, it is of doubtful value. Fibroelastosis of the endocardium is common to both groups, but the gross thickening found in foetal cases is seldom seen in infantile fibroelastosis: in some of the descriptions and photographs of the latter it is so slight that it raises the question of how far the term should be stretched.

Aetiology

Gross (1941) effectively rejected intrauterine inflammation as an explanation for the changes found in foetal fibroelastosis. Subsequently maternal infection and mesenchymal dysplasia have been popular hypotheses, but neither has evidence to support it. However, the microscopical appearances have many features in common with those found in

endocardial fibrosis overlying adult cardiac infarction. The irregular junctional line and dilated vessels, the occasional report of lymphocytic aggregates and calcification, and the evident fibrous replacement of the myocardial fibres bordering the endocardium are all similar and suggest that anoxia may be common to both. The main difference between the two is lack of fibrosis in the myocardium outside the junctional layer in foetal fibroelastosis. An explanation of this may lie in the way in which the anoxia is caused.

For a considerable time *in utero*, until the coronary circulation is fully established, the foetal heart is dependent for nourishment on blood flowing through its cavities. During this period temporary closure of the foramen ovale during the course of its development, along the lines suggested by Johnson (1952), would prevent oxygenated blood in the right atrium from flowing into the left atrium and left ventricle, and this may cause degeneration of the endocardium covering the aortic or mitral valves. In the absence of sufficient blood flow to keep them apart, fusion of the raw edges of the cusps would be expected with little fibrosis or distortion. If aortic stenosis was established in this way, stenosis and consequent anoxia of the blood in the left ventricle would occur and lead to degeneration of the layer of myocardium lining the cavity and the development of the fibrosis found in foetal fibroelastosis. Naturally, the myocardium outside the area supplied from within the cavity would be unaffected and normal in appearance. All the changes found in foetal fibroelastosis would thus be explained.

Support for this hypothesis is found in the rare examples of aortic and mitral atresia accompanied by ventricular septal defects. For example, Dolgopol (1934) described a heart with aortic atresia in which the vestigial left ventricle communicated with the right through a narrow slit: the left ventricular cavity was lined by normal endothelium. One of Halliday's (1954) cases showed mitral atresia and multiple ventricular septal defects. Fibroelastosis was found in the left atrium but not in the left ventricle. If both aortic stenosis and fibroelastosis were the result of mesenchymal dysplasia the presence of an interventricular septal defect would not influence the development of the latter. On the other hand, if fibroelastosis is the result of stasis and anoxia of blood in the left ventricle the change would not occur if oxygenated blood were available from the right ventricle through a septal defect. In fact, no case of aortic atresia has been traced in which fibroelastosis has occurred accompanied by an interventricular defect, and, conversely, no case of aortic atresia with an intact interventricular septum was without fibroelastosis.

Detailed discussion of the aetiology of infantile fibroelastosis does not come within the scope of this paper. However, the rarity of its occurrence within the first two months of life makes a developmental defect of embryonic origin unlikely, and an explanation bringing it into line on the basis of anoxia may be found with further research.

A connexion between cases of foetal fibroelastosis and the group described in adults is most unlikely, for the latter have no valvular defects, while the former all appear to die at a very early age. It is still possible that cases of infantile fibroelastosis may develop into the adult group, but at the moment the gap in age between the two is formidable. An explanation which seems more acceptable is that both are caused by a similar and as yet unknown mechanism.

Summary

Three cases of fibroelastosis accompanied by aortic stenosis or atresia are described.

Study of these cases and of other published reports shows that fibroelastosis in the first year of life may be divided clearly into two groups for which the terms foetal and infantile fibroelastosis are suggested. The first, manifest at birth, is characterized by early death, aortic stenosis, left ventricular hypoplasia, and right ventricular hypertrophy. The second, usually not

covered until 3 months of age or more, has no valvular defects and shows very considerable increase in heart weight due to gross left ventricular hypertrophy.

On morphological grounds anoxia of the cardiac muscle during cardiac development seems to offer the most acceptable explanation of the changes found at post-mortem examination in foetal and infantile fibro-elastosis, and a possible mechanism for this is offered.

The connexion between foetal and infantile fibro-elastosis and the endocardial sclerosis found in adults is discussed.

I should like to thank Dr. W. A. Bourne for his advice and encouragement during the preparation of this paper. I wish to thank also Miss M. K. Lawlor and Dr. J. F. Enright for permission to report on patients admitted under their care. Mr. Jackson very kindly photographed the specimens.

"There is at present a sickness in our country—a sickness of rumour and anxiety, of suspicion and distrust, and, at its worst, of fear and tragedy," said Dr. WEAVER, President of the American Association for the Advancement of Science, in his introductory remarks to the address of the retiring president (*Science*, February 18, 1955). Analysing the causes of this sickness, Dr. Weaver blamed the lack of "constructive courage with respect to the future," the strange lack of faith in scholarly competence, and the misguided zeal of sincere persons with mistaken ideas of good citizenship. At its worst the disease was "the result of political pressure, of personal selfishness, and of the pathological demagogues with small and nasty minds." The effect of these general and recurring fears was that confidence in government promises and even in the "Anglo-Saxon tradition of due process" had been destroyed. Commenting on the universality of this sickness, Dr. Weaver pointed out that science voiced its concern at it, not to demand protection for itself, but primarily because the problem was a universal one. As a remedy he called for the abandonment of timidity, and in its place a "really sensible, constructive stand," giving the warning that wit and patience must be used because "freedom is too precious to deserve rash or stupid support." He hoped that government concern "to improve the whole loyalty-security-secrecy setup" was a sign that the sickness of his country was waning, and at that actual meeting they were celebrating a "rededication to liberal decency."

SOME EFFECTS OF HIGH-ALTITUDE CLIMBING

INVESTIGATIONS MADE ON CLIMBERS OF THE BRITISH KANGCHENJUNGA RECONNAISSANCE EXPEDITION, 1954

BY

D. STAFFORD MATTHEWS, M.B., F.R.C.S.Ed.
M.R.C.O.G., F.R.G.S.

Medical Officer to the Expedition; Calcutta

A. R. ROY, M.B.

Department of Pathology, Medical College, Calcutta

R. CHATTERJEE, D.I.C.

AND

A. GHOSAL, B.Sc.

Department of Chemistry, Medical College, Calcutta

During the 1954 British Kangchenjunga Reconnaissance Expedition the opportunity was taken of carrying out certain biochemical and microscopical analyses of blood and urine samples obtained by the expedition medical officer (D.S.M.) from climbers at various altitudes. These were sent by runners to Darjeeling and dispatched by aeroplane to the Medical College, Calcutta, for assessment. Although many expeditions to the Himalayas have been made, there has unfortunately been little scientific liaison between them. We understand that samples of blood were collected from climbers of the successful 1953 Everest Expedition and sent back to England for analysis. We have not seen the results of those analyses or of any investigations that may have been conducted by other parties. Referable literature is difficult to obtain.

General Observations

A significant feature worth noting in relation to this expedition was the fact that it was primarily a reconnaissance. Knowing this, the party would be less likely to experience the anxiety stresses that are often associated with the anticipation of future efforts required in attempting to reach the summit. It is usually only at levels above those reached on this expedition that the almost inevitable deterioration occurs, no matter what degree of acclimatization is simultaneously taking place.

Our approach to Kangchenjunga was along the Singalila ridge—a high-level route throughout—which, although relatively arduous, must have been responsible for the high degree of acclimatization attained by all members of the party when base camp 18,000 ft. (5,500 m.) was reached on the eighteenth day out. No climber suffered from headache, nausea, or undue breathlessness except that three members experienced occasional spells of characteristic rapid periodic breathing. Sore throat and gastro-enteritis were rare, and there were no cases of frost-bite. Some of the porters who did not wear sunglasses complained of photophobia, and a mild conjunctivitis was found on examination. It was a revelation to watch some of the porters, barefooted, carry loads through snow and ice, and sleep at night in the open with scanty clothing—such is their ability to acclimatize to cold. The sherpanis—we had 16 of these female porters—performed their duties as well as most of the men.

Rothera tests were performed on numerous occasions on the mountain, particularly after climbers had made

exhausting ascents. On only one occasion was acetoneuria found to be present, and that was on the third day out from Darjeeling at 11,000 ft. (3,350 m.). Of the two climbers who had a trace of acetone in their urine, one had enteritis. However, some morning urine samples taken on the mountain and sent to Calcutta contained acetone as detected by the Rothera test. We are at a loss to explain the disparity between the results of tests performed on the mountain and those in Calcutta, unless it is that the mountain tests were performed on samples collected in the evening and those tested in Calcutta were morning urine specimens.

Despite efforts to encourage all climbers to drink large quantities of fluid, the specific gravity of urine specimens obtained from climbers after a day of exertion frequently ranged between 1030 and 1040. It proved impracticable to estimate the total urine output in any one day, but it was apparent that this was reduced. Although members were often dehydrated, thirst, like appetite, tended to be depressed.

The liability to shock following even minor injuries incurred while climbing at high altitudes is noteworthy. It would seem to be somewhat comparable to the increased liability to shock of a woman after a lengthy confinement. One of us suffered a lacerated finger with avulsion of the extensor tendon from the distal phalanx as a result of a blow from falling rock. The degree of shock was out of all proportion to the severity of the injury. Another climber received a lacerated scalp injury from a falling rock. Although the initial shock was minimal, some delayed reaction occurred later. He was confined to bed for 48 hours and forbidden climbing for the remaining week of the trip. Chlortetracycline (aureomycin) was administered on one occasion, but so severe were the toxic effects that the drug had to be stopped. Many of these effects, such as headache, nausea, and vomiting, are aggravated by anoxia.

The following changes in behaviour and thought were noted at the higher altitudes. Memory and concentration were impaired. For example, attempts to memorize from the *Oxford Dictionary of Quotations* failed. When using the cinematograph camera the operator would often forget to turn back the turret after rewinding. Only a routine automatic action can be reliably performed. One periodically became aware of a feeling of mental lethargy, with the result that there was a tendency not to push things to a satisfactory conclusion in the face of difficulties, even though one's physical prowess might not have been exhausted. At meetings held to discuss plans, thinking was not always incisive and conclusive. Insomnia was common; discordant restless mental activity often continued far into the night. Dream content was vivid, as though one had a high fever. There were frequent requests for sleeping pills. It is probable that the effects of altitude were responsible for some unruly behaviour on the part of the porters. Discipline was not always easy to maintain.

Laboratory Investigations

We were hindered by unforeseen difficulties in our attempt to carry out prearranged investigations. The samples were flown to Calcutta from Darjeeling, but there was much unavoidable delay in getting the specimens down to Darjeeling, with the result that many of the blood samples were found to be haemolysed or decomposed when they arrived at the laboratory. The effect of heat would also be responsible for this deterioration. At that time the Calcutta area was in the grip of a heat wave, when the maximum temperature in the shade reached 110° F. (43.3° C.). It is significant that the blood samples taken in Darjeeling and examined in Calcutta during this unusually hot weather were unsuitable, whereas many of those taken later on the mountain were satisfactory. In some cases the blood had completely leaked out of the containers, although they

appeared to be leak-proof in the laboratory before packing. Care was taken on the mountain to ensure that the screw caps were tightened. The reduced atmospheric pressure at high altitude might be responsible for this leakage. We could not, therefore, obtain as many samples from various altitudes as we had hoped. On blood samples, haemoglobin percentages were estimated from iron analyses, a method which is considered by King and his associates (1947, 1948a, 1948b) to be the most reliable, although, of course, it is not absolutely free from error, because a certain small proportion of the iron, from 0.1 to 0.3 mg., is present per 100 ml. of cell-free plasma. Estimations of sodium, potassium, adrenaline, and sugar could not be done. For the study of white cells we had to be satisfied with a differential leucocyte count taken from thin films made on the mountain and sent down to the laboratory. Urine samples were tested for acetone, and quantitative analysis of chlorides was performed.

Haemoglobin Content of Blood.—Samples of blood from six climbers collected at 17,000 ft. (5,200 m.) and from four climbers collected at 21,000 ft. (6,400 m.) were available for examination. Of those collected at 17,000 ft. the iron content ranged from 52.6 to 95 mg. per 100 ml. of blood, with a mean of 74.1 mg. per 100 ml. Translated into grammes of haemoglobin per 100 ml., this comes to 15.7 to 28.4 g. per 100 ml., with a mean of 22.18 g., the percentage of iron content in haemoglobin being 0.334% (Hupfner). Of the samples collected at 21,000 ft. the iron content ranged from 57 to 64.5 mg. per 100 ml., with a mean of 61.6 mg. (17 to 19.3 g. of haemoglobin per 100 ml., with a mean of 18.4 g.).

Chloride Content of Blood.—Estimation of chloride on the above-mentioned blood samples showed a range from 419 to 620 mg. per 100 ml., with a mean of 509 mg.

Leucocyte Picture.—Films from four climbers collected at 17,000 ft. (5,200 m.) and from one collected at 21,000 ft. (6,400 m.) were available for examination. A study of the stained thin films did not suggest any lymphocytopenia or any significant eosinopenia; nor was there any suggestion of a qualitative change in the lymphocytes as found by Frank and Dougherty (1953) in their experimental studies on the effects of stress.

Acetone Bodies in Urine.—Of the two samples of urine collected from two climbers at Darjeeling, neither showed the presence of acetone bodies. Of the six samples collected from six climbers at an altitude of 17,000 ft. (5,200 m.), two gave definite reaction for acetone bodies, one gave a doubtful reaction, while the remaining three gave negative reactions. Of the two samples collected at 21,000 ft. (6,400 m.) from two climbers, both gave a definite reaction for acetone bodies.

Urinary Chloride and Creatinine.—Two samples of urine from 6,700 ft. (2,040 m.), six from 17,000 ft. (5,200 m.), and two from 21,000 ft. (6,400 m.) were available for examination. The mean chloride contents were 1.34 g., 0.878 g., and 0.7 g. per 100 ml. respectively, and the mean creatinine contents were 0.108 g., 0.128 g., and 0.169 g. per 100 ml. respectively.

Summary

A study of the climbers taking part in the 1954 British Kangchenjunga Reconnaissance Expedition was made in an attempt to assess some of the physiological changes which occur at high altitudes. Some general clinical observations are made on the stresses which occur. The results of a small number of blood and urine analyses are recorded.

DERMATOMYOSITIS

A CASE REPORT WITH POST-MORTEM FINDINGS

BY

HILLAS G. SMITH, M.B., B.Ch.

Medical Registrar, Rush Green Hospital, Romford, Essex

Dermatomyositis is an unusual condition in which pathological changes occur not only in the skin and muscles but also in other organs. Such changes have often been reported, and Wainger and Lever (1949), in their study of three cases with post-mortem findings, concentrated their attention on those changes in tissues other than muscle and skin. They were unable to report any specific renal changes either in their own cases or in those from the literature. The fact that renal lesions, hitherto undescribed, have been found in the present case is considered sufficient justification for putting it on record. The unusual severity, the presence of jaundice, and the response to cortisone are further interesting features.

Case Report

A male office-worker aged 30, whose past medical history revealed only pleurisy with effusion in 1947, said that his present illness had started with a severe sore throat about ten days before admission to hospital on April 6, 1954. He was confined to bed, without any specific treatment, for three days. He got up on the fourth day, but because of headache, shivering, and a feeling of nausea, did not feel very well. There was no vomiting. Three days before admission he had a good deal of pain in both ankles and marked sweating. In the 24 hours preceding admission both his ankles became swollen and he had pain in his right knee- and wrist-joints. There had been no upset of bowels or micturition, but appetite had been poor for the previous fortnight.

Examination revealed a thin man, very flushed and sweating profusely. His temperature was 102° F. (38.9° C.). There was marked swelling of the left ankle- and right knee-joints. The skin over the joints was flushed, but not more so than the skin in other areas. These swellings were tender and joint movements were limited. There was some tenderness and limitation of movement in the right elbow- and wrist-joints but no visible swelling in these areas. Muscle tenderness was present, especially in the left calf, but the chief finding was of pain on joint movement. His pulse rate was 120 and B.P. 120/70; there were no murmurs. No abnormalities were observed in other systems and tendon responses were normal. A provisional diagnosis of acute rheumatic fever was made and the patient was started on salicylate therapy.

About 12 hours after admission his condition did not seem to be satisfactory. His pulse rate was increased to 130, and he was restless and complained of a good deal of pain in the right forearm. B.P. 100/70. Examination of the right forearm revealed a turgid, brawny swelling of the muscles, which showed the characteristics of a cellulitis. Joint movement was limited, and there was marked muscle tenderness. One was somewhat surprised to find a swelling of such dimensions that had not been present at the time of admission. A white blood count revealed a leucocytosis of 22,000 per c.mm. (96% polymorphs, 4% lymphocytes); Hb, 106%; E.S.R. (Wintrobe), 33 mm. in one hour. The urine contained a trace of albumin and there was a very heavy deposit of creatine. This latter finding, together with skin and muscle involvement, suggested the diagnosis of dermatomyositis.

The following day cortisone, 50 mg. twice daily by mouth, was given. During the next three days the patient's condition varied considerably. An improvement was noted by the gradual return of the pulse rate towards normal and the lessening of joint and muscle pain. Further swellings

occurred, however: his right wrist- and left elbow-joints and the muscles of the right calf became, in turn, swollen and tender. There was no swelling of trunk muscles, and the orbital tissues were not involved. These swellings occurred with amazing rapidity and seemed to reach a maximum in about six to eight hours and slowly resolve over a period of several days. About the fourth day a diffuse, erythematous mottling was noted in the swollen areas, and later this extended to the trunk and limbs but avoided the face. The dosage of cortisone had to be reduced to 75 mg. daily to prevent hypertension.

On the third day the patient felt nauseated, and vomited several times. Later he developed hiccup. The abdomen was distended and bowel sounds were few. Blood urea amounted to 171 mg./100 ml. Intravenous fluids were given and a Ryle tube was passed with intermittent gastric aspiration. The next day he was jaundiced and the urine contained bile pigments. The serum bilirubin test, performed on the fifth day, was 8.25 mg./100 ml. Although jaundice and paralytic ileus was present, the disease process seems to have been contained, for the skin and muscle swellings became less, and on the sixth day, although the patient was critically ill, there was no dermatomyositis.

On the evening of the sixth day bowel sounds were returning and flatus was passed. Blood urea was now 223 mg./100 ml. The E.C.G. was within normal limits and there was no electrolyte imbalance. The following day he was definitely deteriorating and at times irrational. His mouth was dry and the tongue glazed and swollen. He became comatose and died in the evening of the seventh day after admission.

Pathological Findings

The post-mortem examination was performed 12 hours after death. The subject was a thin male, moderately jaundiced. There was no evidence of swelling in muscles or skin, but well-marked desquamation was present on the arms and hands. Almost all the abdominal viscera were enlarged and flabby. There was some congestion of the mucous membrane of the stomach but no gastric or enteric ulceration.

The skin showed moderate keratinization but no general epidermal thickening. In the rete area there was a moderate round-cell infiltration. In the dermis the fibrous tissue bundles were loosely arranged and broken up. The deeper fat was rather increased and the sweat-gland epithelium showed infiltration with fatty droplets.

Heart Muscle.—Myocardium flabby. Weight 400 g. The cardiac muscle fibres showed fragmentation, with variation in size and shape. The nuclei remained normal on the whole. No changes in the larger or smaller vessels were seen.

Voluntary Muscle.—Many of the fibres had disappeared, but the structure remained normal so long as any portions remained. Striation was well marked. Many sarcolemmal nuclei were seen left free between the remaining fibres, and in places proliferative overgrowth of these nuclei was seen. Groups of pigment granules, negatively staining for iron but positive for melanin, were apparent here and there within sarcolemma sheaths or between fibres.

Adrenals.—Marked oedema, with cortical capillary haemorrhages and disappearance of many cells. Other cells showed loss of nuclei and irregular staining of remaining cytoplasm.

Lung.—Oedema only. Generalized capillary congestion with small haemorrhages. Oedema, patchy in distribution. In places there was endothelial proliferation of the alveolar lining. There was some thickening of peripheral fibrous coat in the arterioles. The interstitial tissue contained plasma cells with focal distribution. A moderate number of pigment-containing macrophages were also present.

Kidneys.—Both flabby, with yellow fatty streaks. 300 g. each. **Cortex:** Some glomeruli were congested; others showed hydropic degeneration. The convoluted tubules showed a marked degree of degenerative change, ranging

from cloudy swelling to necrosis. **Medulla:** A similar degeneration of the straight tubules, many of which contained blood casts. The vessels showed some thickening, chiefly of the muscle coats.

Liver.—2,000 g. Flabby, yellow, and fatty. The cells were irregular in size and shape and were separated by spaces. No cirrhosis or congestion was seen. In the portal areas the vessels and ducts appeared thickened, with loose fibrous tissue rather irregularly disposed. Some lymphocytic infiltration was also present in these areas.

Pathological Data

Date	Throat Swab	Urine	Blood Urea	Serum Creatine	Serum Creatinine	Serum Bilirubin
6/4/54	Predominant growth <i>Str. viridans</i>	Acid. Creatine + +. Many white and red cells. No casts				
9/4/54		Creatine, 840 mg./24 hrs. Creatinine, 1.100 mg./24 hrs.	177 mg./100 ml.	8 mg./100 ml.	4.5 mg./100 ml.	
12/4/54			215 mg./100 ml.			8.25 mg./100 ml.

Discussion

Not only was this case particularly acute and severe but it also presented the unusual features of kidney and liver involvement. It is extremely difficult to evaluate the significance of these hepatic and renal changes. To say that the patient died from a hepato-renal syndrome although the polymyositis was contained is not really informative, neither is it fully in accordance with the facts. The term "hepato-renal syndrome," however poorly defined, would appear to include patients dying often in coma, usually jaundiced, and in whom renal and hepatic damage is demonstrated microscopically. In the kidney severe tubule necrosis, most marked in the convoluted tubules, and in the liver cellular damage, which appears to be further enhanced by the presence of excess bile which stains the liver cells, are the usual histological findings (Dible, 1953). In the case under discussion there was very marked renal damage amounting to a cortical necrosis. Microscopically there were changes in both cortex and medulla. The glomeruli were congested, while the convoluted tubules showed a wide range of degenerative change. The liver cells were not bile-stained and there was no evidence of a primary causative lesion. There seems, then, to be considerable evidence to support the view that the renal lesions in this case resulted from the disease process of dermatomyositis.

It is interesting to record the similarity between the nature of renal lesions occurring in other collagen disease, such as disseminated lupus erythematosus and polyarteritis nodosa, and that of the renal lesions here described. In the two former conditions it is a well-established fact that cortisone and A.C.T.H. may suppress all evidence of the disease except when renal lesions occur, in which case the processes are invariably progressive. A similar failure of these hormones would appear to have been responsible for the advanced renal disease in this case. Ragan (1950) reports improvement in two long-standing cases of dermatomyositis treated with A.C.T.H. In the most recent case report by Clein (1953) mention is made of the benefit derived from cortisone and A.C.T.H. He used both hormones with equal success. He also stressed the high polymorphonuclear leucocyte count, which was also present in the case under discussion.

Summary

A case of acute dermatomyositis with necropsy findings is reported. Renal lesions thought to have resulted from the disease process are described. These do not

seem to have been recorded previously. The response of the muscle and skin lesions to cortisone is noted, while the hormone appears not to have influenced the kidney damage.

It is a pleasure to acknowledge the help and advice of Dr. A. Nelson-Jones, under whose care the patient was admitted. Dr. E. James also gave much helpful advice. Dr. S. Marshall kindly supplied the detailed histological report and Dr. F. Brafield did the biochemical investigations. Miss H. Child was most helpful with the clerical work.

Medical Memoranda

Tropical Pulmonary Eosinophilia in a West African

This paper reports a case of tropical pulmonary eosinophilia in a Nigerian. So far as can be determined, this condition has not been previously reported as occurring in a West African.

CASE REPORT

The patient was a male Nigerian aged 45, whose occupation was a leprosy inspector.

Previous History.—In 1943 he had pneumonia affecting the left side of the chest and was in hospital for three weeks, being treated with sulphonamides. He was in the Army, in Burma, from 1944 to 1946, and in 1944 had pneumonia affecting both sides of the chest. He was ill for five weeks and was treated with penicillin and sulphonamides. In 1946 he was given oil of chenopodium for ascariasis. Later that year he was discharged from the Army in the Owerri province of Nigeria. He remained there until 1952, when he went to Calabar. He returned to Owerri province one month before he was seen with the current complaint.

Present History.—For six weeks he had complained of swellings in the skin on different parts of the body, each lasting a few days. Three weeks before being seen he had developed a dry cough, which was worse on lying down. The cough had improved slightly during the last week. For three weeks he had been short of breath on exertion—for example, on riding his bicycle on the flat. He also complained of a burning sensation all over the inside of his chest, and had been feeling generally off colour.

Examination showed that he was well nourished. Swellings were seen on right cheek, right calf, and right forearm which were probably Calabar swellings. Respiratory system: no impaired movement of the thoracic cage or impaired percussion note; medium crepitations present at both lung bases. Cardiovascular system: N.A.D. Gastro-intestinal system: N.A.D. No hepatomegaly or splenomegaly. Other signs: lymph nodes in the groins and axillae were palpable but unlikely to be pathological. The patient was afebrile.

Laboratory Investigations.—Haemoglobin, 14 g.%; R.B.C., 5,380,000 per c.mm.; W.B.C., 37,800 per c.mm. (polymorphonuclear leucocytes 5%, eosinophils 88%, lymphocytes 7%). No microfilariae were seen in thick blood films made at 12 noon. No autohaemagglutination occurred either at room temperature or when the blood was put into a refrigerator. The stool did not contain any helminth ova. Sputum: no specimen available. X-ray not available.

The blood count remained of the same order over the next seven days, after which penicillin therapy was started with 300,000 units daily for three days. Unfortunately the patient did not receive a full course of penicillin, as the observer left Nigeria at that point. One week after the beginning of the penicillin therapy the total white cell count

had fallen from 37,800 to 24,700 per c.mm. and the eosinophils from 88 to 73%—that is, from 33,264 to 18,031 per c.mm. Two months later, without any further treatment, the white cell count had fallen to 9,400 per c.mm. and the eosinophils to 60% (5,640 per c.mm.). Four months after penicillin the white-cell count was 12,000 per c.mm. and the eosinophils 57% (6,840 per c.mm.). The patient stated that he felt better.

COMMENT

It is regretted that an x-ray examination of the chest could not be undertaken. However, in view of the clinical and haematological findings it would appear likely that the patient was suffering from tropical pulmonary eosinophilia. The possible presence of a *Loa loa* infection would produce a degree of eosinophilia, but hardly one of 88% (33,264 eosinophils per c.mm.). There was no evidence to suggest the presence of another helminth infection. Hunter (1946) reported a case of tropical pulmonary eosinophilia in a European aged 37 who had been resident in Nigeria for 12 years. Wilson (1947) reported the condition in three Africans in East Africa, but it is believed that the present paper reports the occurrence of the condition in a West African for the first time. It is interesting to speculate whether this patient acquired the disease in India some eight years previously and that it had only become manifest recently, or whether it had been acquired in Nigeria.

It is not possible to say with any assurance whether or not there had been any response to penicillin in this case, although there is a suggestion that the drug had some effect.

This case was seen at the Leprosy Research Unit, Uzuakoli, Nigeria. Thanks are due to Dr. J. Lowe for permission to investigate the case and to publish the findings, and to Sister O. Smith for her co-operation.

Long-term Prognosis in Infantile Eczema

In 1953 Purdy published the results of an investigation into the after-history of cases of infantile eczema in Edinburgh. To amplify his findings a similar investigation into the cases of infantile eczema occurring in Dundee over the same period was carried out. Letters were sent to those patients who attended the skin department of Dundee Royal Infirmary with infantile eczema during 1931-7 inclusive. The questionnaire adopted was the same as that used by Purdy, but in addition questions were included regarding the onset and disappearance of asthma. In order to have results as closely related as possible to those of Purdy, the same criteria were followed in the selection of cases from the hospital records.

RESULTS

In a large number of cases it was impossible to locate by letter persons whose last known address was that of 15 to 22 years ago. Thus Table I shows that, of 136 questionnaires sent out, 92 (67.6%) were returned as "dead" letters.

TABLE I.—Result of Questioning

Total No. of persons sent letters	136 (94 males, 42 females)
"Dead" letters returned	92
Useful replies	37 (20 males, 17 females)
Useless replies (deaths at early age)	2
Replies not returned	5

In the 37 useful replies received, 12 patients claimed to have had no sequelae to their primary attack of infantile eczema. Table II gives the incidence of the generally accepted sequelae and compares the figures found in this study with those in Purdy's series. In assessing the final results of the Besnier's prurigo group all patients were examined personally unless they had been seen recently by a consultant of this department.

TABLE II.—Results of 37 Replies

	No.	Asthma	Asthma Denied; Wheezing Admitted	Hay-fever	Besnier's Prurigo	Migraine
Male	20	9	1	5	10	1
Female	17	4	4	5	5	3
Total	37	13 (35.1%)	5 (13.5%)	10 (27%)	15 (40.5%)	4 (10.8%)
Purdy's series	93	37 (39.8%)	10 (10.7%)	39 (41.9%)	23 (24.7%)	7 (7.5%)

The overall figure for asthma is 35.1%. If the five patients who failed to return the questionnaire are classed as having no asthma then a minimum figure of 30.9% is reached. This minimum is too low, as it assumes that none of the wheezing group of five patients and none of the "lost" five patients are asthmatic. If it is conceded that the wheezing group are asthmatic a minimum of 42.8% is reached, and excluding the "lost" five patients the figure is 48.6%. This range of roughly 43 to 49% is similar to Purdy's of 30 to 50%. Asthma developed in 13 patients in the first decade and disappeared in four males and one female in the second decade.

The figures for Besnier's prurigo show a range of 35.7 to 40.5%; the minimum figure presumes a complete absence of the complaint in the five patients who failed to return the questionnaire.

Table III shows a regrouping of the patients and agrees with Purdy that asthma without skin involvement is the most frequent sequela, with a range of 23.8 to 27%.

TABLE III.—Regrouping of Cases from Table II

	No.	Asthma (or Wheezing Attacks) but No Besnier's Prurigo	Besnier's Prurigo but No Asthma (or Wheezing)	Both Asthma (or Wheezing) and Besnier's Prurigo	Hay-fever but No Asthma (or Wheezing)
Male	20	5	2	5	1
Female	17	5	2	3	1
Total	37	10 (27%)	7 (18.9%)	8 (21.6%)	1 (2.7%)
Purdy's series	93	27 (29%)	5 (5.4%)	20 (21.5%)	14 (15%)

Besnier's prurigo in association with asthma is next in frequency, with a range of 19 to 21.6%. Besnier's prurigo alone has a range of 16.6 to 18.9%, which is much higher than that observed in Purdy's series—namely, 4 to 5.4%.

Hay-fever was present in 27% cases in Table II, but in the regrouping in Table III only 2.7% claim to have hay-fever without asthma.

Migraine occurred in four patients, three of them females. I agree with Purdy that it is a very doubtful outcome of infantile eczema.

The answers to questions regarding nervous stability and intelligence were so varied that it was impossible to support or refute the widely held belief that sufferers from infantile eczema are compensated with a high intelligence.

COMMENT

Of the 37 (27%) useful replies received to a questionnaire similar to Purdy's, 25 describe at least one of the recognized sequelae of infantile eczema. Of these 25, 10 had asthma, 8 Besnier's prurigo and asthma, and 7 Besnier's prurigo alone. Although the number of useful replies in this investigation was disappointingly low, it was decided to publish the results so that they may be added to Purdy's findings, and to any subsequent figures recorded from other centres, in order that the ultimate total number may be high enough to yield an accurate picture of the sequelae of infantile eczema.

I wish to thank Dr. J. Kinnear for permission to use his cases and for his helpful advice.

O. A. FINN, M.D.,
Senior Registrar, Department of Dermatology,
Royal Infirmary, Dundee.

Reviews

ALMROTH WRIGHT

Almroth Wright—Provocative Doctor and Thinker. By Leonard Colebrook, F.R.S. (Pp. 286; illustrated, 21s.) London: William Heinemann Medical Books Ltd. 1954.

The story of Almroth Wright is told sharply and succinctly by Leonard Colebrook in his foreword—how he worked in the laboratory away into the night; how when he met with difficulties he developed new techniques to overcome them; how he turned his laboratory at St. Mary's into a vaccine therapy clinic; how he charmed the patients and young men whom he attracted to work with him for a pittance; and how throughout a larger part of his life his spare time was spent in writing a treatise on morals, a treatise which had not appeared when he died in 1947.

There is no doubt that Wright was a great man, and there is no doubt also that he was appreciated abroad more than at home. I saw that when I accompanied him to France in October of 1914. He was a consulting physician in the Army Medical Service, and when he visited French laboratories he was worshipped almost as much as Pasteur.

His great work was vaccine therapy, beginning with anti-typhoid vaccine and spreading to a great variety of infections, but, as the author of this book points out, he did many other good things. Indirectly his work on immunization was the means of bringing the bacteriologist into contact with the patient, thus changing his status from a servant of the clinician to a colleague who was called into consultation like any other "consultant." For this the laboratory workers of the present day should offer him thanks. The author traces his career from the beginning, but naturally by far the greater part of the book is devoted to his work after he left the Army Medical College and came to St. Mary's. There Colebrook was one of his early assistants and his disciple. He tells of the work done in what were quite inadequate laboratories with hardly any equipment except glass tubing, a blow-pipe, and some rubber teats. But out of that work came vaccine therapy.

Then there was his work on septic wounds done in the Casino at Boulogne in the first world war; his serious controversies with Watson Cheyne and others; and his later years somewhat tinged with loneliness.

Colebrook was, of all Wright's pupils, the one who saw most of his private life, and he manages to give a picture of the scientist and the man which is very fascinating. It is of especial interest to me as one who worked in Wright's laboratory from 1906 till he died, but no one who likes to read of great men could fail to enjoy the book and profit by it.

ALEXANDER FLEMING.

HISTORY OF COMMON DISEASES

The History and Conquest of Common Diseases. Edited by Walter R. Bett, M.R.C.S., L.R.C.P. (Pp. 334, 54s.) Norman: University of Oklahoma Press. 1954.

This is a book which the "physician of two continents" would have approved, not only as a medical historian, but because it is an example of the collaboration between British and American doctors which he did so much to encourage in his lifetime. Dr. Bett, through his associations with the United States, is thus promoting Anglo-American friendship in the true spirit of William Osler.

This book, which replaces *A Short History of Some Common Diseases*, edited by Dr. Bett in 1934, is "mainly for patients, but also for the medical profession." Six of the contributors to this volume belong to the United States. Dr. George Rosen, of Columbia University, writes on acute communicable diseases. His history of diphtheria is excellent. The waxing and waning of this disease is remarkable and might have been further emphasized. When it

reappeared about the middle of the nineteenth century, at Ash in Kent, it was then so rare that it was unrecognized by most practitioners, and Simon sent Greenhow and Burdon-Sanderson to investigate outbreaks where it was prevalent. Dr. L. J. Moorman, of Oklahoma City, contributes a history of tuberculosis, but does not allude to the great impetus that was given in this country to medical research and treatment of the disease after 1912. Bodington, incidentally, spelt his name with one *d*. Dr. E. F. Hartung, of New York University, writes on arthritis. An admirable account of the history of Bright's disease is given by Dr. R. H. Major, of the University of Kansas; Dr. D. C. Balfour, Chief, Surgery Division, Mayo Foundation, writes on gallstones; and Dr. W. G. Lennox, of Boston, lucidly traces how the belief that epilepsy was a demoniac possession came to be replaced by modern scientific knowledge.

Of the British contributions one would single out as specially interesting—Dr. Terence East on heart disease, Dr. W. S. C. Copeman on rheumatism, Dr. A. W. Cawadias on diseases of the endocrine glands, and Dr. Bett on appendicitis. The chapter on pneumonia by Dr. E. M. Brockbank and Dr. W. Brockbank reveals how strikingly sulphonamides and penicillin have altered the clinical picture of this disease. Dr. A. White Franklin sketches the history of rickets from Galen to Mellanby, giving due meed of recognition to Daniel Whistler, whose M.D. thesis on rickets at Leyden in 1645 preceded Francis Glisson's famous book of 1650-1. Dr. E. L. Murphy's account of malingering is of value, and Chapter 16, by Mr. Harold Burrows, gives in succinct form an excellent account of the development of knowledge of cancer. The bibliographies are full and useful.

Dr. Bett and his contributors are to be congratulated, while a word of praise is due to the University of Oklahoma Press for the presentation of the volume.

ARTHUR S. MACNALLY.

BIOPHYSICS AND BIOPHYSICAL CHEMISTRY

Progress in Biophysics and Biophysical Chemistry. Volume 4. Edited by J. A. V. Butler and J. T. Randall, F.R.S. (Pp. 339 + viii; illustrated, 63s.) London: Pergamon Press. 1954.

The volume under review provides a refreshing change from some of its predecessors; not only have the editors chosen their subjects wisely, but also—and this is more important perhaps—they have chosen as authors workers who are competent to write in their respective fields.

The problems associated with muscular contraction are dealt with in two articles—"The Transference of the Muscle Energy in the Contraction Cycle," by Weber and Portzehl, and "Facts and Theories About Muscle," by Wilkie—while the behaviour of polyelectrolyte gels, which must be understood if the more physical aspects of muscular contraction are to be elucidated, has been described by Katchalsky. Fernandez-Morán has given a good account of the increase in our knowledge of the structure of the nerve fibre provided by polarization optics, x-ray diffraction studies, and the electron microscope; to a physiologist perhaps the most striking feature of the work is the excellent accord between the calculations of the x-ray diffractionist and the observations of the electron-microscopist. The x-ray diffraction picture of a nerve is a series of spots on a photographic plate; by what must seem to the uninitiated a supernatural intuition the physicist can, from the shapes, positions, and blackness of the spots, state that the myelin sheath is made up of concentric shells some 180 Å thick; under the electron microscope the shells can actually be made visible and measured.

The cause of cancer is most probably to be sought in the pathology of the cell nucleus; it will therefore be satisfying to those who seek some justification for pure research to see in two articles—"The Nucleoprotein Complex of the Cell Nucleus and its Reactions," by Davison, Conway, and Butler, and "Chromosome Breakage," by Koeller—how modern physical and physicochemical techniques are revealing more and more of the secrets of this all-important body. Finally, the present volume contains an article by J. C. Kendrew, "The Crystalline Proteins: Recent X-ray Studies

and Structural Hypotheses." This is necessarily abstruse for the biologist, and its main value here resides in the candour of the author, who modestly emphasizes the paucity of definite knowledge in this field. The most spectacular advances in our knowledge of protein structure have resulted from studies on the fibrous proteins like keratin; such advances have contributed to our knowledge of the physiology of muscle and nerve. The crystalline proteins, such as insulin, albumin, and globulin, present far more serious problems in methodology, but their solution is a pressing need if we are to relate, for example, the phenomena of immunochemistry with the morphology of the proteins that are concerned.

H. DAVSON.

THE OSTEOCHONDROSES

Legg-Calvé-Perthes Syndrome and Related Osteochondroses of Youth. By Charles Weer Goff, M.D., in association with Ned M. Shutkin, M.D., and Myerma R. Hersey, M.S. (Pp. 332+xxiii; illustrated. 77s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications, 1954.

This book contains all the important known facts and theories of osteochondritis deformans juvenilis and the related lesions of other epiphyses. The name of pseudo-coxalgia is discarded and the group named osteochondroses is defined. The author, who had the assistance of Jacques Calvé before his death (he wrote the foreword), has extracted material from the enormous quantity of literature that has been accumulating for 45 years and made observations on groups of children.

This study of a condition which so often causes permanent damage to an epiphysis is most thorough; the subject is well presented and the excellent radiographs are most fascinating. It is a specialist book, and the reader will seek for the cause of the changes in the epiphysis. The "Murk Jansen and Perkins discussion" is reported (Jansen's photograph, but not that of his opponent, is reproduced). Almost all the special examinations and observations were found to be negative, and so did not prove helpful in elucidating the aetiology. However, it is stated that the "constitutional preterminators are proven factors of causality," and environmental factors, such as trauma, are superimposed. Remissions with a second centre developing in the epiphysis are stated to be more common than is usually supposed. Modified recumbency treatment is recommended. An important observation is that every patient who had been followed up for ten years or more, and who was 20 years of age or older, had symptoms of dysfunction. The reports on related osteochondroses follow a similar pattern and are well collected.

An appendix forms a charming tribute to Mrs. Smith, of Farmington, Connecticut, who remodelled on the English system a small farmhouse for the accommodation of ten crippled children. Like several in this country it has grown, and now has nearly 200 beds.

There are a bibliography, an author index, and a subject index, and the author explains his system of references. Even so, the reader will not necessarily be able to find what he may require. For instance, use is made of Burrows's classification and 1950 is placed after his name, but there is no mention of the paper in the bibliography.

This book will be of great help to all dealing with bone diseases in adults as well as in children.

ST. J. D. BUXTON.

SKIN HISTOPATHOLOGY

Histopathology of the Skin. By Walter F. Lever, M.D. Second edition. (Pp. 518+xviii; 281 illustrations, 8 in colour. 96s.) London, Philadelphia, Montreal: J. B. Lippincott Company, 1954.

The second edition of this textbook has been considerably modified and added to in certain sections. As before, the author includes a very short clinical note on each disorder, primarily for the benefit of the pathologist, though in many cases this is of somewhat doubtful value. It is difficult, though not impossible, to think of a few uncommon disorders which a careful search fails to reveal in this treatise,

but the book would no doubt be used for a very long time in current histological work before these omissions were discovered. It has in the past been largely left to dermatologists to develop the study of skin histopathology, and even now, in many places, the pathologist prefers to leave this branch of histology to the clinical dermatologist.

Dr. Lever's book will help to facilitate very greatly more widespread knowledge of dermal histology. The views expressed are thoroughly up-to-date and carefully considered, though in a work of this size there is little room for full-length discussion. This possible drawback is overcome by a well-chosen bibliography, divided into sections, which appears at the end of each chapter. The illustrations are good and show clearly what they are meant to show. There can be little doubt that this is now the best book of its kind, whether as a work of reference, a textbook, or a practical bench-side handbook. Both dermatologist and pathologist need it.

F. RAY BETTLEY.

THE VITAMINS

The Vitamins: Chemistry, Physiology, Pathology. Volume III. Edited by W. H. Sebrell, jun., and Robert S. Harris. (Pp. 665+xi. \$15.) New York: Academic Press, Inc. London: Academic Books Ltd. 1954.

It can be said at once that Volume III of "Sebrell and Harris" lives up to the high standard set by Volumes I and II, reviewed in these columns earlier this year (January 29, p. 272). This instalment completes the work, which, all in all, provides us with the most comprehensive, the most up-to-date, and the best-documented treatment of the biochemistry of the vitamins so far published.

The third volume contains chapters on the following factors: *p*-aminobenzoic acid, pteroylglutamic acid (i.e., the folic acid group), vitamin B₆ (pyridoxin and related compounds), riboflavin, thiamine, vitamin E, and lastly certain new, and as yet unidentified, growth factors. As in earlier volumes, the emphasis is particularly on biochemistry, although physiology and pathology are not overlooked. Clinical aspects and the methods of assay of vitamins are but briefly referred to, as these topics are already dealt with pretty fully in other compendious treatises available elsewhere. Twenty-three authors contribute to the present volume, all but one being American. The exception is Professor B. C. P. Jansen, the doyen of Dutch biochemists, and distinguished as the first to isolate pure crystalline vitamin B₁.

LESLIE J. HARRIS.

LABORATORY TECHNOLOGY

An Introduction to Medical Laboratory Technology. By F. J. Baker, F.I.M.L.T., F.R.M.S., R. E. Silverton, A.I.M.L.T., F.R.M.S., and Eveline D. Luckcock, A.I.M.L.T. (Pp. 330+x; illustrated. 30s.) London: Butterworth and Co. Ltd. 1955.

This modest volume from the technical staff of the Brompton Hospital aims at meeting the needs of student technicians who are preparing for the Intermediate Examination of the Institute of Medical Laboratory Technology. It consists of short descriptions of elementary laboratory methods, including such items as the cleaning of glassware, simple chemical tests, physiological techniques, sterilization methods, and haematological techniques.

There is naturally little to be found here that is not discussed more fully in larger works, but it will no doubt be very convenient for the student technician to find the material all within the covers of one book. As a minor criticism, the directions given are not always sufficiently fool-proof or explicit. For example, on page 283 we are told "the cork borer must be sharp," but the reader is not told what is to be done when it is blunt. Similarly, on page 248 the use of chloroform for killing animals is described without any indication of how it is introduced into the container.

The book is well produced, with a number of useful illustrations, which accounts for the rather high price. On the whole it will prove useful for the purposes intended, and can be confidently recommended to student technicians who feel the need for a special book on their subject.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MARCH 26 1955

RADIATION HAZARDS OF EXPERIMENTAL NUCLEAR EXPLOSIONS

The radiation injuries received by the crew of the Japanese boat *Fukuryu Maru*, with the subsequent death of one of them, gave the first inkling of the scale of radiation hazards associated with the testing of the latest nuclear weapons. But it was not until the recent official report issued by the U.S. Atomic Energy Commission¹ that the true magnitude of the problem became evident. The report deals mainly with the damage caused by the fall-out—that is, the deposition of radioactivity in the vicinity of the explosion. The amount of radioactivity in a fall-out may be measured in units of roentgen square miles, which is the product of the dose in roentgens which a person would receive, multiplied by the total area over which the fall-out occurred. The Bikini bomb tested a year ago gave a fall-out amounting to 20 million roentgen square miles²; since the area covered by the fall-out was about 8,000 square miles, the total dose delivered there, as from one hour after the explosion, was about 2,500 r.

Since the fall-out occurs over a limited area, which in the case of a test would normally be uninhabited, it does not present a very serious problem, except for unfortunate accidents as with the *Fukuryu Maru*. There is, however, the important problem of the radioactivity other than in the fall-out. A bomb with an explosive power one thousand times that of the Hiroshima type may produce, one hour after the explosion, a total amount of radioactivity equal to about 100 million roentgen square miles. Most of the radioactive fragments are sucked up with the hot gases resulting from the explosion and reach great heights, probably over 100,000 ft. (30 km.). Very little is known about the movements of the atmosphere at such heights, but it is likely that the radioactive cloud would circulate the globe many times before all the particles drifted down to the surface. Much comfort has been derived from the fact that during the long time it takes the particles to settle

down most of the radioactivity would have died out. But this safety factor has been overrated. If the radioactive dust took six months to settle down instead of six days, the residual dose delivered would be reduced only by one-half. What is more important is how long the fine dust will stay on the surface before it is washed away by rain or removed by other means: this again is difficult to assess.

The calculation of the global dose resulting from one test is dependent on so many unknown factors that at best it would give a rough estimate. There is, however, no need for such calculation, for some informative data are available. The U.S. report states that the total amount of radiation received from all nuclear detonations so far is about 0.1 r. Although this figure refers to residents of the United States, it presumably applies to any other country. In assessing the significance of this dose it may be pointed out first that, although the report attributes it to the considerable number of atomic explosions carried out so far, probably most of the dose came from the very few hydrogen bombs tested about a year ago. This is so because one H-bomb produces from 100 to 1,000 times more radioactivity than an atom bomb; the contribution of the latter may thus be neglected. The natural background of radiation, due to cosmic rays and the radioactive substances normally contained in the atmosphere, amounts to about 0.1 r per year. We may infer, therefore, that a continuation of tests on the 1954 scale—that is, several H-bombs a year—would double the natural amount of radiation.

What is the consequence of such a world-wide increase in radiation? So far as somatic damage is concerned it is quite negligible. The maximum permissible dose established for those occupationally exposed to radiations is 0.3 r per week, or 15 r per year. From the genetic point of view, however, there is no maximum permissible dose, since every increase of radiation is harmful. In setting up the maximum permissible doses account was taken of the fact that only a small fraction of the population, less than 1%, is habitually exposed to radiation. When the whole population is exposed, the dose considered genetically safe must be reduced correspondingly, which brings it down to about 0.1 r per year. It may be argued that the whole population is already subject to exposures in various radiological examinations. In fact the U.S. report states that the dose of 0.1 r is received in a single chest x-ray examination. But such a comparison is misleading. For the genetic hazard only the dose delivered to the gonads is of significance.

¹ *The Effects of High-Yield Nuclear Explosions*, U.S., A.E.C., February, 1955.

² Lapp, R. E., *Bull. Atomic Scientists*, 1955, 11, 45.

³ *Brit. J. Radiol.*, 1952, 25, 387.

and furthermore it has to be averaged over the whole population. A survey⁷ carried out several years ago in Great Britain has shown that the mean gonad dose received during chest radiography is about 0.0007 r. Even taking into account the much bigger doses received during examination of the pelvis, the survey shows that the mean dose per head of the population from all x-ray diagnostic examinations is 0.005 r per year, or one-twentieth of the natural radiation level.

It is very difficult to estimate the genetic damage which may be caused by raising the level of radiation by 0.1 r per year. Most of the evidence about the rate of radiation-induced mutations comes from experiments on *Drosophila*; only in recent years have experiments been made with mice, but these are not yet complete. At the moment the most probable figure for the dose necessary to double the rate of mutations is 30 r per generation. For man this would correspond to a dose rate of 1 r per year. A dose rate of 0.1 r per year would therefore cause a 10% increase in the rate of mutation, which is by no means negligible. But the assumption that the doubling dose is the same in man as in *Drosophila* is not well founded. Some genes are known to undergo spontaneous mutations at a much lower frequency than others; if this frequency were, say, 10 times lower, the radiation dose necessary for doubling the mutation rate would be correspondingly reduced. If this should apply to man, then the 0.1 r per year would justifiably give cause for worry from the genetic point of view.

One thing emerges clearly, that we know far too little on such an important subject, and that an intense study of it is urgently called for. From what little we do know it would appear that, although the radiation dose from the nuclear explosions carried out so far was too low to have caused much genetic damage, a continuation of the tests at the present scale over a period of many years might constitute a serious genetic hazard.

"CHRONIC APPENDICITIS"

In even the best-conducted hospitals chronic appendicitis is one of the commonest surgical diagnoses. Since treatment is almost invariably by removal of the appendix, allowing not only its immediate careful inspection by the surgeon but its more detailed study by the pathologist later, it would seem reasonable to assume that the diagnosis had long since attained a clear meaning for clinician and pathologist. But this is far from being so, as the

correspondence columns of this *Journal* have testified for some months recently; moreover, the writings on this disease (if disease it be) reveal a remarkable dearth of facts about this most ordinary complaint. As Mr. S. H. Wass says in an article at p. 752 of the *Journal* this week: "Some people believe that chronic appendicitis is a clinical entity of common occurrence, others that there is no such disease."

The problem, as it presents to the surgeon, is that of a patient who complains of recurring pain in the right lower quadrant of the abdomen, sometimes sharp, sometimes dull, and occasionally colicky, often associated with vague digestive upset, flatulence, and constipation, accompanied by, as the only positive physical sign, tenderness sharply localized to McBurney's point. Many possible causes immediately suggest themselves, and the surgeon reviews each in turn. As he casts round diligently for an alternative diagnosis to chronic appendicitis the symptoms continue. The patient and his relatives will probably long since have indicted the appendix, and the harassed family doctor may well have hinted at the necessity of having it out. Little wonder then that under the pressure of events the surgeon reluctantly (or not so reluctantly, for many factors influence his decision) feels obliged to explore the abdomen. Having drawn a blank in his search elsewhere he returns to the appendix, and is duly heartened to find it other than normal. Whether it is long (too long) and distended, or shrivelled and fibrous, or kinked or tethered, or infected, or contains a faecolith, it is removed, for removed it must be. The patient is duly informed that the appendix was scarred and better out of the way and is followed through a short convalescence. The case is duly indexed as one of chronic appendicitis, and if the registrar is in any indecision about whether to record the result as "cured" or only "relieved" he knows that no one is likely to quarrel with his verdict either way.

Meanwhile, the problem passes to the pathologist—with the hope that he will find some deviation from normal or, better still, some striking changes which might reasonably explain the symptoms. If he is

¹⁴ Ackerman, L. V., *Surgical Pathology*, 1953, London.

honest he will at the outset admit to finding the decision a difficult one, and this for a variety of reasons. First, the appendix is known to change with advancing years,¹ and even the standard textbooks of histology seem at a loss to describe the normal. Secondly, it has undergone the trauma of removal. Thirdly, the pathologist may agree that Boyd² was right when he said: "To-day every appendix is condemned by some pathologist somewhere." Little wonder, then, that he often writes a non-committal report which satisfies the surgeon and his own conscience but helps not at all to advance knowledge of the disease.

But when challenged not with the individual case but the general question, Is there such a condition as chronic inflammation of the appendix, and, if so, is it common or rare? the pathologist seems to be more sure of himself.³ Acute appendicitis he knows and understands. The infection varies in intensity, and its effect is profoundly influenced by the presence of obstruction.⁴ When the diagnosis is overlooked or when operation is, for some very good reason, deferred, the acute process may subside and be followed by a resolution which is often remarkable. Inevitably, however, the appendix will carry the scars of this acute infection, sometimes spread diffusely along its length with thickening of the wall and obliteration of the lumen, sometimes limited to one short segment. But, whatever the result, this is not chronic inflammation: it is healed appendicitis. No doubt the same fibrosis can follow recurrent mild attacks of appendicitis; none of them may present clinically as an urgent illness, but the scarring that follows one attack may predispose to the next. Fibrosis obstructing the lumen may also, though rarely, lead to a mucocoele or to one or more diverticula. Of the occurrence of "chronic appendicitis," of a continuing low-grade infection with its typical cellular reaction, the pathologist has no experience. If it exists at all it must surely be a rare disease. He knows of no pathological lesion which fits in with the clinician's conception of a "grumbling" infection—that is, apart from tuberculosis, actinomycosis, and the like.

The surgeon, undismayed by the pathologist's incredulity about chronic inflammation, may speak of appendicular colic due to kinks or bands, to obliteration of the lumen, to obstruction by faecoliths,^{5 6} or even to hypertrophy of the neuromuscular complex of Masson. Even if he admits that, during abdominal operations for other disorders, he often finds equally abnormal appendixes apparently causing no trouble whatever, and even if he fails to explain away the gynaecologist's challenging comments on the high incidence of the disease in women aged between 15

and 45,^{7 8} he can still confidently claim an 80% cure rate following appendicectomy.⁹ However, it is too much to claim that this proves the symptoms were due to chronic appendicitis.^{10 11} While the 80% may live happily ever after, as do their general practitioners,¹² what of the others? It is not good enough to say that the diagnosis was in error and operation unnecessary (but without much risk). How many of them pass on to later troubles? For the easy diagnosis having been used up by removing the appendix the next surgeon is left to make a fruitless search for adhesions.¹³ Surely it is high time for a study to be made of "chronic appendicitis" with a control group of patients treated non-operatively. Until clinical and pathological findings have been carefully compared and analysed, the suspicion is bound to linger among the unconvinced that Ackerman¹⁴ was right when he suggested a change of name from "chronic appendicitis" to "chronic remunerative appendicitis."

ENDOCARDIAL FIBROELASTOSIS IN INFANTS

Endocardial fibroelastosis or sclerosis is not a common condition, but is now well recognized as a cause of death in infancy and very occasionally later in childhood. Its distinctive pathological feature is a thick, white, opaque endocardium in one or more chambers of the heart. The thickening is due to a great increase of fibrous and elastic tissue in the endocardium, with slight fibrosis of the immediately subjacent myocardium in some cases, though not in all. The chambers of the left side are most often affected, especially the left ventricle; the right atrium and ventricle are spared in most cases or are less severely affected.

The condition is encountered either as an isolated lesion in a heart otherwise developmentally normal, or associated with other cardiac anomalies, most often with stenosis or atresia of the aortic or mitral valve, sometimes with an aberrant coronary artery or coarctation of the aorta. In a paper appearing at page 765 of the *Journal* this week, Dr. J. F. Horley has pointed out that the majority of cases of fibroelastosis can be divided into two distinct groups: those associated with aortic valvular lesions and hypoplasia of the left ventricle, in which the infant seldom survives for more than a week or two and the heart is but little enlarged; and those without associated cardiac defects, in which survival for several months is the rule, and the heart is much enlarged owing to dilatation and hypertrophy of the left ventricle. The first type he calls foetal fibroelastosis, because it obviously develops before birth; the second he calls infantile fibroelastosis, apparently on the assumption that it is not congenital but develops after birth.

¹ Gross, P., *Arch. Path. (Chicago)*, 1941, 31, 163.

² Weinberg, T., and Himelfarb, A. J., *Bull. Johns Hopk. Hosp.*, 1943, 72, 299.

³ Ullrich, O., *Z. menschl. Vererb.-u. Konstit.-Lehre*, 1938, 21, 585.

⁴ Johnson, F. R., *Arch. Path. (Chicago)*, 1952, 54, 237.

It is doubtful whether this assumption is justified, despite the fact that fibroelastosis without valvular lesions is very rarely seen in infants less than three months old; for it is to be expected that, when fibroelastosis is an isolated lesion, survival will be longer than is likely in the presence of severe valvular or other congenital cardiac anomalies.

The cause of fibroelastosis is not known. Formerly it and the associated valvular lesions were believed to be a result of infective inflammation and were known as "foetal endocarditis." This theory was decisively rejected by P. Gross,¹ who favoured a developmental origin. The histology of the thickened endocardium and stenosed valves gives little support to the infective theory. A genetic origin has been postulated, and this theory gains support from the occasional occurrence of fibroelastosis in siblings, as reported by T. Weinberg and A. J. Himelfarb,² and by O. Ullrich,³ who described the case of triplets, of whom the two identical were affected, and the third, dissimilar, survived. The theory most generally favoured at the present time attributes the condition to anoxia. It was shown by F. R. Johnson⁴ that the associated cardiac anomalies are usually such as could cause anoxia of the endocardium of the affected chambers. Horley strongly supports this theory. He quotes reports by other workers to show that, when aortic atresia is accompanied by an interventricular septal defect, which admits oxygenated blood from the right ventricle, fibroelastosis of the left ventricle does not occur, although it invariably accompanies aortic atresia in the absence of such a defect. This theory less satisfactorily explains cases of fibroelastosis without other cardiac anomalies, in which there is no evident cause of anoxia of the endocardium.

Fibroelastosis is not often diagnosed with confidence during life. When other cardiac defects exist with it, these are mainly responsible for the clinical features of the case. When there are no associated anomalies of the heart, the infant often appears to be healthy for some months, and then begins to present clinical evidence of heart failure, the heart is found to be enlarged, and the electrocardiogram is indicative of myocarditis. The onset of heart failure may be surprisingly sudden, and death may follow within a few days. The reason for this severe effect on the myocardium is problematical. Gross postulates that the thickened endocardium interferes with the circulation in the heart wall by obstructing the small vessels that penetrate it to open into the chambers. Histological evidence of myocardial degeneration is seldom impressive, and often the clinical evidence of heart failure and the dilatation of the left ventricle seem disproportionate to the microscopical evidence of myocardial damage.

CLUBBING OF FINGERS

If the shade of Hippocrates reads the medical journals he may be surprised and perhaps gratified by the revival of interest in clubbing of the fingers, a sign which he first described twenty-five centuries ago. He must also

feel distressed that his successors have added so little to his own knowledge of the subject. It has now become clear that clubbing of the fingers may be hereditary and of no diagnostic significance, or it may be acquired and signify disease in other parts of the body. Acquired clubbing of the fingers and toes is sometimes said to appear occasionally without any disease being present, but the truth of this assertion may well be doubted because there are so many obscure conditions which may cause it to appear.¹ Indeed, one of the most mysterious features of clubbing is the fact that it is acquired in the course of diseases so different as bronchial carcinoma, congenital heart disease, biliary cirrhosis, lung abscess, and hypothyroidism after thyroidectomy.

In recent years it has been more widely recognized that clubbing of the digits is sometimes only a part of a generalized hypertrophic osteoarthropathy which includes periostitis, synovitis, and painful oedema of the limbs. In the *Journal* this week Drs. T. Semple and R. A. McCluskie report a most interesting series of twenty-four patients in whom this disorder was associated with bronchial carcinoma, a disease which they consider to be the chief cause of the generalized hypertrophic osteoarthropathy. Vogl *et al.*² have recently described the same condition in six patients with bronchial carcinoma and one with a chronic lung abscess. The authors of these two papers have described the classical clinical features of the condition, emphasizing the pain, swelling, redness, and tenderness in the limbs, and the stiffness of the joints in association with progressive clubbing and dusky coloration of the tips of the fingers and toes. Hypertrophic osteoarthropathy commonly calls for attention, and sometimes cripples the patient, before the presence of pulmonary disease is suspected. In such cases it is apt to be diagnosed and treated as rheumatoid arthritis without any benefit to the patient. In contrast, the authors of both papers report rapid and dramatic relief of the "rheumatic" symptoms after treatment of the primary pulmonary disease.

While our clinical knowledge of this interesting condition has advanced, we remain very much in ignorance of the nature of the processes which produce such a curious state of affairs. In 1949 it was observed in an annotation in this *Journal*³ that the subject lends itself to armchair theorizing and that physiological clues were few by comparison with the wealth of clinical data and the numerous hypotheses. The supply of hypotheses has continued to outstrip that of clues, but G. M. Wilson⁴ has confirmed the finding of an increased blood flow through clubbed fingers and has shown that this is not due to the action of vasodilator nerves. He also found that treatment of the intrathoracic disease was

¹ Leopold, S. S., *The Principles and Methods of Physical Diagnosis*, 1st ed., 1952, p. 356, Philadelphia.

² Vogl, A., *et al.*, *Amer. J. Med.*, 1955, 18, 51.

³ *British Medical Journal*, 1949, 1, 228.

⁴ Wilson, G. M., *Quart. J. Med.*, 1952, 45, 201.

⁵ Jack, G. D., *Trans. med.-chir. Soc. Edinb.*, 1952, 132, 75.

⁶ Jackson, W. P. U., *British Medical Journal*, 1949, 1, 216.

followed by a decrease in the peripheral blood flow and a retrogression of the clubbing. An increase in blood flow cannot be the whole explanation, because clubbing is not a feature of hyperthyroidism, in which there is an increased peripheral circulation, but it does appear in some cases of myxoedema, in which the peripheral blood flow is presumably sluggish. Wilson has suggested that the important factor is a blood supply in excess of metabolic requirements, and this may explain some of these apparent anomalies.

Whatever the cause of hypertrophic osteoarthropathy, it is important that the condition should be recognized, because it may be the first clue to the presence of a bronchial carcinoma, and anything which may enable an early diagnosis to be made of this disease is to be welcomed. Moreover, Vogl *et al.* consider that the condition itself is often so distressing and disabling that resection of a bronchial carcinoma may be justified by the relief of symptoms even if it does not eradicate the malignant disease. It is well to remember, however, that G. D. Jack⁵ found only three fully developed cases of hypertrophic osteoarthropathy in 668 patients with bronchial carcinoma and that it took Semple and McCluskie seven years to find twenty-four cases. It is also worth while recalling W. P. U. Jackson's warning⁶ that the combination of a cough and clubbing of the fingers does not by itself justify the diagnosis of a serious pulmonary disease, though it should certainly encourage further investigations.

EPILEPSY AND SCHIZOPHRENIA

In their interesting article on psychical phenomena in temporal lobe epilepsy at p. 748 of the *Journal* this week Drs. S. Karagulla and Elizabeth Robertson draw a number of parallels between these symptoms and those experienced by the schizophrenic patient. They principally concern themselves with hallucinations, taking this term to cover a wide range of abnormal experience. At one end is the disembodied thought, which may be formless and more a subjective experience of something going wrong in the process of thinking. This was observed in an epileptic, and was exactly reproduced by electrocortical stimulation in a strictly localized region of the right temporal lobe. It closely corresponds in form with familiar complaints by schizophrenic patients—for example, of forced thinking, of thoughts being inserted into the mind by an outside agency, or of thoughts getting crossed. In the middle of the range are hallucinatory phenomena, which are experienced as coming from within. Schizophrenics commonly report that they hear a voice coming from some particular part of the body, not infrequently the abdomen; and the authors parallel this with the experience of a 7-year-old epileptic boy, who felt something talking in his stomach as an accompaniment of the aura of an epileptic attack fired off from a temporal focus. Finally there are the completely exteriorized

¹ Grubbe, H. W., *Z. ges. Neurol. Psychiat.*, 1936, 154, 395.

hallucinations, and here the similarities are not quite so close. The schizophrenic remains at all times aware of an external reality, and even when auditory or visual hallucinations seem to him to take place in this external world he usually reports that they have a lesser or different quality of reality than actual objects and events. The pseudo-reality of the epileptic hallucination is often more real than this, as in the case reported in which the patient was blind to everything else.

There are other symptomatic differences between abnormal psychic experiences in the epileptic and in the schizophrenic. Whether the epileptic suffers from a hallucination in isolation, or as part of the aura which precedes a major convulsion, consciousness is usually to some extent clouded or altered. Probably many significant epileptic experiences never come to the notice of the doctor because subsequent memory for them is obliterated. Even when it is retained it may be incomplete. Any demonstrable alteration of consciousness is rare in the hallucinated schizophrenic, although for other reasons he may not be completely in touch, or be unable to give a clear account.

However, it is not only in hallucinations that striking similarities exist between the experiences of the epileptic and of the schizophrenic. A feeling of unreality, sudden, overwhelming, but of brief duration, is extremely suggestive of a temporal lobe attack. Similar feelings, of a more persistent nature, occur in a variety of psychiatric syndromes, but with particular frequency in the early stages of schizophrenia. Sudden changes of mood, depression, panic, ecstatic states, and moods with an other-worldly quality occur both in epilepsy and in catatonic schizophrenia. The *Wahnstimmung*, or state of mind in which everything that is going on seems to have some mysterious significance, or to have some special reference to the patient, is a common and characteristic feature of oncoming paranoid schizophrenia, and is almost as frequently observed in the twilight state which may succeed a closely spaced series of fits or accompany petit mal status. As long ago as 1936 H. W. Grubbe,¹ who was one of the pioneer workers on the psychopathology of schizophrenia, pointed out that there was no phenomenological difference between the form of the primary delusion in schizophrenia and in epilepsy. There are patients in mental hospitals, diagnosed as schizophrenic, who have fits from time to time and even die in status; we may be quite sure that some of them are unrecognized epileptics.

The work of Karagulla and Robertson owes a large part of its interest to the fact that precisely defined and complex psychic experiences could be produced by electrocortical stimulation in a narrowly circumscribed locus in the brain of the conscious subject. This was the work of Wilder Penfield, under whom one of the authors has worked in the department of neurology at McGill. Success in the surgical treatment of epilepsy, a field in which Penfield is the outstanding pioneer, would seem to depend largely on localizing the epileptogenic focus by direct stimulation under local anaesthesia; and neurosurgeons who forgo the advantages of

this technique are neglecting an important aid to localization. The particular moral which Karagulla and Robertson draw from their work, that the phenomenological similarities between epilepsy and schizophrenia are so striking as to merit further intensive study, should also arouse interest and attention.

DANGERS OF MERCURY

Growing appreciation of the importance of enzymes in relation to the action of chemotherapeutic drugs has advanced—and is advancing—rational therapeutics, and gradually the days of traditional and empirical therapy are passing away. Although the scientific approach to treatment has been chiefly concerned with the infections, it shows no signs of stopping there; the times are propitious to investigating whether the old remedies do all that they are supposed to do. One at present the subject of discussion is mercury—a time-honoured recipe for infants both in the form of calomel and as hydrarg. c. cret. (grey powder). Is there any good evidence that either of these preparations is of any value? If not, they should surely be removed from the pharmacopoeia.

Constipation in their infants has been a bugbear to mothers for generations and a "corrective" or laxative is administered to treat and even to prevent the condition—and also to a greater or less extent as a panacea. Any unexplained fever or out-of-sorts state is apt to be treated similarly. Many children are still given a regular weekly laxative—like a talisman to ward off evil things. Teething has naturally been a fruitful subject for catharsis. Some parents attribute any intercurrent upset between the ages of 4 months and 2 years to teething, and administer "teething powders." Are teething powders, of any sort, ever necessary? Teething is a physiological phenomenon like menstruation and pregnancy, and like them it may occasionally become pathological, but undoubtedly less often. Nearly all teething powders contain a laxative, yet there is no evidence that the process of dental eruptions is associated with constipation or that calomel is a febrifuge. Parents should be informed that teething is normally a natural process and that nature seldom requires assistance. If an infant is so upset as to require some treatment he should be seen and treated by the doctor, not by the chemist or grocer, who will undoubtedly continue to supply proprietary remedies if parents continue to demand them. But has the time not come to question the need for grey powders in any disorder?

Mercury is a dangerous drug, especially in infancy, and some doctors have come to consider that it should not be prescribed for internal administration in any form. The Minister of Health is "considering urgently" whether grey powders should cease to be issued from child welfare clinics.¹ If a laxative is necessary, more effective and innocuous preparations are available, such as syrup of figs or syrup of senna. Castor oil is now generally regarded as a grave risk for children,

¹ *Evening Sentinel*, March 15.

and, happily, tragedies from peritonitis due to rupture of an inflamed appendix, as a result of the violent peristaltic contractions produced by castor oil prescribed for a stomach-ache, are much rarer than they used to be. Now that the ill effects of mercury are becoming clearer, a diminution in the incidence of such pathological conditions as pink disease may be hoped for; indeed, there is already some evidence that this is happening.

ROYAL SOCIETY'S NEW FELLOWS

Among the 25 new Fellows of the Royal Society elected on March 17 are three members of the medical profession as well as several scientists whose work has contributed to the advancement of medicine. Professor A. W. Downie, one of the leading authorities on the viruses that cause human disease, is specially noted for his work on the smallpox and related viruses. He has been professor of bacteriology at Liverpool University since 1943, and before that was at the National Institute for Medical Research. Professor K. J. Franklin, of St. Bartholomew's Hospital, has been professor of physiology in the University of London since 1947. His investigations into foetal and renal circulatory systems have been notable for the ingenious techniques, including cineradiography, that he and his collaborators have used. A classical scholar, Professor Franklin has also made distinguished contributions to the study of medical history; his biography of the late Sir Joseph Barcroft appeared two years ago. Sir Harold Himsworth, secretary of the Medical Research Council since 1949, was formerly professor of medicine at University College Hospital Medical School, where his investigations were concerned chiefly with diabetes mellitus, the thyroid, and liver disease. It is good to see clinical research thus honoured in the person of one who has early exercised a great influence on medicine. Since becoming secretary of the M.R.C. Sir Harold has naturally played an important part in the organization of the clinical trials that in recent years have made the Council's work of such unique value to the advancement of rational therapeutics. Dr. D. J. Finney, though director of the Agricultural Research Council's unit of statistics, is well known to many medical men for his development of the statistical methods commonly used in pharmacology, and especially in the assay of biological preparations. Mr. A. F. Huxley, assistant director of research in physiology at Cambridge, has made important contributions to knowledge—in a school renowned for its neurophysiology—about the conduct of impulses in nerves and muscles, latterly with the aid of the interference microscope. Professor O. E. Lowenstein, Mason professor of zoology and comparative anatomy in the University of Birmingham, has been elected for his work on the comparative physiology of the vertebrate labyrinth. Professor G. P. Wells, as professor of zoology, University College, London, comes closely into contact with the medical student in his formative years.

EMERGENCIES IN GENERAL PRACTICE

ACUTE RESPIRATORY OBSTRUCTION

BY

NORMAN A. JORY, F.R.C.S.

Surgeon to the Ear, Nose, and Throat Department, St. Bartholomew's Hospital

Acute respiratory obstruction ranks high on the list of emergencies in which prompt action is necessary to avert disaster. Unfortunately, in some cases the emergency arises so suddenly that death ensues before medical aid can be summoned; but in most cases the obstruction is more or less slowly progressive, giving time for preventive measures at all stages of its development.

Obstruction of the Nose, Mouth, and Pharynx

Lesions in the nose very rarely cause severe obstruction. Some years ago, however, a newly born infant was admitted to St. Bartholomew's Hospital in such respiratory distress that it had to be placed in an oxygen tent. A very large polyp in the left anterior nares completely blocked both nasal passages. Removal of this obstruction gave immediate relief to the distress, respiration at once becoming normal, and remaining so.

The mouth and pharynx provide a number of cases. A large foreign body—for example, a bolus of food—may be inhaled in the deep inspiration of pertussis, completely blocking both food and air passages. The foreign body should be hooked out with the index finger; in infants the retching induced by this manoeuvre often proves most effective. During anaesthesia, and in unconscious states following traffic and other accidents, the lower jaw and tongue may fall back, causing an exactly comparable obstruction. The jaw must be held forward and an airway inserted or the tongue drawn out with a tongue clip.

Acute inflammatory conditions which give rise to gross obstructive swelling include retropharyngeal abscess, usually in young children, and, rarely, lingual abscess. If seen early vigorous treatment with penicillin injections, from 100,000 to 500,000 units twice daily, should be begun, and in most cases the condition will abort. If the response is doubtful, one of the other antibiotics should be substituted: 2 g. of chloramphenicol daily in divided doses for adults, with proportionally smaller doses six-hourly for children depending on their weight; for children the palmitate emulsion is preferred, each drachm (3.5 ml.) containing 125 mg. of chloramphenicol. Alternatively, chlortetracycline ("aureomycin") or oxytetracycline ("terramycin") may be used in half the above dosage. If an abscess has already developed it should be incised. No general anaesthetic is advisable, and it is very doubtful if topical cocaine has any real effect. The child should be laid supine on a table with a sandbag under its shoulders and the retropharyngeal abscess incised. The child should then be picked up by the feet so that the released pus runs from its nose and can be aspirated by a sucker.

Quinsy does not, as a rule, cause much respiratory obstruction unless oedema has spread downwards to the glottic opening. This abscess may be evacuated by the classical stab in the soft palate or, better still, by sharp-pointed sinus forceps passed up along the supratonsillar fossa. If a general anaesthetic seems imperative a non-irritant vapour—for example, chloroform—would be indicated, the patient being placed as for tonsil dissection.

Allergic swelling of the mouth and tongue may follow a wasp or bee sting on the back of the tongue; usually when the insect has been accidentally swallowed with a drink. Or it may be a manifestation of recurring attacks of angio-neurotic oedema or of anaphylaxis in serum disease. In a patient sensitive to penicillin it has followed the introduction of a penicillin cone into a tooth socket after dental extraction. In all such cases the swelling may extend to and involve the larynx.

In severe or rapidly progressive cases the intravenous injection of 5 to 15 minims (0.3–0.9 ml.) of 1 in 1,000 adrenaline hydrochloride will usually control the swelling. If not, laryngeal intubation or tracheotomy should be performed without further delay.

Laryngeal Intubation and Tracheotomy

The choice between intubation and tracheotomy depends on several factors: the instruments available; the probable duration of obstruction; the need for suction in the after-treatment; and the experience of the practitioner. Intubation is indicated in cases of temporary obstruction. Tracheotomy should be performed if the obstruction is likely to last longer than 24 hours; another reason for it is that aspiration is easy to apply through the cannula. Tracheotomy is therefore often used in prolonged states of coma following head injuries, and sometimes in bulbar poliomyelitis. In the minds of older practitioners tracheotomy is associated with laryngeal diphtheria. But since the immunization campaign, begun in 1940, this disease has practically disappeared in Britain. Dr. William Gunn, physician in charge of the infectious diseases department of the Royal Free Hospital, in a personal communication confirming this, states that croup also has virtually disappeared, whether occurring idiopathically or associated with other diseases, notably measles. Nowadays, therefore, the young doctor is unlikely to get much experience of tracheotomy, but he should have had much practice in direct laryngoscopy during his anaesthetic clerking.

The important points in direct laryngoscopy are to have the patient's neck flexed at its lower end and extended at its upper end; and to lift the tongue and epiglottis with the blade of the laryngoscope, and not use the instrument as a lever with the upper teeth as fulcrum. Intubation is effected by direct laryngoscopy. The patient is laid flat on a table and the neck flexed forward at its lower end and extended at its upper end. If the mouth cannot be opened because of spasm this may be overcome by the intravenous injection of 50 mg. of suxamethonium chloride. The handle of the laryngoscope is held in the left hand, while the fingers of the right hand retract the upper lip to prevent its being nipped on the teeth. The blade of the laryngoscope is advanced along the dorsum of the tongue in the midline until the tip of the epiglottis is seen; it is then advanced for just over 1 cm. in a child or 2 cm. in an adult. The laryngoscope is then lifted sufficiently to take the whole weight of the patient's head and the glottis comes into view. As soon as he takes a deep breath the glottis opens, and the endotracheal tube, which is held ready in the right hand, is quickly passed between the cords. Care must be taken to lift the blade, never to use it as a lever with the upper teeth as fulcrum.

For the operation of tracheotomy the patient should be supine, a small sandbag under the shoulders, and the head well extended. The table should be tilted, with foot down, and oxygen given through a mask. An assistant should hold the head, neck, and chest in a straight line. In semi-urgent cases the neck may be infiltrated with local analgesic; in urgent ones no analgesic should be used. The thyroid and cricoid cartilages are grasped with the thumb and middle finger of the left hand, and an incision made, exactly in the midline, from the lower border of the thyroid cartilage almost to the suprasternal notch. This is deepened, bleeding points being ignored, until the corrugated anterior surface of the trachea is felt with the left index finger. This is then

opened by a stab through the second and third tracheal rings—dilators are introduced and the cannula is then passed. If time permits it is better to divide the isthmus of the thyroid gland between clamps, and then excise a circular disk from the anterior tracheal wall at that level. Finally, do not suture the wound too close to the tube, or surgical emphysema may result; and on no account open the trachea through the first ring, as this usually causes a permanent stenosis of the larynx. Difficulties are met if the head, neck, and chest are not kept strictly in line, and if a hasty stab in the trachea is allowed to close before dilators are introduced. Then, especially in infants, the tube may be forced into the fascial planes anterior to the trachea, or between the anterior tracheal wall and its mucosal lining. It needs stressing, however, that if penicillin is given in adequate dosage in the early stages of acute throat infections most of these emergencies will be avoided.

Laryngeal Obstruction

The larynx is by far the most frequent site of obstruction. The loose attachment of the lining epithelium to the underlying structures, especially in the aryepiglottic folds and over the arytenoid and corniculate cartilages, favours the rapid development of gross oedema in these situations. In childhood the larynx is relatively small in proportion to body size, the cartilages are more pliable, the mucosa less closely adherent, and its lymphatic drainage more plentiful than in the adult. Thus acute symptoms are much more readily produced in children. A slowly increasing constriction of the glottic aperture is much more readily tolerated than one which is rapidly progressive.

Foreign Bodies

The familiar condition of "food going the wrong way" produces a temporary spasm for which only the time-honoured slap on the back is necessary. A larger foreign body—for example, food inhaled during the inspiratory phase of coughing—may block the glottis completely or cause marked glottal spasm. If a laryngoscope and laryngeal forceps are immediately available the foreign body should at once be removed. If asphyxia threatens it is better to perform an emergency tracheotomy first.

Vomit or blood may enter the larynx during induction of anaesthesia and, especially when thiopentone is being used, set up severe spasm. The anaesthetic should be stopped and the foreign matter sucked out. A muscle relaxant—for example, suxamethonium chloride, 50 mg.—may be given intravenously, thus permitting the passage of a laryngoscope and, through it, an endotracheal tube. Among other foreign bodies must be mentioned the membranes of laryngeal diphtheria and of acute laryngo-tracheo-bronchitis. These may have to be removed by laryngeal forceps, following preliminary tracheotomy.

Swelling of the Laryngeal Walls

Swelling of the laryngeal walls may be due to one of the following:

Local or Adjacent Infection.—In infants an acute laryngitis may produce alarming symptoms, even to the point of needing tracheotomy. Perichondritis may follow trauma or irradiation and may complicate syphilis, tuberculosis, carcinoma, typhoid, diphtheria, and many of the specific fevers of childhood. Treatment should be directed to the primary cause if possible. Complete rest of the patient and larynx, full doses of penicillin or other antibiotic in the primary form, and tracheotomy if signs of serious obstruction develop are the appropriate measures. If an abscess develops in the larynx it should be evacuated through the laryngoscope. In Ludwig's angina full doses of penicillin may suffice to abort the infection, but if in spite of this the condition worsens incision in the midline of the neck and drainage are employed. Tracheotomy may be necessary if asphyxia threatens.

Trauma.—This may be mechanical, as in traffic accidents or following a high tracheotomy or clumsy instrumentation,

or it may take the form of scalds, as in children drinking from the spout of a teapot or hot kettle, or of burns from inhaling flames in petrol fires or from inhaling caustic fumes in industry. In accident cases early tracheotomy is indicated if obstruction is marked and there is a possibility of intra-laryngeal haemorrhage. In the other cases strict rest in bed, administration of oxygen, and sedatives to reduce the cough are usually sufficient. A careful watch must be kept for signs of impending asphyxia, a tracheotomy set being ready for instant use.

Allergy.—This has already been described in connexion with the mouth and pharynx, together with the appropriate treatment.

Oedema Associated with General Disease.—This occurs, for example, in nephritis, cardiac failure, and idiosyncrasy to iodides.

Neoplasms.—Innocent growths causing serious obstruction are rare. Malignant growths are a much commoner cause, but usually only at a late stage, when they would be the responsibility of the laryngologist. Should the general practitioner have to perform tracheotomy he should make it as low as possible in order to be clear of the growth.

Spasm

Spasm of the sphincter or paralysis of the dilators of the glottis may cause laryngeal obstruction. Spasm may be of central or peripheral origin. Possibly the commonest cause is the induction of anaesthesia, especially with ethyl chloride or ether and, as previously mentioned, with thiopentone. The anaesthetic should be stopped, oxygen administered from the anaesthetic machine, and the bag squeezed when the glottis opens. Alternatively the glottis may be watched through a laryngoscope and quickly intubated as soon as it opens.

In infants congenital laryngeal stridor, which is present night and day, and laryngismus stridulus, which may wake the infant from sleep, occasionally occur. The former causes alarm to the parents, but no great dyspnoea; the latter causes momentary but severe dyspnoea and is treated by sitting the child up, slapping its back, making it sneeze, or hooking its tongue forward with a finger. Both conditions disappear in the first few years of life.

In adults spasm may be hysterical, due to local irritation of the recurrent laryngeal nerve, or of central origin, as in tabes and tetanus. During an attack an ampoule of chloroform or amyl nitrite should be crushed by the patient and the vapour inhaled. Otherwise sedatives are given. Bilateral abductor paralysis is usually due to bulbar lesions, but may be due to pressure on, or severe injuries of, both recurrent laryngeal nerves, as after thyroid gland operations. In an established bilateral paralysis phonation is good, and quiet respiration is possible, but on exertion severe dyspnoea may develop. When no recovery can be expected the choice of treatment is either permanent tracheotomy, with the use of a tube having an expiratory valve, or operation permanently to abduct the posterior part of one cord.

In the diagnosis of these various causes of laryngeal obstruction the history and symptoms are important, but only inspection by mirror, or by the direct method in children, will establish it with certainty. In some cases time will not permit of this inspection. Obstruction sufficient to call for immediate operation is shown by recession at the suprasternal notch and epigastrium, stridor, and restlessness. Cyanosis is late, ashen pallor being more usual. Jackson stresses the importance of recognizing the cause of restlessness in obstruction, lest morphine be given in error, with disastrous results.

In all these cases urgent action is required. It is always better to operate before it is strictly necessary than to delay until it is too late.

Nova et Vetera

SIR THEODORE TURQUET DE MAYERNE 1573-1655

Quid de Mayernio plura?

Mayernium dixeris, omnia dixeris.

So wrote Mayerne's godson, Sir Theodore de Vaux, in the course of a long eulogy for the tombstone in St. Martin-in-the-Fields when Mayerne was buried there 300 years ago. He had died at the age of 82 after a full life, in the course of which he had been physician to four monarchs and had initiated the incorporation of two City companies.

Mayerne's father was a French Protestant and a celebrated writer of history. After the Massacre of St. Bartholomew in 1572 he had fled to Geneva, and it was here that his son Theodore was born in the following year on September 28. Mayerne received his early education in this city, and a classbook of his, which still survives and contains annotated drawings of vessels used in distillation, reflects his early interest in this subject.

From Geneva, Mayerne went to Heidelberg, where he spent four years at the university before going on to Montpellier. It was about this time, when he was only 19, that Mayerne published his first book.¹ It seems to have excited little comment, although in a letter to Humphrey Milford dated March 31, 1919, deploring the lack of a really satisfactory motor road-book, Osler writes: "[There is] not one to be put in comparison with that of my friend Theodore de Mayerne, who . . . issued one of the first and the best in Europe."²

It was probably due to Riverius, first physician to King Henry IV of France and professor of medicine at Montpellier, that Mayerne went to Paris after graduating M.D. in 1597, and was appointed one of the king's physicians. In his medical practice he made considerable use of chemical remedies, which were then regarded as an innovation, and in consequence brought upon himself the condemnation of the College of Physicians of Paris (1603). This doubtless influenced his eventual removal to England, where his reception contrasted favourably with his experiences in Paris, so that some years later, in a letter to his friend Sir William Paddy, Mayerne wrote: "[Thou] didst not look upon me with blear and swollen eyes with the vporous venom of envy; but thou didst entertain me, being a stranger, candidly and with a cheerful countenance. . . ."³ He had been incorporated M.D. at Oxford and appointed physician to the queen on his first visit to this country in 1606. He returned in 1611 after the assassination of Henry IV, and within the space of a few years was appointed first physician to the king and elected Fellow of the College of Physicians.

Power over Distillation

He soon became involved in the preparation of the first edition of the *Pharmacopoeia Londinensis*, in which he is said to have had the assistance of a French Huguenot chemist. Could this have been Gideon de Laune, who, with Mayerne, had so much to do with the founding of the Society of Apothecaries in 1618? Their first charter gave them in theory complete power over distillation of all kinds, but twenty years later, following the incorporation of the distillers, this view was challenged by Mayerne, who contended that the apothecaries were limited (or intended to be) to the preparations in the *Pharmacopoeia Londinensis*. Mayerne had been largely responsible for the promotion of the new company, and for their guidance had assisted Dr. Cademan in the publication of *The Distillers of London* . . . (London, 1639).

Mayerne had been knighted in 1624, and on the accession of Charles I was appointed his first physician, and physician to Queen Henrietta Maria. Aikin seems to think that he

made himself acceptable and necessary to successive queens by condescending to matters beneath the dignity of his profession, such as the preparation of "cosmetics of every kind, pastes, lotions, dentifrices, sweet bags, hair powders and the like."⁴ Here, however, Aikin may be doing less than justice to Mayerne's preoccupation with chemical and other experiments, as a result of which he brought calomel into use and discovered the purple colour necessary for the carnation tints in enamel painting.

In 1634 Mayerne had at last succeeded in arranging for the publication of Muffet's *Insectorum sive minimorum animalium theatrum*. The manuscript had been offered to him by Darnellus, apothecary to Muffet, who had died in 1604. The explanation of the delay in publication has a curiously modern ring, and makes one speculate about the conditions under which Mayerne worked, for he says:

"It lay for some years in my Study cast aside in the dust among Worms and Moths; truly it was not fault of mine, but of the Printers who were so greedy of Money, that though in many Countreys I invited them by my Letters, and did solicit them to receive the Orphan, yet they refused (as they said) to take upon them an unthankful business; they were not pleased with the benefit of a noble Art, unless it would pay more than the freight. O the times wherein the pains of learned men are valued at the price the work will be sold for, and the money that must be laid out for ink and paper. . . ."⁵

Mayerne is known from his portraits to have been very corpulent; it is said that he kept no regular meals, but that he had his table constantly covered so that he could eat whenever he found himself disposed. After the execution of Charles I in 1649, Mayerne was appointed nominal first physician to Charles II, and about the same time, perhaps owing to ill-health, he retired to Chelsea, where he died seven years later on March 22, 1655, from the effects of drinking bad wine.

Reports of Societies

LOCAL MEDICAL SOCIETIES

Joint Meeting of Manchester Medical Society and Liverpool Medical Institution

Speaking at the joint meeting in Manchester on March 2, Professor A. W. DOWNIE discussed the relationship of chicken-pox to herpes zoster. The association of chicken-pox with zoster was well recognized, he said, in that child contacts of zoster cases not infrequently developed a clinical infection indistinguishable from chicken-pox. Yet, because of the difference in clinical picture and pathology, in age and seasonal incidence, there had been in many quarters some hesitation in accepting the thesis that zoster is an infection with varicella virus. Three different views appeared to be held: (i) that one virus causes the two conditions, (ii) that the two clinical entities are due to different but closely related viruses, and (iii) that some cases, but only some cases of zoster, are caused by varicella virus. The recent investigations of Hope Simpson in one of the Shetland Isles seemed to show conclusively that the chicken-pox derived from zoster cases is in no way different from ordinary chicken-pox. The clinical picture, interval between serial cases, and infectiousness were the same, and an attack of the one kind of chicken-pox conferred immunity to the other. The experimental infections of children with zoster vesicle fluid by Kundratitz and by Bruusgaard showed that such infections sometimes resulted in clinically typical chicken-pox with subsequent immunity to further inoculation with vesicle fluid from zoster or chicken-pox cases.

Laboratory investigations had been hampered by lack of susceptible experimental animals, went on Professor Downie, but such information as was available had shown no differences between the virus from chicken-pox and that from zoster patients. The histological features of the skin lesions were the same; by electron microscopy the virus particles were identical; and they were agglutinated by convalescent serum from either type of case. Antigen in vesicle fluids cross-reacted completely in complement-fixation tests with convalescent sera. The laboratory findings thus supported the clinical and epidemiological observations that zoster is a particular kind of infection with varicella virus.

Canal Zone

A clinical meeting was held at the British Military Hospital, Fayid, Canal Zone, Egypt, on February 28, at which paediatric cases were shown and discussed. Dr. B. E. SCHLESINGER, Hon. Consultant in Paediatrics to the Army, was among those present.

Preparations and Appliances

TWO GYNAECOLOGICAL INSTRUMENTS

Mr. H. H. FOURACRE BARNES, surgeon, the Hospital for Women, Soho Square, London, W.1, writes that he finds the two instruments illustrated below of great use in his work.

Vaginal Clamp for Radical Hysterectomy.—It is desirable to obtain a watertight cuff of the vagina below the cervix when carrying out a radical hysterectomy for carcinoma of that organ. In order to obtain this vaginal cuff, the clamp illustrated has been made by John Bell and Croyden. The shank of the clamp is angled to the jaws at a right angle,

Hysterectomy clamp.

so that the handle lies comfortably to one side of the uterus when applied to the vagina, application being made from the side. The ends of the jaws are curved to facilitate cutting across the vagina below the clamp. The jaws are heavy and grooved at right angles to the direction of the shank so as to prevent any slipping on the vaginal tissues.

Intrauterine Forceps.—In order that the cervix need not be dilated to a high degree for the introduction of intrauterine forceps, especially in the elderly, the forceps illustrated have been made by John Bell and Croyden. The small width of the blades ($\frac{1}{4}$ in.—6.3 mm.) and joint ($\frac{1}{16}$ in.

Uterine forceps.

—7.9 mm.) allows easy introduction through the moderately dilated cervix. In addition, the joint is situated at a distance from the ends of the blades so that it lies in the middle of the cervical canal of the normal-sized uterus. This allows the blades to be opened for a distance of 1 in. (2.5 cm.), when the cervix is dilated sufficiently to allow the forceps to be passed.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Chlorpromazine Jaundice

SIR,—Your correspondents Drs. J. G. Macarthur and Bernard Isaacs (*Journal*, September 25, 1954, p. 754) plead for more detailed clinical and histological study of cases of jaundice occurring during chlorpromazine therapy. Their plea has every justification, as the drug is among the most frequently prescribed and the incidence of jaundice occurring during its administration is by no means negligible. Chesney¹ (1954) reports two cases from one general practice, and it occurred in 3 of 18 patients treated by Eagles.² Other writers record a lower incidence. Thus, jaundice occurred in 3 of 71 patients treated by Lehmann and Hanrahan,³ 3 of 142 given the drug by Winkelmann,⁴ and in 6 of 500 observed by Boardman.⁵ Other cases have also been reported by Elkes and Elkes,⁶ Lancaster and Jones,⁷ Zatuchni and Miller,⁸ and Van Ommen and Brown.⁹ We have recently had the opportunity to study a patient who developed jaundice whilst taking chlorpromazine, and are therefore reporting our findings in your columns.

He was a pattern-maker of 48, of temperate habit, who had never had any physical illness and who was given 25 mg. chlorpromazine ("largactil") thrice daily for a long-standing obsessional neurosis. After he had been taking the drug for three weeks he felt feverish over a period of 48 hours, and during the subsequent three days had some vague abdominal discomfort, so he reported to his doctor, who noted that he was jaundiced. The chlorpromazine was stopped, and the patient ceased work and went to bed. During the subsequent ten weeks he remained in bed at home, afebrile, eating well and without pain or dyspeptic symptoms, but deeply jaundiced, suffering much pruritus and with acholic stools and bile in his urine. The only abnormality on physical examination was an enlarged liver which was neither irregular, hard, nor tender. Although it was thought that the jaundice was due to the chlorpromazine therapy, in view of its protracted course he was admitted to hospital for fuller assessment.

The liver function tests showed the pattern of obstruction (see table), the blood count was normal, the stools were negative for occult blood, barium studies of the oesophagus, stomach,

	Weeks After Onset of Jaundice

Flocculation	Negative	Negative	Negative		Negative
Colloidal gold:					
Patterson	2	2	1		2
MacLagen	Negative	Negative	Negative		Negative

duodenum, and small and large intestines were all normal, and the chest radiograph was clear. The blood Wassermann was negative.

In view of the undue persistence of the jaundice as compared with all other recorded cases (except the fatal case reported by Boardman⁵ and the two cases of Van Ommen and Brown,⁹ which have since been published), it was thought advisable for him to have a laparotomy in case a growth was present, especially in view of the absence of evidence of parenchymatous damage in the liver function tests. Laparotomy was therefore carried out by Mr. Gourevitch. The gall-bladder and common bile duct were not dilated, the pancreas was normal, and there was no evidence

of extrahepatic biliary obstruction, but there were some large soft glands in relation to the common bile duct and the liver was rather pale and its surface granular. A liver biopsy was taken and the abdomen closed. Histological examination showed bile thrombi in the bile canaliculi but no dilatation of the bile ducts, gross peribiliary fatty degeneration of the liver cells and slight periportal round cell infiltration but no necrosis of liver cells, no regeneration, no fibrosis, and no reticulin formation. The laparotomy upset the patient very little, and since operation the jaundice has steadily faded, but a trace is still evident and the liver function tests are still abnormal (see table) 15 weeks after the onset of illness. The only treatment given has been a high-protein diet and vitamin supplements.

The histological findings in this case accord very closely with the only other detailed pathological report,⁸ and the biochemical changes are similar to those found by Elkes and Elkes,⁶ Boardman,⁵ Zatuchni and Miller,⁸ and Van Ommen and Brown,⁹ each of whom reported liver function tests showing an obstructive pattern and normal flocculation tests.

Three points are thought to require emphasis: (1) Chlorpromazine appears to be capable of producing a toxopathic hepatitis characterized by damage to the cells at the periphery of the lobule, blockage of the canaliculi by bile thrombi, and periportal cellular reaction. (2) The liver function tests in such cases show an obstructive pattern without evidence of parenchymatous damage. (3) The jaundice may last for several months.—I am, etc.,

Cortisone, A.C.T.H., and Asthma

SIR,—My two-and-three-quarter years' experience of 47 severe asthmatics treated with cortisone and/or an indistinguishable blank substance does not support Dr. H. Herxheimer's enthusiasm (*Journal*, February 12, p. 416), but is in keeping with your annotator's cautious summing up of

- 1—One to two attacks daily, easily relieved } full activities.
2—More than two attacks daily, easily relieved }
3—Spasm on exertion, free at rest.
4—Spasm on exertion plus attacks at rest.
5—Status asthmaticus.

the present position (*Journal*, January 22, p. 216). In status asthmaticus I have seen cortisone fail in high dosage, and the reports of fatal anaphylaxis after A.C.T.H. injections cannot be lightly cast aside.

My results in the long-term control of asthma with cortisone have not yielded a "high percentage of pronounced improvements." Fifty per cent. is the highest I can claim, and this will fall when the figures from a current blind trial are all included. Certainly, cases have been raised from a life of semi-invalidism to near normality; unfortunately this is not the invariable response. Success and

failure in all types of asthmatics, with a wide age range, has occurred. At present it is impossible to foretell the long-term result in any given case, though emphysematous patients with a low respiratory reserve gain no benefit.

The effects of any treatment are difficult to assess in asthmatics, who are so open to suggestion. It is chastening at the conclusion of a blind trial to find that the successful case had been taking the blank solution and the failure cortisone. It is such observations as these which make me echo "*sub judice*" with your annotator. The chart shows the course of a difficult case—the patient still swears by "cortisone," being unaware that he is on a blank solution. That trials should be blind is surely a very happy remark.

It is true that side-effects are not usually severe, but considerable weight gain due to fat or fluid retention must be balanced by material improvement if treatment is to be justified. I shall strongly "discourage its use," except in the most carefully chosen cases. Dr. Herxheimer is enthusiastic: I was much more so a year ago than I am now. Cortisone may soon be freely available; it is very expensive, not without risk, and the results vary. Let us ensure that we do not harm our patients, waste public money, and achieve nothing.—I am, etc.,

Whitefield, Lancs.

RONALD SAVIDGE.

Whither Natural Childbirth?

SIR,—I read with interest the recent letter by Dr. Constance Beynon, "Whither Natural Childbirth?" (*Journal*, February 19, p. 475). I disagree with the writer from the viewpoint of a midwife and that of the mother of two children. As a midwife I witnessed mothers in labour who had, as the writer says, "rehearsed" for it, and those who had a vague and sometimes no idea of what was about to happen. In the first cases fear was banished, which is a big step towards success; the use of drugs was reduced to a minimum, and complications to mother and baby were fewer. Sedation is used to help the mother relax, but often, owing to the use of drugs, the mother is unable to give of her best in the second stage, thus prolonging this stage. Asphyxiated babies are born due to over-sedation or sedation given at the wrong time. Instructions given to women in labour are of little or no avail.

Now from the viewpoint of a mother, which is the most important argument? I practised relaxation for each confinement. Pethidine and gas and air were given towards the end of the first stage when I had my first baby; due to this I neither appreciated what went on during the second stage nor did I help as much as I could have done. I certainly appreciated the use of pethidine and gas and air at that time, and wondered however I should get on without them when I was told when expecting my second baby that I could easily do without. They were certainly available if needed. When I went into labour I tried to relax as I had been taught, but did not achieve 100% success until the arrival of the person who had done the relaxation exercises with me during my pregnancy. I experienced no pain during contractions until the end of the first stage, and then only acute discomfort at the transitory period. The second stage was shorter because I had more energy to help, and I was brighter and more alert after the birth. If the physiotherapist, or whoever teaches the relaxation exercises, could be with the mothers in labour, or if midwives had a course in this art, then painless childbirth would be enjoyed by the many and not the few. Surely the money saved in drugs could be used to foster relaxation exercise clinics, and I am sure midwives would enjoy their work a lot more.—I am, etc.,

London, N.W.5.

HONOR KENNY.

SIR,—I am glad that the subject of natural childbirth is being ventilated in the *Journal*. I agree with Dr. Grantly Dick Read (*Journal*, March 5, p. 604) that "childbirth is a much wider subject than obstetrics" and I welcome his plea for a "full inquiry into the care of pregnant and parturient women." Dr. Constance L. Beynon says (*Journal*, February

19, p. 475) that any other generation would think it absurd that child-bearing requires special training to be natural. But what pitiful stories one hears of child-bearing in the last two generations.

I am not in practice, but I talk to a number of women in my work for the Marriage Guidance Council, and I am impressed with how often difficulties in their own marriage relationship and the functions connected with child-bearing can be traced to the stories they have heard from their mothers, or to previous unhappy experiences of their own. I am also impressed by the eagerness of the young couples to whom I talk, either before or just after marriage, to know about these natural processes and the way this knowledge leads a young wife to the fulfilling experience of labour and motherhood.

I agree that partial knowledge or understanding may sometimes be dangerous, but only if a woman is allowed to go through labour unattended or without instruction at that time. The teaching of the antenatal clinic needs to be implemented in the labour ward; only so shall we enable a woman in labour to use, in the most helpful way, her spontaneous instincts of expulsion.—I am, etc.,

East Croydon.

O. CYNTHIA HARRIS.

Gases in Artificial Respiration

SIR.—May I be allowed to discuss the comments of Dr. K. W. Donald and Professor W. D. M. Paton (*Journal*, March 12, p. 664) on my letter? I asked them for more evidence in support of their recommendation that oxygen with 7% carbon dioxide should be abandoned in the treatment of carbon monoxide poisoning. The only additional evidence they put forward is a paper by Schwerma *et al.*¹ from which they quote the concluding sentence. Anyone interested should read the paper itself before accepting this quotation as having weight in settling the question of oxygen alone versus oxygen and carbon dioxide in the first-aid treatment of carbon monoxide poisoning. The reader will find: (1) The dogs who were given pure oxygen or carbon dioxide and oxygen had their respirations maintained by mechanical resuscitators. Mechanical respiration operates to weight the comparison in favour of oxygen and such respirators would not be likely to be available for first aid. (2) Here I quote the words and italics of Schwerma *et al.*: "It was impossible to keep the resuscitator mask on the dogs after they became conscious. Our clearance studies are therefore based on the effect of a few minutes—usually two to four—of treatment followed by a period of four hours during which the animal was allowed to inhale air." Such brief administration was hopelessly inadequate.

To accord this paper the relevance and importance suggested by Dr. Donald and Professor Paton seems very strange. Even under the peculiar comparative conditions of their experiments, so unpractical when related to human first aid, the findings of Schwerma *et al.*, as recorded in their graph, showed clearance of carbon monoxide from the blood from almost lethal levels (over 80%) to levels compatible with life to be twice as fast—twenty minutes as compared with forty minutes to fall to 45%—in ten dogs who received 7% carbon dioxide and 93% oxygen (without rebreathing) compared with ten dogs who received 100% oxygen. If the time of administration had been adequate and mechanical resuscitators not used (the conditions of first aid to human beings), clearance from dangerous levels would probably have been about four times as fast for carbon dioxide and oxygen compared with pure oxygen.² This paper of Schwerma *et al.*, plus two slight papers, written 30 years ago, seems to be all the evidence, directly relating to carbon monoxide poisoning, that Dr. Donald and Professor Paton have to offer. They have not recorded any work of their own on carbon monoxide poisoning or attempted a balanced survey of the literature in which there are many more publications favourable to the use of carbon dioxide and oxygen than against.

In the first paragraph of their comments they defend their attitude by saying they were concerned with the full range of asphyxial emergencies and that correct diagnosis may not be within the power of the first-aid worker. The implication is that, if oxygen with 7% carbon dioxide is available to first-aid workers for the treatment of carbon monoxide poisoning, it may be wrongly used for patients with other forms of asphyxia in which

there may be carbon-dioxide retention. This objection is hypothetical and not real. The first-aiders concerned are not usually presented with any diagnostic difficulty. There is not much doubt, to worry firemen, mine rescue workers, and ambulance men, about what is wrong with asphyxiated persons removed from burning buildings or gas-filled mines or rooms. Such first-aid workers are trained individuals and they can be told, if it is thought advisable, only to use oxygen and carbon dioxide for poisoning by carbon monoxide.

The most serious aspect of the whole matter is that apparently the Medical Research Council Committee is issuing, or has issued, a memorandum or directive advising cessation of the use of oxygen and carbon dioxide in the treatment of carbon monoxide poisoning—a reversion to the position of the early 1920's. Such a memorandum, coming from the Medical Research Council, will be regarded as authoritative and made the basis of administrative orders regarding the first-aid equipment of the rescue services. If it so happens that the advice is wrong, then many lives will be lost that might have been saved. Experimental re-investigation on animals and human volunteers could be easily and quickly done by use of the resources of the Medical Research Council. With great respect, I submit that it is the responsibility and duty of this Committee to sponsor such work if it is giving official guidance which is contrary to generally accepted opinion.—I am, etc.,

London, W.1.

Mental Confusion after Porto-caval Anastomosis

SIR.—The article by Drs. L. J. Hurwitz and R. S. Allison on recurring mental confusion after porto-caval anastomosis (*Journal*, February 12, p. 387) prompts me to report a similar case which recently came under my notice through the courtesy of Professor F. A. R. Stammers.

The patient was a woman, aged 60, admitted to the Queen Elizabeth Hospital, Birmingham, under his care on June 5, 1954. Two years earlier she had had a haematemesis, and in September, 1953, it was discovered that her spleen was enlarged and that oesophageal varices were visible with a barium swallow. Two weeks before admission she again had a haematemesis, followed a few days later by another. At the time of her admission she was greatly exsanguinated (R.B.C.s 1.82 m., Hb 3.9 g.) and occult blood tests were strongly positive. There were prominent veins on the abdominal wall, and the liver and spleen were both enlarged. Other systems were healthy. Pulse 80 per minute, B.P. 140/65. Liver function tests were abnormal (total serum protein 6.2 g.%, A:G 1.6:1; ZnSO₄ turbidity 5.0 units, ZnSO₄ flocculation +++; thymol turbidity 3.0 units, thymol flocculation +; colloidal gold Patterson 3, Maclagan ++++; serum bilirubin 0.5 mg.%; total cholesterol 145 mg.%; serum alkaline phosphatase 17.1 units%) and a splenogram showed typical intrahepatic portal obstruction. After multiple transfusions Professor Stammers carried out porto-caval anastomosis on June 26, 1954. Post-operatively all went well until July 13, when she suddenly became rather confused and disorientated, but in the course of a few days her mental state improved sufficiently for her to be sent out of hospital on July 22 to convalesce at her sister's home.

However, at her sister's her behaviour became so strange that she was admitted on a temporary order to a mental hospital, from which she was transferred once more to Professor Stammers at the Queen Elizabeth Hospital on August 13. I saw her on August 19, and made the following note: "She is very confused and forgetful, and cannot perform any difficult tasks to order, because she loses the thread of what she is meant to be doing too quickly. She calculated the cost of six 2½d. stamps very fast, and is good with multiplication tables, but more complicated mental arithmetic is quite beyond her—for example, the cost of four gallons of petrol at 4s. 6½d. a gallon. She has no trouble naming her own left or right sides, or her fingers, although she is easily puzzled about the examiner's. Given her dressing-gown to put on, she got into it back to front three times in succession, each time confabulating excuses for its not buttoning up in front. Asked about herself, she says she has been 'a little nervous' since the operation, but that it is 'nothing unexpected' in a person of her age. On physical examination there

is a rhythmic tremor of the head, and a regular alternating postural tremor of the hands appears from time to time (it was most noticeable when she was holding a pencil, and appeared plainly in her handwriting). No definite tremor of legs seen. There is occasional cogwheel snatch to be felt in the wrist and elbow on right, not so distinct on left, and none in legs. The deep reflexes are normal and the plantars flexor. There is a well-marked arcus senilis bilaterally and possibly some pigmentation on the limbic side of this. ? Kayser-Fleischer ring."

Liver function tests were then repeated, and gave results now distinctly more abnormal than before operation (total serum protein 6.8 g.%, A:G 0.94:1, ZnSO₄ turbidity 10.0 units, ZnSO₄ flocculation ++++; thymol turbidity 5.0 units, thymol flocculation ++++; colloidal gold Patterson 5, Maclagan ++++; serum bilirubin 1.5 mg.%; total cholesterol 220 mg.%; serum alkaline phosphatase 20.4 units%). The urinary amino-acid chromatogram showed normal excretion (traces of cysteine, serine, glycine, glutamine, alanine, and valine), and estimation of serum and urinary copper levels also gave results within the normal range (118 µg.% and 33 µg. per 24 hours respectively). Slit-lamp examination did not confirm the suspicion of a Kayser-Fleischer ring. The E.E.G. record was grossly and diffusely abnormal and showed persistent medium and high voltage slow activity at 2.5-5 c/s in all leads, and intermittent phase reversal was seen at both temporal electrodes.

It was clear that the cerebral condition must be of hepato-genous origin, and presumably of the same general nature as that which causes liver coma. From the neurological point of view the interesting points were the tremor of head and hands, which was typically extrapyramidal in appearance, the apraxia over dressing and difficulty in calculating, reminiscent of Gerstmann's syndrome of the parieto-temporal confluence, and the tendency to confabulate explanations of her difficulties. Her E.E.G. abnormality was of the type frequently seen in confusional states arising from a variety of causes, amongst them hepatic coma. The patient was discharged from hospital to her own home a few days after I saw her, and I understand that she subsequently made good progress.—I am, etc.,

Birmingham, 15.

MICHAEL JEFFERSON.

Changes in the Mental Health Services

SIR.—Dr. F. Pilkington (*Journal*, January 29, p. 291) states that there is no clear definition of what constitutes a "mental observation ward." But surely he was arguing against the analysis which he himself submitted—that is, a total of 146 persons admitted under 3- and 14-day order (with no waiting-list or hindrance) and the liberty of the subject safeguarded by judicial authority. Of these, 107 became voluntary. Such transition should be easy and helpful to all concerned. Hence the ward is a "detention ward," vitally necessary for persons who, whilst mentally unbalanced temporarily, may injure themselves or others.

I know of many persons who have been grateful for enforced removal, thus being saved from the results of temporary mental aberration. Sometimes even the shock of a person being removed from his home has the effect of helping to bring him to his senses before the expiration of 3 or 14 days. Then a magistrate can, with doctor's help, discharge the patient to his home, and thus a bed is saved at the mental hospital for psychotic patients. Most mental hospitals are long distances from populated centres, and transport by ambulance over this distance is uneconomical.

Regarding the allegation of an undesirable change of doctor, I suggest that the consultant psychiatrist and his assistants (who are probably attached to the mental hospital) would see these patients anyway, and there would be no change of doctor. In my opinion, the Royal Commission should recommend that "detention wards" known as "observation wards" be instituted and designated in all well-populated areas for the urgent immediate care of the mentally sick, other than voluntary patients, and for the essential help and safeguard needed by the harassed G.P.—I am, etc.,

Plymouth.

A. S. BRADLAW.

Defects of Modern Treatment of Leprosy

SIR.—I have read with interest the report (*Journal*, March 5, p. 597) of the meeting of the Edinburgh Branch of the Royal Society of Tropical Medicine on March 2, at which my friend, Dr. James Ross Innes, spoke on the above subject. With most of what he is reported as saying no one would disagree: he is obviously stressing the important point that modern treatment of leprosy, although a great step forward, has not solved the leprosy problem, and that further research is urgently needed.

I think, however, he rather misstates his case when he says that "the modern treatment of leprosy based on the sulphone group of drugs is unsatisfactory," for the reason that their slowness and imperfection of action suggested that it might prove very hard to eradicate the hard core of endemic infection. Surely a similar statement could be made of the modern treatment of almost any chronic infectious disease, with the possible exception of yaws. This does not appear an adequate reason for labelling a treatment as unsatisfactory.

Regarding the value of sulphone treatment of leprosy in the control of the disease in a community, we can as yet say little because of lack of evidence. Some workers think that with a disease such as leprosy, which usually propagates itself with so much difficulty, and even dies out spontaneously under certain circumstances, sulphone treatment, with all its limitations, may, by reducing the already low degree of infectivity, exert a definite influence in producing a decline of the disease. Other workers, including Dr. Ross Innes, think that before this result is obtained a more potent therapeutic agent is necessary. All workers, however, are keen to find more potent drugs, and trials of new drugs are constantly being made. All are keen, if possible, to apply immunization methods in the control of leprosy, and the possible value of B.C.G. vaccination for this purpose is being studied. It is good that these two lines of study are to be pursued by the research unit of which Dr. Ross Innes is in charge, which, by the way, this association has been instrumental in establishing.—I am, etc.,

London, W.1.

JOHN LOWE,
Medical Secretary, The British
Empire Leprosy Relief Association

A Foreign Body in the Kidney

SIR.—Sir Heneage Ogilvie (*Journal*, February 5, p. 352), referring to a case reported by Dr. Duncan Macaulay and Mr. Thomas Moore (*Journal*, January 22, p. 205), describes a "kirbigrip" as "a small, smooth object, chemically harmless, without projections or points, ideally shaped to go round intestinal curves." Whether this is, or is not, an accurate description depends, as the late Professor Joad would have said, upon what one means by small and points. It is surely the length of a kirbigrip (4.8 cm. in Macaulay and Moore's case) relative to the lumen of the duodenum and the angle of the U-shaped curve of the second part of the duodenum that has to be considered. Though the ends are not sharpened, they are certainly pointed, and their slightly splayed arrangement probably makes it easy for the kirbigrip to impact in the duodenal mucosa. We are not told the age of the patient who swallowed the 6-in. (15.2-cm.) nail. I am, however, wholeheartedly in agreement that of all ingested foreign bodies the kirbigrip has the most evil reputation.

Several times a year one faces the problem of a kirbigrip in the stomach or already in the duodenum of a child, the parents clamouring for instant removal, or alternatively refusing consent for operation if there is a chance that the kirbigrip will pass spontaneously. Sometimes the parents have already been told by their doctor that the foreign body should be removed at once or that it will certainly pass. I believe there is something to be said for removal of a kirbigrip from the stomach of a child of less than 2½ years of age. The operation is almost foolproof, and saves much anxiety and frequent radiological examinations. When the

kirbigrip is in the duodenum, and especially if it remains in the same position, as shown by daily films, it is probably wise to remove it after 2-3 weeks. In my experience a kirbigrip which negotiates the U-shaped bend usually passes without incident. I have only seen three instances of delay at the duodeno-jejunal junction; two were removed after 2-3 weeks' observation and the third passed onwards after two weeks. I have not seen perforation of the bowel at this site.

I have had one child in which the hair-slide was partly in the kidney and partly in the duodenum at the time of operation—there were no urinary symptoms—and one which presented with a limp in which the kirbigrip was removed from the psoas muscle. Both perforated "pointed" end forward; in the second case, by the time the kirbigrip was removed it was in two pieces, the loop end having corroded away. I have probably removed upwards of a dozen kirbigrips from the duodenum after waiting up to three weeks. With good anaesthesia, an adequate incision, and closure of the duodenum with non-absorbable material, the operation is easy and safe.—I am, etc.,

Liverpool.

ISABELLA FORSHALL.

Dyspareunia

SIR.—I was most interested to read that Mr. R. Christie Brown (*Journal*, January 8, p. 106) is starting a clinic to study dyspareunia as a cause of sterility. Here in Uganda we have a tremendously high incidence of sterility, but one hardly ever meets the type of dyspareunia that is seen in the United Kingdom. If difficulty or pain on intercourse is experienced, there is in practically every case a true organic cause—in fact one wonders why it is not a much commoner symptom. Out of 1,035 patients who thought their condition sufficiently serious to come into the gynaecological wards at Mulago Hospital last year, only six complained of dyspareunia. In four of these the cause was only too obvious. Two had a large pyosalpinx, one a badly stenosed vagina following trauma at childbirth, whilst another was an interesting case of a Nubian woman from the Sudan who had undergone female circumcision as a child and, on marriage, discovered that the entrance to the vagina was almost completely occluded. This is a rare complication of circumcision in the female. The other two patients were certainly a little more of the type found at home. A woman of 30 years of age, married about eight years, had an unruptured hymen and complained of dyspareunia. However, she also had uterine fibroids, which seemed to worry her even more. In one case only there was no apparent cause, an examination under anaesthetic revealing nothing abnormal.

Dr. G. W. Theobald states in his letter (*Journal*, January 22, p. 228) that cauterizing the cervix may help to cure some cases—presumably working on the theory that chronic cervical infection causes many gynaecological symptoms. Here we have a superabundance of chronic cervicitis, practically all of gonococcal origin, but only rarely is backache or dyspareunia found. Some do complain of lower abdominal pain, however. It does appear that the complexities and anxieties of civilized life cause many marital difficulties. Here, coitus, childbirth, and breast-feeding are all accepted as perfectly natural functions, and, unless there is something organically wrong, no particular trouble is experienced by the African woman.—I am, etc.,

Kampala, Uganda.

CORALIE RENDLE-SHORT.

Tonsillectomy

SIR.—As an anaesthetist, it is with some trepidation that I enter the tonsil controversy, but, since Dr. H. B. C. Sandiford (*Journal*, March 5, p. 603) has cited anaesthesia as an important factor, I feel justified in joining the fray.

The only advantage of the guillotine operation is presumably that you can do "more than ten rather than less than four per hour." Dr. Sandiford quotes two satisfactory anaesthetic techniques; the first of these, $N_2O \rightarrow O_2 \rightarrow$ ether

with oral or nasal intubation, would have to be carried to at least the second, preferably the third, plane of surgical anaesthesia to produce the ideal operating conditions which Dr. Sandiford so rightly demands. I doubt the ability of many anaesthetists, working single-handed, to anaesthetize more than ten cases in this manner inside an hour, let alone for the surgeon also to operate on them—without a two-minute time limit. Also, the statement that turning off the ether when the gag is inserted "ensures that the patient will be in a light plane of anaesthesia at the end of the operation *regardless of time*" (my italics) is somewhat extraordinary; if the patient is deep enough to tolerate gag, tube, and operation lasting two or three minutes, it is difficult to see by what mechanism he is "in a light plane of anaesthesia" at the end of it; it is, of course, almost completely dependent upon "time." The better the operating conditions and the better the operator, the deeper will be the patient at the finish, whichever way the knobs are turned in the meanwhile.

With regard to the second anaesthetic technique—namely, a single injection of thiopentone only—I can only say that if this technique should become widespread my own children will hang on to their tonsils until they are so bad that even the most enthusiastic guillotinish would not consider them suitable for this type of operation or "anaesthetic," and the inverted commas are intentional.—I am, etc.,

London, W.14.

M. P. COPLANS.

SIR.—I have read with interest Dr. J. B. Stirling's comments (*Journal*, February 26, p. 542). The advantages of the technique I advocated (*Journal*, January 29, p. 285) over that used by Dr. Stirling are that an injection of atropine, with its adverse effects on psyche and soma, is avoided, and that with efficient team-work and the use of a recovery room 16 to 20 cases can comfortably be done in an hour. Relaxation is adequate for opening the jaws and for a clean guillotine tonsillectomy, and tachypnoea does not occur.—I am, etc.,

Hull.

W. N. ROLLASON.

Intramuscular Iron

SIR.—The widespread interest aroused by the introduction of an iron dextran complex ("imferon") for intramuscular administration is evident from the volume of correspondence which has appeared in the *Journal*. There would seem, however, to be some difference of opinion regarding the value of, and indeed the necessity for, such a preparation. It has even been suggested that oral administration of iron is the only method which need be used. We should like to make known our views on imferon, and to stress certain aspects of its use and of the technique of administration.

We first began to use this complex over thirteen months ago when we carried out some of the earliest clinical trials. It was initially given to 30 patients who were selected after full haematological investigation and shown to suffer from iron deficiency: some of them were cases of primary hypochromic anaemia (Witts's anaemia); others were associated with dietetic deficiency occasioned by such conditions as peptic ulcer (even where no frank or occult bleeding occurred), or by financial difficulty in elderly people living alone. Many had been given oral iron in apparently adequate dosage without appreciable effect, while a number had admittedly not been taking the iron prescribed by their doctors. We did not include patients suffering from such conditions as advancing malignant disease or chronic nephritis. All patients underwent bone marrow studies and fractional gastric analysis, and possible causes of chronic blood loss were sought for and excluded. Our conclusions were as follows: (1) Imferon is readily absorbed and produces a completely satisfactory haematological response. (2) It is non-toxic both locally and generally when administered in the correct dosage, and when reasonable care is taken in selecting the site of injection and the type of case to which it is given. (3) Its administration can safely be entrusted to any competent nurse.

We should like to emphasize the importance of ensuring that the substance is deposited in the muscle and not in the subcutaneous fat. If this is not done, then marked staining of the skin

will certainly occur, and, while we have not encountered any serious trouble in this direction, patients are apt to object to the cosmetic effect.

Since the original series was studied we have used imferon on a large number of other patients, and have had no cause to change our opinion that it represents a distinct advance in iron therapy. Its advantages over intravenous preparations are so obvious as to require no further comment. Imferon itself has been given intravenously, but some side-effects have been reported, and there seems to be no valid reason for administering in this way a substance which was expressly produced to avoid the hazards of such therapy.—I am, etc.,

A. GRUNBERG.

J. L. BLAIR.

Birkenhead.

Silver Stool Sign

SIR.—Sir Heneage Ogilvie's memorandum on "Thomas's Sign or the Silver Stool in Carcinoma of the Ampulla of Vater" (*Journal*, January 22, p. 208) appears to have evoked considerable correspondence. The following case may consequently be of interest.

A male patient aged 71 years was admitted on February 10 with a ten-day history of painless jaundice of increasing intensity following upon an attack of bronchopneumonia. The patient died from cholaemia 17 hours after admission, but before death passed a stool of unusual appearance, which was kept by the night staff for me to see. To my surprise this stool was the colour of aluminium paint, and, having read of the diagnostic import of Thomas's sign, I consequently made a confident post-mortem diagnosis of hepatic failure following upon carcinoma of the ampulla of Vater. To my disappointment necropsy revealed a carcinoma of the gall-bladder, with metastatic deposits around the porta hepatis and quite normal ampulla of Vater.—I am, etc.,

Gravesend, Kent.

C. A. M. WALKLEY.

SIR.—In my memorandum (*Journal*, January 22, p. 208) I did not make it sufficiently clear that the Thomas stool has the grey colour of oxidized silver or aluminium paint rather than the sheen of a new half-crown. Fatty acid crystals appear in the faeces in various disorders of fat metabolism and give the stool that metallic lustre to which your correspondents have drawn attention, but the appearance is that of brass filings rather than of silver. The classical Thomas stool is due to the mixture of blood (black) with fat (white) and it is rarely seen except in cancer of the ampulla.—I am, etc.,

London, N.W.8.

HENEAGE OGILVIE.

Grants for New Hospitals

SIR.—I disagree with Mr. R. S. Murley's objection (*Journal*, March 5, p. 600) to the building of new hospitals, and with his preference for the improvements that may be possible in old and unsuitable buildings. It is very encouraging that regional boards are to have control of new hospitals. In order to produce the greatest effect of this encouragement it is hoped that the Minister of Health will announce the aim to provide patients in every part of the country with medical facilities and with amenities of a modern standard. This will need a more equal expenditure than at present on all hospitals—teaching and non-teaching; regional boards owe it to the patients in their hospitals to press unceasingly for this.—I am, etc.,

London, W.1.

J. M. ALSTON.

Fluoridation of Public Water Supplies

SIR.—We are gratified that the members of the U.K. Mission on Fluoridation (*Journal*, March 12, p. 667) share our desire for more knowledge (*Journal*, January 29, p. 284); the need for this was the main stimulus of our letter. We note they believe the strongest evidence against dietary fluoride having any deleterious effect comes from the study

of two areas in Texas; the validity of the statistics from these areas has already been questioned (*Journal*, February 26, p. 538).

The members of the mission regard as misleading our statement that the effect on dental caries in adults of the ingestion of water containing 1 p.p.m. is much less certain than the well-established effect in children up to the age of about 8 years. Yet a member of the mission himself stated (*Journal*, January 22, p. 224) that one of the four main conclusions of the mission was that there is abundant evidence that lifelong consumption of such water "results in a substantial reduction of the incidence of dental caries in children, and probably in adults also." If there is this doubt about adults who have consumed such water from birth, we still feel justified in believing the effect upon caries in adults partaking of it after childhood to be "much less certain" than the "well-established" effect in children.

If we interpret the members of the mission correctly, they suggest the "severe dental fluorosis" found by one of us (D.C.W.) in Oxfordshire might have been caused by the hypoplasia due to exanthematous diseases or nutritional disturbances during enamel development. The original publication¹ included a photograph of teeth which do not seem to us or to those whom we have consulted to resemble changes that could arise from either of these two conditions: more important, the publication mentions that Dr. Ainsworth, to whom we are all indebted for the classic description of teeth at Maldon,² himself visited one of the Oxfordshire villages and verified the findings.

We doubted the statement of the mission in their report that "in theory any fluorine compound which will ionize in aqueous solution should have the same action on teeth." The mission now appear to agree that their statement was not true, but they claim that, even if we were correct, our objection would not be a valid one, since no one, they allege, is proposing to use stannous fluoride. Fortunately, chemical theory is not altered by what anyone proposes to add to public water supplies.

Finally, we are surprised to learn from the members of the mission that fluoridation of water supplies would not be carried out in the neighbourhood where fluoride dust might settle. The horticultural industry uses such dusts, as is implied in a statement the mission quotes in its report (p. 57): "Fruits and vegetables may be contaminated with residual fluoride dusts following the use of fluoride-containing insecticides in orchards and fields." There may be further difficulty in implementing this assurance, since there are at least 28 known sources of atmospheric contamination by fluorides. And there would remain the problem of industries other than the horticultural industry that might be introduced later into an area that was already using fluoridated water: of such the recent outbreaks of animal fluorosis on lands which had been altered by opencast coal-mining are a reminder.³—We are, etc.,

H. M. SINCLAIR.

SIR.—I was interested to read the report of the Board of Faculty of Dental Surgery of the Royal College of Surgeons of England on the fluoridation of domestic water supplies (*Journal*, February 26, p. 535). When studying the incidence of dental fluorosis in certain districts in India, Dr. D. C. Wilson¹ noted that when dental fluorosis was present so also was goitre. In England geological formations containing fluorine are found in certain districts. One of these is Derbyshire, where it appears as fluorspar, and where it is, or until recently was, mined. At one time goitre was very prevalent in certain parts of this county; it is now much less common, probably as a result of improved water supplies. Rocks containing fluorine are found in other districts in England, and these districts are places where goitre is more or less prevalent. On her return to England Dr. Wilson

continued her investigations, and obtained additional evidence that fluorine in drinking-water may be a factor in the causation of endemic goitre.

Two points suggest themselves to me for consideration. First, how is the amount to be kept approximately at the fluorine dilution decided upon, and, secondly, would an action for damages lie against those responsible for the addition of fluorine to the water supply by one who developed goitre or the disfigurement of dental mottling?—I am, etc.,

Watford.

THOMAS FENTEM.

Hexamethonium Ileus

SIR.—The memorandum by Dr. H. J. Goldsmith (*Journal*, February 26, p. 522) draws attention again to the dangerous complication of ileus which may arise from parenteral or, more commonly, oral dosage of hexamethonium, which has been commented upon previously. The large dosage of hexamethonium used in the case cited is attended by severe risk of inhibition of gastro-intestinal activity, owing to the generalized ganglionic blockade produced by this drug. Constipation and diarrhoea constitute an indication for immediate withdrawal of dosage.

Four cases of ileus were encountered when hexamethonium was first applied in the Royal Alexandra Infirmary, Paisley. Subsequently an investigation of methonium homologues¹ showed that pentolinium has much less effect upon the bowel than upon the blood pressure. This ganglion-blocking agent has been used since without producing ileus even during sustained oral dosage, although constipation has occurred infrequently. As Smirk *et al.* have shown,² the combination of pentolinium and reserpine is very useful in the treatment of patients with severe hypertension, and these drugs have almost entirely replaced hexamethonium in the treatment of hypertension in this hospital.—I am, etc.,

Paisley.

Manipulation and Low Back Pain

SIR.—In our recent letter (*Journal*, January 29, p. 288) we suggested that Cyriax or his colleagues should produce figures to back up his claims of almost total success with manipulation in the treatment of disk lesions of the cervical, dorsal, and lumbar regions. In the *Journal* of March 19 (p. 705) two of his colleagues have published some results of manipulative treatment in that syndrome which can be described as "lumbago."

Drs. Anthony B. Coyer and Ian H. M. Curwen have treated a series of 152 patients by carrying out manipulations, or advising rest in bed with analgesics, to alternate patients. Comparison of the figures of these apparently contradictory methods of treatment shows several differences. The first is that 50% of the manipulated patients and only 20% of the others recovered during the first week. The second is that 28% of those rested had persisting symptoms after six weeks as compared with only 12% of those manipulated. There is a third difference in that 16 (21%) of the rested cases "did not carry out instructions, or did not report for assessment"; and these 16 are omitted from the results group in 2. Every one of the 16 was of working age (Table I), and it is important to know whether they had recovered spontaneously and returned to work in a week or so, or had sought treatment elsewhere and remained uncured. If they had in fact recovered within a week, the first outstanding difference in Coyer and Curwen's results would disappear, and we should then find from Table VI that, whether manipulated or not, about 50% of all the patients had recovered in a week, and about 30% after a further two weeks. That about 80% of patients suffering from an attack of "lumbago" will recover from that attack more, or less spontaneously within about three weeks is a

piece of information which, probably, most of the readers of this *Journal* would confirm from their own clinical or even personal experience. However, like most orthopaedic surgeons, we have found that quite a few cases of acute low back pain with fixation (lumbago) can be relieved immediately by a single manipulation without anaesthesia, if seen early enough and especially within a few hours of onset of the attack.

With regard to the second outstanding difference, is it possible that chance can have placed, in the whole of Group II, an uneven proportion of cases more difficult to deal with? We feel that this may be so because, comparing the two, in the second group there were 9% more patients over 30 years of age (Table I); 20% more had significant radiological changes (Table V: disk lesions, osteophytosis, osteoarthritic changes, etc.); and 12% more were using a sagging bed so perhaps went home to rest in those same beds (Table IV).—We are, etc.,

London, N.W.1.

W. D. COLTART.

H. OSMOND-CLARKE.

Incubation Period of Herpes Zoster

SIR.—The incubation period of herpes zoster does not appear to be definitely established. The following case seems to point to an interval of two weeks from exposure to appearance of rash.

The patient, a woman of 50, had been indoors for six weeks and had had no visitors when she visited her hairdresser on February 9. The hairdresser had been in contact with his mother, whom I had attended for herpes zoster. My patient complained of severe lumbar pain on February 16, a week later. On February 23 the typical rash appeared in distribution L.2. Apart from her own family, the only outside contact had been her visit to the hairdresser, a fortnight before the appearance of the rash.—I am, etc.,

London, N.W.10.

H. BROSTOFF.

Clinical Staging of Carcinoma of the Breast

SIR.—Those who work among cancer patients are becoming increasingly aware of the difficulties of comparing the results of treatment methods owing to the lack of agreement about staging this disease. The cervix uteri is the only site for which an international staging exists, and it is a reproach to cancer specialists all over the world that in the last 25 years there has, until recently, been no real effort to do the same for other sites. At the sixth congress of the Union Internationale Contre le Cancer held in Brazil in July, 1954, the staging of carcinoma in several sites was discussed—for example, the breast, larynx, and pharynx. Oddly enough, the staging of cancer of the larynx, which is a rare disease and which is treated on a large scale in comparatively few centres, provoked long and even acrimonious discussion. By contrast, breast staging was the subject of a number of proposals, but these aroused little interest and scarcely any debate.

It seems to many of my colleagues at the Royal Marsden Hospital (formerly the Royal Cancer Hospital) that international agreement on the staging of breast cancer is more urgently required than for any other site in the body, and this for the following reasons: (1) the high incidence of the disease; (2) the large number of clinicians treating the disease; (3) to discover the effect of any one treatment upon the disease so that different methods of treatment can be compared; (4) because the comparatively high survival rate would surely make this comparison worth while; and (5) because there seems to be a reasonable hope of achieving earlier diagnosis in cancer of the breast by appropriate propaganda than in most other cancer sites and therefore it is important to try and find out whether such propaganda would succeed in improving the results of treatment.

No doubt the World Health Organization is the proper body to decide the matter, and only they can effectively advise the universal adoption of a staging which will inevitably dissatisfy many people. The next meeting of the International Union against Cancer is in London in 1958. Is it

too much to hope that before then British surgeons and radiotherapists may have met, discussed, and agreed upon a clinical staging for carcinoma of the breast so that clinicians of this country at least can put forward a basis for discussion which already commands firm support?

This letter is written in the hope of stimulating interest and action and to say that the Royal Marsden Hospital is willing to take the initiative in arranging such meetings of clinicians as would be necessary to determine this matter if no official body is likely to do so in the very near future.—I am, etc.,

London, S.W.3.

MICHAEL HARMER.

Hypodermic Injection Technique

SIR.—I feel that Dr. L. P. Lockhart's letter (*Journal*, February 12, p. 415) about hypodermic injections should be loud-pedalled. The law of averages is pretty safe, but the exception could often prove a fatality, especially with some of our heterogeneous penicillin formulations. On these grounds alone I deplore the growing popularity of the "cartridge" syringe.—I am, etc.,

Wrexham.

R. P. W. KUP.

Coarctation of the Aorta

SIR.—In view of the recent correspondence on this subject, the following case merits recording.

The patient was admitted to Westminster Hospital under the late Sir James Purves-Stewart. She was aged 45 and had been short of breath for 20 years, during which she had had seven pregnancies, including a pair of twins at the age of 34, after which her breathlessness became more severe. There were three miscarriages. On examination she was severely dyspnoeic, the heart was enlarged, and there was a loud systolic murmur at the apex. Tortuous arteries were palpable in the neck and posterior and lateral aspects of the thorax. Blood pressure in the arms was 170/110. E.C.G. showed abnormal notching of the ventricular complex. She died suddenly of cardiac failure. At necropsy the aorta was so constricted that a $\frac{1}{4}$ -in. (3.2-mm.) probe could not be passed. The aorta beyond this point was reduced to $\frac{1}{8}$ in. (12.7 mm.) in diameter, but the collateral circulation was greatly hypertrophied. The ductus arteriosus was reduced to a fibrous cord and the other viscera showed signs of chronic venous congestion.

The case came to my notice because of the specimen of heart and aorta in the pathological museum at Westminster Medical School.—I am, etc.,

London, S.W.1.

Doctors and the Press

SIR.—Surely Dr. R. W. Cockshut (*Journal*, March 19, p. 731), in insisting on a policy of no capitulation and no compromise with the Press, is a little unrealistic. It rather reminds one of America's one-time splendid isolation. As a practical point it is the duty of the B.M.A.'s Public Relations Department to try to keep on friendly terms with the Press. There have been times when we have been only too glad of their help. One does not remain friends by a glassy stare and a reiteration of "No comment!" The popular press is, by definition, popular. Dr. Cockshut may not like it, but most of his patients do, and they not only lap up with avidity the sort of material he objects to but in many cases would rejoice to see themselves, complete with their troubles, right on the front page. Still, he wishes to protect them against their worse selves.

The majority of journalists are highly responsible people, and, if we wish to get their co-operation in restraining their more ebullient colleagues, surely compromise and mutual understanding are essential. A surgeon is fully entitled to object to reporters invading his hospital. I imagine there would be an equal objection if a squad of doctors burst into an editorial conference of the *Daily Mirror* and wished to take the temperatures of all present. Such things are insufferable, but there are old and tried methods of coping with gate crashers, and we do not need special medical measures.

All doctors object to personal publicity, and the Press, plagued every day by publicity hunters, finds this difficult to understand. Only by friendliness can we make them understand—but remember that anything in print in the *Medical Directory* or in *Who's Who* is public property, legally and ethically quotable. All one can ask is for no fulsome additions. We must, of course, always shield our patients—provided they wish to be shielded. But, as I have said, quite a lot do not, and will treasure all their lives the copy of the paper with their deformed picture on the front page. If we withhold information, they give it—so do their friends and neighbours.

In short, this is not a simple problem of "mind your own damned business," but one which well deserves a most thoughtful conference.—I am, etc.,

Ashted, Surrey.

W. EDWARDS.

SIR.—Dr. R. W. Cockshut (*Journal*, March 19, p. 731) appears to be rather out of touch with the facts. For some time it has been the accepted custom for doctors of the highest ethical standing to publish news bulletins on the state of health of persons deemed of interest to the public. Dr. Cockshut's urging the medical representatives at the forthcoming conference with the Press "to present the view that the physical and mental misfortunes of our patients do not constitute legitimate 'news'" is, therefore, even further removed from reality than his statement that Professor Ian Aird recently wrote a letter to the *Observer* on this subject. It was, in fact, an interview.

The exploitation of human misery by the Press or, of course, by the medical profession is damnable. But I have an uneasy feeling that some of the indignation being felt over the plight of the person most concerned in the news story that first drew attention to this whole matter is misplaced. In the course of a lengthy interview with Mrs. Davies she told me that she read "all the papers, especially the picture ones." She liked what they said about her and the twins. She thought that all the reporters who had come to see her were "very nice," with two exceptions. These, by the way, were not free-lance journalists. As for the public's reaction to what appeared in the newspapers, she had found everyone sympathetic and kind. She seemed delighted with the presents, letters, messages of good will, and offers of prayers that came her way because of the Press. Seeing that Boko and Tomu were "news" it was a great pity, when Mrs. Davies's permission was forthcoming, that the distribution of news from the hospital was not more adroitly handled. Scanty news bulletins were issued through the press officer of the large business house which had a finger in the pie, but none of the 11 doctors involved in the preliminary investigations or the operation was available to answer the obvious questions, while the surgeon most mentioned in connexion with the case refused to answer the telephone.

The unhappy result of this policy was that reporters waiting outside the hospital on the day of the operation sought news from any available source. One of the doctors who had just left the theatre said that the operation had been a success and that "Professor ——— had been wonderful." This news was rushed to afternoon papers which came out on the streets about the same time as the message from the hospital reached other parts of the hospital that one of the twins was dead.

The Press had another grievance. One national newspaper asked to use some of the pictures being taken during the operation. But the reply was that these pictures were intended for strictly medical or scientific scrutiny. Yet shortly afterwards some of these pictures were published by a weekly non-medical illustrated magazine. How did this leakage occur? And why was there no protest from the hospital at the time?

Over a year ago (*Journal*, January 16, 1954, p. 141) you mentioned the need for a clearer understanding by the medical profession and the Press of each other's problems and your hint has finally been taken. But on the same

occasion you suggested that if any surgeon were faced in the future with the dilemma that confronted Professor Aird over the Davies twins he would be well advised at the outset to seek the help of the public relations officer of the B.M.A., and thus make use of the facilities available in his own professional organization. According to a letter from your public relations officer, Mr. John Pringle, to *The Times*, this help was offered in connexion with the recent Siamese twins, but was refused. Now, Dr. Cockshut, commenting on Mr. Pringle's letter, says that it "seemed to impute that the surgeons concerned bore some responsibility through a failure to approach him or accept his offer of help." If the phrase means responsibility for what happened between the Press and the other interested parties, then I am in hearty agreement with your official in his belief that if the B.M.A. public relations officer had been invited to intervene between the doctors and the Press much of the ensuing unpleasantness could have been avoided.

In this I believe I am voicing the views of many of my colleagues in journalism. The B.M.A. "Press office" is the clearing-house for an immense amount of reliable medical information which is given promptly to the Press. That office promotes the best possible relations between the profession and the Press to the benefit of both. I feel confident that if the help of the B.M.A. had been accepted in the two cases under consideration Mr. Pringle and his staff would "have had the courteous co-operation of all but the least reputable elements of the Press."—I am, etc.,

London, E.C.4.

ALFRED BYRNE,
Medical Correspondent,
Manchester Guardian.

The Discovery of Penicillin

SIR,—To your excellent leading article "The Discovery of Penicillin" (*Journal*, March 19, p. 711), in which you quote from Alexander Fleming's first paper on penicillin, I would like to add two more paragraphs from two other of his papers: "It is quite likely that it [penicillin] or a chemical of a similar nature will be used in the treatment of septic wounds," and: "It [penicillin] has been used on a number of indolent septic wounds and has certainly appeared to be superior to dressings containing potent chemicals."

It is marvellous to see how thoroughly Fleming carried out alone his remarkable work, and how he insisted, in three different publications in 1929, 1931, and 1932, on the possible therapeutic use of penicillin in the treatment of septic wounds infected with penicillin-sensitive microbes.—I am, etc.,

Madrid.

Relief for Medical Victims of New South Wales Flood Disaster

SIR,—I have ascertained that the New South Wales Branch of the Association is organizing a fund for the relief of the doctors who have suffered as a result of the recent floods which caused widespread devastation in that State. I am sure that many members of the Association at home will welcome an opportunity of making a small contribution to this fund, and that help of this kind from the profession in the mother country will be greatly appreciated by our Australian colleagues. I shall therefore be happy to receive donations for transmission to the New South Wales Branch in Sydney.

Will contributors please make their cheques or postal orders payable to "The British Medical Association" and send them to the Chairman of Council, B.M.A. House, Tavistock Square, London, W.C.1, marking the envelope "N.S.W. Relief Fund" in the top left-hand corner?—I am, etc.,

London, W.C.1.

E. A. GREGG,
Chairman of Council.

Obituary

MAX NEUBURGER, M.D., Ph.D.

Professor Max Neuburger, the great historian of medicine, died in his native Vienna on March 15 after a long illness. He was in his 87th year, and for over forty of these he had taught his subject in the University of Vienna. He had written or edited seventeen books and about 180 papers, had founded and equipped a famous institute largely without official help, and had received decorations from five countries and honorary fellowship or membership of many learned bodies.

Max Neuburger was born in Vienna on December 8, 1868. He was descended from Jewish families which

had long been resident in Munich and Hamburg. His father, Ferdinand Neuburger, was a brilliant linguist: a native of Munich, he migrated to Vienna as a youth and became an Austrian subject in 1859. Max attended the Piaristengymnasium and then studied medicine at the University of Vienna, having among his teachers such famous men as Billroth, Nothnagel, Kraft-Ebing, Fuchs, and Politzer. Very important for his early career was Moritz Benedikt, who taught neurology. Neuburger graduated as a Doctor of Medicine in 1893, and he then spent two years as resident physician (*Secundararzt*) at the Rudolfspital. In 1896 he became assistant to Benedikt at the Allgemeine Poliklinik, a post which he held until 1908, and he became a well-known neurologist. Although he wrote little on the modern aspects of his subject, he influenced its development by his historical writings. He had a private neurological practice until 1914, but he voluntarily sacrificed more and more of this lucrative work for the sake of his humanistic studies. During the first world war he was in charge of several military hospitals, and the end of the war marked the close of his active clinical career.

For the following account of Professor Neuburger's work as a medical historian we are indebted to Dr. E. ASHWORTH UNDERWOOD: While he was still a student Neuburger published several short historical-philosophical articles. At this time the chair of the history of medicine was held by Theodor Puschmann, who had published his history of medical education in 1889. After his graduation in 1893 Neuburger was inspired and encouraged by Puschmann to carry out historical studies. Within the next two years he wrote several papers, one of which demonstrated the pioneer work of Giuseppe Zambecari as an experimental physiologist. Puschmann now encouraged Neuburger to become a Dozent, and for this it was necessary for the candidate to submit a published thesis. The result was Neuburger's important work on the history of the experimental physiology of the brain and spinal cord to the time of Flourens (1897). In 1898 he was appointed as a Privatdozent—an honorary lecturer—and his real career had officially commenced. Thus started his long association with Robert Ritter von Töply, who was twelve years his senior. Von Töply was an active military surgeon who later rose in the Austrian Army to a rank corresponding to our Director-General of

Medical Services. He was a keen medical historian, and he also was appointed Privatdozent under Puschmann: a few years later he wrote the long section on anatomy in the famous *Handbuch der Geschichte der Medizin*. Puschmann died in 1899, and the teaching was carried on by the Dozents, von Töply and Neuburger. In 1904 Neuburger became extraordinary professor, and full professor in 1912. He retired officially in 1934, but continued the work until 1938.

Neuburger's work falls naturally into two parts—his writings and the foundation of the Vienna Institute for the History of Medicine. For his research work he was superbly equipped by nature, by training, and by experience. He was endowed with a consuming interest in the medicine of all ages and of all peoples, without which none can aspire to the title of general historian, and with a historical sense which is given to few. He was gifted with a literary style of great purity and dignity. To these assets he could add his sound basic training in many languages and in historical methods. He made few detailed studies of ancient texts, and his main interest was the synthesis of the history of a subject in relation to the various cultures of the periods discussed. He has been rightly called the most philosophical of the great historians of medicine.

Neuburger's first book, his *Habilitationsschrift* on the history of the experimental physiology of the brain and spinal cord, published in 1897, is a very learned discussion of this difficult subject from Willis to Flourens and Magendie. Two other monographs, on specific nutrition and on the early history of antitoxin therapy, followed quite soon. Puschmann had expressed the wish that the enormous *Handbuch* which he had planned was, in case of his death, to be edited by Neuburger, but when Puschmann died with his task scarcely begun the publisher requested Julius Pagel, of Berlin—it would seem quite rightly, in view of the size of the work—to act as co-editor with Neuburger. The first volume, dealing with the whole field up to the Middle Ages, appeared in 1902. The second and third volumes, dealing with the histories of individual subjects, were published in 1903 and 1905. Neuburger's long introduction to the second volume is evidence of the accuracy of his scholarship and the width of his interests: in itself it would have been sufficient to establish him as a considerable historian. Of the other books which he later wrote, mention must be made of his definite biography of Hermann Nothnagel, and of his several major contributions to the history of the Viennese School. His long book on the doctrine of the *vis medicatrix naturae* (1926) in itself demonstrates the main characteristics of his work.

While he was labouring on the *Handbuch* Neuburger was also engaged on preparing his own *History of Medicine*. The first volume of this work was published in 1906, and carries the subject to the end of classical antiquity. The second volume—to the close of the Middle Ages—appeared in 1910. Neuburger never finished this great work. From a letter written late in life it is clear that he was preparing the Renaissance section in 1920. Under the sponsorship of Osler an English translation began to come out in 1910 and was completed in 1925. The history was not intended for the specialist. It is learned, very accurate, and puts each subject against the background of its time. Its only disadvantage is the intentional paucity of references.

Puschmann had intended to found an institute for the history of medicine at Vienna, but after his death the funds with which he intended to accomplish this were diverted to Leipzig. The new institute was founded there in 1905. It was endowed from the start and Sudhoff became its first director. In 1906 Neuburger and von Töply presented a memorandum to the Ministry of Education in Vienna, emphasizing the necessity for an institute, and explaining how its museum collection could be built up from material already in the possession of other institutes and hospitals. They launched a newspaper appeal for books, portraits, and museum objects. Von Töply soon retired from active participation, and the building up of the institute is due to Neuburger alone. He presented to it 1,000 books and reprints from his own library and worked unceasingly

to expand the collections and to obtain rooms for them and his seminars. They were first housed in a small space below a lecture theatre. In 1919 Neuburger had them transferred to three rooms in the national building called the Josephinum. The medical library of the Josephinum and its magnificent collection of 1,200 wax anatomical models were added to the institute. By 1934 the institute was occupying 15 rooms. On his 60th birthday a volume of essays was issued in his honour, and his portrait-medal was struck in Vienna. In 1930 Fielding H. Garrison edited in his honour a volume of translations of twelve of Neuburger's studies.

In 1939 arrangements were made for Neuburger to join the scientific staff of the Wellcome Historical Medical Museum. He arrived in London on August 26, 1939 with two suitcases and five shillings. Kind friends looked after him in his new surroundings. During the war he underwent a serious operation, and he stuck doggedly in London throughout the bombing. Practically all his previous work had been written in German, but he now began to write and publish in English. His interests became more and more centred on British medicine, and in 1943 he published a charming little book entitled *British Medicine and the Vienna School: Contrasts and Parallels*. He continued to work steadily until June, 1948, when he departed for the United States to live with his son in Buffalo. Later that year another volume of essays in his honour, edited by Dr. Emanuel Berghoff, was published in Vienna. Dr. Berghoff's biography of Neuburger, in German, was published at the same time. During four somewhat restive years Neuburger tried to accustom himself to the American way of life, but his heart and his thoughts were in Vienna. In 1952 at the age of 83 he astonished everyone by flying back to his native city, where he received a cordial official welcome. His happiness was complete. Unfortunately, before the end of that year he fell in his home and fractured his femur. Although physically incapacitated thereafter, he retained much of his mental activity until near the end.

I became acquainted with Neuburger early in the war years, and I was much impressed by the enthusiasm and the modesty of the man. He was an Honorary Fellow of the Royal Society of Medicine, and on December 1, 1943, we put out, for the meeting of the History Section on that day, a fairly complete exhibition of his printed books and papers in commemoration of his approaching 75th birthday. Neuburger was immensely touched. From 1946 until 1948 I was in much closer contact with him at the Wellcome Museum. He was still an ardent student, and his whole life was centred on the history of the healing art. He was by this time rather deaf and very myopic. Nine times out of ten, on opening the door of his room one found him poring over a book or a manuscript, using a reading-glass and with his head almost touching the page. Here in a flash was a vision of the mediaeval scholar. He never failed to express in many minor ways, sometimes unconscious, his gratitude to the people and the country that had given him freedom. His first article, in 1892, was on philosophy and medicine. A year ago he published what is possibly his last note, a brief article on the future of medicine based on its history. History and philosophy: these were the threads which ran unbroken through his long life.

In 1899 Neuburger married Johanna Conrad. They had two sons: the elder went to Tasmania in 1939, and the younger, Frederick, has been practising medicine in Buffalo, N.Y., since 1938. Frau Neuburger died in 1930. From his letters and from personal conversations it is evident that Neuburger was long and deeply affected by her death.

Dr. WALTER PAGEL writes: One of my earliest recollections is the photograph, on the drawing-room mantelpiece of my paternal home some 50 years ago, of a tall, martial figure in full Imperial Austrian court uniform, with plumed helmet, sword, and medals—and yet displaying the fine features of the scholar. It bore the familiar signature of Max Neuburger and was taken after his presentation to the Emperor when he had been appointed titular professor of medical history in the university of Vienna. Max

Neuburger was the last exponent of what may be called the "heroic" generation of medical historians. Its foremost exponents were Julius Pagel (1851-1912) and Karl Sudhoff (1853-1938). It was "heroic" because of the stupendous achievements which are due to these three men—and even more so because of the heavy odds against which they had to work at a time when historical studies in medicine were frowned upon and when there was no recognition of medical history as a subject for university teaching, departments, or research grants.

Of the three men, Sudhoff, as a practitioner well over 50, acquired an institute and, much later, a full professorship. Julius Pagel remained a practitioner throughout life, since his "extraordinary" professorship entitled him to lecture but not to "live." Neuburger, having been a practising neurologist, was given a full professorship and a department at the age of 50—yet his life before and after was a continual struggle with adversities. His stipend was always poor. He had to go through all the misery of post-war Vienna, when, hungry and cold, he wrote his masterpieces on the Vienna school in the kitchen of his flat in Neubaugasse. At the age of 70 he was subjected to the routine humiliations of Jewish scholars of highest standing at the "hearing" before an exalted member of the all-too-numerous Viennese Nazi mob. Finally, stripped of all earthly possessions, he found himself isolated from his children. This was the reward for nearly 50 years of devoted service and the sacrifices he had made for his department, to which he had given his precious library and collections. Neuburger was lucky in catching an aeroplane to London—the last leaving Vienna before war was declared.

A man of "great stature," erect and brave, Neuburger went through the London "Blitz" and a major operation—all the time working intensely and coming forward with ingenious ideas and unexpected finds. One such idea was to trace the personal contacts between British and Continental doctors, notably of the Vienna schools, and their repercussion on the development of medicine. All his works are classics of enduring vitality. Neuburger concentrated on the full presentation of subjects such as the history of neurophysiology (1897), the concept of the healing power of nature (1926), and indeed the whole of ancient and mediæval medicine (1906-11)—rather than on the detection and first edition of manuscript sources (as Pagel and Sudhoff had done).

Neuburger was an idealist whose life may be fittingly inscribed with the conversion of a famous adage: "Primum philosophari, deinde vivere." Regardless of prospects and career he followed the creative spark in himself which had been kindled in his early schooldays by his headmaster, an inspiring teacher of history. Somewhat temperamental in disposition, he fearlessly and sincerely criticized friend and foe. Already in his earlier correspondence with such friends as Julius Pagel "saturnine" streaks of pessimism, impatience, and suspicion are recognizable. This was aggravated later on by the totalitarian attitude of Sudhoff, who, as Sigerist said, treated Neuburger unfairly. All this explains why recognition and honours meant much to Neuburger, especially in his later life—and it is gratifying that he lived to see himself rightly and universally hailed as the princeps of medical historians. It is with deep sorrow that we part from the last of a generation of fine scholars and great men.

Miss S. R. BURSTEIN, of the Wellcome Historical Museum, writes: Max Neuburger was essentially a social person: people were the staff of life to him. He delighted in the written recognition of his work or his birthdays. Quick to flare up in discussion, he sometimes offended people, but he was always sad if anyone dropped out of his life. An omitted greeting from anyone—be it colleague or cleaner—could darken his day. Yet he was capable of monumental patience. Venerating scholarship to the point of hero-worship, he was full of patience, sympathy, and kindness to the self-taught. To the younger generation he freely offered all the riches of his knowledge and experience. In historical biography he hated denigration of great characters,

but he loved to seek out characters overlooked by history, especially those who seemed to have had their thunder stolen by greater personalities.

L. N. ROBINSON, C.B.E., M.D.

Dr. L. N. Robinson, formerly senior physician at the Hertford British Hospital in Paris, died at Reading on March 15, aged 85.

Leonard Nicholas Robinson was the son of Samuel Henry Robinson, of Howrah, Bengal. From Malvern College he went on to study medicine at Edinburgh, where he graduated M.B., C.M. in 1893, proceeding to the M.D. five years later. He was also a Doctor of Medicine of the University of Paris, where he continued his studies for some years and where he decided to live. In 1900 he was appointed physician to the Hertford British Hospital and he soon became widely known and respected both by his French colleagues and by the British residents in Paris. For some years he was senior member of the Medical Board for France of the Egyptian Civil Service, and in 1914 he was appointed president of the Paris Branch of the British Red Cross Society. During the first world war he served in the R.A.M.C. as a lieutenant-colonel and was mentioned in despatches. He was appointed C.B.E. in 1920 and an officer of the Legion of Honour in 1933. He continued to practise in Paris (where his telegraphic address was the word *Crusoe*), until the second world war, when he returned to live in England. The last years of his retirement he spent at Biot in the Alpes Maritimes.

Dr. Robinson married Victoria, daughter of Mr. D. Hoef, in 1903, and he is survived by his widow and daughter.

We are indebted to Dr. C. G. JARVIS for the following appreciation: The passing away of Dr. Leonard N. Robinson further reduces the very small number of British practitioners in France. For many years he had been their respected and popular senior. He will be remembered for his manifold beneficent activities. For twenty-five years he was senior physician to the Hertford British Hospital in Paris. This institution was very near his heart and he gave it unstinted time and trouble. He was also a trustee of the British Charitable Fund and honorary physician to the British Legion, giving freely to all the benefit of his wisdom and experience.

When the first world war broke out he lost no time in organizing a local branch of the British Red Cross which rendered invaluable service. In the second world war he had settled near Exeter, where he acted as chairman of the West of England section of the Committee for British Subjects Evacuated from France. Here again he freely provided assistance and advice and strove to maintain constant contact between the exiles. After the war he retired to his pretty villa on the French Riviera. Unfortunately his eyesight gave him considerable trouble and this tribulation he keenly felt, for he was a great reader.

Robinson had in Paris a wide circle of friends, and many were those whom he had assisted and advised, for his kindness was proverbial. His always pleasant manner, his sense of humour, his utter lack of petty jealousy, and his readiness to help made him a very pleasant colleague. His devotion to duty was one of his predominating characteristics. He will long be remembered by those who were privileged to know him.

D. A. PRITCHARD, C.B.E., F.R.A.C.P., M.R.C.P.

Surgeon Rear-Admiral D. A. Pritchard, Director of Naval Medical Services in the Royal Australian Navy, died in Melbourne on March 11 at the age of 59.

Denis Adrian Pritchard was born at Stanmore, New South Wales, on April 26, 1895, and from Sydney

Grammar School he went on to Sydney University, where he studied science. During the first world war he came to Britain and worked as a scientist in munition factories. He returned to Sydney to study medicine, and graduated M.B., Ch.M. in 1922. In the following year he joined the Royal Australian Navy, in which he had a distinguished career. During the last war he served as squadron medical officer in H.M.A.S. *Perth* and *Australia*, and he was present at many Pacific actions. In 1946 he was appointed Director of Naval Medical Services and an honorary physician to the King. He was a Fellow of the Royal Australasian College of Physicians, and since 1935 had been a Member of the Royal College of Physicians of London. In 1952 he was appointed C.B.E. Surgeon Rear-Admiral Pritchard married Mary, daughter of Canon Harold Portis, and she survives him with their daughter.

Sir ALEXANDER FLEMING, M.D., D.Sc. F.R.C.P., F.R.C.S., F.R.S.

Mr. A. G. CROSS, dean of St. Mary's Hospital Medical School, writes: Sir Alexander Fleming, to one who had known him as a teacher and later as a colleague, showed, apart from his scientific accomplishments, the two outstanding characteristics of modesty and of great loyalty both to St. Mary's Hospital Medical School and to the Wright-Fleming Institute, of which he had been director. He accepted all the honours which came to him as a result of the discovery of penicillin in a spirit of incredulity and with the suggestion that he was not really deserving of all these tributes. He was always ready to undertake any task for the medical school and was a constant supporter of the students in all their activities. A keen swimmer and a good shot in his younger days, he was for many years a regular supporter of the rugby and cricket teams, and he was always interested in the results of the various inter-hospital competitions. The world by his death has lost a great benefactor and St. Mary's has lost a loyal friend.

Mr. H. H. DU BOULAY, honorary consulting surgeon to the Weymouth and Dorset County Royal Eye Infirmary and to the Weymouth and District Hospital, died at Chandler's Ford, Hampshire, on March 1 at the age of 94. The eldest son of the Rev. J. T. H. Du Boulay, Hubert Houssemayne Du Boulay was born on December 8, 1860, and was educated at Winchester College, where his father was a house-master. He received his medical training at Guy's Hospital and qualified by taking the M.R.C.S. in 1885 and the L.R.C.P. in the following year. After qualification he studied ophthalmology at Leeds, and then, in 1889, he settled in general practice at Weymouth in partnership with Dr. Christopher Childs, and soon afterwards was appointed assistant surgeon to the Weymouth and Dorset County Royal Eye Infirmary. A little later he became general surgeon at the Royal Hospital, Weymouth, where he worked in close association with the late Dr. P. S. B. Wetherall. In 1921 he, together with Dr. Wetherall, Dr. J. Macpherson Lawrie, and Dr. T. H. Sanderson-Wells, was instrumental in amalgamating the Royal Hospital with the Princess Christian Hospital, to become the Weymouth and District Hospital. When he retired from practice in 1924 he became consulting surgeon to the eye infirmary and to the hospital. He then went to live at Chandler's Ford, returning to Weymouth in 1925 to receive the freedom of the borough, and at the time of his death he was the borough's oldest surviving freeman. During the 35 years he was at Weymouth Dr. Du Boulay became a well-known and respected figure. Many years ago he created something of a sensation when he gave up wearing the conventional medical attire of frock-coat and top hat and appeared in an ordinary suit with a bowler hat. Although he practised as a general physician and surgeon he was particularly interested in ophthalmology, and for a long time he was the only ophthalmologist in the town.

He never accepted the panel system and always continued in private practice. He was much better known as an ophthalmologist in south Dorset than a general practitioner, and it is chiefly through his association with the eye infirmary at Weymouth that he is remembered. An associate brother of the Venerable Order of St. John of Jerusalem, he was a lecturer to the St. John Ambulance Brigade and to the ambulance classes of the local railways, and during most of the time he was at Weymouth he acted as surgeon to the old Great Western Railway's provident society. A widower for many years, he devoted much care to his invalid wife during her lifetime. He is survived by two sons, both of whom live in Canada.

Dr. E. VIPONT BROWN, who was in general practice at Manchester for over fifty years, died on February 26 at his home at Yealand Conyers, near Carnforth, Lancashire, where he had been living in retirement since the end of the second world war. He was 92 years of age. Edward Vipont Brown was born at North Shields on February 12, 1863, and was educated at Bootham School, York, where he matriculated in 1880, and at Owens College, Manchester. He then entered St. Bartholomew's Hospital Medical College as a medical student and qualified by taking both the M.R.C.S. and L.S.A. diplomas in 1886. In later life he enjoyed telling how he and other Bart's students would absent themselves from lectures at their own medical school in order to listen to Sir Joseph (later Lord) Lister, who was then teaching at King's, a procedure which, understandably enough, annoyed the professor of surgery at St. Bartholomew's. Pursuing his studies after qualification, he obtained the London M.B. in 1888 and proceeded to the M.D. in 1901. Dr. Vipont Brown settled at Manchester in 1894 in partnership with his brother-in-law, the late Dr. Owen Gwatkin, but the latter had to leave the district soon afterwards for health reasons, and Dr. Vipont Brown succeeded to the practice and soon proved himself to be a good and reliable doctor. In time many of his patients were of the second and often the third generation of the same family, and all came to regard him not only as a doctor but as a friend in whom they could place full confidence and to whom they could always appeal for help. Throughout his long life Dr. Vipont Brown, who was a Quaker, worked hard as a disciple of peace, and he was keenly interested, also, in the temperance movement, being himself a lifelong abstainer, while, as one who attended postgraduate classes until he was in his seventies, it was perhaps natural that he should give his encouragement to adult education. Possessed of the gift of speech, he was in demand as a speaker not only by the Society of Friends but by other denominations as well. All these interests were reflected in his writings. As long ago as 1902 he wrote on Christianity and war, and in other publications he discussed the Quaker aspects of truth, the medical aspects of the temperance question, the effects of alcohol as seen by medical men, and instinct, intelligence, and religion. He became a member of the Manchester Medical Society in 1887 and was a familiar figure at its meetings until he retired at the age of 82. He was auditor of the society in 1894, a member of its committee in 1899, and a vice-president in 1920. A member of the British Medical Association for over sixty-five years, he represented Manchester (South) at the Annual Representative Meeting held at Belfast in 1909. Dr. Vipont Brown was always extremely active and busy. While at school he held the record for the mile, and in his youth cycled from York to Edinburgh on a "penny-farthing" machine. As a young practitioner he usually used a horse and trap to visit his patients, but up to an advanced age he could be seen riding his bicycle, for motor-cars never appealed to him and he could never learn how to drive one. He had the happiness to live long enough to celebrate his diamond wedding anniversary in January this year, and is survived by his widow, formerly Miss Dorothy Crowley, whom he married in 1895. His son carries on the practice at Manchester.

Medico-Legal

FORGOTTEN SWAB

In the Queen's Bench Division on March 15 Mr. Justice Pearson gave judgment for £3,000 damages in favour of Mrs. E. B. J. Urry, aged 31, of Maidenhead, against Mr. Immanuel Bierer, gynaecological surgeon, of London, W.1, and the proprietors of the Harley Street Nursing Home in respect of a caesarean operation at the nursing-home on January 7, 1953. Mrs. Urry complained that a pack about 10 in. (25 cm.) square was left inside her, necessitating an operation on January 13 for its removal.

The defendants denied any negligence. A similar action against the surgeon who assisted at the operation, Dr. Max Odens, was dismissed with costs awarded to him.

Mr. Justice Pearson, giving judgment, said the nursing-home and the theatre sister, Mrs. Gwendolen Cole, had and deserved to have the highest reputation. Mr. Bierer had long and wide experience and held a number of appointments. The nursing-home provided the packs. Mr. Bierer had not operated at the nursing-home before nor had he operated with the same theatre sister. His Lordship said the surgeon normally asked the theatre sister if swabs were correct. Then there was what might be called the ritual of the sister's count of the used packs together with any outstanding pack or packs left for the surgeon's use later. Mrs. Cole's evidence was that on this occasion there were eleven used packs and one available for Mr. Bierer. Mrs. Cole and her assistant both counted the packs audibly, and Mrs. Cole ended by pointing out the twelfth and last pack, which was available for Mr. Bierer. The judge said his view on the balance of probabilities was that it was a pre-count pack which was left behind. On that assumption, it followed that there was an error in the count, and it had been admitted that on that finding there was negligence and the nursing-home was liable.

Mr. Bierer had agreed, said the judge, that the surgeon had a duty to take reasonable precautions against leaving a pack behind, but thought that duty was performed by relying solely and exclusively on the sister's count of the swabs. His lordship found that it was not proved that that was in accordance with any approved practice. The sister's count was fallible, and some other precaution was needed. The fact that some other precaution was also fallible was not a sufficient reason against adopting it. Both Mr. Bierer and the theatre sister failed in their respective duties, and if either duty had been performed the pack would not have been left behind. There was no reason to divide the responsibility other than equally. Mrs. Urry's pain and suffering had been very great, and there would be a third operation to remove the scar and internal adhesions. There was some hope that physically she would be completely cured. Psychologically there had been terrible damage.

His lordship entered judgment against Mr. Bierer and the nursing-home for Mrs. Urry for £3,000 damages with costs. On a counter claim by the nursing-home for fees judgment was entered for £270 against the plaintiff's husband, Mr. Urry, who was given judgment for £1,146 as agreed special damages. A stay of execution with regard to £2,000 of the damages awarded to Mrs. Urry was granted pending the consideration of an appeal.

The Medical Defence Union instructed Messrs. Hempsons, solicitors, to act for Mr. Bierer and Dr. Odens.

HOSPITAL BOARD PAYS UP

In 1950 and 1951 a radiologist was employed by the South-west Metropolitan Regional Hospital Board as a part-time locumtenent consultant radiologist at various hospitals. On a number of occasions he was engaged to and did undertake a total of more than nine sessions per week, when he was employed in two or more such locumtenent posts concurrently. When he asked for payment at the rate of 3½ guineas

for each session he was told that under paragraph 7 of the Terms and Conditions of Service of Hospital Medical and Dental Staff (England and Wales) and by virtue of a Ministry of Health circular R.H.B. 49 (115) he was not entitled to be paid for more than nine sessions in any week, however many he had actually performed. As a result the board withheld the sum of £102 18s. from his remuneration. After considerable correspondence the radiologist issued a writ against the board. He has now been informed that the board proposes to pay his claim in full.

The Medical Defence Union instructed Messrs. Hempsons, solicitors, to act for the radiologist.

Medical Notes in Parliament

Teething Powders

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) asked the Minister of Health what advice he had received on the association of mercury poisoning in infants, following the ingestion of teething powders or tablets containing mercury, with pink disease; how many infants had died within the last two years from pink disease, and how many from mercurial poisoning; and in how many cases both factors applied. Mr. IAIN MACLEOD, replying on March 14, said he was advised that the degree of association between mercury poisoning and pink disease had not been clearly established. Many cases of pink disease had no demonstrable association with ingestion of mercury, and the great majority of children who had been given mercurial preparations showed no sign of the disease. It seemed possible that some few infants might have an exceptional sensitivity to mercury. In 1952 and 1953, 64 children under 5 years old were certified as dying from pink disease, and 4 from mercury poisoning; in 2 cases both pink disease and mercury poisoning were mentioned in the death certificate.

Pneumoconiosis Diagnosis

Mr. W. N. WARBEY (Buxton, Lab.) asked the Minister of Pensions and National Insurance whether he would institute an inquiry into the causes of the wide variation in the proportion of pneumoconiosis claims diagnosed as such by the pneumoconiosis medical panels in the different areas. Mr. OSBERT PEAKE replied on March 14 that he did not think the inquiry suggested would serve any useful purpose. Mr. WARBEY said that the wide variation was causing a good deal of unrest in the mining industry. It was as high as 78% in Scotland and 70% in the West Midlands, and as low as 47% in the East Midlands. Now that the scheme had been working for some years would it not be a good thing to have an inquiry, both into the diagnostic criteria and into the question whether it was really a good thing to have a panel of medical experts functioning as a final appeal tribunal for claims to benefit? Mr. PEAKE said that he could not accept that the proportion of successful claims in different districts showed that there was any wide variation in diagnosis in those districts. Conditions giving rise to the disease, the form of the disease itself, and the awareness of the risk of disease, varied greatly from district to district.

1914-18 War Pensioners

Mr. C. J. SIMMONS (Brierley Hill, Lab.) on March 14 asked the Minister of Pensions and National Insurance whether he had considered the opinion expressed in the Report of the Rock Carling Committee that some limbless and other seriously wounded men of the 1914-18 war found their disabilities more burdensome in advancing years, and had now reached a stage deserving of reconsideration; and what action he proposed to take in this matter. Mr. OSBERT PEAKE said that he was always willing to review the case of any war pensioner who applied to have his assessment reconsidered on the ground that his war disablement had grown worse. There were, he also said, 23,000 limbless pensioners, and 356 increases of assessment had been made between the

merger of the Ministries of Pensions and National Insurance in September, 1953, and the end of 1954. There were 144,000 other wounded from the first world war, and 1,000 had been given increases.

Factory Accidents

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) asked the Minister of Labour on March 15 whether he had noted the unsatisfactory figures for the number of accidents that occurred among women and girls in factories and establishments supervised by the Inspectorate of Labour; and what steps were being taken to bring the accident rate among these groups to a lower level. Mr. HAROLD WATKINSON, the Parliamentary Secretary, replied that the Chief Inspector of Factories again drew attention to the unsatisfactory trend of these accidents in his last annual report, and urged that industry should devote more thought to means of reducing the number of accidents to female workers. Inspectors of factories paid attention to this problem in their inspections of establishments employing female workers. The National Joint Advisory Council had appointed a subcommittee to make recommendations on the means by which greater freedom from accidents to workpeople generally might be achieved. He would not agree with a submission by Dr. Stross that the inspectorate tended to become grossly weakened year by year in the technical skill of its entrants. It was, he said, a special problem that had been clearly outlined, and there was an expert subcommittee working on it. He agreed with Mr. F. LEE (Newton, Lab.) that more safety committees inside some types of factory would do a great deal to help.

Vole Vaccine

Mr. JOHN RANKIN (Glasgow, Tradeston, Lab.) asked the Secretary of State for Scotland on March 15 if he had reached any conclusions as to the effectiveness of vole vaccine in the treatment of tuberculosis, as the result of the inoculations given to the children at Bridge of Weir Home. Mr. J. STUART replied that vole vaccine, like B.C.G. vaccine, was a protection against tuberculosis, not a form of treatment. So far as could be established by testing all those who were vaccinated, the effectiveness of the two vaccines was closely comparable. There had been no cases of tuberculosis in the Homes since vaccination began in 1951.

Helicopter Ambulance

Mr. J. GRIMOND (Orkney and Zetland, L.) asked the Secretary of State for Scotland on March 15 if he would arrange for a helicopter to be available in cases of emergency for serious medical cases in the Highlands, especially in islands on which the present air ambulance could not land. Mr. J. STUART said that while he was advised that there were risks in using single-engined helicopters on over-water crossings, he was considering with the First Lord of the Admiralty the extent to which use could be made of naval helicopters in extreme medical emergencies.

Resettlement in Malaya

Mr. H. HOPKINSON, Minister of State, Colonial Office, stated in answer to Mrs. LENA JEGGER (Holborn and St. Pancras South, Lab.) on March 16, that every resettlement village in Malaya had either a dispensary or a maternal and child health centre. In 1954 medical work in these "New Villages" was provided for by grants of \$2,500,000 to the Governments of the States and Settlements, and \$1,350,000 to the Red Cross, the St. John Ambulance Brigade, and the missions, all of which had since 1952 been making a magnificent contribution under emergency conditions in the rural areas.

Food and Drugs Act.—The date of bringing into operation the Food and Drugs Amendment Act has not yet been decided, but the Minister intends to bring it into force as soon as possible.

Industrial Diseases.—The Beney Committee appointed to inquire into industrial diseases not covered by the Industrial Injuries Acts is understood to be working on its report.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending March 5 (No. 9) and corresponding week 1954.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Vital Statistics

Infectious Diseases

The only large variations in the trends of the notifications of infectious diseases in England and Wales during the week ending March 5 were increases of 2,753 for measles, from 23,700 to 26,453, and 160 for whooping-cough, from 1,678 to 1,838.

The largest increases in the incidence of measles were 718 in London, from 2,694 to 3,412, 551 in Yorkshire West Riding, from 3,335 to 3,886, 446 in Kent, from 986 to 1,432, 346 in Essex, from 1,392 to 1,738, 224 in Derbyshire, from 998 to 1,222, 195 in Warwickshire, from 1,579 to 1,774, 192 in Surrey, from 807 to 999, 192 in Middlesex, from 616 to 808, 146 in Nottinghamshire, from 1,275 to 1,421, and the only large fall was 124 in Hertfordshire from 319 to 195. 648 cases of scarlet fever were notified, being 27 fewer than in the preceding week, and no large variations were recorded in the trends. The largest rises in the incidence of whooping-cough were 53 in Lancashire, from 158 to 211, and 35 in Kent, from 80 to 115. 17 cases of diphtheria, 4 more than in the preceding week, were notified.

14 cases of acute poliomyelitis were notified. These cases were 2 more for both paralytic and non-paralytic cases than in the preceding week. The multiple notifications were Yorkshire West Riding 5 (Leeds C.B. 2) and London 2.

For the ninth consecutive week a rise has been reported in the number of notifications of dysentery. During the week reviewed 1,265 cases were notified, an increase of 28. The largest returns were Lancashire 524 (Blackpool C.B. 155, Oldham C.B. 115, Blackburn C.B. 102, Manchester C.B. 30, Liverpool C.B. 20, Royton U.D. 18, St. Helens C.B. 12, Chadderton U.D. 12, Darwen M.B. 12, Lytham St. Anne's M.B. 12), Northumberland 95 (Newcastle-upon-Tyne C.B. 30, Morpeth M.B. 19, Whitley Bay, M.B. 17), Yorkshire West Riding 85 (Huddersfield C.B. 29, Leeds C.B. 21), London 64 (Chelsea 9, Durham 62 (South Shields C.B. 10, Easington R.D. 10, Lanchester R.D. 10), Norfolk 50 (Norwich C.B. 30), Northamptonshire 47 (Northampton C.B. 31, Kettering M.B. 13), Leicestershire 37 (Leicester C.B. 24), Cheshire 37 (Stockport C.B. 22), Surrey 27 (Egham U.D. 13), Nottinghamshire 26 (Beeston and Stapleford U.D. 12, East Retford M.B. 10), Glamorganshire 26, and Yorkshire North Riding 20 (Middlesbrough C.B. 19).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the nine years 1946-54 (influenza, 1952-4) are shown thus -----, the figures for 1955 thus ————. Except for the curves showing notifications in 1955, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Week Ending March 12

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 780, whooping-cough 1,881, diphtheria 9, measles 25,321, acute pneumonia 958, acute poliomyelitis 11, dysentery 1,407, paratyphoid fever 8.

Universities and Colleges

UNIVERSITY OF OXFORD

Theodore Williams Scholarships in Pathology have been awarded to Margaret R. Blears (Lady Margaret Hall) and Rosemary E. Troughton (Scholar of Somerville College).

In Congregation on January 20 the following medical degrees were conferred:

B.M.—W. G. Cowell, C. S. K. Ruck, D. Severs, Audrey M. Grumitt, and G. D. H. Lynne-Davies (in absence).

UNIVERSITY OF LONDON

In Convocation on January 8 it was announced that Dr. Patricia M. Elliott had been elected and Dr. C. A. H. Franklyn re-elected as representatives of the Faculty of Medicine on the Standing Committee of Convocation for a period of three years.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

Drs. W. R. Shanahan and O. M. P. Tobias were admitted to the Membership of the College on February 4 and Dr. K. M. Basu on March 4 (in absentia).

The Services

The *London Gazette* has announced the following awards:

Third Clasp to the Territorial Efficiency Decoration.—Brigadier A. L. Crockford, D.S.O., O.B.E., M.C., T.D., Q.H.S. (Honorary Colonel of a T.A. Unit).

Second Clasp to the Territorial Efficiency Decoration.—Major J. E. Elliott, T.D., R.A.M.C.

First Clasp to the Territorial Efficiency Decoration.—Captain (Honorary Major) H. E. Blake, R.A.M.C.

Territorial Efficiency Decoration.—Colonel R. W. Raven, O.B.E., Major (Honorary Lieutenant-Colonel) J. H. Haslett, Majors H. W. W. Good and G. H. Smith, Captains (Honorary Majors) E. W. O. Adkins, H. E. Blake, and H. S. Shucksmith, and Captain J. C. Cameron, R.A.M.C.

Medical News

Tetracycline on Prescription.—The Ministry of Health, Department of Health for Scotland, and Ministry of Health and Local Government, Northern Ireland, have arranged with the manufacturers concerned for tetracycline to be available on prescription from April 4. The Health Departments are advised by the Medical Research Council that tetracycline is suitable for the treatment of the same conditions as chlortetracycline ("aureomycin") and oxytetracycline ("terramycin"), and its toxicity is also similar, so that the same precautions should be observed in its employment (see the statement prepared by the Medical Research Council and printed in the *Journal* on October 23, 1954, p. 984).

Committee on Homosexuality and Prostitution.—The special committee of the B.M.A. which is preparing evidence for submission to the Departmental Committee on Homosexuality and Prostitution is considering whether there is any relationship between endocrine factors and some forms of homosexuality. For this purpose it wishes to invite the co-operation of medical practitioners who have among their patients homosexuals prepared to answer certain questions. Will any practitioner willing to assist kindly communicate with the Secretary of the Association, B.M.A. House? All information obtained will be regarded as confidential and anonymity will be preserved. The Secretary would also be glad to hear from practitioners with experience or information relevant to the committee's work.

David Anderson-Berry Prize.—The Royal Society of Edinburgh invites application for the 1956 David Anderson-Berry Prize, consisting of a silver-gilt medal and a sum of about £100. The prize will be awarded to the person who, in the opinion of the council of the Society, has recently produced the best work on the therapeutic effect of x rays on human diseases. Applications, which may be based on both published and unpublished work, must be in the hands of the secretary of the Royal Society of Edinburgh, 22, George Street, Edinburgh, 2, by March 31, 1956.

Alan Newton Prize.—The Royal Australasian College of Surgeons announces that the subject for the next Alan Newton Prize essay will be "The Pathogenesis and Surgical Treatment of Developmental Abnormalities of the Kidneys and Ureters." The prize is awarded biennially and is open to Fellows of the Royal Colleges of Surgeons of Australasia, England, Edinburgh, and Ireland, and to Fellows in Surgery of the Royal Faculty of Physicians and Surgeons of Glasgow. Essays, not exceeding 75,000 words in length, must reach the secretary of the Royal Australasian College of Surgeons (from whom further details may be obtained), Spring Street, Melbourne, C.I., by December 1, 1956.

Butterworth Gold Medal.—This is an award to be presented annually to the College of General Practitioners by Messrs. Butterworth and Company, the medical publishers, for an essay by a member or associate of the College on a subject connected with general practice. The subject for this year's essay is "The Influence of Home Conditions during the First Five Years of Life on the Physical and Mental Health of Children." Essays, identified by motto only and not exceeding 10,000 words, should be submitted to the chairman of the Awards Committee, College of General Practitioners, 14, Black Friars Lane, London, E.C.4, not later than September 30.

Buckston Browne Prize Essay.—The council of the Harveian Society of London has chosen "Hypertension" as the subject for the next Buckston Browne Prize Essay. The prize, consisting of a medal and £100, is open to any member of the medical profession "registered in the British Isles or Dominions" under the age of 45. The closing date for the receipt of essays is August 31, 1956. Further details

from the hon. secretaries of the society, 11, Chandos Street, Cavendish Square, London, W.1.

Welsh National School of Medicine.—Dr. A. T. JONES, senior administrative medical officer of the Welsh Regional Hospital Board, has been appointed Provost of the Welsh National School of Medicine in succession to Professor R. M. F. PICKEN, who is due to retire on September 30.

Chair of Biochemistry, Sheffield.—Dr. Q. H. GIBSON, at present reader in physiology at Sheffield, has been appointed to the vacant chair of biochemistry from April 1. He succeeds Professor H. A. Krebs, F.R.S., who left on his election last year to the Whitley Professorship of Biochemistry at Oxford. Dr. Gibson graduated at Queen's University, Belfast, in 1941, and from 1941 to 1947 was successively demonstrator and lecturer in physiology at Queen's. In 1947 he moved to the department of physiology at Sheffield. He is particularly interested in haemoglobin, and has published important papers on methaemoglobinemia.

Glasgow Medical Graduates near Sheffield.—Will those interested in forming a Sheffield Region Glasgow University Male Medical Graduates Association communicate with Dr. E. MILLAR, 5, Far Lane, Sheffield, 6?

National Spastics Society.—The society made £270,000 from its Christmas sales appeal at the end of last year. The appointment is now announced of a director-general (Lieutenant-Commander I. R. HENDERSON) to "direct and co-ordinate the increasing work of the society in connexion with its big development programme to help spastic children by opening new treatment centres and clinics throughout the country."

Sir Russell Brock has been awarded the West London Medico-Chirurgical Society's triennial gold medal. It will be presented to him at the annual banquet of the society on June 23 at the Royal College of Surgeons.

Sir Godfrey Huggins, C.H., F.R.C.S.—On February 26 we reported (p. 550) that the Queen had approved the conferment of a viscounty on Sir Godfrey Huggins, Prime Minister of the Federation of Rhodesia and Nyasaland. The name, style, and title are now announced as Viscount Malvern, of Rhodesia and of Bexley in the County of Kent.

COMING EVENTS

Edinburgh Medical Exhibition.—Professor D. M. DUNLOP will open the Edinburgh Medical Exhibition at the Assembly Rooms, George Street, at 11.30 a.m. on April 25. The exhibition will be open daily, 11 a.m. to 6.30 p.m. (7.30 p.m. on April 27), until April 29.

Fertility and Sterility.—Second World Congress will be held in Naples, May 18-26, 1956. Those wishing to contribute papers should get in touch with Dr. G. I. M. SWYER, Obstetric Hospital, University College Hospital, Huntley Street, London, W.C.1.

European Society of Cardiovascular Surgery.—The Fourth Congress will be held at Copenhagen on July 28 and 29, during the week of the International Society of Surgery. On the first day there will be a discussion on "Surgical Treatment of Chronic Pericarditis," and on the second a symposium on angiography will be held with the International Society of Surgery. The subjects of communications and discussions must be received before April 15 by the secretary-general—Dr. G. ARNULF, 41, rue Sainte-Hélène, Lyon, France. The local secretary of the Congress is Dr. A. Gammeltoft, Københavns Amts Sygehus, Copenhagen, to whom application for accommodation in Copenhagen should be made as soon as possible.

Association of Sea and Air Port Health Authorities.—The annual meeting will be held in London, June 8-10. Details from the hon. secretary, Dr. H. C. MAURICE WILLIAMS, Health Department, Civic Centre, Southampton.

NEW ISSUES

British Journal of Pharmacology and Chemotherapy.—The new issue (Vol. 10, No. 1) is now available. The contents include:

- THE MODE OF ACTION OF ANTIHYDROD DRUGS: FURTHER OBSERVATIONS ON IN VITRO INHIBITION OF OXIDATIVE PROTEIN JODINATION.** Russell Fraser, M. G. W. Hanco, and W. R. Pinney.
- IN VITRO TESTS OF CHEMICAL COMPOUNDS ON ASCARIS LUMBRICOIDES AND FASCIOLA HEPATICA.** A. Mackie, G. Marjorie Stewart, A. A. Cuder, and A. L. Misa.
- THE EFFECT OF ANTI-CHOLINESTERASE AGENTS ON THE RAT'S BLOOD PRESSURE.** P. Dirnhuber and H. Cullumbine.
- STUDIES ON THE TOXICITY OF ALKYL TIN COMPOUNDS.** H. B. Stoner, J. M. Barnes, and Janet I. Duff.
- A CORRELATION BETWEEN CHOLINESTERASE INHIBITION AND INCREASE IN MUSCLE TONE IN RABBIT DUODENUM.** Heather Shelley.
- THE ISOLATED HEART OF MYA ARENARIA AS A SENSITIVE PREPARATION FOR THE ASSAY OF ACETYLCHOLINE.** Brodie Hughes.
- THE EFFECTS OF ADRENALINE, NORADRENALINE, AND DIHYDROERGOTAMINE ON EXCISED HUMAN MYOMETRIUM.** William J. Gartell.
- THE EFFECT OF NALORPHINE ON THE ANTI-DIURETIC ACTION OF MORPHINE IN RATS AND MEN.** H. Schniedner and E. K. Blackmore.
- HISTAMINE RELEASE AND THE "STRESS" PHENOMENON.** P. A. Nasmyth.
- THE FORMALDEHYDE DERIVATIVES OF AMINO ACIDS AND THE MODE OF ACTION OF A FORMALDEHYDE-TYROSINE DERIVATIVE AGAINST INFLUENZA A VIRUS IN OVO.** Lois Dickinson.
- THE ACTION OF LYSERGIC ACID DIETHYLAMIDE ON MAMMALIAN CHOLINESTERASES.** R. H. S. Thompson, A. Tickner, and G. R. Webster.
- CARDIOVASCULAR AND RESPIRATORY ACTIONS OF 5-HYDROXYTRYPTAMINE IN THE CAT.** S. R. Kotteroda and Joan C. Mott.
- ANTITUBERCULOUS EFFECTS OF CERTAIN SURFACE-ACTIVE POLYALKYLENE ETHERS.** J. W. Cornforth, P. D'Arcy Hart, G. A. Nicholls, R. J. W. Rees, and J. A. Stock.
- HISTAMINE RELEASE IN RABBIT BLOOD BY DEXTRAN AND DEXTRAN SULPHATE.** C. G. Haining.
- THE SPASMODIC PROPERTIES OF THIOPHENYLIC ACID ESTERS AND RELATED COMPOUNDS.** M. W. Parkes.
- THE EFFECT OF COMPOUND 48/80 ON GANGLIONIC TRANSMISSION.** S. B. Gertner.
- THE EFFECTS OF SODIUM SALICYLATE ON BLOOD GLUCOSE IN THE RAT.** M. J. H. Smith.
- THE THERAPEUTIC ACTIVITY OF SOME SULPHONES AND SULPHOXIDES IN EXPERIMENTAL TUBERCULOSIS OF GUINEA-PIGS.** S. K. Gupta and R. N. Chakravarti.
- OBSERVATIONS ON Ω -AMINO-POLYMETHYLENE TRIMETHYLAMMONIUM COMPOUNDS.** R. B. Barlow, H. Blaschko, Jean M. Humms, and U. Trendelenburg.
- THE ACTION OF HETEROCYCLIC BISQUATERNARY COMPOUNDS, ESPECIALLY OF A PYRROLIDINIUM SERIES.** D. F. J. Mason and R. Wien.

Issued quarterly; annual subscription £4 4s.; single copy 25s.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, March 28

- INSTITUTE OF ORTHOPAEDICS.**—5 p.m., Dr. W. R. Bett: Medical Writing—The Use of Medical Libraries and the Preparation of Papers for Medical Journals.
- MEDICAL SOCIETY OF LONDON.**—8.30 p.m., discussion to be introduced by Dr J. T. Ingram and Dr. C. Allan Birch: Cutaneous Manifestations of General Disease.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.**—5.15 p.m., Mr. E. G. Muir: Treatment of Cancer of the Rectum; 6.30 p.m., Mr. N. R. Barrett: Mediastinal Tumours.

Tuesday, March 29

- INSTITUTE OF DERMATOLOGY.**—5.30 p.m., Dr. P. M. F. Bishop: Steroid Therapy.
- MIDDLESEX COUNTY MEDICAL SOCIETY.**—At North Middlesex Hospital, Silver Street, Edmonton, N., 3 p.m., clinical meeting.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.**—5.15 p.m., Mr. Rodney Smith: Treatment in Acute Intestinal Obstructions; 6.30 p.m., Professor R. McWhirter: Tumours of High Radiosensitivity.
- ROYAL STATISTICAL SOCIETY: STUDY CIRCLE ON MEDICAL STATISTICS.**—At Westminster Medical School, 6 p.m., Dr. C. J. Donellan, Dr. K. W. Cross, and Professor R. M. Tumuss: Hospital Statistics: A Discussion of Ends and Means.
- WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.**—5.30 p.m., Mr. G. C. Knight: Diagnosis and Treatment of Facial Pain and Trigeminal Neuralgia.

Wednesday, March 30

- INSTITUTE OF DERMATOLOGY.**—5.30 p.m., Dr. R. W. Riddell: Trends in the Study of Mycotic Diseases.
- INSTITUTE OF UROLOGY.**—4.30 for 5 p.m., Dr. E. G. B. Calvert: Surgery and the Diabetic.
- LONDON UNIVERSITY.**—At St. Thomas's Hospital Medical School, 5 p.m., special university lecture in pharmacology by Professor Mark Nickerson (Maritoba): Specific Inhibition of Adrenergic Responses.
- MANSFIELD MEDICAL SOCIETY.**—At Mansfield and District General Hospital, 8.30 p.m., Dr. C. M. Fletcher: Miners' Lung. Members of the Nottinghamshire Branch, B.M.A. are invited.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.**—5.15 p.m., Professor R. S. Pilcher: Pathology and Treatment of Bronchiectasis; 6.30 p.m., Mr. D. J. Browne: Congenital Dislocation of the Hip.
- ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.**—3.30 p.m., Mr. I. Minton: Prevention of Blindness in Infancy and Childhood (illustrated).
- ST. MARYLEBONE HOSPITAL FOR PSYCHIATRY AND CHILD GUIDANCE.**—5.30 p.m., Dr. J. Flint: Psychosomatic Disorders.

Thursday, March 31

- INSTITUTE OF DERMATOLOGY.**—5.30 p.m., Dr. W. R. Bett: Medical Writing.
- LIVERPOOL MEDICAL INSTITUTION.**—8 p.m., annual meeting; 8.30 p.m., Mr. R. Roaf: Hospitals and Medical Schools in India.
- ROYAL ARMY MEDICAL COLLEGE.**—5 p.m., Dr. B. E. Schlesinger: Indications for Cortisone Therapy in Paediatrics.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.**—5.30 p.m., Otolaryngology Lecture by Professor Lambert Rogers: Vascular Diseases in Relation to Otolaryngology.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.**—6.30 p.m., Mr. T. Holmes Sellers: Constrictive Pericarditis.
- ROYAL EYE HOSPITAL.**—5.30 p.m., Dr. T. H. Whittington: Some Aspects of Refraction Work: (6) Hypermetropic and Myopic Patients Compared.
- SOCIETY OF ANAESTHETISTS OF SOUTH WALES.**—At Seabank Hotel, Porthcawl, 7.30 for 8 p.m., (1) Dr. E. Harvey Franks: Intra-arterial Thiopentone; (2) Professor W. W. Mushin: Trilene Analgesia in Midwifery; (3) Dr. W. W. Mapleson, Ph.D.: Things Aren't Always What They Seem; (4) Dr. H. G. Middleton: Anaesthesia in the Treatment of Burns.

Friday, April 1

- INSTITUTE OF DISEASES OF THE CHEST.**—5 p.m., radiological demonstration by Dr. Franklin G. Wood.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.**—5.15 p.m., Mr. N. C. Tanner: Treatment of Cancer of the Stomach; 6.30 p.m., Mr. E. W. Riches: Retention of Urine.
- SOCIETY OF MEDICAL OFFICERS OF HEALTH: WELSH BRANCH.**—At B.M.A. House, 195, Newport Road, Cardiff, 6.30 p.m., joint meeting with West of England Industrial Medical Officers. Discussion: Foot Hygiene. Speakers: (a) Mr. Gwyn James, (b) an Industrial Medical Officer, (c) a representative of the British Boot, Shoe, and Allied Trades Research Association.
- WHITTINGTON CLINICO-PATHOLOGICAL SOCIETY.**—At Archway Wing, Whittington Hospital, N., 5.15 p.m., demonstration by Dr. A. L. Jacobs. Illustrated lecture by Mr. W. W. Davey: Is Your Gastrectomy Really Necessary?

Saturday, April 2

- MIDLAND TUBERCULOSIS SOCIETY.**—At King Edward VII Memorial Sanatorium, Hertford Hill, near Warwick, 3 p.m., clinical meeting and annual general meeting.

APPOINTMENTS

- HOSPITAL FOR SICK CHILDREN,** Great Ormond Street, London, W.C.—Aileen B. Donison, M.B., B.Chir., Assistant Resident Medical Officer, Tadworth Court; Barbara G. Ockenden, M.B., B.S., Assistant Morbid Anatomist; G. C. Lloyd-Roberts, M.B., F.R.C.S., Part-time Consultant Orthopaedic Surgeon; Dragomir Vuckovic, House-physician to Neurological and Neurosurgical Department; J. A. Cheese, M.D., D.C.H., and Rosemary Stephens, M.B., B.S., D.C.H., House-physicians; F. N. Bamford, M.B., Ch.B., House-surgeon.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

- Abraham.**—On March 12, 1955, at the Bristol Maternity Hospital, to Beryl (formerly May), wife of Dr. Ross Abraham, a sister for Lindsay—Susan Diane.
- Bird.**—On March 11, 1955, at the Jessop Hospital for Women, Sheffield, Yorks, to Nora (formerly Bateman), wife of Dr. Julian Bird, a daughter.
- Carstairs.**—On March 5, 1955, to Jean (formerly Dutton), wife of Captain J. R. L. Carstairs, R.A.M.C., British Military Hospital, Up Park Camp, Kingston, Jamaica, British West Indies, a son—Andrew James.
- Herrman.**—On March 14, at Crickhowell, Brecon, to Betty Howarth, M.B., M.R.C.P., wife of G. J. S. Herrman, M.B., a daughter.
- Roche.**—On March 4, 1955, at St. Teresa's Maternity Hospital, Wimbledon, London, S.W., to Susan (formerly Margaret), wife of Dr. G. K. T. Roche, a brother for Patricia, Peter, and Stephen.

DEATHS

- Holker.**—On February 25, 1955, at Withington, Glos, John Holker, M.D., D.Sc., late of Manchester, and Florida, U.S.A.
- Hyslop.**—On February 23, 1955, at Newcastle-upon-Tyne, Vincent Hyslop, M.R.C.S., L.R.C.P., of Newcastle, and 3, Prince Edward Mansions, London, W., aged 61.
- Low.**—On March 4, 1955, at Muirlands, Larbert, Stirlingshire, Nathan Chaim Low, M.D., aged 43.
- Macdonald.**—On February 10, 1955, in a nursing-home, Chrisslelle Macdonald, M.B., Ch.B., of "Dornoch," Golborne, near Warrington, Lancs.
- Macpherson.**—On March 3, 1955, at 9, Bellevue Crescent, Edinburgh, Alexander Macpherson, M.B., Ch.B., late of Accra, Gold Coast.
- Martin.**—On February 20, 1955, at Weston-super-Mare, Somerset, Philip Stanley Martin, M.C., M.R.C.S., L.R.C.P., aged 69.
- Moorhead.**—On February 26, 1955, at "Nantail," Tower Road, Jersey, C.J. John Moorhead, L.R.C.P.&S.Ed., L.R.F.P.S., aged 88.
- Nuttall.**—On February 19, 1955, at Rivermead, Rickmansworth, Herts, Arthur Peel Nuttall, M.D., late of Bury, Lancs, aged 85.
- Palmer.**—On February 26, 1955, at his home, 14, Windlesham Road, Brighton, Charles Spencer Palmer, M.R.C.S., L.R.C.P., late of Redhill, and Torquay, aged 88.
- Parsons.**—On March 4, 1955, at Kirkcudbright, Wilfred Parsons, M.R.C.S., L.R.C.P., Major, R.A.M.C., retired, of Colchester, Essex, aged 76.
- Powell.**—On February 27, 1955, at Pemberton House, Hay, Hereford, Hubert Wybrants Powell, L.R.C.P.&S.Ed., L.R.F.P.S., formerly of Passage West, Co. Cork.
- Reed.**—On February 20, 1955, at The Vicarage, Westbury-on-Trym, Bristol, William Henry Reed, L.M.S.S.A., formerly of Charlton, London, S.E., aged 90.
- Russ.**—On February 26, 1955, Charles Russ, M.B., of 7, Carlton Road, Ealing, London, W.
- Scruby.**—On March 2, 1955, Zilla Mary Scruby, M.B., B.S., D.P.H., of "Corrie," 21, Newton Road, Cambridge.
- Shipsey.**—On March 4, 1955, at Hospital of St. John and St. Elizabeth, London, N.W., William Edward Shipsey, L.R.C.P.&S.I. & L.M., of Beckenham, Kent.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Breads for Diabetics

Q.—Which of the various kinds of special breads is best for diabetics?

A.—There is not a great deal of difference between the carbohydrate values of the various proprietary diabetic breads. They vary from about 10 to 14 g. of carbohydrate per ounce (28 g.) compared with about 12.5 g. for wholemeal and 15.2 g. for white bread. The chief advantage of the special breads is that they are lighter in texture so that a greater bulk goes to the ounce. For example, four slices of one brand of diabetic loaf contain about 10 g. of carbohydrate, which is the same as one small slice of ordinary bread. The choice of bread for any individual diabetic is a matter of taste, but it should be realized that whichever bread is used the actual weight eaten for a given carbohydrate intake will not vary much, although the size of the slices may.

Head Lice

Q.—What is the most effective (a) prophylactic and (b) curative treatment for a girl, aged 7, who is being constantly reinfected at school by other children harbouring head lice? The child is clean, from a good home, and well cared for.

A.—It is not definitely known how, or to what extent, lice spread among children at school. One possibility is the use of communal hair brushes and combs, and if they are provided by the school in question the girl should be told not to use them. A short and easily combed hair style might be adopted as being less liable to become infested.

The best treatment for head lice is a thorough combing with a fine-toothed metal comb (a "Sacker" comb) to remove nits, followed by the application of an efficient insecticide. One of the best is 0.2% aqueous suspension of gammabenzene hexachloride (lindane); 2% dicophane (D.D.T.) emulsion is nearly as good. About 5–15 ml. is applied and rubbed in. The insecticide is imperceptible and should not be washed off for a week, when a further treatment is applied after a shampoo.

These insecticides could be applied regularly as prophylactics, though it is unfortunate that this should be necessary. If the girl's medical adviser is convinced that school is the source of the trouble, he might bring the matter to the attention of the school medical officer.

Prognosis and Treatment of Asthma in Children

Q.—May I seek your advice on the prognosis of asthmatic bronchitis in children and its treatment? My son, 3 years old, started the attacks a year ago after whooping-cough. The attack begins with coryza, then cough, and within a day or two wheezing and dyspnoea develop. He is also subject to urticaria. As the attack progresses the respiratory rate drops slowly to reach normal within two days. Chest radiography showed increased hilar shadow.

A.—The prognosis of asthmatic bronchitis in children is good, especially so under favourable environmental circumstances. Collins¹ in the United States has shown that the annual case rate for asthma decreases from 3.3 per 1,000 in the under 5 years of age to 0.7 per 1,000 in the age group 15–19 years (based on records of 9,000 families in 18 States visited periodically for twelve months).

Prophylactic treatment is based on reducing the tendency to nasopharyngeal and chest infection. Adequate sleep, avoidance of excessive excitement and over-tiredness, adequate vitamins, prevention of chilling by correct clothing

and warmth in the bedroom in the colder months, together with the avoidance of transference of colds from other members of the family by correct hygiene are basic requirements. It is unlikely for there to be any focus of infection in the upper respiratory tract at the age of 3 years, but the advice of an E.N.T. specialist might be obtained. Vaccines are of doubtful value. Prophylactic antibiotic therapy is perhaps best left as a last resort until all other measures have failed, and one should bear in mind the natural tendency to improve. The possibility of extrinsic allergens, foods and inhalants, playing a subsidiary or even occasionally precipitating part must be considered, especially in a child with urticaria; nor should the psychological factor be overlooked.

The treatment of the attack should start at the onset of the coryza, when there is presumably a temperature, with warmth and plenty of fluids and glucose. Antibiotics (preferably by mouth) should be given early on, at least as soon as the cough develops, and continued until the attack and temperature have ceased. The usual treatment with ephedrine and expectorants, to relieve spasm and liquefy the sputum, should also be started as soon as the cough and wheeze occur.

Sterilizing Infected Laundry

Q.—As an economy measure all laundry from a fever hospital is in future to be sent to a communal laundry for hospitals in the group. Prior to dispatch it must be "suitably sterilized." What method is recommended? One view is that a formalin candle would be sufficient.

A.—The procedure advised in the Medical Research Council Memorandum *The Control of Cross Infection in Hospitals* (Memorandum No. 11, 1951) is soaking overnight in a 1 in 160 solution of an efficient disinfectant of the "white fluid" type. Exposure to a low concentration of formaldehyde at room temperature, besides being more difficult to provide for, would probably fail to disinfect heavily soiled linen.

Fertility in Unilateral Cryptorchidism

Q.—A man of 35 with one undescended testicle, untreated, wishes to marry. The penis, the testicle present, and the secondary sexual characteristics appear normal. He has never had intercourse, but experiences desire and has had erections. His general health and development are satisfactory. Is he likely to be normally potent, and what is the prognosis as regards fertility? Is any treatment or investigation recommended? He is one of four children, and his fiancée comes from a fairly fertile family.

A.—From the information given, there seems no reason to doubt that this man would be normally potent, but the prognosis as regards fertility is less certain. If, in fact, the scrotal testis is normal, then he should be normally fertile, but it is a matter of experience that the scrotal testis in a case of unilateral cryptorchidism is often dysplastic to a varying extent even though it may always have been fully descended.

On the whole I would advise against investigation at this stage, since the decision to marry should not be contingent upon the certainty of fertility. If, however, the patient has other views, then of course a seminal analysis should settle the point.

"Ronicol"

Q.—Can you please tell me what are the dangers of, and contraindication to, giving "ronicol" a trial in the treatment of baldness?

A.—"Ronicol" (β -pyridyl carbinol) has a dilating effect upon the small arteries and arterioles. This lowers the peripheral vascular resistance and tends to lower the blood pressure. Large doses may therefore produce giddiness, faintness, or vasovagal attacks. The dosage should be small to start with and later increased, provided no

signs of intolerance are shown. It is usual to start with 25 mg. orally four-hourly and later increase it to 50 mg.

There are no particular contraindications to the use of this drug in otherwise healthy individuals, but it would be unwise to take the drug immediately before a hot bath, as the risk of a vasovagal attack would then be greater.

The observation that a good crop of hair grew on the bald scalps of two patients under treatment with ronicol for intermittent claudication¹ does not seem to have been repeated. Had the beneficial effect of this drug on baldness been established there would be no lack of reports about it, and it seems reasonable to suppose, therefore, that the growth of hair must have been coincidental.

Electrical Alternation in the E.C.G.

Q.—What is the significance of electrical alternation seen in the E.C.G.? Can it occur as an isolated phenomenon, and, if so, what significance does it then have?

A.—This is a fatigue phenomenon and probably means that not all the myocardium can respond every time to each stimulus. It is not uncommon with very fast rates, but occurring with slower rates it means myocardial disease. It is unlikely to be met with as an isolated phenomenon.

Treatment of Cyclical Agranulocytosis

Q.—Is there any known treatment which is effective for cyclical agranulocytosis? The condition has been present for 18 months in a boy of 8. Splenectomy has been considered, but in view of its uncertainty postponed. The matter is one of urgency, as the child's life is endangered during each incident of neutropenia, in some of which the granulocyte count falls to nil.

A.—There is no effective specific treatment for cyclical agranulocytosis, so far as the writer knows. A.C.T.H. has been used in several patients, but does not seem to be of benefit.¹ However, according to Reimann and de Berardinis,² who reviewed 16 cases, splenectomy produced amelioration of the symptoms or in the severity of the neutropenia in four out of six patients. There also appears to be a possibility of spontaneous improvement, and, if it is decided not to proceed with splenectomy, palliative treatment with antibiotics to cover the periods of agranulocytosis seems to be the best that can be done.

NOTES AND COMMENTS

Oversexed Women.—Dr. MARGUERITE STEWART (London, S.W.4) writes: The reply in "Any Questions?" on oversexed women (February 26, p. 553) is deeply disturbing. It shows the wide cleavage between the materialistic and the Christian approach. To support masturbation as the answer is defeatist, leaving the person feeling degraded at being encouraged to regard a standard of behaviour which she feels less than the highest as adequate for her. In over 25 years of handling of every type of human problem in general practice, I have seen that the miracle of change and victory is possible. This needs to be stated.

Dr. J. KOHARI (London, S.E.11) writes: I was perturbed to note the ignorance of your expert on the problem of the oversexed woman ("Any Questions?" February 26, p. 553). After treating the patient with phenobarbitone and ethisterone he indulged in the praise of masturbation, using the Kinsey report as an authority. Does he suggest this as medical advice, or, if not, why mention it? This is a straightforward example of crooked thinking, because masturbation is connected with sexual stimulation and it is the sexual excitement that we want to cure. The breathlessness of those with congestive cardiac failure is not treated with climbing stairs, or the heartburn of those with peptic ulceration is not treated with irritating spices. Further, let us have the facts right. I would be interested to know whether the 96% of males or 60% of females who in the Kinsey report are said to masturbate applies to those who continuously indulge in this procedure throughout life or do so for a short period, perhaps during puberty while they actually discover the function of

their own body. The oversexed woman cannot be treated with tablets alone without regard to the background of her life. I refer to the reading of stories obsessed with sex and the viewing of similar motion-pictures. I do not wish to be misunderstood. I do not wish to limit anyone in these entertainments, but if my professional advice is sought on the treatment of sexual hyper-excitability then I should advise against them. Nor is this all. This is the negative side of the question. The patient should be told to find other activities—for example, sports, hobbies, social work, etc.—which will divert her mind and sap her unlimited energies. Also it is not a bad idea to have children, as they will probably provide an object for her adoration and an additional outlet for her trouble.

Dr. J. W. DIGNAN (London, E.7) writes: It is regrettable that the note on oversexed women (February 26, p. 553) should, in a medical journal, occupy itself with morals and should proclaim masturbation to be a normal activity free from moral or psychological stigma. One cannot but be startled by the assertion that "such advice would probably be given by most present-day psychiatrists." Surely psychology ranks masturbation as a symptom of an immature personality.

OUR EXPERT writes: I am sorry that my brief comment on masturbation in oversexed women should have caused offence to some readers. My reply was designed for doctors. It seemed reasonable, therefore, to dismiss quite shortly the obvious, time-honoured advice—which Dr. Kohari rightly stresses—by my sentence, "Sensible advice about behaviour, masturbation, and the avoidance of alcohol would doubtless also help." Indeed, every doctor must know that one advises "sports, hobbies, and social work" to men or women who suffer from sexual strain; and for married women childbearing is normally the best solution.

I assumed from the wording of the question that it related to unmarried women, and anyone who advises students and young people will know how, in some cases, the degree of effort needed to suppress sexual tension may be so great as to become in itself almost a whole-time task. For such a person I suggested that it might be better to accept the natural relief of masturbation rather than to be obsessed by a physiological tension which self-discipline, overwork, and over-exercise cannot really suppress. In Victorian times the condemnation of self-relief reached, in this country, fantastic levels: the young were threatened with insanity, impotence, and so on if they indulged in it. Surely thoughtful people nowadays take a more rational attitude. It is often possible for the doctor to give infinite relief by reassuring a patient that this practice will not have damaged his or her future marital capacities.

Dr. Dignan misrepresents what I wrote. I did not state that masturbation is "free from moral and psychological stigma," but I suggested that it might be considered "normal in the celibate adult," although "admittedly the question is a complex one." Dr. Dignan implies that there are absolute standards in matters of psychological maturity: a point of view with which I should not, personally, agree. If a married person prefers masturbation to sexual congress, one would obviously diagnose a condition of psycho-sexual immaturity. But situations differ. Troops when overseas and away from their wives quite often resort to masturbation in preference to infidelity, and that surely does not brand them as immature personalities.

Correction.—Dr. M. I. Drury's address at the foot of his letter on isophane insulin (*Journal*, March 19, p. 730) should have been given as Dublin, not Sunderland.

Books of "Any Questions?"—The second and third volumes of "Any Questions?" are available, price each 7s. 6d. (postage 6d.), from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller. Each contains some 200 selected expert answers, and the third volume a cumulative index to the three published books.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: *Atiology, Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

THE PAEDIATRICIAN'S PART IN THE MATERNITY SERVICES*

BY

N. B. CAPON, M.D., F.R.C.P.

Professor of Child Health, University of Liverpool; Senior Physician, Royal Liverpool Children's Hospital and Alder Hey Children's Hospital, Liverpool; Senior Paediatrician, Liverpool Maternity Hospital

If one turns back to the middle of the eighteenth century the early Bills of Mortality give some idea of the appalling threat to infant life at that time. For instance, during the period 1730-49 almost 75% of the children born in London died before the age of 5 years. No one would contend that the Bills of Mortality presented a fully accurate picture, and at that time there was, of course, no subdivision of infant deaths into neonatal and post-natal groups. But it is reasonable to assume that stillbirths and neonatal deaths were at that time at a level that constituted a national menace. Fortunately for this country, as Sir George Newman indicated in his Charles Heath Lectures (1932), a generation of brilliant general physicians arose during the eighteenth century—men like Mead, Heberden, Haygarth, and Jenner, whose clinical abilities were backed up by a wealth of sound common sense that encouraged them to introduce "preventive" ideas. Some of these men, like Lettsom and Cadogan, called attention to the very high rate of mortality among infants; and the former, in his *Medical Memoirs* (1774) commented upon improvements noted, even at that time, in these words: "In the nurture and management of infants as well as in the treatment of lying-in women, the reformation hath equalled that in the small-pox; by these two circumstances alone incredible numbers have been rescued from the grave."

It was in the same century that the obstetrician (or man-midwife) began to exert a significant influence—men like William Smellie and that famous son of Manchester Charles White, who published in 1773 his remarkable volume *On the Management of Pregnant and Lying-in Women, and the means of curing, but more especially of preventing, the principal disorders to which they are liable*. He strongly recommended antenatal supervision of the mother, and he is therefore entitled to an important place in the history of preventive neonatal paediatrics.

The next major event in the history of my subject was the arrival upon the scene of some of the leaders in public health. Again we find a Manchester man playing a highly important part. Edwin Chadwick—not a doctor—held the office of Secretary to the Poor Law Commission, and in 1842 there appeared his monumental

*Lloyd Roberts Lecture delivered at Manchester on November 23, 1954.

report on the conditions under which the labouring classes lived. This caused a great sensation: the Government set up a Royal Commission in 1843 to consider the facts which had been brought to light, and cities and districts began to appoint medical officers of health. Perhaps I may be permitted to remind you that Liverpool set a fine example in 1847, when she appointed a man of great distinction, Dr. William Duncan, to be the first medical officer of health in the country (Frazer, 1947). Britain was awakening to the need for a co-ordinated attack upon the causes of ill-health in general, and the Board of Health, which might perhaps be described as the great-grandfather of our Ministry of Health, was set up in 1849.

At that time Dr. Lloyd Roberts was 14 years of age, and it is a remarkable fact that his long life in active practice stretched right through the successive eras of the Medical Department of the Privy Council (which in a general sense succeeded the Board of Health), the Local Government Board (1871), and the first year or so of the Ministry of Health (1919). I have no doubt that Lloyd Roberts—a man of alert, progressive mind—read the very able reports prepared by John Simon (later Sir John Simon) when he was Officer in Charge of the Medical Department of the Privy Council, and by Dr. William Farr, who, in 1839, had been appointed Compiler of Abstracts in the newly opened General Register Office. In so far as child health was concerned, it was natural that these men should be occupied mainly with environmental causes of disease—such as sanitation, food, employment, and so forth: but we should particularly note that Farr referred to prematurity as a serious problem, and he stressed not only that infant morbidity should be taken into account as well as infant mortality, but also that more accurate clinical and pathological diagnosis was needed. Both Farr and Simon were far-seeing, courageous workers who never hesitated to express their views in unequivocal terms. It was largely through their remarkable reports that doctors, and the public, began to think constructively about foetal and neonatal mortality and morbidity.

Concern With Infant Mortality

During the last quarter of the nineteenth century there was increasing concern that the downward trend of infant mortality was lagging behind the much more

satisfactory decline of the general death rate. Furthermore, as Chalmers (1918) pointed out, the steady fall of the birth rate was tending to emphasize the comparatively stationary infant mortality rate; and the similarity between the known causes of infant mortality and of physical inefficiency among the survivors began to receive more attention. It is interesting to note, also, that the several commissions of inquiry held after the South African War of 1899-1901 underlined, perhaps rather indirectly, that the health of young children still left much to be desired and was worthy of closer attention. At all events, in the early years of the present century there were several national conferences on infant mortality, and gradually interest became focused upon the mortalities of the early weeks of life, as distinct from those occurring in the subsequent months of the first year.

Indeed, when the seventeenth International Congress of Medicine was held in London in 1913 the Section of Obstetrics and Gynaecology, under the Presidency of Sir Francis Champneys, and with Dr. Lloyd Roberts as one of the Vice-Presidents, held a full discussion on "Infant Mortality in the First Four Weeks of Life." The opening paper was by Dr. Henry Koplik, of New York, and in a masterly address he emphasized, among other things, the close relationship existing between the ills of the newly born baby and the health of both his parents. People were asking whether there might not be fundamental differences between ill-health due to congenital disorders on the one hand, and environmental causes on the other; the threats of nature as distinct from those of nurture, as it was sometimes expressed.

The time was ripe for detailed studies of foetal pathology to be undertaken, and it was fortunate for the further progress of the subject that this work was already in hand in Edinburgh, and that the investigator was an obstetrician, Dr. J. W. Ballantyne. There can be no doubt that he did more than anyone else in his time to preach the essential unity of the mother and her unborn child, with the placenta as go-between; and he gave practical expression to his teaching when he proposed that there should be "pre-maternity" units, with careful antenatal supervision of the mother, not only in her own home but at clinics.

It was my good fortune to know Ballantyne in the later years of his active life, and I am but one of many indebted to him for his guidance and inspiration. The immense experience of foetal and neonatal pathology that he had accumulated, recorded in his two great volumes on antenatal pathology and hygiene (1902-1904) was available to those who took up this line of attack upon the mortalities of antenatal and neonatal life. To quote Ballantyne's own words: "I began this work in a spirit of something very like active curiosity; I have prosecuted it with an ever-deepening interest, and I have brought it thus far with the growing sense that I have been dealing with a subject of tremendous importance for the future of the race and the individual, with, in fact, preventive medicine in its simplest and most hopeful because in its earliest aspects." These are the words of a true pioneer, and among those who came after him I give first place to Eardley Holland (now Sir Eardley Holland), whose brilliant studies of cranial stress in the foetus (Holland, 1920, 1922) had the double effect of guiding obstetrical practice and of encouraging the promotion of further work upon foetal and neonatal pathology.

Public Reaction

By the end of the first world war in 1918 public opinion was reacting strongly and constructively to the terrible loss of about one million young lives during the preceding four years; and in official circles note was being taken of the fact that during the last quarter of 1918, for the first time since the establishment of civil registration, there was an excess of deaths over births amounting to 79,443. Sir Walter Fletcher, Secretary of the Medical Research Council, had appreciated the significance of Holland's work, and his Council sponsored a scheme of pathological investigation of stillbirths and neonatal deaths in a number of centres (London, Edinburgh, Glasgow, Cardiff, and Liverpool, where I was fortunate to be the worker), and a joint report was published (Holland and Lane-Claypon, 1926).

Perhaps the greatest benefit that came from this 1919-23 epoch was that it stimulated the medical profession to take a much closer and more detailed interest in babies and the dangers which threatened them before, during, and immediately after birth. And as a natural consequence obstetricians saw to it that children's physicians with special experience of the newly born were invited to become associated with them in their work. This was indeed a novel development of the greatest significance, for it meant that individual status was to be accorded, in a practical way, to newly born babies, who from then onwards were to be regarded as *persons* entitled to enjoy the care of doctors specially charged with this duty.

I should like, on behalf of my fellow paediatricians, to express our gratitude to the obstetricians for the generous and friendly welcome they extended to us when we began to encroach upon their field of activity. If it is true that in their own early history obstetricians thought it discreet to enter the lying-in chamber on all fours, I have no doubt that their professional ability and tact soon gave them entitlement to assume the erect position. But having achieved this more comfortable posture, they might reasonably have expected to be able to advance boldly across the room without over-the-shoulder glances to see whether another figure was creeping along in the rear. All the more credit, then, to the broadmindedness and wisdom of obstetricians. I, personally, can never be grateful enough for the happiness I have enjoyed and the interest I have found in working with them. And it is highly satisfactory to note that the relations between the Royal College of Obstetricians and Gynaecologists and the British Paediatric Association have always been cordial, and have led to useful results.

Scope of the Paediatrician

The paediatrician is now firmly established as an essential member of a team which also includes obstetrician, general practitioner, and medical officer of health; he is held mainly responsible for the specialist paediatric care of newly born babies, both in maternity units and, when required, in domiciliary midwifery. His scope has widened out of all recognition during the past 30 years, as I know from personal experience; and during the same period many factors, including better obstetrics, more enlightened nursing care, and a general upgrading of the social, environmental, economic, and dietetic circumstances of the mothers, have combined to cause a considerable decline of the stillbirth rate and the neonatal mortality rate. The neonatal morbidity rate is more difficult to measure than the mortality rate, but I am convinced that with the exception of neonatal infection—to which I refer later—there has been a corresponding improvement. Even congenital malformations, which are probably no less frequent than formerly, now cause less anxiety because the prospects of effective treatment are much more hopeful, provided that diagnosis is made early and accurately and that highly skilled specialist aid is available.

As it will be necessary for me to call attention to some of the less satisfactory conditions under which our paediatric work is done in maternity hospitals, let me first try to

maintain a proper sense of proportion by giving you a brief statement summarizing the outcome when 1,000 babies (including hospital and domiciliary cases) are born in a large city like Liverpool. I think you will agree that in a general sense the results are satisfactory—in fact, very satisfactory in comparison with former times, yet undoubtedly capable of being improved. Taking the year 1950 as my example, 963 of the 1,000 babies survived not only the neonatal period but the whole of the relatively dangerous first year of life. (For comparison, it may be pointed out that in 1920 only 920 of these babies would have lived longer than one year.) Some 20 of the 1,000 babies died during the neonatal period and 11 or 12 of them had been born prematurely. In addition to the 20 neonatal deaths, there was an additional loss of 17 babies during the remainder of the first year.

About 80 of the 1,000 babies were born prematurely, and 11 or 12 of them died in the neonatal period. Babies with a birth weight under 4½ lb. (2 kg.) are in need of special care and supervision, and 35 (44%) of the 80 came into this category.

When considering loss of infant life associated with pregnancy, labour, and the neonatal period one must also take stillbirths into account. In 1950 there were in Liverpool 23 stillbirths to be remembered alongside each group of 1,000 live births.

The full statistics for 1950 showed that in Liverpool there were 16,485 births, of which 375 (or 22.7 per thousand) were stillbirths. The neonatal deaths numbered 316 (or 19.6 per thousand live births). About 65 to 70% of all births took place in the four main maternity units.

The paediatrician has important duties in connexion with the general nursing care of the babies, their feeding (both breast-feeding and, when necessary, artificial feeding), the diagnosis and treatment of their diseases, and the measures which should be taken to prevent neonatal infection. He may be responsible for the breast-milk bank, and for B.C.G. inoculation (Gaisford and Griffiths, 1954). The variety of his clinical experience is wide, but I shall comment only upon the four chief problems that confront him—namely, congenital malformations, birth injury and asphyxia, prematurity, and neonatal infections.

Congenital Deformities

There are, of course, many varieties of malformation, ranging in severity from a small supernumerary digit to a gross deformity of the skull and brain, such as anencephaly. In live-born babies the incidence of deformity is found to be about 2 to 3%; and in a series of 8,716 live-born infants recently reported by Harris and Steinberg (1954) the frequency of obvious defects was found to be at least 5%. Even a relatively slight deformity, such as a birthmark on the skin or deformed toes, should be regarded as a possible psychological or physical handicap to the individual in later life. The paediatrician needs to know not only the kind of treatment available but where it can be obtained and the best time for its application (Craig, 1954).

The diagnosis of some of the internal malformations, like oesophageal atresia, tracheo-oesophageal fistula, duodenal stenosis, and some varieties of cardiovascular deformity—to mention only a few of our problems—may be difficult, involving radiological and other special examinations. Yet many of these deformities of internal organs, which in the past were usually fatal, now receive successful treatment if the expert surgeon and anaesthetist are given their opportunity by accurate and early diagnosis. In every large district there should be a suitably staffed and equipped surgical centre for the reception of these cases from the surrounding area. Centralization is essential if the surgeons, anaesthetists, and nurses are to become thoroughly competent. At the Liverpool Neonatal Surgical Unit, in Alder Hey Children's Hospital, there are eight cots, and during the year ending May, 1953, 120 babies were admitted, and 101 of these patients required major operations.

Birth Injury and Asphyxia

To speak of birth injury and neonatal asphyxia (or anoxia, to use the more modern word) together is reasonable: from the clinical point of view, because the two conditions are often combined. But we have learnt—largely as a result of the outstanding contribution made by Barcroft (1946) and his colleagues, and Barclay *et al.* (1944)—to think of this subject in terms of physiology rather than pathology; we have to ask ourselves whether the baby's oxygen requirements are being met before, during, and after birth. In each case our study is of a moving picture, so to speak, that extends from before the onset of labour to some hours, or even days, after its termination; and harmful influences may operate, in varying and complicated fashion, from either the maternal or the foetal side. For instance, the foetus may be in a state of anoxia before birth if the mother is unhealthy or the placenta is abnormal; if there is accidental haemorrhage or placenta praevia; or when the child is post-mature and has outlived his placenta. During birth itself the influence of birth trauma (especially intracranial) or of drugs and anaesthetics administered to the mother may interfere with the child's ability to expand his lungs immediately after birth. Obstruction of the baby's air-passages by liquor amnii or blood is another possible cause of asphyxia. Ballantyne used to speak of the "physiological readjustments at birth," comprising a variety of changes which must occur if the baby is to make a successful transition from foetal life to the separate, independent mode of living that we all know. The onset of pulmonary respiration is the most important and dramatic of these physiological readjustments, and the fact that it must of necessity occur almost simultaneously with the physical stress of the birth process makes one of the major problems in obstetrics.

It is generally accepted that the foetus performs gentle, rhythmic respiratory movements before birth, and inhales liquor amnii into his bronchi. After birth, in the normal case, the liquor drains away from the mouth or is absorbed; and the prenatal respiratory movements become augmented under the influence of cutaneous and chemical stimuli acting through the respiratory centre in the spinal cord. The newly born baby is able to tolerate a relatively low oxygen concentration in his blood (hypoxia) without suffering harm; and indeed Cross *et al.* (1954) have emphasized that hypoxia is a necessity of foetal life and plays an important part in inducing pulmonary respiration. In the past there was a tendency to be over-enthusiastic about resuscitation of the anoxic baby; to-day there is general agreement that the baby should be handled with great care and gentleness, but opinions differ about the details of technique, especially for clearing the air passages of obstruction and for administering oxygen. The subject has been well reviewed by Smith (1948), Potter (1953), and Gairdner (1954). Clearly prevention, when possible, should be the keynote, and as an observer of obstetrics during the past 30 years I have been greatly impressed by the progress made in this direction.

Paediatricians, with the help of radiologists, have learnt to recognize a number of interesting respiratory conditions that may be associated with neonatal asphyxia, such as malformations, interstitial and interlobular emphysema, pneumothorax, pneumomediastinum, pulmonary haemorrhage, and hyaline membrane, with resorption atelectasis; and the possibility of infection, especially pneumonia, must always be remembered.

Prematurity

It is questionable whether there is any branch of medical practice, in any age group from birth to senility, that requires keener clinical acumen and a higher standard of nursing skill than the care of premature babies. When one remembers that about 45,000 premature babies are born each year in England and Wales, and that about 35 to 40% of these—approximately 16,000 infants—are in special need of skilled care, the importance of the subject will be apparent. The mortality rate for premature babies is falling quite well

(Taylor, 1954), and the following figures illustrate our experience in one of the Liverpool maternity units: during the period 1936-9 (inclusive) there were 679 premature births, and 140 (20%) died in the neonatal period; in the period 1949-52 (inclusive) there were 750 premature births, and 95 (12.7%) died. (It should be noted that the percentage of small-weight babies was almost identical in the two groups under consideration.) It is interesting also to note that in the earlier of the two periods mentioned the total death rate (premature stillbirths and deaths of prematures) associated with prematurity was 41.3%, and in the second period 31.3%. Between 1936 and 1952 the perinatal* mortality rate (mature and premature) of this maternity unit fell from 9.6 to 4.4%.

The improved outlook for premature babies is due to many causes—obstetrical, paediatric, nursing, social, etc. So far as their hospital care is concerned, full credit should be given to the modern types of incubator, which allow the child to be nursed naked, in an atmosphere of controlled heat and humidity, and with oxygen supply also under control. The initial period of starvation, used nowadays in many centres, has also proved helpful, though I think it may be overdone; and we believe that retrolental fibroplasia may usually be avoided by care regarding oxygen tension in the incubator.

It is a definite advantage to have the smaller premature babies accommodated together in a "prematurity unit," to which such babies born in their own homes may also be admitted when necessary. The nursing care required by these babies reaches a higher standard when selected sisters and nurses make the subject their special study; and for this the babies must be grouped together rather than scattered in various parts of the hospital; and other members of the hospital's nursing staff may be drafted into the unit to provide basic training. Furthermore, midwives, nurses, and health visitors working under the local authority scheme may also be given postgraduate "refresher" instruction in the prematurity unit. There should be close co-operation between obstetricians, paediatricians, general practitioners, and the medical officer of health in order to ensure that an adequate service is arranged for both the domiciliary and hospital care of prematures; the Newcastle and Bristol schemes, described respectively by Miller and Walton (1954) and the Southmead General Hospital Group Management Committee (1951), illustrate what may be achieved by enthusiasts.

The Joint Committee on Prematurity published a report in 1951 upon the care of premature babies in both urban and rural areas, and it should be consulted by all responsible for maternity arrangements. A valuable survey has recently been made by Crosse (1954), who has done so much for the premature in this country.

Infections

Some infections, such as syphilis, are passed from the mother to her child before birth; but I am speaking mainly of neonatal infections contracted by the child during or after birth, when, as is well known, the body's defence mechanisms are relatively imperfect. I shall not comment upon the clinical forms that infection may take in these young babies, except to say that almost every tissue in the body may be affected; the skin, eyes, respiratory tract, and intestinal tract are the commonest and the most obvious, but we also see pyelonephritis, meningitis, arthritis, osteomyelitis, septicaemia, and a few rarer types. Each neonatal infection, even if trivial when judged by "adult" standards, is potentially dangerous to the child, and constitutes a menace to other babies that are cared for in the same nursery and by the same nursing staff. In my earlier days it was unusual to see any evidence of neonatal infection in private practice. Nowadays the prevalence of such infections, at all events in maternity units, is considerable, and is increasing, as the accompanying table shows.

*Using the term "perinatal" to signify stillbirths plus neonatal deaths.

Neonatal Infections in Maternity Unit "A" Liverpool (Including Eyes, Skin, etc.)

Year	Infants Born Alive	Stillbirths	Neonatal Deaths	Neonatal Infections		Total Infections	%
				Survived	Died		
1932	1,840	137	43	38	3	41	2.2
1937	2,161	135	52	45	5	50	2.3
1942	2,115	107	50	81	2	83	4.0
1947	2,490	100	48	113	16	129	5.2
1952	2,639	83	37	231*	(10 prems) 8 (5 prems)	239	9.0

*Including blepharo-conjunctivitis (115) and skin infections (61).

In the same maternity unit, during the ten-year period 1938-47 inclusive, there were 714 (3.5%) cases of neonatal infection, made up as follows: skin, 217; eyes (non-gonococcal), 413; eyes (gonococcal), 14; respiratory, 59; alimentary, 11. The live births during this period numbered 20,479.

As evidence that this scourge is not a local problem in the Liverpool area, it may be noted that the neonatal infection rate in a maternity unit in a Yorkshire city (April to September, 1953) was 14%, and in a London maternity unit (1951) 11.1%.

It may be argued that a false impression of danger is given by the inclusion of many relatively trivial local infections (especially of the eyes and skin); but even when these are omitted the figures are significant—for example:

Maternity Unit "A," Liverpool, 1952:	
Total live births	2,639
Neonatal infections (excluding eyes and slight skin lesions)	About 95 (3.6%)
Maternity Unit "D," Liverpool, 1953:	
Total live births	2,297
Neonatal infections (excluding eyes and slight skin lesions)	137* (6%)

*Of these, 6 died.

Happily the mortality rate in neonatal infections is usually low, but this fact should not be allowed to encourage complacency. Morbidity is to be considered before mortality, for it is a truer index of the potential danger, not only to the individual patient but to all the other babies in the same ward or nursery.

Here is a problem demanding urgent attention, especially in regard to prevention; and there are at least two possible causes. One is that the natural immunity of babies to infection during the neonatal period is lower than in the past, perhaps as a result of the widespread and sometimes foolish use of antibiotics for trivial diseases, both in hospital and in domiciliary practice. Furthermore, many strains of the common infecting agents are now resistant to penicillin and sometimes to other antibiotics. But the more probable cause is the great and increasing pressure under which maternity units must work, with two disadvantages so far as the babies are concerned: firstly, there is overcrowding; and, secondly, the nurses find much difficulty in not working hurriedly. This statement implies no criticism of the nurses, who deserve congratulation for the splendid and devoted service they give under difficult conditions. We must, however, remember that the nursing care of babies takes time if their delicate skin and other tissues are to be preserved from even the slight trauma that can open the way to infection. The present position is one of danger and should be studied now, before it deteriorates. We are well aware of the pressure exerted upon maternity units to admit more and more patients, sometimes for sociological considerations, sometimes for the obstetrical needs of the mothers; and at present there are limits to hospital expansion and to the recruitment of nurses. But I feel that paediatricians have a duty to emphasize that newly born babies usually remain free of these troublesome infections if their nursing care is given under conditions which permit gentle, thoughtful handling, and when adequate accommodation is available for the infants.

Various steps may be taken, and are usually taken in maternity units, to reduce the present danger to a minimum;

but I must emphasize that a hospital giving service to children of any age must see to it that a patient who is suspected of having a contagious illness (and this includes all types of neonatal infection) shall be segregated at once. I would also urge that, except in special circumstances, the use of antibiotics should be restricted to those patients whose clinical condition indicates that their natural defence mechanisms will not be adequate.

The Door of Opportunity

I now turn to the future and deal with the stimulating opportunities that lie before paediatricians in this fascinating age-period embracing antenatal as well as neonatal life. If there should still be anyone who believes that paediatrics begins only when the child is born, let him turn his thoughts back to 1635, when Sir Thomas Browne wrote: "Every man is some months elder than he bethinks him; for we live, move, have, a being and are subject to the actions of the elements, and the malice of diseases, in that other world, the truest microcosm, the womb of our mother." Clearly the obstacle confronting anyone wishing to study the unborn child is the relative inaccessibility of the subject. Ingalls (1953) has summed up the situation very neatly in these words, "The nearly insurmountable obstacle to clinical study of prenatal sickness arises in the fact that the patient voices no complaint, remembers nothing about his illness, hides himself from view and puts off his visit to the doctor until the last possible moment." But the clinical application of modern techniques now available to physiologists, pathologists, epidemiologists, experimental embryologists, immunologists, biochemists, and physicians is opening up new fields, hitherto largely unexplored. As yet we comprehend little more than this: that before birth the baby is one component in a system made up of several parts or units, each with its sphere of influence; these units are mother, placenta, child, and father (as represented within the child's constitution). Generally speaking, the interrelationships within the system are sufficiently harmonious to maintain a balance within the limits of what we define as health; but we still know little about the fine adjustments by which such balance is maintained.

And the range of possible influences exerted by the individual units is wide—for instance, genetic, hormonal, chemical, immunological, and bacterial. An important phase in this concept of antenatal life was reached when the late F. B. Chavasse coined the phrases "maternal threat" and "foetal threat." It was in 1920, when he was working on the ABO blood groups of mother and child in the Liverpool Maternity Hospital for his M.D. thesis, that he discovered that in some cases there was incompatibility between the bloods. This was in the early days of transfusion studies when immunity reactions in blood-relationships were little understood, and long before the Rh factor was discovered in human blood. Chavasse examined the hypothesis that toxæmia of pregnancy might be caused by foetal (blood) threat to the mother, but he could find no proof. (It is interesting to note that Pike and Dickins (1954) have shown a significant excess of Group O women in a series of 541 patients suffering from toxæmia of pregnancy.)

At the same time I was working on general oedema of the foetus and was able to confirm the findings of Schridde and others that the foetal tissues (especially the liver) in this condition suggest that very active blood regeneration is occurring. I discussed with Chavasse the possibility that maternal (blood) threat to the child might be causing this remarkable response. We were not far from the truth, but neither of us appreciated that maternal threat might be a reaction to foetal (or perhaps more correctly, paternal) threat. I mention this chapter in history to illustrate the complexity of the reactions possible within the system, some advantageous, some dangerous. In general pattern, the adjustments may be as simple and smooth as the up-and-down movements of a seesaw: sometimes they can be likened to a key turning the mechanism in a lock; sometimes the end-results are happy, sometimes harmful or even tragic.

Sir Macfarlane Burnet's (1954) stimulating paper reveals how wide is the scope in regard to immunity-relationships between mother and child; and our knowledge of their hormonal relationships is growing quickly. No matter whether the paediatrician's interests are directed mainly to infections, to heredity, to immune reactions, to nutritional studies, or to any other of the possible fields of work before him, he cannot neglect the remarkable events occurring during antenatal life, and it is in studies such as these, in co-operation with obstetricians and with various specialists whose work is not primarily clinical, that the paediatrician is likely to find his most satisfying and constructive opportunities. But spectacular results may not be achieved for some time, and there are immediate problems to which attention should be given urgently.

Some Urgent Problems

First of these is the still considerable loss of infant life associated with maternity. In 1952, though maternal deaths associated with child-bearing in England and Wales had fallen to 492 (complications of pregnancy, 181; abortion, 90; complications of labour, 130; complications of the puerperium, 91), stillbirths were 15,636, and neonatal deaths 12,331, making a total of 27,967 infants who died before birth, during birth, and in the first four weeks after birth. In 1953 there were 15,681 stillbirths in England and Wales and approximately 12,113 neonatal deaths—a total of 27,794. It would be idle to pretend that, had they lived, all these babies would have been free from deformity and disease. But even when the figures are viewed in a severely critical and unprejudiced light they still come as a shock, especially to those who believe that considerable improvement is possible. One suggestion might be to hold a national investigation; but in my view it would be more valuable to invite a limited number of maternity units, located in different parts of the country, to make a careful investigation of each stillbirth and natal and neonatal death occurring in its practice. A small team composed of obstetrician, paediatrician, and pathologist would review all the circumstances of each fatality, preferably within one week of its occurrence, and would attempt to reach a firm opinion not only upon the primary cause of death but also upon the child's probable state of health if it had survived.

This type of investigation has been made in Aberdeen by Professor D. Baird and his colleagues (1954), and is an important step of great practical significance, though I suggest that its usefulness would be increased by including, as I have already proposed, the whole of the neonatal period in the review. Professor Baird uses the term "obstetric death rate" to include stillbirths and neonatal deaths occurring during the first week of life. This same group of foetal and neonatal deaths has sometimes been called "perinatal mortality," while other writers have included the whole of the neonatal period (the first four weeks after birth) in their definition of perinatal mortality. Clearly the group covered by Baird's "obstetric death rate" is of special concern to obstetricians, as it is also to paediatricians. But, as paediatricians well know, morbidity and mortality during the second, third, and fourth weeks of the neonatal period are by no means negligible and are due partly to delayed "obstetrical" causes—for example, subdural haematoma, haemolytic disease, and various pulmonary conditions; and partly to the special circumstances of neonatal life, with such problems as neonatal infections and failure of breast-feeding.

It is therefore essential that the classification ultimately adopted should take cognizance of happenings during the whole of the neonatal period.

Crosse and Mackintosh (1954) have reported the results of similar studies in Birmingham. I have spent some time making an analysis of the stillbirth and natal and neonatal deaths occurring during the year 1950 in three of the Liverpool maternity units, and as a result of this experience I am confident that findings of much practical importance would

be brought to light by the plan I suggest, and that each individual case inquiry should be conducted by the clinicians in charge and while the details are fresh in their memory.

Still another opportunity for paediatricians will be found in extending the "follow-up" work which takes place now in a number of centres. As I know from experience, this task is difficult, especially when families change their place of residence rather frequently. But we want to know more about the future for post-mature and premature babies, for babies born by caesarean section, for asphyxiated babies, for birth-injured babies, etc. Retrospective studies are not very satisfactory; but the young paediatrician who decides to keep in touch, so far as is possible, with the babies he has seen at their birth will be able to make a valuable contribution not only to paediatrics but also to obstetrics. And such work will help to give him the background essential to one who will undoubtedly find increasing opportunities for the application of what Ingalls (1953) terms "preventive prenatal paediatrics."

Conclusion

Finally, in the planning and working of the maternity service the paediatrician will be invited to make a fuller contribution than has been expected of him in the past, and if he undertakes this task with enthusiasm and in a fully co-operative spirit his services will be invaluable. He can do much to encourage contacts with general practitioners and with all those who carry out maternity duties under the local authority; he can hold "refresher" courses for doctors, midwives, and health visitors, and can use his influence to ensure that those whose work is done mostly in hospitals shall have opportunities for studying maternity and infant welfare work in the homes of the people. He can, and I think he should, seek opportunities for co-operating in the very important work of antenatal clinics, particularly (1) in regard to the education of young mothers in respect of infant welfare, and (2) to encourage breast-feeding, as Professor Gaisford suggested at the 13th Congress of Obstetricians and Gynaecologists at Leeds in 1952.

But the heart of the matter is this, that the paediatrician is now recognized as a full member of the team concerned with maternity and the aftercare of the baby; his future scope is immense, and he is anxious to give his best services.

Summary

The status of newly born babies has been rising steadily for many years, and this movement was greatly accelerated when pathological studies of stillbirths and neonatal deaths were vigorously undertaken during the first two decades of the present century.

The appointment of paediatricians to the staffs of maternity units has already yielded valuable results and is likely to be even more fruitful in the future.

The loss of infant life by stillbirth and neonatal death is still considerable (27,794 in 1953) and should receive fuller attention, along with the problems of morbidity in the neonatal periods.

The pressure under which maternity units are working at the present time presents dangers so far as the babies are concerned. Questions such as the accommodation and nursing care of the babies need careful study if the incidence of neonatal infection is to be reduced and its spread more effectively controlled.

The proper treatment of the premature baby requires special provision in maternity units, and adequate arrangements for the domiciliary care of those that do not require admission to a ward for the premature.

More should be done to give expectant mothers training in mothercraft, and to advise them in regard to diet, hygiene, preparation for breast-feeding, etc. Paediatricians are well equipped to assist in this service.

In studying the causes of stillbirth and neonatal death it is essential that each case should be considered jointly by obstetrician, pathologist, and paediatrician, bearing in mind that several causes may operate simultaneously or in succession. These causes may be primarily maternal, paternal, placental, or foetal. Conclusions based upon studies made mainly from one angle, whether obstetrical, pathological, or paediatric, are open to the criticism of over-simplification. In each case of stillbirth or neonatal death it is necessary that an agreed aetiological "priority order" should be reached. And if, as is reasonable, the conclusions are to be of value in preventing morbidity as well as mortality in young infants the studies should not be restricted to the antenatal period and the first week after birth, but should include the whole of the neonatal period.

I wish to express gratitude to my colleagues Drs. J. D. Hay, F. P. Hudson, and Anne McCandless, who have paediatric charge in three of the Liverpool maternity units; and to Sir Arthur Gemmell, President of the Royal College of Obstetricians and Gynaecologists; Professor D. Baird; Dr. J. A. Scott, Medical Officer of Health, London County Council; Dr. Dorothy Taylor, Ministry of Health; and Professor Andrew Semple, Medical Officer of Health of Liverpool, and Dr. Vida Stark, for their assistance.

ORAL PREPARATIONS OF RAUWOLFIA SERPENTINA IN TREATMENT OF ESSENTIAL HYPERTENSION

BY

S. LOCKET, M.B., M.R.C.P.

Senior Physician, Oldchurch Hospital, Romford, Essex

The older Indian literature records the liberal use over several centuries of preparations of the roots of *Rauwolfia* species, and particularly *Rauwolfia serpentina*, for the treatment of dysentery, snakebites, and fever (? malaria). In more recent times these preparations have been used in India as sedatives and also for insomnia and insanity. By the end of the seventeenth century this use of rauwolfia root as a sedative had apparently reached Europe. The genus *Rauwolfia* belongs to the Apocynaceae and contains some 40 to 50 species, but *R. serpentina*, a large twining shrub found in India and Malaya, appears to be the main member used for these purposes, and it is therefore this plant whose roots were credited with all these most desirable qualities.

Preparations of these roots of *R. serpentina* were found to have definite hypotensive properties when tried in animals (Chopra *et al.*, 1933) in addition to producing hypnotic and sedative effects. This hypotensive action on the blood pressure has apparently been confirmed in varying degree in hypertensive patients (Vakil, 1940, 1949; Bhatia, 1942; Wilkins and Judson, 1953; Ford *et al.*, 1953; Arnold and Bock, 1953; Klausgraber, 1953; Joiner and Kauntze, 1954).

The hypotensive and hypnotic action of preparations of *R. serpentina* root would appear to reside in the content of alkaloids, of which some 15 have so far been isolated, two of the most active of these being rescinnamine and reserpine, ester alkaloids chemically related to yohimbine, differing only in the acid moiety (trimethoxycinnamic and trimethoxybenzoic acid). Reserpine makes up about 0.1% of crude preparations, and would seem in man to be more likely to cause drowsiness and diarrhoea than rescinnamine. In dogs it has only half the hypotensive potency (Cronheim and Toekes, 1955), but there is a marked variation in relative activity of these alkaloids in different animal species. There would also appear to be at least one other, as yet unidentified, highly active alkaloid in the crude extract.

Since, experimentally, rauwolfia does not interfere with transmission at the autonomic ganglia and in therapeutic dosage is neither adrenolytic nor sympatholytic, it has been suggested that the hypothalamus is the site of its activity, but this has not been proved.

Our past experience when using recommended hypotensive agents given by mouth for the treatment of essential hypertension had been most unsatisfactory. When rauwolfia became available two years ago it was therefore decided that a carefully controlled trial was essential. A prolonged period of observation by observers, if possible unchanged during the trial, of a suitable series of hypertensive patients in need of treatment, using each patient as his own control, would, it was felt, be most likely to yield results of any value at this stage of our knowledge of the treatment of hypertension.

This paper is a report to date of such a trial with a group of 39 severely hypertensive patients (38 of whom had essential hypertension) treated for a minimum period of six months and a maximum period of 20 months with rauwolfia ("rauwilloid").

Type of Hypertensive Subjects Participating and Nature of Drugs Used

The trial was confined entirely to out-patients who were fully ambulatory. So far as was practicable every patient was seen at least once every two weeks, but many were seen far more often, though in some cases these intervals had to be increased. When ill-health caused a patient to take to bed or be admitted to hospital, he or she was immediately excluded from the trial from that date, the information then available being used, however, in arriving at our conclusion.

Every patient observed had a minimum diastolic pressure when attending the out-patient department of never less than 130 mm. Hg (see Table). No patient was used in this particular trial who had been known to us for less than six months, and some had been under our observation for several years, a few having participated in our early trials with the oral administration of methonium compounds (Locket *et al.*, 1951, 1952).

All the patients (except one) were suffering primarily, so far as could be judged clinically, from essential hypertension, and none came into the category of labile hypertensives. So far as possible, all cases of severe renal insufficiency from any cause, or any cause of hypertension other than essential hypertension, were excluded. Renal insufficiency developing during the trial did not exclude the patient.

The 39 patients (see Table) consisted of 31 females, average age 55 (range 34-72) and 8 males, average age 47 (range 37-64).

Each patient on attending the out-patient department was given a number by which he was identified to the dispensary during the trial, the numbers being consecutive. According to the number of the patient, using a chart of random numbers, the pharmacist, Mr. Williams, prescribed either control tablets or active drug. At some time later during the course of the trial the patient was changed from active drug to control tablets, or vice versa. At no time were any of the clinicians or patients concerned in the trial informed whether the participant was receiving dummy (control) tablets or active drug.

In the first ten months of the trial the active preparation used was total root extract (1,000 mg. daily). Since then (January, 1954) we have used total active alkaloids (8 mg. daily). We began this trial with the oral preparations known as rauwilloid, and these have been used consistently. However, when the trial was well under way we included some patients receiving other varieties of rauwolfia, with little apparent difference. Sixteen consecutive patients in addition received 8-10 mg. of *Veratrum viride* extract ("veriloid") daily, during their entire observation period—that is, both with control tablets and with active rauwolfia.

In some patients, owing to the persistence of certain symptoms (later proved to be due to the drug), it was thought advisable to reduce the dose to 500 mg. of total rauwolfia extract, or 4 mg. of total active alkaloids, and occasionally even to stop this medication entirely. The clinician nevertheless, though suspecting that he was in these cases giving active drug, did not know this for certain until the final analysis.

Since we could detect little difference in hypotensive effect between 500 and 1,000 mg. of total root extract or between 4 and 8 mg. of total active alkaloids (nor between total extract and total alkaloids), the results of both alkaloids and total extract are considered together.

Method of Classification of Data

In assessing these results the initial observations were confined entirely to the level of the blood pressure, using

The upper figure in columns 3 and 4 records the average untreated blood-pressure level, and the lower two figures the range.
L.V.F. = Left ventricular failure. A. of E. = Angina of effort. Int. C. = Intracranial catastrophe. Cereb. thromb. = Cerebral thrombosis. RE = Rauwolfia total root extract. RA = Rauwolfia total active alkaloids. V = *Veratrum viride* extract. O = No hypotensive action. S = Slight—i.e., fall 10–20 mm. Hg. A = Appreciable—i.e., fall more than 20 mm. Hg. G = Good—i.e., fall to below 100 mm. Hg diastolic and in excess of 30 mm. Hg.

to divide the patients into several separate categories. We then attempted to observe the relationship, if any, between these blood-pressure categories, the patient's symptoms, and any objective findings. In this trial, laboratory and other investigations were those essential for the diagnosis, observation of progress, and treatment of any case of hypertension of this degree of severity.

We were mainly concerned with the level of the diastolic pressure, since there is far less spontaneous variation in the diastolic level than in the systolic in these hypertensives. Also, the future expectation of trouble for these patients depends upon the height of the diastolic pressure.

All readings were obtained with the patient sitting. In every case where these showed a fall or rise in excess of 10 mm. Hg. from earlier pre-trial readings, they were checked on both arms by more than one observer.

The patients were divided into four groups according to the recorded fall of diastolic blood pressure. These were: O = no fall; S = slight consistent fall—that is, 10–20 mm. Hg; A = appreciable fall, greater than 20 mm. but not

falling below the level of 100 mm. Hg; and G = fall to a level consistently below 100 mm. Hg, and the fall was therefore always in excess of 30 mm. Hg (see Figs.).

Results

Of the 39 patients, 16 showed no consistent fall in diastolic blood pressure, 7 a slight fall, 12 an appreciable fall, and 4 a fall to below 100 mm. Hg. Of the 16 patients with no consistent fall in blood pressure, 4 had during the entire trial received either the control tablets alone or with extract of *Veratrum viride*, but never an active rauwolfia preparation. In the other 23 cases (except for one case in group A receiving extract of *V. viride* only) the fall in blood pressure occurred only whilst the patient was receiving the active rauwolfia preparation. When the patient was transferred to the control tablets the blood pressure, after a brief interval, began gradually to rise (see Figs.), and, similarly, transfer to active tablets resulted in a fall. Of 34 patients receiving active rauwolfia tablets at some period during this trial, 22 (67%) showed a fall in blood pressure of varying degree (slight in 21%, appreciable in 34%, and good—that is, to below 100 mm. Hg—in 12%) whilst actually taking the active preparation and not when on the control.

The combination of *V. viride* extract and rauwolfia gave 6 patients out of 13 who showed a hypotensive effect, as against 16 patients who showed a fall in blood pressure out of 21 receiving rauwolfia without additional *V. viride* extract. Nevertheless, the only patient in the trial who showed an appreciable fall in blood pressure without rauwolfia was actually receiving *V. viride* extract, and two of the four patients (see Fig. 2, Cases 14 and 15) in whom the diastolic blood pressure fell to below 100 mm. Hg were receiving both rauwolfia and extract of *V. viride*. It will be seen that the fall in blood pressure in Case 15 antedated the use of rauwolfia slightly, and with cessation of active drug rose slowly to a lower level than the control. This most satisfactory result, too, may be partly due to the *V. viride* extract.

The average age of patients who failed to respond to rauwolfia was 50 (range 34–64), whereas the average age of all patients who responded was 56 (range 44–64). Of the eight males, seven received rauwolfia and six (average age 55.2 years) showed a hypotensive effect (S: 1; A: 2; G: 3). Three of the seven males were receiving *V. viride* extract with the rauwolfia. Of the 31 females, 27 received rauwolfia, and of these 15 (average age 56.6 years) showed a hypotensive effect (S: 6; A: 9; G: 1). Of these 27, 10 were receiving extract of *V. viride*. The average age of the 11 females who did not respond to rauwolfia was 48.3 years.

Albuminuria in varying degree was present in 50% of patients in each of the four categories, but of 10 patients showing papilloedema 6 were in group O, 3 in group S, and only 1 in group A.

FIG. 1.—Graph of Case 7.

FIG. 2.—Graphs of Cases 14 and 15.

There were 8 patients who at the beginning of this trial were complaining of angina of effort—1 each in groups O and G, 2 in group S, and 4 in group A.

Four deaths occurred during the trial. One patient aged 48 who died of uraemia due to chronic nephritis (the only nephritic in the series) failed to show any hypotensive response and was actually receiving active drug at the time of her death. Two other deaths occurred in women aged 41 and 40, from cerebral haemorrhage, and one of these was receiving the active drug at the time of death. The fourth patient, a man aged 56, died of a dissecting aneurysm whilst receiving the control tablets.

In no case did we find a precipitate fall in blood pressure associated with circulatory symptoms due to hypotension which is said to occur due to "hypersensitivity" to the drug, and no patient developed postural hypotension.

In every case in which the patient responded to the drug there was a delay in the onset of the hypotensive effect, usually of 7 to 14 days, but occasionally as long as four weeks elapsed before the fall in blood pressure began. In about half the patients several further weeks on active drug were necessary before the diastolic blood pressure reached its lowest level (see Figs.). Stopping the active drug resulted in a gradual rise of blood pressure level in every case (see Cases 14 and 15, Fig. 2), but again, though in most patients one to two weeks elapsed before the blood pressure reached its previous height, in three patients (two receiving *V. viride* extract) it took at least six to eight weeks for this to happen.

Side-effects

Side-effects were seldom severe enough to necessitate cessation of treatment, though they occurred in more patients than we had been led to believe from reading the published clinical results (Klausgraber, 1953; Meilman, 1953a, 1953b; Vida, 1952). Many patients, while complaining, for example, of diarrhoea, would nevertheless state that they felt better than ever before.

Though within the limits of our trial there was little difference in the hypotensive effects using 4 or 8 mg. of total alkaloids, or alternatively 500 or 1,000 mg. of crude extract, we noticed an appreciably higher incidence of undesirable side-effects with the larger doses. Side-effects, nevertheless, occur at all therapeutic dosage levels.

Depression was complained of by 5 patients (15%), and in fact one patient who had been receiving the active drug for nine weeks with no effect on her blood pressure was admitted to hospital as a case of attempted suicide from coal-gas poisoning. Nine patients (26%) complained of one or more of the following, though rarely in any severe degree—namely, fatigue, lack of energy, drowsiness and muzziness, loss of interest, loss of libido (one male), feeling "strung up inside," and vague general malaise. These symptoms did not bear any relation to the hypotensive effect of the drug, occurring relatively as often in those who failed to respond as in those who responded adequately.

Three patients complained of flashing lights in their field of vision, and in one of these patients this was followed by a period of amaurosis lasting two or three minutes. Another patient had several brief episodes of amaurosis lasting less than a minute. In all four patients eventual transfer to the control tablet produced complete relief of these visual phenomena.

A complaint of buzzing or fullness in the head was made by five patients (15%). Nasal congestion was complained of by five patients (15%), but response to an antihistamine occurred in only two of them.

Three patients complained of nausea and vomiting (one of these was also receiving *V. viride*). Diarrhoea occurred in eight patients (24%), necessitating cessation of treatment in two and halving of the dose of drug in two.

In four cases the side-effects were severe enough for it to be necessary to discontinue the drug (two patients with depression and two with diarrhoea). One patient in fact felt so depressed at work, which he had previously enjoyed,

that he wished to change his job. Within two weeks of stopping the drug he was happy and contented again. A fifth patient, admitted as a case of attempted suicide, had the drug discontinued.

Increase in weight and in appetite occurred three times as often in the group when on the active drug, and two patients gained over 1 stone (6.4 kg.) in weight during five months on the drug. On the other hand, one patient who gained over 1 stone (6.4 kg.) in eight months never received any rauwolfia during this period.

Conclusions and Summary

In a carefully controlled series of 39 severe cases of hypertension (38 with essential hypertension and 1 with nephritic hypertension) treated for 6 to 20 months with rauwolfia preparations, we found a definite consistent fall in blood pressure in 67% of cases when actually receiving active preparations of *R. serpentina*. In most cases there was a proportionate fall in both systolic and diastolic blood pressure, but in several the fall in the diastolic appeared to be relatively greater than in the systolic. The fall was slight (10–20 mm. Hg diastolic) in 21% but appreciable or marked in 46% (greater than 20 mm. Hg diastolic), and in four patients the diastolic blood pressure fell to below 100 mm. Hg. Within the limits of dosage set by this trial, and contrary to some other published work (Meilman, 1953a, 1953b; Wilkins and Judson, 1953), these results did not appear to be appreciably contributed to by the continued simultaneous administration of oral preparations of *V. viride* extract in 13 cases, by hydrazinophthalazine in three cases, or by pentapyrrolidinium bitartrate in two cases. The use of *V. viride* extract seemed, however, to delay the rise of blood pressure, on stopping the rauwolfia. There was suggestive evidence to indicate that the better response occurred in males, and in the older hypertensive patients with arteriosclerotic manifestations, rather than the younger patients, and also that the presence of papilloedema usually meant that those patients would not respond to this drug, or only slightly.

All patients with angina of effort found it necessary to continue to use nitroglycerin, even though in one case the blood pressure dropped to normal figures. There was certainly no worsening of the pain in either its severity or its frequency, but there did not appear to be any real alleviation either.

The presence of albuminuria in varying degree did not significantly affect the hypotensive response.

There was no evidence in this series to suggest that only the mild, labile, or relatively symptomless cases respond. Quite severe cases (as judged by the blood-pressure level), symptomatically incapacitated, frequently responded better than the symptomless and often less severely hypertensive patients. Many symptoms responded well to treatment, but in a way more closely allied to reassurance than to actual specific drugs.

The cessation or amelioration of complaints of headache (but not the severe occipital headache often made worse by reclining), palpitations, precordial discomfort (frequently occurring at rest and not resembling angina of effort), vertigo, and tinnitus occurred in 80% of patients with and without active drug, and appeared to be related to the interest shown in their illness rather than the actual fall in blood pressure. Subjective symptomatic relief and objective improvement in blood-pressure levels did not show the close parallel that might be expected.

It was also our impression that, contrary to the usually accepted belief, once the patient was aware that he had

a "raised blood-pressure" repeated visits to hospital and blood-pressure measurements reassured him quite considerably.

We were not particularly impressed by the sedative or so-called "tranquillizing" action of the drug when given in the doses used by us.

From our experience in this clinical trial we felt that this was by far the most effective and useful orally administered agent for reducing blood-pressure which we have yet used. In our opinion this substance is fully worthy of a trial in every case of essential hypertension in which treatment is thought to be necessary. The severe cases, which always need treatment, are as likely to respond as the mild.

I am grateful for the constant help I received from my house-physicians and registrars, Mr. Williams, the hospital pharmacist, and the staff of the dispensary, as well as from Sister Wills and the nursing staff of the out-patient department of Oldchurch Hospital, while making these observations. This work would, however, never have been possible had it not been for the willing and active co-operation of all the hypertensive patients who have participated. I wish to thank Mr. J. A. Lumley and Riker Laboratories Ltd. for providing an adequate supply of rauwolfia extract and, later, total active alkaloids, control tablets, and *Veratrum viride* extract which enabled this work to be carried out. Finally, I am indebted to Dr. W. S. M. Grieve for many discussions and criticisms, and to my secretary, Mrs. E. D. Price, for her patience and excellent secretarial assistance.

RESERPINE IN HYPERTENSION

BY

INDER SINGH, M.B., B.S., F.R.F.P.S., M.R.C.P.Ed.
Lieutenant-Colonel, I.A.M.C.

Reserpine ("serpasil") is a colourless, crystalline, ester-alkaloid derived from the roots of *Rauwolfia serpentina*, crude and unstandardized preparations of which have been used in the treatment of hypertension for the past 20 years or so. It has a melting-point of 266 to 270° C., and its empirical formula, $C_{33}H_{40}O_9N_2$, contains a pentacyclic nucleus.

It is claimed that reserpine is a single entity and does not produce any of the undesired effects of the unknown alkaloids of the whole root, but possesses only its sedative and antihypertensive actions. The fall in blood pressure is characterized by a gradual beginning and a prolonged duration, and occurs in about two-thirds of all cases of essential hypertension, and may occur in renal hypertension and hypertension associated with hyperthyroidism. The desired effect is obtained even in severe cases and in cases of hypertension which have remained at a fixed level for a considerable time.

The fall of blood pressure is sustained, so that sharp fluctuations do not occur, and the effect may not disappear for several weeks after the drug has been discontinued. Experiments in anaesthetized cats show that

the hypotensive effect cannot be increased beyond a certain point despite the increase in dosage. This is taken to suggest that the drug acts mainly by protecting from abnormal tensile stimuli the autonomic nerve centres which regulate blood pressure. Postural hypotension has not been observed.

The fall in blood pressure is always associated with slowing of the pulse rate and, in some patients, with improved cardiac output. The depth of respiration is somewhat increased, but the rate remains more or less unaltered. Intestinal motility is increased in dogs but not in monkeys or rats. Diarrhoea may occur in human beings.

Reserpine produces a pronounced central sedative effect in cats, rabbits, and dogs. The animals remain quiet and sleep unless disturbed. The sedative effect is not a narcotic effect, and no electroencephalographic changes have been recorded in rats. It also does not protect against convulsant drugs. In man the lethargy is easily counteracted by caffeine or dextro-amphetamine sulphate in small doses. It occurs generally in the earlier stages of administration of larger doses, but even then it usually abates with time. Lower maintenance doses are well tolerated. In most patients there is subjective improvement associated with a sense of well-being.

The minimum lethal dose in rabbits and rats is about 10 mg. per kg., whereas its pharmacological effects are noticeable with doses of 1 µg. per kg. daily for five days. Thus the drug in recommended dosage (see below) has a wide margin of safety. In rabbits the prolonged administration of 0.1 mg. per kg. daily for 12 days or on alternative days for 24 days did not produce any changes in the heart, spleen, liver, kidneys, adrenals, stomach, or intestines. Side-effects in human beings with recommended dosage are mild and tolerable. They consist of nasal congestion—which is relieved by local vasoconstrictors—nausea, anorexia, more frequent or looser stools, headache, dizziness, heaviness of legs, and urticaria, which is relieved by antihistamines.

The initial therapeutic dose is 0.25 mg. three or four times daily, and is continued till the blood pressure falls. This occurs after a latent period, and the cause of delayed action is not known. Massive doses as used in acute experiments are not recommended. Subsequently the daily maintenance dosage may be 0.1 to 1 mg. Patients do not develop tolerance, and withdrawal symptoms do not occur. The drug is not habit-forming and there are no known contraindications to its use.

Literature

Recent clinical reports substantiate the above claims to varying extent. Löffler *et al.* (1953), using reserpine in doses varying from 0.75 to 1.5 mg. a day on 51 hypertensive patients, found that its hypotensive effect was insignificant in 27 and the blood pressure actually was higher than before in 6. In 14 the lowered pressure lasted only 12 days in spite of continued dosage, and in only 4 was the lower pressure sustained throughout the period of observation in hospital. Increase of dosage above 1.5 mg. a day did not increase the hypotensive activity, but it increased the incidence and severity of side-effects: 17 felt fatigued, 11 were depressed, 8 complained of heaviness of the limbs, 5 saw flickers in front of the eyes, 2 had bradycardia, 2 became mentally excited, 1 complained of dryness of the mouth, and 1 had miosis.

Vakil (1953) treated 25 cases with 0.5 mg. twice a day after meals for four weeks followed by a similar two-weeks course after an interval of a fortnight. After four weeks' treatment the systolic pressure dropped by 25 to 68 mm. Hg

in 11 cases, by 10 to 24 mm. in 7, and by less than 10 mm. in 3. In 1 case the systolic pressure was unaltered and 3 showed a rise of 2 to 16 mm. In 5 cases the diastolic pressure dropped by 15 to 26 mm., in 12 by 5 to 14 mm., and in 2 by less than 5 mm. Hg. In 2 cases it was unaltered and 4 showed a rise of 2 to 8 mm. During the two weeks' cessation of treatment, in 2 out of 19 cases the blood pressure fell further, in 9 it continued to remain at the lowered level, in 7 it rose but remained below the pre-treatment level, and in 1 case it returned to the original.

During the second course there was a drop in systolic pressure in 23 cases, but there was a rise in 2. There was a drop in the diastolic pressure in 21 cases, in 2 it remained unaltered, and in 2 it was higher than before. Both the systolic and the diastolic pressures fell in 19 cases. In 1 case, however, the systolic pressure rose and the diastolic pressure fell; the opposite occurred in another case. Four cases responded well to the first course but did not respond to the second; the opposite occurred in 2 cases. Side-effects were mild and infrequent: 4 had weakness, 3 suffered from excessive drowsiness, 2 had diarrhoea, 2 complained of anorexia, 1 had nasal congestion, 1 had frontal headache, and in 1 the existing vertigo was aggravated. Vakil concluded that a good result was likely in one-half to two-thirds of cases of systolic hypertension under 200 mm. Hg, and in practically all cases with pressures above 200.

Doyle and Smirk (1954) found that single doses of 2 or 3 mg. of reserpine by mouth produced a significant fall of blood pressure about four to six hours later. In 6 out of 9 patients the systolic pressure fell by 40 mm. Hg and the diastolic by 20 mm. or more. When 2 or 3 mg. was given thrice daily the blood pressure fell on the first or second day in 16 out of 20 patients. In all of these 16 cases the systolic fall was over 40 mm. Hg, and in 12 of them it was over 60 mm. The diastolic fall was over 25 mm. in 17 out of 20 cases, and more than 45 mm. in 7 of them. Some of the lowest pressures recorded were well below the basal blood-pressure levels. Slight postural hypotension was noticed when the blood pressure had fallen to normal or below normal levels. After discontinuance of the drug the blood pressure continued to remain at a significantly lower level for 12 to 24 hours. With these large doses, however, side-effects were severe. Combination with hexamethonium or pentolinium tartrate ("ansolysen") gave an additive effect, and the lowered blood pressure was more steady than with hexamethonium alone.

Douthwaite (1954) treated 12 cases of chronic benign hypertension with basal blood pressures ranging between 210/120 and 250/160 mm. They had symptoms of high blood pressure for five years or more and associated secondary cardiovascular changes; 2 had retinal haemorrhages and exudate. A sustained reduction of systolic pressure of 30 to 40 mm. and of diastolic pressure of 10 mm. was obtained with a daily dose of 4 mg. in 2 cases and with a daily dose of 8 mg. in 8 cases. Doses of 16 and 8 mg. were ineffective in 2 cases. Bradycardia occurred within three days of treatment, but had no relationship with blood-pressure readings. With a daily dose of 8 mg. 2 cases developed coarse tremor with occasional twitching of limbs, chattering of teeth, and mental distress.

Present Clinical Trial

Reserpine was administered to 24 patients with benign hypertension and to 2 with malignant hypertension. In addition it was given to 1 case of hypertension associated with chronic nephritis, to 2 cases associated with advanced arteriosclerosis, to 1 case associated with thyrotoxicosis, and to 3 cases associated with severe anxiety state.

One case of malignant hypertension and one case of chronic nephritis had advanced renal failure and characteristic changes in the fundus. The second case of malignant hypertension had early renal failure, tachycardia, cardiac asthma, and characteristic fundus changes. Eleven cases of chronic benign hypertension had associated cardiovascular changes, five of them had albuminuria with slightly impaired

renal function, five had fundus changes only, and one suffered badly from cardiac asthma.

Apart from two cases of malignant hypertension and one case of chronic nephritis, all patients were ambulant and went about their ordinary daily work. There were no restrictions in diet or salt intake. Blood-pressure readings were taken immediately the patient reported and subsequently every five minutes till they were constant for at least three readings. To begin with they were taken daily. Later, when the patients were stabilized, they were taken twice or thrice weekly.

All cases had already been under care for periods varying from two months to seven years. Their normal blood-pressure variations were therefore known. All previous treatment, if any, was reasonably discontinued before reserpine was tried. The initial dosage was 0.25 mg. three times a day for systolic pressures below 200 and 0.5 mg. three times a day for systolic pressures above 200.

Results

The effect of reserpine varied a good deal, and depended on the type of hypertension treated and individual susceptibility. The main results are summarized in Table I.

TABLE I.—Effect of Reserpine Treatment in Various Types of Hypertension

Type of Hypertension	Initial B.P.	No. of Cases	Fall of B.P. below				Maintenance Dose of Reserpine (mg. Day)
			145/90	160/100	170/110	185/115	
Benign	165-180	4	4	4	4	4	0.2 to 0.5
	95-115						
	180-200	10	7	10	10	10	0.3 to 1
	90-115						
	180-220	4	0	2	2	0	0.3 to 0.75
	110-120						
	170-240	4	1	0	0	3	0.75 to 1.5
	100-140						
	210-260	1	0	0	0	0	1.5
	140-150						
Malignant	230-290	1	0	1*	0	0	1.25
	125-130						
	165-250	2	0	0	0	0	1.5
Chronic nephritis	110-150						
	185-225	1	0	0	0	0	1.5
Arteriosclerosis	110-125						
	165-265	2	1	0	0	1	0.75
Thyrotoxicosis	70-95						
	165-195	1	0	1	0	0	0.5
Anxiety state	85-95						
	165-185	3	1	2	0	0	0.5 to 0.75
	90-105						

* During periodic fluctuations the basal blood-pressure levels rose to 220/110-120 mm. Hg.

Response in Malignant Hypertension and Chronic Nephritis

With daily doses of 1.5 mg. it was not possible to lower the blood pressure appreciably in malignant hypertension and advanced chronic nephritis. The drop in systolic pressure varied from 20 to 50 mm., and in diastolic pressure from 5 to 25 mm. But these readings were almost within normal fluctuations before treatment, and the net drop did not exceed 20/10 mm. in any case. Gross fluctuations, however, appeared to be less frequent. In all these three cases it was possible to maintain more or less a constant blood pressure between 125/80 and 135/90 throughout the day along with hexamethonium bromide, 25 mg. intramuscularly three-hourly. With the same dose of hexamethonium bromide alone the fluctuations were greater and tolerance was often produced, the lowest readings varying from 125/85 to 170/100.

Response in Benign Hypertension

In benign hypertension it was possible to bring the blood pressure to normal or within reasonable limits in less severe

TABLE II.—Effect of Reserpine Therapy on a Patient's* Blood Pressure

Day:	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	27	29	33	36	40	44	47	50	55	57

* A man aged 38, height 5 ft. 11 in. (180 cm.), weight 198 lb. (90 kg.), with moderate cardiac hypertrophy and normal renal function. Fluctuations in blood pressure before treatment varied from 170/100 to 195/115 mm. Hg.

and less chronic cases, whereas in the more severe and more chronic cases the results obtained were similar to those obtained in malignant hypertension. Periodic fluctuations up to plus 45/20 mm. Hg continued to occur, and to keep the blood pressure at the lower levels the dosage had to be adjusted from time to time. In some individuals rises occurred at irregular intervals on any day for no obvious predisposing cause (Table II). To these fluctuations the rises associated with the ordinary day's work were additive.

Sometimes fluctuations chiefly affecting the systolic pressure also occurred when the patient was resting in bed. Owing to these variations it was impossible to record the basal blood pressure in such cases. These fluctuations during rest were especially noticeable a few days before the blood pressure started falling and during the transition period, when it was actually falling. The systolic and diastolic pressures were not necessarily always proportionately affected either during the transition period or finally when lowered—for example, a case with an initial blood pressure varying from 185/120 to 230/140 finally settled between 140/115 and 150/115, whereas another case with fluctuations between 170/110 and 185/110 settled between 120/80 and 160/100.

With the dosage employed the blood pressure started falling between the fourth and the nineteenth day and continued to do so amidst variations till the lowest level for a particular individual was reached. This took altogether from 9 to 40 days. In 5 out of 24 individuals there was a further fall of blood pressure after it had been more or less constant for periods varying from 6 to 20 days. With the dosage used, however, readings below 115/75 were not obtained in any case. Trials with higher doses at this stage were not undertaken. In seven cases which reached blood-pressure levels round about 120/80 the drug could be discontinued for 3 to 13 days before the blood pressure started to rise again.

The time taken for the blood pressure to fall and the decision whether reserpine could be discontinued for a few or more days were dependent on individual response and were quite unpredictable. It certainly did not depend on the initial blood-pressure level or the duration of the blood pressure, the emotional set-up of the individual, or his weight, age, or sex. For example, in a rather highly strung woman aged 34, who was known to have had hypertension for about two years, the initial basal blood pressure of 185/110 took 19 days to drop to 160/100, 25 days to drop to 130/90, and 40 days to drop to 125/85-90 with reserpine 0.75 mg. daily. Reserpine was discontinued when the blood pressure was 125/85-90, and she showed the first rise to 135/95 after 13 days. On the other hand, a man aged 38 with a similar blood pressure (180/110) for about the same duration, with the same dose, dropped to 130/80 in five days. He required a maintenance dose of 0.3 mg. of reserpine daily, but had a tendency to periodic rises every three to four weeks, during which he required a daily dose of 0.75 mg. The maintenance dose could not be omitted at all in this case, and a day's omission caused an immediate rise to 150/95 or more.

A case of myocardial infarction with two attacks within two years showed a poor response to 0.75 mg. of reserpine daily for 35 days. His blood pressure, which was initially 175/95 to 185/110, continued to fluctuate between 160/95 and 175/105.

In severe cases of benign hypertension in which reserpine alone was not very effective in lowering the blood pressure,

combined therapy with phenobarbitone, mannitol hexanitrate, and hexamethonium had the following effects: phenobarbitone did not aid, mannitol seemed to help, but hexamethonium compounds were very effective. In one case, in which the original basal blood pressure of 230/115 was reduced to 160/90 with reserpine, the equivalents were: 0.25 mg. of reserpine six times daily equalled 0.25 mg. of reserpine plus 375 mg. of hexamethonium bromide three times daily, equalled 50 mg. of hexamethonium bromide intramuscularly four to six times daily, and equalled 750 mg. of hexamethonium bromide six times daily by mouth.

Other Results

Response in Arteriosclerotic Hypertension.—In arteriosclerotic cases both systolic and diastolic pressures fell, as a result of which the pulse pressure still remained relatively high and symptoms such as giddiness, throbbing in the head, and insomnia, were only partially relieved. Day-to-day variations in pressure were greater than in cases of benign hypertension due probably to effects of arteriosclerosis itself.

Response in Hypertension with Anxiety State.—In hypertension associated with anxiety state gross daily fluctuations were mostly controlled, but maintenance doses were relatively high.

Effect of Ordinary Day's Work.—The effect of an ordinary day's work, so far as could be ascertained, showed that fluctuations in blood pressure were quite common when readings were recorded at different times of the day. The fluctuations affected the systolic as well as the diastolic pressures, and rises of 10-35/5-20 mm. Hg were seen. The tendency was to revert towards the pre-treatment basal levels, although usually the rise was not so great. The effect of subsequent rest varied. Some patients took a few minutes to return to pre-exertion levels, while others took two to three hours. For example, a man of 39 suffering from chronic benign hypertension of six years' duration with lowest pre-treatment basal blood pressure of 175/110 and with lowest basal blood pressure of 130/95 under reserpine, 0.75 mg. daily, showed rises up to 165/110, which took nearly three hours to revert to 130/95, whereas a woman of 45, suffering from chronic benign hypertension of about seven years' duration with lowest pre-treatment basal blood pressure of 170/120, and with lowest basal blood pressure of 130/90 under the same dose of reserpine, showed rises up to 140/110, which took only five minutes to revert to 130/90.

Effect of Standard Exercise.—In those patients who reverted to the pre-exertion levels within a few minutes of a standard exercise-tolerance test, reserpine *per se* did not influence the types of responses to exercise. The responses depended entirely on the blood-pressure levels. As the blood pressure fell the patterns described by Fowler and Guz (1954) progressively reverted towards the normal (see Table III).

Postural Hypotension.—Some degree of postural hypotension was present in nearly all patients, especially those with systolic blood pressure above 200 who received reserpine 1.5 mg. daily. The maximum difference recorded between pressures taken lying supine on a bed and sitting up on a chair was plus 20/15 mm. Hg. Under the influence of 1/50 gr. (1.3 mg.) of atropine intravenously this effect was abolished. But the change affected mostly the diastolic pressure, which rose to pre-treatment or almost pre-treatment levels. Thus in one case the blood pressure rose from 220/100 before atropine to 220/120 after atropine.

TABLE III.—Responses to Standard Exercise at Various Blood-pressure Levels in a Case of Chronic Benign Hypertension Under Reserpine Treatment 1.5 mg. Daily. Blood-pressure Readings were Taken in Supine Position

Initial B.P. Level	B.P. Levels at One-minute Intervals							
	0	1	2	3	4	5	6	7
225	195	205	235	230	225	220	215	210
100	105	100	100	100	95	95	105	100
190	215	215	220	212	200	192	185	185
90	100	100	100	100	95	95	95	95
160	195	190	180	175	165	160	155	155
90	95	95	90	90	85	85	85	80

Side-effects

The severity of side-effects was a matter of individual tolerance and the dosage of reserpine used. Nasal congestion, anorexia, dryness of the mouth, depression, muscular weakness, heaviness of limbs, giddiness, diminished vision associated with miosis, and drowsiness occurred with varying severity and frequency. They were more frequent and more pronounced when the dose of reserpine was above 0.75 mg. daily. However, it was possible to tell the patient confidently that these would abate with time. With doses below 0.75 mg. daily, most patients could tolerate the drug comfortably after a few days, usually less than a week. A chronic alcoholic did not complain of any side-effects with 1.5 mg. daily.

Under the influence of the drug slowing of the pulse rate from 20 to 36 beats was a consistent finding. In seven cases the pulse rate slowed down to between 46 and 52 a minute. In one case with a pre-treatment pulse rate of 48 to 52, however, no further reduction took place. It increased with exercise, but remained relatively low. The bradycrotic effect was completely overcome by atropine, 1/50 gr. (1.3 mg.) intravenously. This was less noticeable in the supine position and became maximum when the patient assumed the upright posture. The bradycrotic effect was also influenced by infection. In a patient who developed pneumonia the pulse rate rose from 68 to 110 a minute.

There was no direct relationship between the bradycrotic effect and the degree of fall of blood pressure. For example, in the case mentioned above, although the pulse rate remained constant between 48 and 52, the blood pressure fell from 230/125 to 160/90 with reserpine, 1.5 mg. daily. This patient also complained of precordial discomfort, which was not complained of before. An electrocardiogram showed a prolonged S-T interval. This was also the only change in six other individuals with bradycardia. The second case of malignant hypertension mentioned above, however, developed a silent posterior infarct during the course of treatment. This may be a coincidence, but it does raise a point whether the excessive bradycrotic effect along with the fall of blood pressure favours coronary thrombosis.

The excessive bradycrotic effect caused giddiness in three of the patients with pulse rates between 46 and 52.

When the initial side-effects began to pass off all patients showed subjective improvement. Among the symptoms that were most relieved were headache, giddiness, insomnia, palpitation, and worry. The subjective improvement was not always related to fall of blood pressure or the actual state of the patient, but also appeared to occur independently of them. Thus a patient with malignant hypertension and another with severe chronic benign hypertension who died had felt well during reserpine treatment. A gratifying side-effect was relief from constipation.

Conclusion

Reserpine is a useful drug in the treatment of all types of hypertension. It lowers the blood pressure to normal or to within reasonable limits in all cases of less chronic and less severe benign hypertension, and the same effect may also be obtained in some of the more chronic and severe cases.

In the remaining chronic and severe cases and in malignant hypertension subjective symptoms and early cardiac failure are relieved and treatment with hexamethonium is facilitated. The blood-pressure readings are more steady and the dosage of hexamethonium is lowered. This is a great advantage, as adverse effects of large doses of hexamethonium are avoided.

Summary

Thirty-three cases of hypertension were treated with reserpine—24 had benign hypertension, 2 had malignant hypertension, 1 was associated with chronic nephritis, 2 with arteriosclerosis, 1 with thyrotoxicosis, and 3 with anxiety state.

Fifteen patients whose basal systolic blood pressure at the time of treatment was above 200 mm. Hg were treated with reserpine 1.5 mg. daily. Eighteen patients whose basal systolic blood pressure was below 200 were treated with 0.75 mg. daily. In the former group 2 patients were reduced to below 145/90, 5 below 160/100, 7 below 170/110, and 10 below 185/115. In the latter group 12 patients were reduced to below 145/90 and 18 below 160/100.

More details in relation to previous fluctuations and diastolic pressures are given in Table I.

Lack of adequate response was associated with chronicity of hypertension and myocardial and/or renal failure.

Periodic fluctuations up to plus 45/20 mm. Hg continued to occur, and required suitable adjustment of dosage. In some subjects irregular rises of blood pressure of about the same degree occurred on any day. Fluctuations chiefly affecting the systolic pressure occurred in some patients during rest, and it was not possible to record the basal blood pressure in them. Rises associated with routine daily work varied from plus 10–35 systolic to 5–20 mm. diastolic. The tendency in these circumstances was to revert towards pre-treatment levels, but the rise was never so great.

The blood pressure started falling between the fourth and the nineteenth days, reaching its lowest in 9 to 40 days. Sometimes after being constant for a few days it fell further, but readings below 115/75 were not obtained. In some cases it was possible to discontinue the drug for 3 to 13 days before a rise started again.

Some degree of postural hypertension was present in those who received reserpine in doses of 1.5 mg. daily.

Appreciable additive effects with hexamethonium were obtained.

Side-effects occurred with varying severity and frequency, especially with doses above 0.75 mg. daily. Within a week or so, however, they either cleared or were tolerable. When the side-effects abated there was marked subjective improvement in most cases. Constipation had a tendency to be relieved.

In some patients the bradycrotic effect was very marked and precordial discomfort was complained of. Only a prolonged S-T interval was observed in the electrocardiogram.

The bradycrotic effect was abolished by atropine, but exercise had much less effect on it.

Atropine also abolished postural hypertension. The effect was mainly on the diastolic pressure.

I am indebted to Dr. A. N. Soni, of Ciba Pharma Ltd., for the necessary literature and for a free and generous supply of serpasil, and to all the patients, without whose co-operation day-to-day observations would have been impossible.

THE TREATMENT OF ESSENTIAL HYPERTENSION WITH PENTOLINIUM TARTRATE COMBINED WITH RAUWOLFIA ALKALOIDS

BY

C. W. CURTIS BAIN, M.C., D.M., F.R.C.P.
 Senior Physician, Harrogate General Hospital

F. ASHTON, M.B., Ch.B., B.Sc.
 Medical Registrar, Harrogate General Hospital

AND

B. P. JONES, M.B., Ch.B.
 General Practitioner

The autonomic ganglion-blocking agent pentolinium tartrate (pentapyrrolidinium; "ansolysen") is acknowledged to be an effective agent in the control of hypertension (Smirk, 1953). Difficulties have been experienced in its continued use because of the unpleasant effects of its indiscriminate ganglion-blocking activity—for example, constipation, dry mouth, visual disturbances, etc.—which accompany the hypotensive activity. The rauwolfia alkaloids have been in extensive use in India for a variety of conditions for many years. Vakil (1949)

showed that the drug has hypotensive properties. It is a central sedative and also stimulates the smooth musculature of the intestinal tract. The combined use of a rauwolfia alkaloid (reserpine) with pentolinium tartrate was described by Smirk, Doyle, and McQueen (1954), who found that less of the latter was required and that the effect was more sustained. They recommend a method of control by these drugs.

We have used this method, and present a short series of cases in which stabilization had been achieved on pentolinium tartrate alone and which were later restabilized on that drug with the addition of rauwolfia alkaloids ("rauwoiloid" 4 mg.), taken in a single dose each evening.

All the patients had essential hypertension. Their blood pressure before treatment varied from 300/160 to 240/130. None had evidence of renal involvement. The average dose of pentolinium tartrate when given alone was 840 mg. a day. The average daily dose of that drug when combined with rauwolfia alkaloids was 240 mg., a reduction of over two-thirds. One patient who required 440 mg. of pentolinium tartrate a day was restabilized on the combination with 60 mg. a day.

The corresponding decrease in the undesirable effects of the ganglion-blocking agent was very great, and some patients who had found it impossible to continue with pentolinium tartrate alone are now well stabilized and able to live active lives.

Discussion

The combined use of pentolinium tartrate and rauwolfia seems to offer a promising treatment of hypertension. In

Case No.	Sex and Age	B.P.	Clinical Features	Control by Pentolinium Tartrate Alone			Control by Pentolinium Tartrate and Rauwoiloid

P.T. = Pentolinium tartrate.

patients who are already stabilized on pentolinium tartrate alone, the dose on adding rauwolfia has usually been reduced to one-third and final adjustments made from that level.

A patient who has had no previous treatment is given rauwolfia for some weeks, as suggested by Smirk *et al.* (1954). Then pentolinium tartrate is added, starting with 20-mg. doses and increasing by increments of 20 mg. until satisfactory levels are obtained. We have found that a better control is achieved when the drug is given three times rather than twice daily.

The reduction in dosage reduces or abolishes the undesirable effects of the ganglionic blockade. Where formerly postural hypotension was a problem, this has been less evident on the combination. Rauwolfia has been shown to stimulate the intestine, and this, in addition to the smaller dose of pentolinium tartrate required, makes the control of the bowels easier. There is therefore less risk of cumulative effect through retention and subsequent absorption of pentolinium tartrate in the bowel.

Patients have been definite in expressing their views that they are much more comfortable, and have been willing to continue treatment, whereas formerly on pentolinium tartrate alone they were incapacitated by weakness, dry mouth, visual disturbances, constipation, and the variability of effect on the degree of hypotension this produced.

In most cases there is no urgency in the control of the hypertension, and gradual reductions of the blood pressure are better tolerated. The aim should be the maximum reduction which keeps the patient comfortable, since the symptoms and signs of hypertension will regress when the pressures have been reduced to levels which are still above the accepted normal.

It would seem also that, once the diagnosis of essential hypertension has been established, cases are better controlled with the patient living his normal life.

Summary

The use of pentolinium tartrate in combination with rauwolfia alkaloids in the control of essential hypertension is compared with the use of the former drug alone.

The dosage necessary with the combined drugs is greatly reduced.

The undesirable effects of the ganglionic blockade have been much lessened and patients have found the treatment more acceptable.

The Medical Section of the Library Association held a week-end conference in Birmingham on March 25-28. Members were the guests at dinner of the Vice-chancellor (Professor ROBERT AITKEN), in whose absence Professor H. A. CRONNE presided, supported by Professor J. F. D. SHREWSBURY. In a symposium on medical libraries and literature in 1984 the chief topics discussed were the establishment of national editorial assessment boards and a consequent reduction in the number of medical periodicals, academic courses in medical librarianship, changes in the medical profession itself and their effect on library provision, national economic changes and their effects on medical libraries, and the potentialities of new technical methods in documentation. A visit was paid to the Birmingham Medical School, where the sub-dean, Professor C. F. V. SMOUT, announced plans for a new medical library building on a scale commensurate with the other splendidly equipped departments. Special exhibitions of rare medical books were on view, both at the School and at the Birmingham Medical Institute.

INEFFECTIVENESS OF CHICKEN ANTI-ULCER FACTORS IN TREATMENT OF GASTRIC AND DUODENAL ULCER IN MAN

BY

K. BRØCHNER-MORTENSEN, M.D.

N. B. KRARUP, M.D.

E. MEULENGRACHT, M.D., LL.D.

AND

Aa. VIDEBÆK, M.D.

(From the University Hospital of Copenhagen, Medical Department A, and from Bispebjerg Hospital Medical Departments B and C)

The present study, carried out in collaboration with Professor H. Dam, is aimed at deciding whether materials acting prophylactically against gizzard ulcer in chicks have any curative effect in gastric and duodenal ulcer in man. Dam (1954) has set out the reason for undertaking this work.

The development and prevention of ulcers in the muscular stomach (gizzard) of the chick have been described by Dam (1934, 1946, 1951), Dam and Schönheyder (1934), Dam and Segal (1945), Dam, Noer, and Søndergaard (1950), Cheney (1938, 1940, 1942), and others. According to Dam and his associates young chicks reared on an artificial diet containing cod-liver oil develop ulcers which are often severe and may perforate. The disease may be prevented by including in the diet hog liver, calf's brain, or certain extracts therefrom. The prophylactic effect is associated with the lipid fraction as well as with the residue that remains after these organs have undergone extraction with fat solvents. A marked prophylactic effect is obtained by a combination of the lipid extract and an aqueous extract of calf's brain. The aqueous extract contains vitamin B₁₂ and may be replaced by this vitamin. In the lipid extract it is the highly unsaturated fraction of the fatty acids that carries protective activity. Arachidonic acid has shown such effect, while fatty acids from fish oils aggravated the symptom.

Material

We studied 152 patients with gastric or duodenal ulcer. They were admitted to the medical departments B and C of Bispebjerg Hospital and the medical department A of the University Hospital of Copenhagen during the period July 1 to December 1, 1954. Of these patients, 82 were treated with anti-gizzard-ulcer factors and 70 were given placebos. Diagnosis was based on anamnesis, x-ray examination (niche deformation), and, if present, demonstrable haemorrhage. All patients showed typical ulcer symptoms.

The patients in the two groups were chosen at random. Each of the three hospital departments was divided into two halves. All patients with gastric or duodenal ulcer admitted to one half formed the experimental group; those with the same diseases admitted to the other half formed the control group. The groups did not differ significantly in sex, age, location of the ulcer, symptoms, or duration of the disease before admission to hospital (Table I).

Treatment

Patients in the experimental group were given daily for four weeks 80 g. of "preparation A," a granulate consisting of ether extract of calf's brain mixed with three parts of

sucrose. The amount of ether extract in the 80 g. corresponded to 300 g. of fresh brain. The preparation was swilled down with milk or water. In addition, these patients received three times a day one tablet containing 5 µg. of vitamin B₁₂ ("cycobemin") and intrinsic factor corresponding to 1.8 g. of fresh hog pyloric mucosa.

The patients in the control group were given corresponding amounts of "preparation B" (placebo), a granulate consisting of one part of powder of autoclaved milk (at 120° C. for one hour) mixed with three parts of sucrose. Instead of vitamin B₁₂ tablets they received placebo tablets consisting of lactose and potato starch. Patients and nurses did not know which of the preparations given contained the anti-gizzard-ulcer factors.

Both groups were subjected to the following regimen: light confinement to bed for three weeks, thereafter out of bed. All received a purée diet, and, daily, one tablet containing vitamin A, 5,000 I.U.; vitamin D₃, 600 I.U.; vitamin B₁, 3 mg.; vitamin B₂, 3 mg.; vitamin C, 75 mg.; and nicotinamide, 20 mg. Tablets consisting of 0.15 mg. of atropine sulphate, 500 mg. of sodium bicarbonate, and 500 mg. of basic magnesium carbonate were given as required when cardialgia occurred. The number of tablets given daily was carefully recorded.

Preparations A and B were tested for anti-gizzard-ulcer activity in the Department of Biochemistry and Nutrition, Polytechnic Institute, by Mr. E. Søndergaard, as described by Dam, Noer, and Søndergaard (1950), using the mode of graduation of gizzard ulcers introduced by Cheney (1942). Preparation A together with vitamin B₁₂ showed the same

protective activity against gizzard ulcers as was found in earlier experiments (Dam, Noer, and Søndergaard, 1950) for ether extract of calf's brain given with vitamin B₁₂. Preparation B showed no protective effect in the chicken test.

Results

Several criteria were used to evaluate the result of treatment: (1) complaint of pain, which was also estimated by the number of tablets of atropine and alkali consumed; (2) intensity and duration of visible or occult bleeding, measured by benzidine tests on each stool; and (3) comparison of x-ray pictures of the stomach taken just before, during, and after treatment.

Pain.—In the experimental group 50 patients had pain which continued after they had been confined to bed and given the purée diet; 11 had pain all through the experimental period. In the control group 53 patients had pain at the beginning of the treatment, and 10 of these still had pain after four weeks' treatment. Fig. 1 shows that the cardialgia disappeared equally fast in the two groups. After one week's treatment 75% of the experimental group had pain as compared with 78% of the controls; after two weeks 56% and 54% respectively still had pain; and after three weeks 35% and 28% had pain. Fig. 2 shows that the number of atropine and alkali tablets required was a little larger in the experimental group than in the control group.

Haemorrhage.—Fig. 3 expresses the intensity and duration of haemorrhage in the two groups as measured by the number of positive benzidine reactions. Melaena was given 4 points; in cases with occult bleeding an immediately positive benzidine reaction was given 3 points; a reaction which became positive within 30 seconds, 2 points; and a reaction which was positive after 30 to 60 seconds, 1 point. The sum of each day's points for the 82 experimental patients and for the 70 control patients was then calculated as if there were 100 patients in each group. Bleeding diminished at the same rate in the two groups. In the experimental group, 29 had melaena or haematemesis, against 25 in the control group. The average time required for cessation of bleeding in the two groups was 9½ and 10 days respectively. Evaluating the treatment by reduction or disappearance of pain and/or bleeding, as shown in Table II, indicates that the results obtained in the experimental and the control group were approximately equal.

TABLE III.—Radiological Evaluation of Result of Treatment in Experimental and Control Groups. Comparison of X-ray Pictures of Stomach and Duodenum Taken Immediately Before Treatment, After Two and Four Weeks of Treatment, and Again Two Weeks After Cessation of Treatment

	Experimental Group (82 Patients)	Control Group (70 Patients)
Unchanged ..	36 (44%)	30 (43%)
Improved ..	28 (34%)	27 (39%)
Aggravated ..	5 (6%)	3 (4%)
Questionable ..	13 (16%)	10 (14%)

X-ray Examination.—The evaluation of the results of the treatment from a radiological point of view is based on examinations immediately before treatment, after two and four weeks of treatment, and again two weeks after discontinuation of treatment. Only obvious differences have been taken into consideration, especially diminution of niche and marked change in the deformation of the duodenal bulb or the prepyloric canal. In cases of major haemorrhage the ulcer could not always be demonstrated, and thus the x-ray pictures from such patients could not contribute to the evaluation of the treatment. Table III shows the results of the x-ray examination. Also, no difference could be demonstrated radiologically between the experimental and the control group.

Summary and Conclusions

Eighty-two randomly chosen patients with gastric or duodenal ulcer have been treated with "anti-gizzard ulcer factors" (ether extract of calf's brain plus vitamin B₁₂). Seventy similarly chosen control patients were subjected to the same regimen with placebos substituted for "anti-gizzard ulcer factors." After a preliminary short follow-up period the results of the treatment were evaluated. Diminished pain and bleeding and comparison of repeated x-ray examinations were used as criteria. The experimental and the control groups did not differ at all in their response to treatment. "Anti-gizzard ulcer factors" were thus of no value in the treatment of gastric and duodenal ulcer in man.

Thanks are due to A/S Orthana Kemisk Fabrik, Copenhagen, for generous assistance in preparing and furnishing the preparations used in this study.

The Atomic Energy Authority has lent to the Science Museum at South Kensington a large working model of the "B.E.P.O." atomic pile, the larger of the two pioneer piles set up at Harwell. This pile went into operation in July, 1948. It is used for research purposes, and for "cooking" radioactive isotopes for use in medical research and treatment, in agricultural research, and in industry. The model goes through a complete cycle of operations in five minutes, and shows the working of the control and shut-down rods which govern the heat output of the pile, and the movement of the hoist for loading uranium rods into the pile. The uranium rods are the pile's fuel, and during its operation some of the uranium is "burnt up," and the rods become contaminated by the products of combustion. The rods then have to be removed and processed to remove the fission products.

ERYTHRODERMIA WITH LIPOMELANIC RETICULUM-CELL HYPERPLASIA OF LYMPH NODES

(DERMATOPATHIC LYMPHADENITIS)

BY

R. C. NAIRN, M.D., Ph.D.

Senior Lecturer in the Department of Pathology, University of Aberdeen

AND

T. E. ANDERSON, M.D.

Dermatologist, North-eastern Regional Hospital Board, Scotland

The association of an unusual type of hyperplasia of the superficial lymph nodes with certain pruritic skin disorders, first fully discussed by Pautrier and Woringer (1937), has been amply confirmed by subsequent authors (Hurwit, 1942; Soloff, 1942; Laipply, 1948; Obermayer and Fox, 1949; Laipply and White, 1951; Jarrett and Kellett, 1951; Wilson, 1954). There is substantial agreement that the lymph-node change is merely reactive, though there is some doubt whether the condition always remains benign: occasionally it has been found in association with leukaemia (Laipply and White, 1951) or mycosis fungoides (Bluefarb and Webster, 1950).

This syndrome is not a rarity, but its significance is still not generally recognized. The present paper is a clinico-pathological account of 13 further cases, with follow-up of from one to four years, and reaffirms the essentially benign reactive nature of the condition.

The following case reports have been classified in four groups according to the clinical diagnosis.

(a) Generalized Exfoliative Erythrodermia

Case 1.—Female, aged 74 on admission, November, 1951. The eruption had been present for a few months and there was a generalized lymphadenopathy of moderate degree. She gave a history of a previous attack in 1947 which developed at the beginning of a course of gold injections for arthritis. Psychogenic factors were marked. Biopsy of a lymph node from the groin showed pronounced reticulum-cell proliferation to form large pale-staining sheets, though the general architecture of the rest of the gland was well preserved. Eosinophils were numerous; abundant melanin, almost entirely intracellular, was scattered throughout the medulla. There was no lipid or iron pigment. After a short course of A.C.T.H. the skin condition almost settled and the lymphadenopathy subsided. She was discharged in February, 1952, and her own doctor reports that the skin gave no further trouble. The patient died in the summer of 1952 of perforated appendicitis, peritonitis, and carcinoma of the ovary. At necropsy the skin was healed and there was no residual lymphadenopathy or evidence of reticulo-endothelial disease elsewhere.

Case 2.—Male, aged 51 on admission, August, 1952. The eruption, present for 11 months, had begun with pruritus and erythrodermia of the head and neck with rapid generalization. Exfoliation, beginning two months later, was associated with generalized alopecia. Psychogenic factors, profuse sweating, and a burning sensation in the skin were notable features. On admission there was moderate lymphadenopathy and the liver was enlarged 2 cm. below the costal margin. The peripheral blood picture was normal though the sternal marrow was very cellular (10% plasma cells). Biopsy of the skin showed a moderate infiltration of the

superficial dermis by lymphocytes, reticulum cells, neutrophils, eosinophils, and plasma cells. In the lymph nodes there was the characteristic reticulum-cell hyperplasia and infiltration by eosinophils and plasma cells, with deposition of melanin pigment and very little fat; iron pigment was present in small amount. Liver biopsy revealed slight fatty change and the presence of a few eosinophils and plasma cells in the portal tracts. The patient was in hospital for more than a year, during which time he developed polyradicular neuritis and thrombophlebitis of the legs and, later, superficial necrotic changes in the tips of his fingers. The response to general and local measures was slow; most benefit was obtained from A.C.T.H. He was discharged in September, 1953, with his skin condition settled apart from some excoriations of the legs. When seen in December, 1954, the skin condition had remained quiet and the lymphadenopathy had subsided. Biopsy of a node at this time showed no sign of the dermatopathic reaction.

Case 3.—Female, aged 68 on admission, August, 1952. The eruption had been present for five weeks and there was a history of a previous attack in 1942. Her skin showed patchy thickening in addition to the exfoliative erythrodermia and there was marked lymphadenopathy, especially in the epitrochlear nodes. Pruritus was intense and the psychogenic element was very marked. In October, 1952, a vesicobullous phase developed, followed by a thickened and deeply pigmented eruption over the whole integument except the face and the anterior aspect of the trunk. The liver was enlarged 2 cm. below the costal margin though liver-function tests were normal. There was persistent eosinophilia (15–23%) in the peripheral blood. Biopsy of the skin showed a moderate, largely round-celled though slightly pleomorphic infiltrate of the superficial dermis. A lymph node showed reticulum-cell hyperplasia, and slight eosinophil and plasma-cell infiltration. There was abundant melanin but no fat or iron pigment. In May, 1953, she was discharged with the skin condition quiet, though patchy pigmentation was present. This state of affairs persisted, apart from minor localized recurrences associated with emotional upsets, until October, when, according to her own doctor, she became markedly depressed and her skin condition relapsed. She developed oedema of the face, dyspnoea, and ultimately generalized oedema with stupor, and died in November, 1953, with pulmonary oedema. Permission for necropsy was not obtained.

Case 4.—Male, aged 76 on admission, December, 1952. An intensely pruritic exfoliative erythrodermia associated with marked lymphadenopathy had been present for six weeks. Eight per cent. of eosinophils was found in the peripheral blood, and the sternal marrow was normal. Biopsy of the skin showed mild parakeratosis, blurring of the stratum granulosum, and patchy atrophy of the stratum spinosum. There was an abundant, slightly pleomorphic, mononuclear infiltrate in the superficial dermis and a few foci of similar cells were seen near the vessels and glands. The usual reticulum-cell hyperplasia with a notable amount of lipid was found in a superficial lymph node. Melanin was scanty and iron pigment was absent. The skin condition settled slowly and the patient was discharged in June, 1953. He was still clear in December, 1954.

Case 5.—Female, aged 57 on admission, February, 1952. Exfoliative erythrodermia with marked pigmentation, pruritus, and superficial lymphadenopathy had been present for three weeks. Emotional and vasomotor lability was pronounced. The peripheral blood showed mild leucocytosis with eosinophilia up to 33%. The skin condition settled and she was discharged in June, 1952, but further emotional upset precipitated a relapse. She was readmitted in February, 1953, by which time her liver was palpably enlarged. Biopsy of the skin showed the histological features of erythrodermia. The characteristic reticulum-cell reaction and lipid and melanin deposits were found in a superficial lymph node, but there was no iron pigment. A liver biopsy showed many eosinophils in the vascular spaces and a few amongst the cells of the portal tracts; otherwise

there was no abnormality. Her condition improved and she was discharged in March, 1953, since when the erythrodermia has fluctuated; there was a further exfoliative attack in November, 1953. In November, 1954, apart from minimal changes, the skin condition had been inactive for eight months, although some lymphadenopathy had persisted. There was, however, no sign of the reticulum-cell reaction and no melanin in a lymph node taken at this time, though lipid was abundant.

Case 6.—Male, aged 50 on admission, November, 1950. Exfoliative erythrodermia, present for three months, settled with routine treatment in January, 1951. It was subsequently aggravated by contact irritants, and he was readmitted in July with widespread pruritic erythrodermia and axillary and inguinal lymphadenopathy. Eosinophilia was found in the peripheral blood and sternal marrow. The pruritus subsided and the erythrodermia cleared completely by August, 1951, when he was discharged. During the next three years there was only intermittent minor papulation of the face, neck, and flexures of the elbows, except for a slight relapse in January, 1954. Biopsy of the skin and superficial lymph nodes was carried out on three separate occasions during the observation period. In the skin there was a somewhat pleomorphic dermal cellular infiltrate; eosinophils were present in appreciable numbers. The lymph nodes all showed the characteristic reticulum-cell reaction; the amount of melanin was variable. A liver biopsy was normal. In November, 1954, papulation and enlargement of lymph nodes were minimal; biopsy of a node showed no sign of the dermatopathic reaction.

(b) Exfoliative Psoriasis

Case 7.—Female, aged 37 on admission, April, 1952. Psoriasis, present since 1939, had fluctuated in severity until March, 1952, when there was a severe flare-up during treatment. On admission she had extensive psoriasis of the scalp with scattered plaques over the trunk and extremities. Her right ankle was painful and swollen, though there was no radiological evidence of bony change. Slight pyrexia was present and the E.S.R. was 75 mm. in 1 hour (Westergren). "H.P.C." (3-hydroxy-2-phenylcinchoninic acid) therapy was followed by reduction of the ankle swelling, but it caused a vesicular skin reaction, which settled on withdrawal of the drug; the arthropathy then reappeared, this time in the right knee and left wrist. Another course of H.P.C. was tried, but further skin reaction necessitated its gradual replacement by cortisone. In June, 1952, despite the cortisone therapy, joint pains and stiffness increased, especially in the spine. The cortisone was stopped and A.C.T.H. tried instead, but the skin condition deteriorated to a generalized exfoliative erythrodermia accompanied by oedema of the eyelids and ankles. There was no conspicuous enlargement of the superficial lymph nodes. Stiffness gradually extended to most joints, and periarticular swelling and some osteoporosis developed. Further treatment by cortisone and also by mepacrine was ineffective. In October, 1952, the erythrodermia showed no improvement. Biopsy of a superficial lymph node showed sheets of reticulum cells and abundant melanin; lipid and iron pigment were absent. The patient's condition deteriorated and there was increasing pyrexia associated with cough and purulent sputum; enlargement of the liver was now detected. Later in the month she complained of chest pain, and within half an hour became comatose and died. Clinical pathological findings during her illness were not informative until the day before her death, when she was found to have complete agranulocytosis (total leucocyte count, 1,200 per c.mm.); one month before her death her leucocyte count had been normal. At necropsy the findings were those of an acute aleukaemic monocytic leukaemia and exfoliative arthropathic psoriasis.

Case 8.—Female, aged 61 on admission, October, 1952. Psoriasis had been generalized at the age of 16, but subsequently only a few chronic patches had been present until June, 1952, when she developed a generalized exfoliative

attack with intense pruritus. Lymphadenopathy was confined to the inguinal nodes. Biopsy of the skin showed the usual features of psoriasis with an occasional eosinophil in the dermal infiltrate. In an inguinal lymph node there were sheets of reticulum cells, many plasma cells and eosinophils, but no lipid or pigment. She was discharged, very much improved, in December, 1952, and two years later still showed only a few isolated patches of psoriasis and no lymphadenopathy.

Case 9.—Male, aged 51 on admission, November, 1952. Psoriasis had been present intermittently for 35 years, but despite treatment it had become generalized and exfoliative six weeks before admission. In hospital the psoriasis resolved with A.C.T.H. therapy, but superficial lymphadenopathy and hepatomegaly developed. Biopsy of a lymph node showed reticulum-cell sheets with lipid and abundant melanin. In a biopsy of liver there was mild fatty change and some increased cellularity of the portal tracts with minimal pleomorphism. He was discharged almost free of symptoms in February, 1953. In October, 1954, the psoriasis remained minimal though the liver was still enlarged.

Case 10.—Male, aged 55 on admission, April, 1953. This was an example of localized exfoliative psoriasis. A few plaques of psoriasis, mainly on the legs, had been present since 1949; one was at the site of a healed stasis ulcer of the left leg. On admission the psoriatic lesions of the legs were exfoliative and the regional nodes were enlarged. Biopsy of the skin confirmed the clinical diagnosis. A lymph node from the left groin showed reticulum-cell sheets and abundant melanin but no fat or iron pigment. The skin lesions resolved with routine measures and the patient was discharged in May, 1953.

(c) Besnier's Eczema on Ichthyosis

Case 11.—Female, aged 29 on admission, September, 1952. Ichthyosis with severe atopic dermatitis had been present since infancy and there was also a history of asthma. On admission there were widespread excoriations and generalized lymphadenopathy. Emotional lability was pronounced. Biopsy of a superficial lymph node showed reticulum-cell sheets, an abundant infiltration by eosinophils, but only minimal lipid and melanin; iron pigment was absent. Her condition improved and she was discharged a month after admission. When last seen in October, 1954, lichenification and pigmentation of the skin with excoriations were still present; the lymphadenopathy was unchanged.

Case 12.—Female, aged 40 on admission, May, 1953. Ichthyosis with minor atopic dermatitis had been present since infancy and she had had asthma for 10 years. The skin condition had deteriorated during the past three years and on admission was severe and generalized; lymphadenopathy was minimal. Emotional lability was a conspicuous feature. Biopsy of the skin showed a patchy, mainly perivascular, mononuclear infiltrate with slight cellular pleomorphism; the stratum corneum and stratum granulosum were well defined. In a lymph node from the groin there were reticulum-cell sheets with a moderate infiltrate of eosinophils, plasma cells, and lipid-laden cells: melanin and iron pigment were present in small amount. She improved with routine measures and was discharged in July, 1953. In November her skin condition remained controlled, showing only moderate lichenification with minimal scaling. The lymphadenopathy appeared to have subsided. Biopsy of an axillary node at this time revealed no sign of the dermatopathic reaction though there was some infiltration by eosinophils and plasma cells and an occasional particle of iron pigment. In October, 1954, her condition had remained quiet.

(d) Reticulosis

Case 13.—Male, aged 64 on admission, July, 1952. A pruritic skin condition with photosensitivity had been present for six months. On admission erythema with thickening of the skin was generalized apart from the legs and a few

small islands on the front of the chest; there was some exfoliation on the face. The axillary and inguinal nodes were moderately enlarged and the liver was palpable 2 cm. below the costal margin. The peripheral blood and sternal marrow were normal. Biopsy of the skin showed a diffuse, abundant infiltration of the dermis by mononuclear cells; pleomorphism, though present, was not conspicuous. Reticulum-cell sheets with moderate amounts of melanin and iron pigment and minimal lipid were found in a superficial lymph node. The condition was provisionally regarded as pruritic erythrodermia and he was given a course of urethane, which had to be stopped after five weeks because of nausea and vomiting. As the skin had improved vastly and the pruritus had disappeared he was discharged in September, 1952. However, he was readmitted six months later as the eruption had recurred with much scaling. Biopsy of the skin now showed considerably more pleomorphism of the dermal infiltrate. The histological appearances of another lymph node were the same as previously. Biopsy of liver showed minor increase in cellularity of the portal tracts, including a few eosinophils and plasma cells. Further treatment with urethane combined with R 48 (β -naphthyl-di-2-chloroethylamine) until July, 1953, largely controlled the skin condition for a further six weeks, when an acute relapse occurred with severe generalized lymphadenopathy. The peripheral blood showed a leucocytosis (12,700 per c.mm.) with up to 26% eosinophils. He developed extensive oedema and died in November, 1953. Permission for a necropsy was refused.

Clinical Review

The 13 cases described, all showing lymphadenopathy with the characteristic dermatopathic reaction in the nodes, have in common a pruritic skin disorder with exfoliation at some stage. Emotional instability, as emphasized by Jarrett and Kellett, was a feature of seven of our cases, and eosinophilia was found either in the peripheral blood or in the tissues, or both, in all but three psoriatic patients. Case 10 illustrates the fact that a generalized erythrodermia is not essential to the development of the lymph-node picture, since the lymphadenopathy here occurred in the drainage area of a purely localized lesion. Our series showed no sex preponderance (seven females and six males): this is in accord with the observations of Laipply and White, and suggests that the preponderance of males noted by Jarrett and Kellett may have been fortuitous. All the patients were adults, of ages ranging from 29 to 76; other workers have found much the same age distribution.

Pathological Review

Methods.—All tissues were fixed in formol acetate; the lymph nodes were transected as soon as possible, always within 24 hours, and one-half of each was transferred to Carnoy's fluid for paraffin sections. Haematoxylin and eosin staining was used routinely on all specimens. In addition, sections of the lymph nodes were stained for eosinophils (eosin and methylene blue), plasma cells (Unna-Pappenheim), melanin (blackening by Fontana's silver method and bleaching by Mayer's method), iron (Perles), and reticulin (Foot). Frozen sections were stained for fat (Sudan III). The skin sections were also stained for melanin, and the liver biopsies were examined by special stains when required.

Results.—The skin, examined histologically in nine cases, showed the usual features of the different diseases and nothing specifically characteristic of the dermatopathic syndrome.

The lymph nodes were variably enlarged, up to 3 cm. in length, and showed no outstanding macroscopic features to distinguish them from those with simple reactive hyperplasia or grave reticulosis.

The histological changes are summarized in Table I. Reticulum-cell hyperplasia was found in all cases: the reticulum cells occurred in pale-staining sheets in the medullary part of the gland, particularly in the outer part, so

R = Reticulum-cell sheets. S and F = Sinus and follicular hyperplasia respectively.

that they sometimes separated the follicles widely. In all but two cases there was also a minor degree of the more usual type of reactive lymphoid hyperplasia, either sinus or follicular in type, or both. Less constant features were infiltration by eosinophil leucocytes and plasma cells. Foam cells bearing sudanophil fat were found in moderate numbers in 7 out of 12 cases examined by frozen section; they occurred scattered throughout the medulla and especially in or around the sheets of reticulum cells. Melanin pigment, mainly intracellular, was found in all but two cases, and was abundant in six; it occurred anywhere in the medulla, and its deposition seemed to be related to the degree of pigmentation of the skin drained by the node. Iron pigment was found in three cases. Reticulin fibres were scanty in the areas of reticulum-cell hyperplasia; there was no increase of collagen.

The typical histological picture was not restricted to enlarged nodes, as it was often found in those of normal size removed at the same time. The presence of both melanin and lipid together in a single node was noted in only six cases, and in only one were both present in abundance. Because of this we agree with Hurwitt and with Jarrett and Kellett that the term "dermatopathic lymphadenitis" for the reaction is preferable to the older term of "lipomelanotic reticulosis."

For practical reasons we have been unable to obtain much histological evidence about the fate of such glands. So far as can be judged, however, the picture seems to be reversible, since in most of our cases the lymphadenopathy had subsided when the skin condition cleared. In four cases a lymph-node biopsy at this time showed persistence of a little pigment or lipid, but no sign of the dermatopathic reticulum-cell reaction. The lesion therefore should be regarded as a benign reactive change, and its recognition by histopathologists is of great importance. Unfamiliarity with the condition may lead to diagnosis of grave reticulosis or, at best, to guarded opinions.

Liver Biopsies.—We have not been able to find any previous report of the state of the liver during life in this

syndrome. Needle biopsies were performed in five of the present cases with mild hepatomegaly as it was thought desirable to exclude the possibility of a generalized reticulo-endothelial reaction. In none was there any evidence of reticulosis; four showed scanty leucocytic infiltration of the portal tracts and two of these livers were fatty.

Necropsies were performed on two of the four patients who died. One of these (Case 1) died of an unrelated cause and had no sign of generalized reticulosis *post mortem*. The other (Case 7) died of an acute leukaemia, but the question whether this termination was coincidental or not cannot be decided.

Control Observations

In an attempt to establish whether the lymph-node reaction could be found in conditions other than pruritic skin disorders with exfoliation we have investigated cases of pruritic and non-pruritic skin disorders without exfoliation by the methods already described. In addition, many routine lymph-node biopsies of patients without skin disease have been carried out for any evidence of similar changes; in a few of these the full range of staining techniques was used.

The control skin cases, seven in number, were chosen because of the close similarity to the first series: they were all pruritic and had some lymphadenopathy, though none had exfoliation. Their clinical and pathological features are summarized in Table II. The only consistent difference in the histological picture in the lymph nodes from that found in the main series was the absence of reticulum-cell hyperplasia. Some of the other features, apart from iron-pigment, were found in every case, though the changes were usually mild.

The lymph-node changes found in our main series of cases, with the exception of the reticulum-cell hyperplasia, are not specific to exfoliative pruritic skin disorders, or, for that matter, to any skin disorder. This has been made clear by control observations on nodes from routine biopsy and necropsy material from patients without skin disease. We have frequently been able to demonstrate small amounts of melanin or sudanophil lipid in otherwise normal superficial nodes or in those showing only simple reactive hyperplasia: as the likely source of these substances is the skin, it is not surprising that their incidence and intensity in the lymph node be greater in pruritic skin disease. Moreover, it is well known that eosinophil or plasma-cell infiltration is a common finding in many other diseases. Reticulum-cell hyperplasia, on the other hand, appears to be a rarity apart from its association with exfoliative pruritic skin disease: we have found only one example of appreciable hyperplasia of this type in a control series of 100 patients in which 200 superficial or deep nodes, mostly showing simple reactive changes, were specially examined for this feature. We feel, therefore, that the presence with-in a superficial lymph node of reticulum-cell sheets, particularly if associated with a notable deposition of melanin or

TABLE II.—Clinico-pathological Features of Non-exfoliative Cases

Case	Age and Sex	Diagnosis	Duration (Years)	Other Features	Skin Histology	Lymph-node Histology
A	26 M	Besnier's eczema without ichthyosis	25	Asthma. Emotional lability	Conforms with diagnosis	Sinus and follicular hyperplasia
B	36 M	Psoriasis	15	Died of chronic nephritis. P.M. confirmation obtained	Typical	Mild sinus hyperplasia. Moderate amount of melanin
C	33 F	"	20	Treated syphilis		Sinus hyperplasia. Melanin scanty. A few eosinophils and plasma cells
D	58 M	Reticulosis	73	Blood eosinophilia. Hepatomegaly: liver biopsy—mild fatty change	Suggestive of early mycosis fungoides	Follicular hyperplasia. Many eosinophils and moderate amount of melanin
E	49 M	Prurigo	10	Intrinsic cerebral tumour	Erythrodermatous picture	Sinus hyperplasia. Melanin and lipid in small amounts
F	44 M	"	14	Blood eosinophilia. Emotional lability	Non-specific inflammation and eosinophilia	Sinus and follicular hyperplasia. A few eosinophils and small amounts of melanin and lipid
G	56 M	Disseminated neuro-dermatitis	1	Emotional lability	Conforms with diagnosis	Sinus and follicular hyperplasia. Moderate lipid and scanty eosinophils and plasma cells

lipoid, is almost pathognomonic of a dermatosis with exfoliation and pruritus in the skin drained by the node.

The single exception in the control series was found in a lymph node from the lymph drainage area of a malignant melanoma; it contained melanin but no recognizable tumour cells and there were sheets of reticulum cells in the melanotic areas. This isolated observation may be significant, though it could easily be coincidental, since we have not seen another example of this reaction in other equally melanotic nodes. Moreover, it will be recalled that reticulum-cell hyperplasia was absent from the melanotic nodes from our control cases with non-exfoliative skin disease.

Discussion

The present findings suggest that the dermatopathic syndrome is a specific entity in which chronic dermatosis with erythema, exfoliation, and pruritus is associated with hyperplasia of reticulum cells in the regional nodes: all our 13 cases with this skin picture have, without exception, exhibited the reticulum-cell reaction. The study has been made over the past four years, during which time we have probably seen most of the cases of severe dermatosis in the North-eastern Region of Scotland: a stable and well-defined community with a total population of nearly 500,000, of whom approximately 60% are in the age group concerned—that is, over 25 years. However, our figures for the prevalence of the syndrome in the area cannot be precise, since not every case manifesting these dermatological features in minor degree has been submitted to lymph-node biopsy. Nevertheless, it is felt that the study gives a useful idea of the prevalence of the overt case in this area.

The pathogenesis of the lymph-node reaction has not yet been elucidated, but certain observations are of interest. The common association with eosinophilia and emotional instability may well be significant as indicating possible allergic or neurogenic factors in the development of the syndrome (Jarrett and Kellett): our cases show the same relationship. We have found the characteristic lymph-node changes in association with several unrelated dermatoses, but the reticulum-cell sheets have occurred only in association with exfoliation. We have no good explanation to offer for this association: there may be some common responsible factor, or the reticulum-cell hyperplasia may be secondary to processes occurring in the exfoliating skin. The presence of melanin in the node may also play a part in the development of the reaction.

The prognosis of our cases depended upon the underlying dermatological condition and bore no relationship to the lymph-node picture. However, we are unable to affirm that the lymph-node hyperplasia does not on occasion result in malignant change, as two patients (Cases 7 and 13) died respectively of acute monocytic leukaemia and a grave reticulosis (probably mycosis fungoides). The association may be coincidental or the reticulosis may have caused the exfoliative skin condition. Nevertheless, the possibility that the neoplasia supervened on the reactive hyperplasia cannot be dismissed, since experimental studies (Gillman and Gillman, 1952; Richmond, 1954) have shown that reticulum-cell hyperplasia, artificially induced by such methods as injecting trypan blue into animals, may in fact go on to frank neoplasia.

The treatment of our cases has been by routine methods supplemented by A.C.T.H. alone in two cases (Nos. 2 and 9) and with the addition of cortisone in one case (No. 7). (Hormone therapy is fully reviewed in the M.R.C. Report (1954) and the *British Medical Journal* (1954).) The effect of A.C.T.H. was beneficial in Cases 2 and 9, but both hormones were disappointing in Case 7. This case (an example of exfoliative and atrophopathic psoriasis) is of special interest, as it was the one in which leukaemia developed, apparently as a terminal event, since clinical and pathological investigations during the earlier part of the patient's illness showed no evidence of the disease. She had been exposed to long courses of powerful drugs other than the hormones, and we

have the uncomfortable feeling that the generalized reactive changes in the lymph nodes may have been affected adversely by the therapy.

Summary

Twenty cases of different clinical types of pruritic skin disease with varying degrees of lymphadenopathy have been studied clinically and pathologically during a four-year period. Seven of these cases had no exfoliation and showed only non-specific changes in the lymph nodes, under which term we have included the presence of small or moderate amounts of melanin and lipoid. The other 13 cases, however, all had an exfoliative phase and showed, in addition to the non-specific changes in the nodes, a characteristic proliferation of the reticulum cells. This change, which we have referred to as dermatopathic lymphadenitis, is almost pathognomonic of an exfoliative pruritic dermatosis.

The dermatopathic syndrome is a fairly well defined clinical entity, and its prevalence in overt form in the North-eastern Region of Scotland, with a population of nearly 500,000, can be roughly assessed from the knowledge that our 13 cases probably represent the sum total in that area over a four-year period.

The importance of the syndrome to the pathologist is that unfamiliarity with its manifestations may lead to confusion of the lymph-node picture with that of some grave reticulosis. However, the changes are merely reactive in nature and are essentially benign; they regressed when the skin condition settled, and the prognosis of the cases was that of the primary skin disease. Nevertheless, the possibility that the reactive hyperplasia may occasionally go on to frank neoplasia has not been excluded.

Our thanks are due to Professor J. S. Young for advice and helpful criticism.

The ninth report and statement of accounts of the Joint Committee of the Order of St. John and the British Red Cross Society contains much interesting information about the excellent work being done for war casualties and for the population in general. The great bulk of the funds under the control of the Joint Committee is derived from the allocation of £6½m. from the Joint War Organization to cover expenditure for a period of roughly thirty years on the discharge of liabilities arising directly from the war of 1939-45; and the main, though not the sole, activity of the Joint Committee is the relief of ex-Servicemen and women disabled in the two world wars and their dependants. Since the end of the last war some £2m. of capital funds has been expended on the various activities of the several departments of the committee. Four institutions are administered direct by the Joint Committee; one—the rehabilitation centre at Headington Hill Hall, near Oxford—is maintained on behalf of the Ministry of Pensions and National Insurance, and eight others receive recognition and support. In the year ended June 30, 1954, assistance in one form or another was given by the emergency help and aftercare department to 81,000 men, women, or children.

AMYLOID DEPOSITS IN THE BRONCHI

BY

W. GORDON, F.R.C.S., F.R.C.S.Ed.

St. George's Hospital, London

Amyloid may be deposited in typical sites such as the liver, spleen, kidneys, and adrenals, with little or no amyloid in other organs, or it may be found in other tissues, largely or entirely sparing the more usual sites. No matter where the deposits occur, the abnormality may be associated with a bewildering variety of diseases, more usually tuberculosis or chronic suppuration, but it may be present as the only known disorder. The pathogenesis and treatment of amyloid lesions are unknown.

Localized amyloid disease is very rare. According to Lunzenauer (1952) it occurs in the form of tumours, but he showed that tumour formation can occur when the disease is not localized. Amyloid tumours are uncommon and tend to develop in the atypical sites. They have been reported in the larynx especially, but also elsewhere in the respiratory tract, in the tongue, pharynx, bones, conjunctiva, bladder, urethra, uterine tube, and skin. Schottenfeld *et al.* (1951) reported a case of amyloid tumours of the lower respiratory tract and reviewed 13 cases described previously, but omitted the case reported by Haynes *et al.* (1948). Lunzenauer described two cases of amyloid tumours of the lungs and accepted nine observed by other workers, but four of these were included in the list of Schottenfeld *et al.* Noring and Paaby (1952) reported a case of diffuse amyloid infiltration of the air passages. Whitwell (1953) described a case of amyloid deposits in the bronchi, and thought that two of the cases reported previously were not acceptable.

It would appear that the literature contains reports of some 21 authentic cases of amyloid tumours of the trachea and lung and that in at least six of these cases amyloid deposits were present in the bronchi. The amyloid lesions were not associated with any specific infection or known metabolic disorder. In nearly all of the cases the diagnosis was made at necropsy, and where there was pulmonary involvement multiple tumours were found in both lungs, although not in all lobes. In the case reported by Haynes *et al.* the diagnosis was made after the lung had been removed in the belief that it contained a malignant growth. The patient reported by Schottenfeld *et al.* appears to be the first in whom a bronchoscopic biopsy established the diagnosis of amyloid deposits in the lower respiratory tract. In the patient described by Whitwell the diagnosis was made again by bronchoscopic biopsy. As this was the first case to be reported in the British literature, the following similar case should be of interest.

Case Report

An upholsterer, born in 1900, was admitted to St. Charles's Hospital in November, 1951. He had experienced recurrent attacks of bronchitis for 14 years, but because of recent intermittent slight haemoptyses he underwent bronchoscopy, when a diagnosis of inoperable carcinoma of the left main bronchus was made. He left hospital, but continued to suffer chronic cough and dyspnoea with acute exacerbations, usually relieved by antibiotic therapy. He lost a good deal of weight during the last few months of 1952.

On December 21, 1952, he was admitted to Whittington Hospital with fever, severe cough, mucopurulent sputum, and increasing breathlessness for six days. On initial examination he was found to be a wasted, cyanosed man, with severe dyspnoea. The heart rate was 125 a minute, regular, with no murmurs; blood pressure 115/70. The trachea deviated to the left side, and there was dullness with moist rales, widely over the left lung.

On December 31 an x-ray film showed mediastinal displacement to the left and extensive shadowing over the left lung field with small translucencies in the lower zone suggestive of bronchiectatic cavities; also severe emphysema of the right lung. In the left lateral view there was a triangular area of shadowing in the lower posterior angle, with a concave anterior border suggesting collapse of the left lower lobe. At this time culture of the sputum produced *Staphylococcus aureus* and *Streptococcus viridans*. The white blood cell count was 21,100, polymorphonuclears 85%.

Under treatment in an oxygen tent, with penicillin and sulphadimidine, the acute symptoms abated and the patient made a good recovery from the acute infection. On January 28, 1953, an x-ray film showed considerable clearing of the shadowing of the left lung, but the appearance of collapse of the left lower lobe persisted. The appearances were similar on February 23.

On March 3 bronchoscopy by Dr. A. L. Jacobs showed the left main bronchus retracted to the left and more horizontal than usual. It was partly occluded by a mass of greyish warty tissue, apparently arising from its inferomedial wall and bleeding freely on contact. A firm nodule of this tissue was removed with the bronchoscopy forceps.

Dr. J. Lavertine's report on this biopsy specimen was: "Chronic inflammatory infiltration of surface epithelium over mucous gland adenofibroma of bronchus showing peculiar hyaline degeneration of stroma with foreign-body reaction and indefinite metachromatic reaction for amyloid. No evidence of malignancy."

On March 15 the patient was discharged from Whittington Hospital and was referred to St. George's Hospital to be considered for surgical treatment.

On admission to St. George's Hospital on June 20, his trachea was deviated to the left, respiratory movement of his barrel-shaped chest was poor, and rhonchi were scattered throughout both lungs. No other abnormalities were detected clinically. Direct examination and culture of the sputum revealed normal flora. The urine was normal on microscopical and chemical examination. Blood haemoglobin concentration was 14 g. per 100 ml. and white cells 17,000 per c.mm., 78% polymorphonuclears. The concentration of serum albumin was 3.7 g.%, and globulin 4.1 g.%. After intravenous injection of Congo red, uptake of the dye was similar to that in a control patient.

Screening showed that diaphragmatic movement and barium swallow were normal. Tomography (Fig. 1) revealed a mass which surrounded the left main bronchus and narrowed its lumen irregularly in the lower two-thirds. The mediastinum was deviated to the

FIG. 1.—Tomogram showing a mass which is narrowing and distorting the left main and lobar bronchi.

left. On June 23 bronchoscopy by Mr. A. H. M. Siddons showed the main carina to be distorted and widened; a swelling extended along the medial wall of the left main bronchus, which was narrowed slightly, and an irregular mass was seen protruding from the lower lip of the left

Fig. 2.—Section of bronchial biopsy specimen showing surface epithelium (on the left) and several dilated gland ducts surrounded by amyloid deposits (arrows). (Haematoxylin and eosin. $\times 75$.)

upper lobe bronchus. Biopsy specimens were taken from the swellings of the left main and left upper lobe bronchi. They showed bronchial epithelium and glands in connective tissue rich in amyloid deposits (Fig. 2). Characteristic reactions were obtained when the deposits were stained with both methyl violet and Congo red. There was no evidence of neoplasm. Bronchography on July 8 showed that the left upper lobe bronchus was occluded (Fig. 3). At

Fig. 3.—Bronchogram showing occlusion of the left upper lobe bronchus.

On July 17 the patient was discharged from St. George's Hospital, but during November he again became ill with increased cough and dyspnoea, and his condition steadily deteriorated. On December 21 he was readmitted to Whittington Hospital. He was then gravely ill, mentally confused, cyanosed, and dyspnoeic. There was no response to antibiotic treatment, and he died on December 24. Necropsy showed that death was due to acute purulent bronchitis superimposed on chronic bronchitis and emphysema. Massive amyloid infiltration was present in the submucosa, muscularis, and adventitia of the left and right main bronchi. The deposit in the left main bronchus had made its wall up to 0.4 cm. thick. Histological examination of the liver, kidneys, and spleen did not show evidence of amyloid. The other organs did not show any significant disease.

Summary

The literature of amyloid tumours of the trachea and lung is reviewed briefly.

A case of amyloid deposits in the bronchi is described. The condition should be borne in mind when considering the nature of a bronchial tumour.

This case is published with the kind permission of Dr. A. I. Jacobs, physician, and Dr. A. B. Bratton, pathologist, both of Whittington Hospital, and Mr. A. H. M. Siddons, thoracic surgeon, St. George's Hospital.

SIGNIFICANCE OF PHYSIOLOGICAL PATTERN OF ANIMAL STRAINS IN BIOLOGICAL RESEARCH*

BY

ELIZABETH S. RUSSELL, M.A., Ph.D.

Jackson Memorial Laboratory, Bar Harbor, Maine

Serious problems are presented in all biological research by differences in the characteristics and reactions of experimental and control animals caused by genetic and/or environmental variables. One large source of variation, genetic difference, can be practically eliminated by the use of inbred animals. Forty-two different inbred strains of mice are maintained and studied in the Inbred Nucleus of the Jackson Laboratory, Bar Harbor, Maine, U.S.A. The majority of mouse inbred strains were originally developed for cancer research, in which their first function was to prove the existence of genetic factors influencing the incidence of cancer and the independence of inheritance of different types of tumours. The same process of inbreeding which fixed the cancer-influencing genes in each of these strains fixed practically all of the 10^4 to 10^6 genes carried by any one strain. The individuals within each of the more than 100 inbred mouse strains which now exist are as alike genetically as it is possible to make and keep living material.

Classification

What types of characters are fixed in these strains? How do they differ from each other? The classification of strain differences given in Wright and Eaton's (1929) classic paper still does very well as a description of the type of differences between inbred groups. It is particularly valuable for its demonstration that genetic differences are very important even in cases in which they do not produce obvious effects under all conditions. Their first category, *complete fixation of a phenotype*, in cases in which the genes concerned have an all-or-none effect, might be exemplified for the mouse by the difference between white BALB/c mice, carrying the genes *cc* for albinism, and black C57BL mice, carrying the genes *CC* for intense colour. The second category, *fixation of average grade*, may be illustrated by comparing the incidence of mammary tumours in C3H females with 96%, DBA/1 females with 66%, and

*This investigation was supported by a research grant C-1074(C3) the National Cancer Institute, of the National Institutes of Health, U.S. Public Health Service. The paper is slightly altered from an address in the Proceedings of the Fourth Annual Meeting, Animal Care Panel, December 2 and 3, 1953, Chicago, Illinois, U.S.A.

C57BL/6 females with less than 1%.* These averages have remained fairly constant through the past 15–20 years.

Dr. Gowen, of Iowa State College, is responsible for the development and study of an excellent example of the third category, *fixation of relative rank*. He produced a series of mouse inbred lines differing in relative susceptibility to mouse typhoid (Gowen, 1950), the actual proportions succumbing depending, of course, upon the existence and extent of their exposure to salmonella organisms. This category overlaps in some cases the fourth, *fixation of reaction to conditions*. The high susceptibility to sound-induced seizures characterizing the DBA strain and completely lacking in the C57BL strain (Fuller and Smith, 1953) is, however, an unequivocal example of this fourth category. A qualification which should be added to this classification has to do with a similarity rather than a difference. A considerable proportion of the animals in any generation of an inbred strain must grow to fertile healthy adulthood if brother-sister matings are to continue indefinitely. During inbreeding there will tend to be a reduction in fertility, since chance prevents accumulation of all favourable genes in one package. However, genes causing all or a high proportion of individuals to have severe early abnormalities could not be fixed in a strain. Genes leading to a high proportion of serious deleterious effects appearing late, after the production of a number of litters, have, however, been fixed in many strains. These effects include various cancers as well as other types of disease. Thus in all inbred strains extremely severe genetic effects cannot appear very early in the life span.

Pulling from a hat four type-examples of characters differing among inbred strains of mice would do little to convince a jury that the use of inbred animals is essential to most types of animal research. The judges may feel that coat-colour, tumour susceptibility, typhoid resistance, and reaction to loud noises have nothing to do with the problems faced by most investigators. It is hoped that presentation of a few further examples garnered from recent literature may give some indication of the probable extent of genetic influence upon physiological characteristics. In the library of the Jackson Laboratory there are more than 1,200 references, from 1951 to 1953 journals, to studies based on inbred mice. These have been catalogued and classified in a subject-strain bibliography (Staats, 1954) which provides rapid access to literature pertinent to a particular strain or condition. For the purposes of this presentation I have listed some of the newer physiological differences among strains gleaned from this bibliography, but I have omitted from consideration a much larger number where a single strain was used simply to provide genetic uniformity or because previous work had shown it to be the best for a particular purpose.

Strain Differences in Reactions

Different strains have been shown to react very differently to several external environmental factors. The nature of disease produced by a certain pathogen may depend upon the genotype of the host. For example, the Newcastle virus usually causes pneumonia when administered intranasally to DBA/2 and C3H mice, but produces encephalitis in DBA/1 mice (Liu and Bang, 1952). Genetic difference may alter the survival time of individuals infected with a certain

*Inbred Nucleus means animals born 1948–50.

pathogen. The average survival of DBA/2 mice after standard inoculation with the malaria-producing *Plasmodium berghei* is 9.9 days, of C57BL mice 13.2 days, and of their hybrid DBA $\times$ C3H F₁, 19.7 days (Greenberg *et al.*, 1953). The longer survival of the hybrid is due to its greater ability to tolerate parasitaemia rather than to delay in infection. Certain strains of mice are frequently plagued with diseases which never hit mice in adjacent pens. The infantile diarrhoea of C3H mice (Runner and Palm, 1953; Russell, 1954) is an example of this type of *strain-limited susceptibility*. It may hit as many as 50% of litters born in winter months, and is especially frequent in first litters.

Strains differ in their capacity for *antibody production* (Fink and Quinn, 1953). Antibodies against protein were produced in five strains by intramuscular injection of egg albumen. Animals of the highest strain, DBA, were more than four times as reactive as those of the lowest strain, BALB/c. Injection of pneumococcus polysaccharide also showed significant differences among the same five strains, but the order of reactivity is very different. A Lilly, the most sensitive, was four times as reactive as C57BL/6.

Experiments which involve taking research animals to outlying districts have created a necessity for finding animals which can tolerate very low temperature and sudden change. Weanling BALB/c mice have such *cold tolerance*, and when put outdoors in winter can easily survive for 30 days, including periods of 0° F. temperature, while C57BL mice under the same conditions die in less than a single day (Curran, 1955). On at least three occasions serious loss to animal colonies has resulted from fumes of chloroform or allied products (Deringer *et al.*, 1953; Shubik and Ritchie, 1953). Males only of particular strains are affected. In a Jackson Laboratory catastrophe more than 74% of DBA/2, 51% of DBA/1, 32% of C3H, and 10% of BALB/c breeding males died within a week with a characteristic *toxic destruction* of the kidney. This event had no effect on females of these strains or on large colonies of six other strains in the same room.

It is clear that variations in reactions to external agents such as have been described above could wreck an experiment using non-homogeneous animals. It is also clear that there are "strains of choice" for particular experiments. There is also considerable evidence that the endocrine picture varies with genotype in a way which may interfere with interpretation of experimental results. It has been shown that strains differ in their *content of particular hormones*. Evidence has been presented indicating the gonadotropin content of DBAs is 1.5 times that of mice of the A or 020 strains (Mühlbock *et al.*, 1952). The thyroxine level of C3H appears to be approximately 1.5 times that of C57BL (Gross and Schwartz, 1951). Strains also vary in their *sensitivity to particular hormones*. It has been shown that the C57 group of strains is approximately 12 times as sensitive as the DBA, BALB/c, or 129 strains in its eosinophil response to adrenal cortical hormones (Wragg and Speirs, 1952). The type of reaction of different tissues to a particular hormone varies with strain. The susceptibility to oestrogen of breast, vaginal epithelium, and endometrium of three strains has been compared (Silberberg and Silberberg, 1951). The Silberbergs reported the mammary tissue of DBA and A more susceptible to oestrogen than that of C57BL, and the vaginal epithelium and endometrium of C57BL very sensitive, of DBA intermediate, and of A strain relatively resistant. Recent work by Drasher (1955) indicates that the strain difference in uterine reaction may be one of duration of reaction rather than of initial susceptibility.

Strains of mice differ qualitatively in their *reaction to extirpation* of endocrine organs. Removal of ovaries from day-old C57BL mice does not alter the fate of their adrenals. The same operation on DBA females eventually leads to nodular hyperplasia of the adrenal, with secondary effects on other endocrines. In CE females the same operation results in adrenal cortical carcinomas. Recent work

on the inheritance of these differences (Woolley *et al.*, 1953) has shown 100% adrenal cortical carcinomas in the F₁ hybrids of both C57BL and DBA with CE.

At present a rapidly expanding field of study is strain difference in enzyme activity. In this field I am not qualified as an expert, but can at least list enzymes which have been studied. For example, within the past three years differences among strains have been described in liver β -glucuronidase (Law *et al.*, 1952; Fishman and Farmelant, 1953; Sie and Fishman, 1953), mammary glucuronidase, and esterase (Cohn and Bittner, 1951), serum tributyrinase (Tuba, 1952), and serum alkaline phosphatase (Tuba, 1953). The work on probable mode of inheritance of difference in liver glucuronidase activity, which is less than one-tenth as high in C3H as in A strain mice (Law *et al.*, 1952), is particularly impressive.

Physiological Strain Differences

In addition to the Jackson Laboratory's attempt to keep up with the growing knowledge of the characteristics of inbred strains by following the literature, certain observations have been carried out on the animals maintained in the Inbred Nucleus of the Jackson Laboratory which indicate physiological strain differences. A study of the formed elements of the blood of young adults from 18 different inbred strains, for example, showed that differences among strains contributed very significantly (0.1% level) to variations in erythrocyte number, haematocrit, and haemoglobin, even though there were great overlaps between strains (Russell *et al.*, 1951). The mean haemoglobin content varied from 12.2 g.% for C3H/Jax to 15.0 g.% for BALB/cJax. Strain differences in leucocyte characteristics were also very conspicuous in spite of the wide variation within strains to be expected in a character so easily influenced by environmental factors. The mean total leucocyte counts for the various strains ranged from 5.87×10^9 for RIII/Jax to 11.43×10^9 for C57BL/6Jax, and strain differences contributed very significantly (0.2% level) to the total variance. The differential leucocyte count also varies significantly with strain (0.1% level), with the entire C57 group of strains very low in granulocyte percentage. Subsequent work has shown that different genes affect granulocytes and agranulocytes (Budds *et al.*, 1953), since the rank order for granulocyte number (C3H>DBA/1>BALB/c>DBA/2>A>AKR>C57BL/6) is very different from that for agranulocyte number (C57BL/6>DBA/1>BALB/c>DBA/2>A>C3H>AKR).

In the Inbred Nucleus breeding mice are retired at 1 year of age, but they are allowed to live out their life-span for

Mean Life-span of Male and Female Mice from the 10 Largest Inbred Colonies

Strain	Mean Life-span (Days)	
	Females	Males
<i>High-moderate Mammary Tumour Strains</i> (in order of decreasing incidence)		
C3H	314.4	424.3
DBA/1	399.4	411.5
DBA/2	431.0	401.0
A/He	389.2	453.8
<i>Low Mammary Tumour Strains</i>		
A/Jax	447.8	467.4
AKR	284.2	272.2
BALB/c	485.0	475.4
C57BL/6	562.7	529.4
C57BR/cd	482.9	457.2
C57L/He	513.5	490.6

the study of their potentialities for specific types of disease. The Table compares the mean life-span of males and females from the ten largest inbred colonies, using animals born during a three-year period, 1948-1950 (Russell *et al.*, 1955). Several conclusions can be drawn from these data. They confirm the previous observation that mammary tumours strike at different ages in different strains. As a general rule, the longevity of females in mammary tumour strains is less than that of males, but there is one exception in our data, in DBA/2. The extent of the sex-differential

in survival in mammary tumour strains also varies with the strain. The differences among means of males of all strains and females of the low mammary strains show that factors other than mammary tumour susceptibility strongly affect survival, so that strain means can run from approximately 280 days for the AKRs, which usually die with lymphatic leukaemia, to approximately 550 days for C57BL/6. In low mammary strains, under the conditions of our colony, females tend to outlive their mates slightly, although there are exceptions. It is clear that ageing processes must vary greatly with strain. It is hoped that analysis, now under way, of necropsy data collected on these strains will increase our knowledge of patterns in mouse gerontology. Whatever the causes behind these genetic ageing differences, their existence could lead to erroneous results from long-term experiments involving heterogeneous animals, and could dictate the choice of inbred animals to fit the time requirements of particular experiments.

Importance of Genetic Differences

The literature examples on endocrine balance and response and on enzyme activity, plus the Inbred Nucleus examples on blood picture and longevity pattern, show that there must be great differences in internal constitution and relationships influenced by genes. As with the reactions to external agents, such differences within an experiment could lead to fallacious conclusions. If we could only come to know each strain well enough, such differences between groups could be invaluable tools. There is so very much to know. The million or so genes carried by a single mouse may have direct or indirect effects on many characters. The nature of effect of any particular gene may depend a great deal on its interaction with other genes. We have seen that genetic differences do not always have an all-or-none effect, but may alter average grade, relative rank, or reaction to conditions.

This means that two genetically different individuals may under some conditions be identical for a given character, but under other circumstances will differ. It also means that there are variations within as well as between inbred strains. The recent rapid increase in examples of strain differences means that more and more investigators are coming to realize the importance of genetic difference and are beginning to tap the mine of information that is waiting for them in the already established inbred types. Many of them have started their experiments to test a hypothesis on the basis for a known strain difference, as the incidence of a certain type of tumour (Gross and Schwartz, 1951; Silberberg and Silberberg, 1951; Mühlbock *et al.*, 1952; Greenberg *et al.*, 1953), but more often than not they have turned up what appears at present to be a completely independent attribute of the strain difference. Other investigators have accepted the extremely valuable concept of "strains of choice" for a given experiment, and start their investigations with a cross-strain test of their particular procedure or substance. This is an extremely wise course of action, since they eventually obtain both suitable and genetically homogeneous material. Unless they are theoretical geneticists, however, their interest ends with establishing their base-line.

Since this is a paper on the significance of physiological pattern of animal strains, it seems suitable to mention the great importance of variations within strains to students of the relation between heredity and environment. Analysis of association of intra-strain differences with life-history differences, including parental effects, is the most valuable tool in this field (Wright and Eaton, 1929; Runner and Palm, 1953; Russell, 1954). For characters with great intra-strain variation, greater variation between strains often provides geneticists with the only evidence that genes have anything to do with the character (Russell *et al.*, 1951; Budds *et al.*, 1953).

Thus the rapidly increasing knowledge of inherited differences between strains in their reaction to conditions, their internal balance, and their normal levels of certain cells or

substances makes it more and more apparent that genetic homogeneity is essential to most physiological work, and that genetic variety between strains provides an array of valuable tools for particular types of physiological experiments.

Summary

The use of inbred strains in biological research is essential for fixation of either phenotype, average grade, relative rank, or reaction to conditions. Examples are presented of each type of strain differences in mice, gleaned from 1951-3 literature and from research in the Inbred Nucleus of the Jackson Laboratory. These include differences in disease susceptibility, nature of disease produced by a given pathogen, survival time of infected individuals; capacity for antibody production, cold tolerance, reaction to specific toxins; sensitivity to and content of various hormones and reaction to endocrine extirpation; and differences in normal blood-cell levels, life-expectancy, and pathology pattern.

The Singapore Anti-tuberculosis Association has recently published a well-illustrated account of the origin and activities of the Royal Singapore Tuberculosis Clinic, which has been in existence since 1948. In a foreword to the book the Right Hon. MALCOLM MACDONALD, Commissioner-General for the United Kingdom in South-east Asia, refers to the great increase in the work of the clinic, and continues: "Despite this attack, tuberculosis still remains a vast and dangerous problem in Singapore. Just how vast and how dangerous is still far from understood by the general population." The figures given in this book should dispel complacency. There may be as many as 50,000 patients needing treatment for tuberculosis in Singapore. Every day at the Royal Tuberculosis Clinic, which is a voluntary organization, some 20 new cases of tuberculosis are discovered—a steady 8 to 9% of those x-rayed each month. In all, nearly 60,000 radiographs are taken every year and 55,000 blood sedimentation tests performed. Between three and four thousand patients are under treatment at any one time, and in 1953 the total of patient attendances was over 150,000. The work of the clinic is carried on in two separate units, one for diagnosis and the other for treatment. There are no beds, but domiciliary treatment has proved remarkably successful, particularly among the Chinese. A children's clinic has now been started, where some 130 children a month are brought by their parents.

PELVIC TUBERCULOSIS

A REPORT ON 19 CASES

BY

ALEX KOUYOUMDJIAN, M.D.

American University Hospitals, Beirut

Morgagni (quoted by Norris, 1931), in the eighteenth century, was the first to recognize pelvic tuberculosis, but no further mention of the disease is found in the medical literature until 1831. Since that time numerous reports have appeared. The recent advent of streptomycin, P.A.S., and isoniazid has stimulated a new interest among gynaecologists.

The incidence of pelvic tuberculosis in the female is said to vary in different parts of the world. Sharman (1952), in Glasgow, and Rabau (1950), in Israel, have reported a high incidence of the disease in their respective clinics. I consider that pelvic tuberculosis in the Lebanon is more common than is generally believed, and this report is the first of its kind from that country.

Material

A review of the records at the American University Hospitals, Beirut, revealed 35 cases listed under the heading of pelvic tuberculosis for the seven-year period July 1, 1946, to June 30, 1953. However, a careful study of the case records shows that the diagnosis was established histologically in only 19 cases, and this study is confined to these 19 proved cases. The age incidence is shown in Table I.

TABLE I.—Age Incidence

Age	No. of Patients	Percentage
10-19 ..	0	0
20-29 ..	7	36.8
30-39 ..	6	31.6
40-49 ..	4	21.1
50-59 ..	2	10.5
Total ..	19	100

Nulliparae, 8 (42%); average age, 28.6 years. Multiparae, 11 (58%); average age, 36.6 years.

During the same seven-year period there were 2,492 admissions to the gynaecological service of this institution. Thus the incidence of pelvic tuberculosis in these 2,492 admissions was approximately 0.8%. This is considerably lower than Leon's (1950) figure of 2% for all gynaecological conditions. Greenberg (1921) gives the incidence of tuberculous salpingitis among 24,155 gynaecological admissions to the Johns Hopkins Hospital as 0.83%.

Symptoms

Abdominal Pain.—The commonest symptom encountered in this series was low abdominal pain. This was present in 57.8% of the cases. Typically, the pain was of a dull nature, beginning in one of the lower quadrants and later being bilateral. Acute abdominal pain with fever simulating acute salpingitis or appendicitis has also been reported. Usually the attacks of pain became worse during the menstrual periods, but dysmenorrhoea *per se* was the admission complaint in only 15.8% of our cases. Backache was present in 27.4%.

Sterility.—The next commonest complaint was sterility (52.7%). It was primary in 42.2% and secondary in 10.5%. These figures are in sharp contrast to those given by Brown *et al.* (1953), who report it in only 6.9% of their cases. Greenhill (1951) states that tuberculosis is an infrequent cause of sterility, but in some parts of the world 5 to 6% of all endometrial biopsies performed on infertile women show tuberculosis. Sharman (1952) found histologically proved endometrial tuberculosis in 5.2% of 2,985 patients

with primary sterility. Liljedahl and Rydén (1951) state that among 499 women who were sterile the incidence of genital tuberculosis was 10%. During the seven-year period of this study 250 sterile women were admitted to the gynaecological service of the American University Hospitals. Ten of them were found to have genital tuberculosis, an incidence of 4%.

Fever.—This was usually of a low-grade nature and often unnoticed by the patient. It was present in nine cases (47.4%).

Leucorrhoea.—The discharge was usually not profuse and was of a watery character. It was found in seven cases (36.8%). Two patients reported the discharge as foul-smelling.

Ascites.—Swelling of the abdomen due to fluid, either in the past history or on admission, was present in six patients (31.6%). One patient also had a pleural effusion.

Menstrual Disturbances.—These may take various forms. In our series the commonest complaint related to the menses was an irregularity of the periods (27.4%). Amenorrhoea and menorrhagia had an incidence of 21.1% each. The amenorrhoea in these cases was the result of the general condition of the patient rather than infection in the genital tract. The incidence of dysmenorrhoea in our series, 15.8%, is lower than the figure given by Greenberg (62%).

Findings

Physical.—Bimanual pelvic examination often yields very instructive information in cases of pelvic tuberculosis. In 31.6% of our patients pelvic masses were felt unilaterally or bilaterally, usually the latter. However, a simple thickening, induration, or fixation of the adnexal tissues was just as common (31.6%). The fundus was found retroverted and fixed in 27.4%. In 15.8% of the patients the uterus was enlarged and the pre-operative diagnosis was myoma of the uterus. In three cases the pelvic findings were regarded as normal (15.8%). In one case the cervix was granulating, and bled easily on examination. Carcinoma of the cervix was suspected, but the biopsy revealed tuberculosis.

If one combines the cases diagnosed as myoma of the uterus with those in which the findings were normal, it will be seen that 31.1% of the patients had no indication of the presence of the disease.

Owing to the widespread use of antibiotics, the younger generation of gynaecologists rarely see the large tubo-ovarian masses of gonorrhoeal or streptococcal origin so often encountered in the past. The presence of such masses should nowadays arouse a suspicion of their nature.

Laboratory.—Once the diagnosis of genital tuberculosis is made, an x-ray examination of the chest should be made routinely. This was done in 13 of our 19 cases (68.4%), and evidence of healed or active pulmonary lesions was found in 7 (53.8% of those subjected to the examination). The total leucocyte count was below 10,000 in 11 patients (57.8%). When such a result is found in a febrile patient the possibility of tuberculosis should be strongly entertained. The differential count showed lymphocytosis (lymphocytes over 30%) in 27.4% of our cases. Anaemia as measured by an erythrocyte count lower than 4 millions was present in 42.2% of our patients.

Table II gives a comparison between our results and those of other authors.

Histological (Tables III and IV).—One or both Fallopian tubes were available for histological study in 10 cases, and all were found positive for tuberculosis. This illustrates the fact that pelvic tuberculosis is primarily tuberculosis of the tubes. Endometrial tissue was studied either by biopsy or from a uterus removed at operation in 13 cases. Tuberculous lesions were found in 11 (84.6%). The cervix was examined in five cases and found positive in two (40%). One or both ovaries were available in 10 cases, and lesions were found in two (20%). Both these were cases of tubo-ovarian abscess. The ovary is believed to be protected from

TABLE II.—Comparison of Our Statistics with Others

Finding	Present Series (19 Cases)	Brown <i>et al.</i> (1953) (158 Cases)	Greenberg (200 Cases)
Abdominal pain ..	57.8%	69%	80%
Sterility ..	52.7%	6.9%	60%
Primary ..	42.2%		
Secondary ..	10.5%		
Fever ..	47.4%	35.4%	62.5%
Leucorrhoea ..	36.8%	62.6%	72%
Backache ..	27.4%	10.1%	30%
Ascites ..	31.6%	21.5%	
Irregular periods ..	27.4%		
Amenorrhoea ..	21.1%	15.8%	6.5%
Menorrhagia ..	21.1%	20.2%	41.5%
Dysmenorrhoea ..	15.8%	8.8%	62%
Dyspareunia ..	5.3%	3.8%	
Positive chest x-ray film ..	53.8%	27%	
Leucocytes below 10,000 ..	57.8%	78%	+65%
Lymphocytosis ..	27.4%	24%	

Note.—Greenberg's 200 cases are all of tuberculous salpingitis only.

TABLE III.—Sites Affected

Site	No. of Cases	Percentage
Endometrium ..	11	57.8
Fallopian tubes ..	10	52.7
Peritoneum ..	4	21.1
Ovaries ..	2	10.5
Cervix ..	2	10.5
Myometrium ..	1	5.3

TABLE IV.—Relation Between Tissue Available for Histological Study and Percentage Positive

Tissue	No. Available	No. Positive	% Positive
Oviducts ..	10	10	100
Endometrium ..	13	11	84.6
Cervix ..	5	2	40
Ovaries ..	10	2	20
Myometrium ..	6	1	16.6

infection by its thick capsule of tunica albuginea. Lesions in the myometrium were found in only one of the six specimens examined (16.6%).

Peterson (1922) found tubal involvement in 86.3%, uterine in 50%, and ovarian in 43%. Tuberculosis of the vagina and vulva is extremely rare. This was absent in the present series.

Methods of Diagnosis

The diagnosis in all our 19 cases was established histologically. This is an ideal that cannot always be achieved. Since early diagnosis is desirable, and since tissue is not always available for study, other methods of establishing the presence of the disease have been devised. Apart from the history and the pelvic findings, the following measures are at the disposal of the gynaecologist:

1. **Diagnostic Curettage.**—According to Brown *et al.* (1953) 18.9% of cases are diagnosed by study of the endometrial curettings. Some investigators stress the danger of spreading the infection by curettage, and Sharman (1952) maintains that a single negative biopsy does not rule out the disease.

2. **Culture of Menstrual Blood and Cervical Mucus on Löwenstein's Medium.**—Kirchoff *et al.* (quoted by Greenhill, 1952) had positive cultures in 10 out of 19 cases of proved genital tuberculosis. In eight of the nine missed cases tubal but not endometrial tuberculosis was present. Furuhashi (quoted by Greenhill, 1952) believes that the most efficient way of diagnosing genital tuberculosis is by culture of the vaginal contents on several pre-menstrual days or of menstrual blood.

3. **Guinea-pig inoculation of menstrual blood.**

4. **Hysterosalpingography.**—Ekengren and Rydén (1950) have advanced detailed criteria for the radiological diagnosis of tuberculous salpingitis. A closer co-operation between the gynaecologist and the radiologist is necessary to achieve better results in this field.

Discussion

As stated at the beginning of this paper, 16 out of 35 cases were discarded because of the lack of positive proof of the diagnosis. Had we used some of the investigative measures outlined above we would undoubtedly have found a higher incidence of genital tuberculosis among our patients. In many of the 16 discarded cases there was strong presumptive evidence of the disease, and guinea-pig inoculation or culture of the menstrual blood would almost certainly have established the diagnosis in some.

Summary

Data of 19 cases of tuberculosis of the female genital tract investigated at the American University Hospitals, Beirut, are presented. The commonest complaints and physical findings are discussed and details of the histological findings in biopsy specimens analysed.

Pelvic tuberculosis is not rare. Its incidence among 2,492 gynaecological admissions to this institution is 0.8%. The diagnosis of the disease would be more frequently established if the measures outlined could be routinely used.

I wish to thank Dr. D. Homer Rea for permission to publish these cases and for advice on the preparation of this paper.

Medical Memoranda

Extreme Fluid and Electrolyte Loss Due to Villous Papilloma of the Rectum

A case of a large mucus-secreting villous papilloma of the rectum producing extrarenal uraemia, acidosis, and dehydration as the result of severe diarrhoea is here described. Recovery followed treatment of the fluid and electrolyte loss and resection of the tumour.

CASE REPORT

A single woman of 57, who had previously been in good health, began in 1951 to have attacks of diarrhoea. She said that during the attacks she might pass as many as 20 motions a day, which were fluid and often colourless. At the start the attacks did not last longer than 48 hours, and then the bowel action might be normal for weeks. She never passed any blood. She gradually began to lose weight and strength, but never consulted a doctor. A week before her emergency admission to hospital in May, 1953, the diarrhoea became extreme with almost continuous rectal fluid loss. She also complained of paroxysms of severe pain in the back of the legs and in the abdomen. There was occasional vomiting. She did not remember the 18 hours previous to coming into hospital.

On admission she was moribund, and the immediate clinical impression was that she was in the terminal stage

of diabetic coma. There was intense acidotic breathing, and, from the flaccidity of the skin and the low eyeball tension, evidence of extreme dehydration. The tongue was dry and furred, the pulse feeble and rapid, and the systolic blood pressure only 60 mm. Hg. She was catheterized, but no urine was found in the bladder. A bowel action occurred which consisted of clear fluid apart from a few flecks of white mucus.

Her condition was so poor that she was not moved from the casualty examination couch. An intravenous infusion of normal saline was set up and 5 pints (2.8 litres) run in as fast as possible. Methylamphetamine, 30 mg. intravenously, was also given. Her condition immediately improved. She became conscious and the systolic blood pressure rose to 100 mm. Hg. She was then transferred to a ward and given a further 3 pints (1.7 litres) of normal saline intravenously during the night. The next morning she had improved greatly, and, as she was now able to drink, the drip was discontinued. Streptomycin sulphate, 0.5 g. four times a day, was given for three days. The stools on the first of these days continued to be fluid and frequent, but thereafter, over the next week, gradually became coloured and infrequent, although they were still fluid and contained mucus.

The day after admission the serum chemistry was as follows: blood urea, 205 mg. per 100 ml.; sodium, 295 mg. per 100 ml. (128 mEq/litre); chloride, 327 mg. per 100 ml. (92 mEq/litre); potassium, 15.8 mg. per 100 ml. (4.1 mEq/litre); CO₂ combining power, 25 vols. % (11.2 mEq/litre). A blood count showed: red cells, 5,960,000 per c.mm.; haemoglobin, 120% (17.8 g.%), white cells, 15,700, of which 82.5% were polymorphonuclears. The stools contained mucus, pus cells, occasional red blood cells, and macrophages, but no cysts, ova, amoebae, or *Giardia lamblia*. No pathogens were isolated in culture. The urine contained pus cells, red cells, and fairly numerous granular casts. There were no organisms. Twenty-four specimens of urine were collected, and, as might be expected, of the intake of 5 g. of sodium chloride daily the average output was 0.05 g. of chloride and 0.1 g. of sodium in 24 hours. In spite of this salt retention and unrestricted fluid intake the serum chemistry was very slow to return to normal.

Six days after admission the serum chemistry was as follows: urea, 155 mg. per 100 ml.; sodium, 275 mg. per 100 ml. (120 mEq/litre); chloride, 312 mg. per 100 ml. (88 mEq/litre); potassium, 16.2 mg. per 100 ml. (4.2 mEq/litre); CO₂ combining power, 40 vols. % (17.9 mEq/litre). Twelve days after admission it was: urea, 65 mg. per 100 ml.; sodium, 273 mg. per 100 ml. (119 mEq/litre); chloride, 324 mg. per 100 ml. (91 mEq/litre); potassium, 24.8 mg. per 100 ml. (6.4 mEq/litre).

She was placed on 15 g. of salt daily, and on the sixteenth day the blood urea had fallen to 28 mg. per 100 ml. The urine was free from albumin and there were no casts. The general appearance of the patient was quite normal.

There were never any abnormal findings on abdominal examination, but a soft mass was just palpable on rectal examination. On sigmoidoscopy a papillomatous growth of the pelvo-rectal junction was seen. The pedicle had a wide base. On attempting to pass the sigmoidoscope above the papilloma vision was obstructed by the rush of fluid faeces escaping from above. The rectal mucous membrane was quite normal. Histologically the biopsy specimen had the appearance of a villous papilloma.

Four weeks after admission Mr. B. N. Brooke opened the abdomen through a left paramedian incision. A large tumour was found in the lower sigmoid and the upper rectum, the rest of the colon being quite normal on inspection and palpation. The tumour was excised and an end-to-end anastomosis performed.

Post-operative recovery was uneventful and the patient was discharged ten days later. When seen subsequently she felt and looked well, and there was no complaint of diarrhoea.

The specimen was a villous papilloma of the colon. Section of the growth showed marked cellular hyperchromatism and occasional mitoses, but there was no invasion of the bowel wall at the base of the tumour.

COMMENT

The classification of benign tumours of the colon and rectum is much confused. Bockus (1944) gives a separate place to the villous papilloma as a variety of adenoma. Bacon (1938) describes the villous papilloma as a rare and single tumour, which may often become very large. He says it is more common in men than in women, and occurs between the ages of 35 and 55. On section the tumour is made up of innumerable villi lined with columnar cells, and the very large surface area of the tumour explains the opportunity for fluid loss. It is stated that malignant degeneration occurs in 20% of the cases (Rankin *et al.*, 1932). Burns (1950), in reporting nine cases, does not mention fluid loss to the point of dehydration. Eight of his patients are alive and well following various operations; one died from the operation. Further perusal of the literature has not revealed a case record in which the amount of fluid and electrolyte lost from the surface of the tumour was so great that extreme salt depletion and extrarenal uraemia was produced.

My thanks are due to Dr. C. F. Hawkins and Mr. B. N. Brooke for their help and permission to publish.

Recovery from an Incompatible Blood Transfusion Complicated by Anuria

Grossly incompatible blood transfusions have become rare since the intricacies of the indirect and direct matching tests have been appreciated. Nicholson (1948) reported from a group of blood banks 67,844 transfusions with 18 haemolytic reactions and 3 deaths. It is unlikely, therefore, that any individual doctor will see or treat many cases of incompatible transfusion.

Discombe (1952) discussed the causes and treatment of six ABO incompatibilities which had occurred during the transfusion of over 10,000 bottles. He emphasized the two types of clinical response to incompatible transfusion: one with immediate circulatory collapse, which carries a very high mortality; the other ordinary haemolytic reaction, with pain in the loin, rigor, fever, and haemoglobinuria, sometimes followed by anuria, which is less lethal. None of the cases described by him developed anuria, and all recovered. He attributed this success to the Borst (1948) regime (Bull *et al.*, 1949), which in his experience had changed a 100% mortality following the forcing of fluids and intravenous sodium sulphate into a 100% recovery.

The following case developed complete anuria which lasted for 12 days, and is therefore thought to be worth recording.

CASE REPORT

A Chinese woman aged 28 was admitted to hospital in the early hours of the morning with the typical signs and symptoms of a ruptured ectopic pregnancy. She had had amenorrhoea for seven weeks. She was advised immediate operation, but refused. During the day her symptoms increased in severity, and 14 hours after admission she consented to laparotomy. By this time she was slightly shocked. Following the administration of two bottles of plasma substitute her condition improved. Laparotomy

confirmed the diagnosis: there were 3-4 pints (1.7-2.3 litres) of free blood in the peritoneal cavity. The right Fallopian tube was removed.

After the operation her condition was fairly satisfactory, but, influenced by her relationship to a member of the nursing staff and the appearance of three males who wished to donate blood to her, it was decided to give a transfusion on her return to the ward. Two of the donors were declared to be compatible, and before recovery from anaesthesia had taken place 1,000 ml. of blood was given. Nothing abnormal was noticed during the transfusion. Twelve hours later she was seen to be slightly jaundiced. As she had not passed urine spontaneously, the bladder was catheterized and 2 oz. (57 ml.) of dark brown urine obtained. This was found to contain free haemoglobin, and was the last urine to be passed for 12 days.

An immediate cross-check on the compatibility of the blood was carried out and the patient was found to be Group A and both donors Group B. Although the laboratory technician had cross-matched the blood, he had failed to group either the donors or the recipient. 80 ml. of 5% sodium bicarbonate was given intravenously, and the patient started on the Bull-Borst regime:

Glucose	..	400 g.	
Peanut oil	..	100 g.	
Acacia	..	q.s. to emulsify	
Water	..	to 1,000 ml.	per 24 hours

via an intragastric drip.

No previous experience with such a small fluid intake in a tropical climate with high humidity was to be found in the available literature, and no facilities for biochemical investigation were at hand.

Twenty-four hours later her condition appeared to be deteriorating. Her jaundice was by this time intense: she complained of severe nausea, her temperature was 103° F. (39.4° C.), and her pulse was weak and rapid. The relatives were told that the prognosis was almost hopeless.

On the following day her condition was unchanged, and she vomited three times. The vomit was strained and returned to the stomach. On the fifth day her general condition had slightly improved: the jaundice was less intense and her temperature was normal. She complained of severe thirst, but as her tongue was moist extra fluid was withheld. The bladder was again catheterized, but no urine was obtained. The blood urea at this time was 90 mg. per 100 ml. From then on, subjectively, she showed slight daily improvement; however, daily catheterization proved that no urine was being secreted. The blood urea on the 10th day was 165 mg. per 100 ml.

On the 12th day 3 oz. (85 ml.) of urine was removed from the bladder. She was allowed small quantities of fruit juice by mouth, and also drank 150 ml. of Darrow's (1950) potassium solution. On the next day she passed 30 oz. (850 ml.) of urine spontaneously, and the intragastric drip was stopped.

Penicillin, 500,000 units b.d., was given throughout the period of anuria.

From then on recovery was uneventful. She was discharged from hospital on the 22nd day. At this time she still had a slight icteric tinge. Two weeks later this had completely disappeared and the blood urea was 28 mg. per 100 ml. When last seen, three months later, she was extremely well: the blood urea was unaltered, a urea concentration test was within normal limits, and the blood pressure was 120/75.

I wish to express my thanks to the Director of Medical Services, Federation of Malaya, for his permission to publish this case.

Reviews

GENERAL PRACTICE IN THE U.S.A.

The Physician and His Practice. By eighteen authorities. Edited by Joseph Garland, M.D. (Pp. 270+xii. \$5.) Boston and Toronto: Little, Brown and Co. 1954.

This book, which is edited by the editor of the *New England Journal of Medicine*, contains nineteen essays by eighteen hands, and is intended to guide the American doctor about to settle in practice. Its main interest for the British reader therefore lies in the picture it gives of the American scene and in the contrast with conditions in this country. It is stated in one article that at least half the community rely upon general practitioners for their medical care, and that 85% of all conditions in the community can be treated by well-trained general practitioners. Dr. Donald Clark, employing what may be called the Collings estimate of the general practitioner, which has been so much criticized in this country, reckons (writing apparently of the immediate past) that not more than 10 to 20% of general practitioners could be said to be competent. He classifies general practitioners into three classes: (1) those who have been inadequately trained by one year or less of "rotating" internships; (2) those who have been more adequately trained by two or more years of resident appointments; and (3) those who have by their continued industry developed into general-practitioner specialists. He adds the warning (in italics) that the more interested the general practitioner becomes in a specialty the less competent he may be as a general practitioner. If this assessment of the adequate training of the general practitioner is accepted here, it can be said that its implications have not yet been realized by those responsible for his education and his employment.

All the essays are informed by this same high seriousness, this starry-eyed sense of mission which makes the modern American so formidable a competitor. Even the doctor's wife and the doctor's children are bladen to realize the obligations of their high calling. One can imagine nothing more likely to diminish the marriage rate among English doctors than that all our sixth-form girls be given by their careers mistress the chapter entitled "The Doctor's Wife" to read. Yet the author of this essay provides the only joke in the book when she writes, "How very fortunate is the doctor's family that has encountered no greater dereliction than an enterprising young son's sale of tickets for admission to his father's library to view illustrations in medical books!"—a jest which she improves by a delightful mixed metaphor: "The doctor's and the clergyman's children share alike the pains of the halo that pinches."

This book also tells the embryo doctor how to manage his office, his aide, his partnerships, his investments, his insurances, his income tax, his real estate, and his will—in a word, his business as well as his profession. The disparity in our financial situations is illustrated by the advice to the practitioner to buy 100,000 dollars of life insurance and to pay his aide 54 dollars a week, and by the facts that the medical student spends more than 2,000 dollars a year, and that an unmarried doctor whose net income is 12,000 dollars a year has 8,000 dollars left to spend after paying his income tax.

There are some excellent chapters in this book, particularly one by Sidney Burwell on the evolution of the doctor, and another on the choice of opportunities by J. H. Means.

D. V. HUBBLE.

A STUDENT'S BIOCHEMISTRY

Biochemistry. By Abraham Cantarow, M.D., and Bernard Schepartz, Ph.D. (Pp. 848+xxv; illustrated. 55s.) Philadelphia and London: W. B. Saunders Company. 1954.

This is a new book which, according to the authors, is designed primarily to meet the needs of the first-year medical student. Its 848 pages follow conventional lines of treatment,

in which first is discussed the chemistry of carbohydrates, lipids, and proteins, including nucleoproteins. A chapter is then devoted to the chemistry of haemoglobin, porphyrins, and related substances. Vitamins, enzymes, and digestion are followed by a section on metabolism, including intermediary metabolism, water balance, and "inorganic metabolism." The book concludes with chapters on hormones, on the chemical composition of tissues, blood and other body fluids, and on urine function and renal function.

The authors have had long experience of teaching medical students, and this is shown in their lucid treatment of fundamental matters which may cause difficulty to those beginning the course in biochemistry. But in some instances the authors set their didactic sights too high. It is doubtful if the average medical student will understand the expression "Bonds hybrid, ca 2.3 covalent" (p. 119) in the formula illustrating methaemoglobin; nor is he likely to follow the argument that, because the designation "vitamin B₁₂" is applied to cyanocobalamin, in which the CN is bound co-ordinatively to the Co atom, "accordingly, B_{12a} (same as B_{12b}) is hydroxocobalamin" (p. 205).

The volume contains more than the number of slips in structural formulae usual in a new book. On page 129 the structures of vitamins A₁ and A₂ are identical, a reference to carbon atoms by numbers in the text being rendered nugatory by the absence of numbering in any of the formulae. The formula for ascorbic acid on page 141 is incorrect, and many double bonds are lacking on page 172. On page 663 the structure called pregnenolone is correct, but confusion will arise because this name is more commonly applied to an isomeric structure. Many of these slips will doubtless be corrected in any future edition, but the bulk of this rather discursive book is unlikely to be substantially reduced.

F. G. YOUNG.

THE THEMATIC APPERCEPTION TEST

The Thematic Apperception Test and the Children's Apperception Test in Clinical Use. By Leopold Bellak, M.D., with the assistance of Marjorie Bristol. (Pp. 282+x. \$6.75.) New York: Grune and Stratton. 1954.

This is a book for the specialist, being principally addressed to clinical psychologists and psychiatrists. It has the further limitation that those psychologists and psychiatrists who are still allergic to psychoanalysis should avoid it. Dr. Bellak is a psychiatrist and psychoanalyst, and his understandings and formulations would in large part be meaningless to those of too different a persuasion.

The thematic apperception test (T.A.T.) consists of a series of rather vague pictures to which the patient is asked to tell a story. It was invented by H. A. Murray in 1935. The large literature concerning the test is listed in the bibliography. Murray's original method of interpretation has, in fact been little used. Dr. Bellak here attempts to systematize interpretation by a method of scoring on rather complicated sheets. The rationale of this system is explained. To this reviewer it seems that the system is unnecessary, and so cumbersome that only wealthy American clinics could afford the time to use it. On the other hand, Dr. Bellak's interpretations in the many clinical examples given seem logical and indeed, in most cases, inevitable. The examples are numerous, and the chapters on interpretation are honest in admitting the limitations of the method. No one using or wishing to use the T.A.T. should fail to read this book.

The analogous Children's Apperception Test was invented by Dr. Bellak. It consists of a series of pictures of animals, devised in the belief that children identify with and project on to animals more easily than on to people, which is probably often true. This test is also described and many clinical examples of stories and their interpretations are given. Again the scoring sheet seems unnecessarily and Germanically complicated.

This is an extremely valuable book requiring hard work on the part of the reader.

STEPHEN COATES.

BIOCHEMISTRY OF SEMEN

The Biochemistry of Semen. By T. Mann, M.D., Sc.D., Ph.D., F.R.S. (Pp. 240+xiv; illustrated, 16s.) London: Methuen and Co., Ltd. New York: John Wiley and Sons, Inc. 1954.

Workers in the field of semen chemistry and physiology (and they now include a substantial number of biochemists, clinicians, zoologists, and veterinarians) will be greatly indebted to Dr. Mann for having written this treatise with masterly skill. The information which it compresses into a very modest compass is culled from numerous sources, the majority of which are comparatively inaccessible, and the bibliography of nearly a thousand items speaks eloquently for the completeness of this survey. To the writing of this book Dr. Mann has brought not only his authoritative knowledge of the subject, a clarity of expression, and preciseness, but also a conspicuous degree of scholarship. No better choice of author could be conceived for this contribution to the series of monographs on biochemical subjects published by Methuen.

The book begins with an account of the main structural and physiological features of spermatozoa and the accessory glands, and proceeds with a detailed description of the physical and chemical properties of semen and of the methods used for the evaluation of its quality. A particularly happy feature is the inclusion of much comparative data from many mammalian as well as non-mammalian species. Next, the influence of extraneous factors—hormones, sperm-egg interacting substances, spermicidal agents, sperm diluters, ionizing radiations, and deep freezing—receives consideration. Later chapters deal with metabolic processes which supply the spermatozoa with energy for their motility and survival. The identification of the sugar of seminal plasma as fructose was one of Dr. Mann's numerous original contributions to this subject, and it is therefore fitting that this substance, its secretion by the accessory glands, and its metabolism by spermatozoa, should receive special attention. Other chapters discuss the occurrence of inositol, lipids, and citric acid; nitrogenous bases including spermine, choline, and ergothioneine; and the protein constituents and enzymes of spermatozoa and seminal plasma.

This book ought to be in the possession of anyone who in any way is concerned with animal reproduction.

G. I. M. SWYER.

ANAESTHESIA

Fundamentals of Anaesthesia. Prepared under the Editorial Direction of the Consultant Committee for Revision of *Fundamentals of Anaesthesia*, a publication of the Council on Pharmacy and Chemistry of the American Medical Association. Third edition. (Pp. 279; illustrated, 30s.) Philadelphia and London: W. B. Saunders Company. 1954.

This excellent manual will be remembered by most anaesthetists working during the early part of the war as one of the best summaries of the subject. The present edition, appearing after an interval of ten years, brings the material up to date with little increase in the number of pages. The authors are all familiar names in the American literature on anaesthesia, and their contributions have been welded into a remarkable uniformity of style. The field covered is comprehensive. The physiology, chemistry, physics, pharmacology, and toxicology of anaesthetics, local analgesia, complications, and every other aspect of the subject are all dealt with. Any anaesthetist is certain to find something of interest here. This includes candidates for examinations, who may justifiably consider this one of the best books for revising their subject. The style is one of brevity both of words and of illustrations; tabulation is used throughout. One surprising, but at the same time comforting, feature of the book is the little divergence between British and American views on anaesthesia, either theoretical or technical.

The book is thoroughly recommended, and the authors are sincerely congratulated on a valuable contribution to the teaching literature on anaesthesia.

W. W. MUSHIN.

PERIPHERAL VASCULAR DISEASES

Peripheral Vascular Diseases: Diagnosis and Treatment. By William S. Collens, M.D., and Nathan D. Wilensky, M.D. Second edition, by 17 contributors. (Pp. 622+xxxii; 366 illustrations, 66 in colour, 86s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications Ltd. 1954.

The second edition of this well-known textbook is conceived on broad lines, and includes within its scope not only vascular diseases of the extremities, but also affections of the vascular tree of the central nervous system, the skin, and the viscera. This breadth of viewpoint is further illustrated in the section on arteriovenous fistulae, where the haemodynamic alterations associated with this condition are discussed and the reduction in size of the heart after excision of the fistula is shown. Recent advances have been made in the understanding of the basic physiology of capillaries, and these are discussed in relation to the genesis of peripheral vascular diseases. In particular the work of Chambers and his associates in this field is summarized. Due emphasis is given to the importance of modern antibiotics in controlling secondary infection complicating peripheral vascular diseases. The authors stress the fact that antibiotics have probably been responsible for saving more limbs than any other recent therapeutic advances.

The book, which is well arranged and clearly illustrated, is divided into two main sections. The first deals with the physiology, anatomy, and pathology of peripheral vascular diseases, and there is a full section on clinical methods and diagnosis. A second portion of the book is devoted to treatment. The importance of the application of the basic laws of physiology to general treatment is stressed, and a detailed account of the specific therapy for individual diseases given. It is a pity that the index of subject-matter is so incomplete.

The book is a most readable and comprehensive monograph in which the practical therapeutic approach to disease is never lost sight of.

J. P. D. MOUNSEY.

EYE SYMPTOMS IN NEUROLOGY

Klinik der Augensymptome bei Nervenkrankheiten. By Werner Kyrleis. (Pp. 153+xi; illustrated, D.M. 32.) Berlin: Walter de Gruyter and Co. 1954.

This book on eye symptoms in neurology by Werner Kyrleis is an elementary exposition of neuro-ophthalmology. The first section of six chapters deals with eye symptoms in nervous disorders, discussing optic atrophy, papilloedema, field defects, pupil anomalies, motor anomalies, and disturbances of the cranial nerves. A further eight chapters give a more strictly neurological approach. Here the common nervous disorders are discussed with special emphasis on the ocular anomalies. The simple plan of this book and the rather confident teaching are eminently suitable for an elementary exposition.

ARNOLD SORSBY.

Antibacterial Drugs, a Short Review by S. W. BIBLE, Lecturer in Pharmacology in the University of Ceylon (Ceylon University Press), was written at the behest of a Committee of the Faculty of Medicine of that university, following inquiries which showed that difficulty was being experienced in keeping abreast of knowledge in this subject. It describes the properties and uses of sulphonamides and the principal antibiotics, defining the indications for and appropriate dosage of each, and mentioning any toxic or other undesirable effects which may result. There are sections on combined treatment, and a concluding summary of clinical applications which ventures on the difficult task of making a first and second choice of drug for treating each infection. It is characteristic of the rational attitude adopted that infections are primarily classified here according to the organism causing them. The instructions given are clear, well-informed, and orthodox; if they were strictly followed, many patients would benefit and much of the misuse now so common would be obviated. This pamphlet deserves a wider circulation than in Ceylon, or alternatively authorities elsewhere might consider issuing something similar. Of the 52 items in the reference list, 16 are papers or editorials in this *Journal*.

GENETIC EFFECTS OF NUCLEAR RADIATION

A new dimension was added to our understanding of the biological effects of ionizing radiations when H. J. Muller discovered, not quite thirty years ago, that they affect the determinants of heredity. As is well known, every animal receives from each parent a set of hereditary factors, or genes. The two sets, coming together in the process of fertilization, determine the potentialities which will be realized to a greater or less extent as the circumstances of the individual's development allow. The genes are remarkably stable, being passed on from parent to offspring through many generations without alteration. But even under normal circumstances the stability is not absolute. Occasionally a gene will change suddenly into a new form—a process known as "mutation." This word merely names the process; it does not describe it, since in fact we have very little idea of what happens when a gene becomes altered or in what the alteration consists. However, if ionizing radiations reach the genes, which lie on the chromosomes within the nucleus of every cell in the body, mutations are provoked. Mutation may contribute to the deleterious effects of ionizing radiations on somatic tissues, but most adult tissues can probably put up with a fairly high rate of mutation without showing any very harmful effects. The situation is much more serious when ionization reaches tissues which will ultimately give rise to the germ cells. A mutation produced here will, again, probably have little effect on the cell in which it occurs. But if the germ cell which is eventually formed carries the mutated gene, the individual to which it gives rise in the next generation will start life with a set of genes of which one is abnormal; and the mutated gene may be handed on again and again through many subsequent generations.

A mutated gene will often not make its presence felt immediately after it has arisen. Each individual receives two of each kind of gene, one from each parent. If one of the two is abnormal—is present only "in single dose," as genetic jargon has it—either of two situations may arise: the single normal gene may confer on the animal almost normal developmental potentialities, or the abnormal gene may, to a varying extent, exert some influence on development. The former situation, in which the abnormal gene is

said to be recessive and its effects are concealed if there is a normal partner for it, is probably the more common, at least where genes with striking effects are concerned. But that tentative conclusion is based mainly on experience with lower animals. We have not yet anything like a full understanding of what may be the situation in man, in whom recessive genes are hard to detect. In particular it is not at all certain that it applies to genes with slight effects; they may well be the commonest type, but are extremely difficult to identify.

During the course of evolution, natural selection will have ensured that, by and large, the most useful form which a given gene can take will have become the most widespread form; any change from it will almost certainly be a change for the worse. An increase in the frequency of mutation is not to be encouraged. A certain amount of mutation is probably inescapable. In the main, this natural mutation seems to be due to an inherent instability of genes; but to an extent which is probably slight, though in man not fully known, it is brought about by cosmic rays and the radioactivity of the earth's surface. The effect of artificially caused ionization is to add to this natural background. Geneticists have extensively studied the effect of ionization in provoking mutations, but nearly all the work has been done on such cheap, rapidly reproducing organisms as flies, moulds, and bacteria. The investigations which have been made on mammals have been chiefly on the mouse, and have nearly all been devoted to studying the effects of heavy doses of radiation which will cause mutations frequent enough to be discovered even when only small numbers of animals are bred. These experiments have contributed much to the theory of the situation, but by their very nature they miss giving direct answers to the questions which, we hope, are most germane to human affairs.

If atomic bombs were to be exploded in warfare, some of the survivors would probably be exposed to rather large doses of irradiation, of the same order of magnitude as have been used to provoke high rates of mutation. Even if we escape that catastrophe, we may still have to reckon with the possible effects of low intensities of ionization. Not only are x rays becoming more widely used both in industrial practice and in medicine, but, as we discussed in these columns last week,¹ experimental explosions of hydrogen bombs liberate ionizing particles which add their quota to the background of radiation over a very wide area.

It is obviously of the greatest importance to discover how much additional ionization is being produced in this way, but the figures given in the recent House of Commons debate² seem open to

¹ *British Medical Journal*, March 26, p. 775.

² For report see p. 856.

several interpretations. The Minister of Health quoted from the report by the United States Atomic Energy Commission on the effects of test explosions, which states that "the total amount of radiation received by residents of the United States for all nuclear explosions to date . . . has been about one-tenth of one roentgen unit." And he pointed out that the natural background radiation is about 0.1 r per year. This would suggest that we have already, in the ten years or so since the first atomic explosions occurred, accumulated the equivalent of an extra year's natural radiation. Experimental explosions are becoming more frequent and larger in scale, and their effects on atmospheric ionization are to some extent cumulative, both of which points suggest that the next year's additional radiation will take considerably less than ten years to accumulate. On the other hand, Mr. Macleod went on to say that "the figure is calculated on the assumption that a man stands outside in the open for 24 hours a day for 50 years," which seems to imply that mankind has not yet received an extra 0.1 r, but is being subjected to it at a rate of only 0.02 r per year. This is the interpretation which has been put on the figures by the more conservative leading geneticists, such as Professor C. H. Waddington in Britain and Professor A. H. Sturtevant in the U.S.A. It is essential that the point should be cleared up in an authoritative way. Are we accumulating an excess annual dose in something less than ten years, or in fifty? And how fast is the rate increasing? It would seem sensible, and quite easy, to set up a monitoring service which would keep a watch on atmospheric ionization, at first on a national and perhaps eventually on an international basis. The driver of a motor-car about to free-wheel down a slope might think it only prudent to examine as carefully as possible the lie of the land ahead and to inspect the brakes.

At present we have no precise knowledge of the rate of mutation produced by low intensities of radiation in any mammal, let alone in man, and are forced to argue by extrapolation from results obtained with flies or moulds. Even with these simpler organisms experiments with low intensities have been few, and their results not altogether consistent. The best estimate to which they lead, according to Professor Sturtevant, is that the excess ionization produced by atomic explosions so far would cause about one extra very harmful mutation per 50,000 conceptions, and perhaps about the same number of slighter ones in addition. This is based on the estimate that the excess ionization has been at the rate of 0.1 r per generation. But the figures, although they probably give a rough idea of the order of magnitude, are largely guesswork. Energetic steps should

be taken to measure the actual mutation rates of mammals (presumably our long-suffering friend the mouse is cast for the part) exposed to low-intensity radiation. Experiments with other animals have failed to show that any dose is too low to be effective, but we need to make sure whether some fortunate circumstance causes there to be a safe "tolerance" dose in mammals. Again, in some species it seems probable that if a dose of irradiation is received in a limited period of time its effect gradually wears off, in the sense that most of the mutations are concentrated in germ-cells which were at a particularly sensitive phase of their development at the time of exposure. We have as yet no knowledge whether this is true in mammals, or, if so, how long it takes for the effect to wear off. The practical problems which call for further scientific research are innumerable. Mr. Macleod did not allay anxiety when he stated that the expenditure of the Medical Research Council on all research connected with the effects of radiation amounted to £208,000. How much, or perhaps we should ask how little, of this sum was devoted to work directly concerned with the genetic effects of low-intensity ionization on mammals?

AGRICULTURAL POISONS

The application of toxic chemicals to control weeds and insect pests begins early in April and will continue for several months. Since 1951 few cases have been recorded in Britain of poisoning due to these potentially dangerous substances, though they have been increasingly used. This satisfactory record is due largely to a greater awareness of the risks, particularly to spray operators working in fields and orchards, where protective measures and adequate supervision are difficult to arrange, and to the action taken to ensure that everyone concerned in pest control handles these chemicals carefully. The Agricultural (Poisonous Substances) Act, 1952, and its regulations provide statutory protection for persons applying certain toxic chemical substances in agriculture by defining the conditions in which these substances may be used.

Although measures to prevent poisoning are being revised and improved, the risk of poisoning, which may be rapidly fatal, remains for everyone concerned in the manufacture and application of these substances. Because spraying must be carried out when weather conditions and the stage of the crop's growth are favourable, there is a temptation for spray materials to be used hurriedly and without due care. In such circumstances poisoning may result for which the correct treatment promptly administered may save

life. Dr. E. F. Edson, in an article at p. 841 of the *Journal* this week, summarizes the knowledge available about the nature of the substances used as weed-killers, insecticides, fungicides, and crop defoliants and their effects upon man, and describes the treatment of poisoning by these substances. Experience suggests that the risk of poisoning by many of them is slight except when large amounts are ingested accidentally or with suicidal intent. For poisoning by the hydrocarbon group of insecticides the treatment is non-specific and along the lines generally adopted for any form of acute poisoning following ingestion. This group includes D.D.T., B.H.C., and lindane, aldrin, dieldrin, heptachlor, chlordane, and toxaphene. These substances can be absorbed through the skin, and a case has been reported of a young woman dying within 40 minutes of spilling chlordane concentrate on her dress.¹ The symptoms of acute poisoning by the chemicals in this group include stimulation of the central nervous system, with convulsions and coma preceding death. When poisoning is due to ingestion, the symptoms from the central nervous system are preceded by nausea, vomiting, and diarrhoea. Treatment is symptomatic, and sedation by means of adequate doses of barbiturate is most effective. The liver and kidneys may later show signs of being affected, and patients recovering from acute poisoning should be kept under observation. Although D.D.T., chlordane, B.H.C., and similar substances have been used in considerable quantities in many parts of the world, there is no evidence to suggest that persons using them as insecticides suffer any serious risk of acute or chronic poisoning.

Medical emergencies arising during the manufacture and use of spray materials are almost entirely due to two groups of compounds—the dinitro-compounds, such as dinitro-*ortho*-cresol (D.N.C. or D.N.O.C.) and dinitro-2-secondary-*butyl*-phenol (dino-seb, D.N.B.P.), and the organic phosphorus compounds, of which T.E.P.P. and parathion are the best-known. It is to these two groups of substances that the regulations under the Agricultural (Poisonous Substances) Act, 1952, apply. The danger of both groups of compounds lies in the fact that the effects of absorption are cumulative, and the early symptoms may be misinterpreted or ignored by both workman and doctor. The progress from this stage to serious illness and possibly death may be extraordinarily rapid.

Poisoning by D.N.C. or other dinitro compounds occurs most commonly during a spell of hot weather and in people who have been at risk of absorbing it for several days. Experiments on human volunteers have shown that repeated small doses of D.N.C. by mouth cause the concentration in the blood to rise, without causing symptoms, to a level of about 20 μ g.

per g. of whole blood. At this point the administration of a further small dose, less than 1 mg. per kg. body weight, causes a sharp rise in the concentration of D.N.C. in the blood associated with headache, lassitude, and general malaise. Estimation of blood D.N.C. in cases of poisoning indicates that the symptoms can be related to the blood D.N.C. concentration. These observations suggest that spray operators and others at risk of absorbing D.N.C. should be transferred to other work when the blood D.N.C. concentration is above 20 μ g. per g. of whole blood. Dr. Edson refers to simple methods for the estimation of dinitro compounds in the blood.

The early symptoms and signs of poisoning by dinitro compounds are an unusual feeling of well-being, sweating, mainly at night, insomnia and restlessness, increased thirst, anorexia, yellow coloration of the sclera, chrome-yellow urine, and raised basal metabolic rate. Late signs, which may develop rapidly and less than an hour before death, are an anxious appearance, profuse sweating (described in one case as so excessive that the sternal notch filled with sweat as one watched), intense thirst, yellow skin, air hunger, listlessness and apathy, rising temperature and pulse rate, and a striking increase in basal metabolic rate. Convulsions and coma, probably due to anoxia, precede death.

Since these symptoms are due to acceleration of the oxidative mechanisms in the body, resulting in an increased need for oxygen and efficient heat loss, and since no antidote to D.N.C. poisoning is known at present, treatment must be directed towards ensuring adequate oxygen intake, promoting heat loss, replacing lost fluids and electrolytes, and allaying anxiety. The skin should be washed, but since D.N.C. dyes the tissues washing will not remove the yellow colour. Absorption through the skin is not of great importance in this form of poisoning. Successful treatment of a man seriously poisoned with D.N.C. is described in detail by A. B. Pollard and J. F. Filbee.² The scheme of treatment was similar to that recommended by Dr. Edson. Patients recovering from poisoning by dinitro compounds should not resume work with them until the concentration of D.N.C. in the blood is less than 5 μ g. per g. of whole blood.

The organic phosphorus compounds inhibit the enzyme cholinesterase, so that acetylcholine (a transmitter of nerve impulses), which is destroyed rapidly by cholinesterase, accumulates at nerve endings throughout the body. The signs and symptoms of poisoning are those of excess acetylcholine acting at particular sites. They include, first, those due to muscarine-like action of the poison, such as anorexia, nausea, vomiting, cramp-like abdominal pain, excessive sweating and salivation followed by pallor,

¹ Barnes, J. M., *Toxic Hazards of Certain Pesticides to Man, Wld Hlth Org. Monogr. Ser.*, 1953, No. 16, p. 58.
² Pollard, A. B., and Filbee, J. F., *Lancet*, 1951, 2, 618.

miosis, diarrhoea, involuntary micturition and defaecation, broncho-constriction, pulmonary oedema, and cyanosis; secondly, those due to action on the central nervous system, such as giddiness, apprehension, restlessness and headache, progressing to ataxia, tremor, drowsiness, and convulsions; and thirdly those due to nicotine-like action, such as twitching of the muscles of the eyelids and tongue, spreading to affect the muscles of the face and neck and the extraocular muscles, and finally generalized weakness of voluntary muscles. In the individual case of poisoning by an organic phosphorus compound some, but by no means all, symptoms and signs from each group will be observed. The presenting symptoms will depend on the properties of the substance responsible and the route by which it has been absorbed. Accordingly the symptoms may be predominantly gastro-intestinal or pulmonary in the first stage, or may be mainly from the central nervous system. Anyone who has recently been at risk of absorbing an organic phosphorus compound and who develops any of the symptoms listed above should be presumed to be suffering from poisoning until the diagnosis is disproved. Confirmation of the diagnosis of organic phosphorus poisoning can be obtained by estimating the blood cholinesterase. Edson discusses the methods and the interpretation of results.

Atropine is a specific antidote to the muscarine-like action of the poison on the central nervous system: 1-2 mg. (1/60-1/30 gr.) should be given by intramuscular injection as soon as possible after the onset of symptoms and repeated at hourly intervals until signs of atropinization appear. If pulmonary oedema is already present, postural drainage to remove fluid should be attempted, and oxygen under slight pressure should be administered when necessary to overcome bronchoconstriction. In contrast to the dinitro compounds, the organic phosphorus compounds are absorbed readily through the skin, so that clothing should be removed promptly and the skin washed thoroughly. The nicotinic effects are not altered by the administration of atropine and no antidote to them is known. Close observation is necessary to ensure that muscular weakness does not cause failure of respiration or difficulty in swallowing, with aspiration into the lungs. Artificial respiration may be necessary for long periods. Some of the organic phosphorus compounds cause damage to the central nervous system, and two cases have been observed in which paralysis of all four limbs developed in the third week following apparent recovery from the acute effect of poisoning by an insecticide. Patients should be kept under observation until this possibility is excluded, and until blood cholinesterase is within normal limits.

In treating patients poisoned by these substances there may be little time in which to apply life-saving

measures so that they can be effectual. Consequently there must be no delay in carrying out the emergency treatment and in arranging for the patient to be admitted to hospital.

TETRACYCLINE

April 4, 1955, is a significant date in the history of therapeutics in this country, for on it the last of the present major antibiotics is to be derestricted. It thus marks the end of a period of over ten years during which successive antibiotics from penicillin onwards have been available either only in hospitals or, in addition, only from the Ministry of Health for limited indications—this at a time when they were freely available in the United States and some other countries. The time lag between such availability in America and with us has varied, that for aureomycin (chlortetracycline) having been the longest—fully five years—and for erythromycin the shortest. The subject of this final derestriction is tetracycline ("achromycin," "tetracyclin"), which has the structure common to both chlortetracycline (aureomycin) and oxytetracycline (terramycin) without the minor attachments characterizing the two latter. As might be expected, the action of all these three antibiotics is very similar: there is little to choose between them in their activity against the commoner bacteria, and cross-resistance between them is complete. Minor differences are the somewhat greater activity of oxytetracycline against *Ps. pyocyanea*, of tetracycline against *Proteus*, and of chlortetracycline against *Str. faecalis* and *Staph. aureus*.¹ Chlortetracycline has also been found more effective than the other two in the treatment of experimental pasteurellosis.²

There may also be minor differences in the degree of absorption and the concentrations attained in the blood,³ and a further advantage claimed for tetracycline (probably of little clinical significance) is greater stability, but the claim of this drug to superiority rests mainly on its alleged lesser tendency to produce side reactions. The importance of this advantage, if it is real, should not be minimized. It has long been recognized as a drawback of the broad-spectrum oral antibiotics that they often cause nausea, with or without vomiting, and diarrhoea: these effects led to an emphatic preference for injections of penicillin by the patients in the Medical Research Council trial in pneumonia. A sore mouth and pruritus ani are apt to follow, and occasionally the multiplication of *Candida albicans*, which is responsible for these symptoms, may lead to more serious consequences. Any antibiotic treatment which suppresses most of the flora of the alimentary tract—and this includes not only chlor- and oxytetracycline but the combination of penicillin and streptomycin—may be complicated by infection with antibiotic-resistant staphylococci. This sometimes takes the form of a fulminating and even fatal enterocolitis, and the published accounts of this condition convey the impression that it more readily develops in patients who have undergone a major abdominal operation.

¹ Love et al., *Proc. Soc. exp. Biol. (N.Y.)*, 1954, **85**, 25.

² English, *Antibiot. and Chemother.*, 1954, **4**, 1082.

⁴ *J. Amer. med. Ass.*, 1954, **154**, 561.

⁵ *New Engl. J. Med.*, 1955, **262**, 173.

What evidence is there that tetracycline administration involves a lesser risk of either the milder or the more severe of these complications? The original claim to this effect was borne out by the observations of Finland and his colleagues,⁴ who found tetracycline least, and oxytetracycline most, liable to produce diarrhoea—chlortetracycline being intermediate between them. Tetracycline may well be better tolerated in the general sense, but there is no evident reason why it should render the alimentary tract any less susceptible to infection by a staphylococcus which will be as resistant to it as to the other two drugs. It is not certainly known how these superinfections arise, but all that we now know of the behaviour of this organism points to cross-infection in a unit where a resistant strain has become established as the most likely source. How will patients treated with tetracycline fare in such an environment? The study of Frei and his colleagues⁵ of the tetracycline treatment of pneumonia perhaps gives an answer to this question, although it includes no evidence confirming the hypothesis of cross-infection. They treated 26 patients with tetracycline in a dose of 1 g. every six hours and 31 with soluble penicillin, 300,000 units being given twelve-hourly. There was no distinguishable difference in therapeutic efficacy as judged by any of five criteria, but, whereas none of the penicillin-treated patients experienced any ill effects, eight of those given tetracycline had side reactions. Four had nausea, vomiting, and a profuse diarrhoea—with *Staph. aureus* predominating in the faeces—necessitating the abandonment of the treatment and the substitution of penicillin; three other patients are mentioned as having had a milder form of the same condition; and one patient had a glossitis and pharyngitis which was in part staphylococcal, another a skin rash, while the remaining two had superinfections due to other organisms. It can be argued that the dose of tetracycline was excessive: on the other hand, this study proves this drug has the same defect as oxy- and chlortetracycline in at least some degree. In the opinion of these authors, "a direct comparative study is still needed" to define the relative merits of these drugs from this standpoint. It will now be open to anyone with suitable clinical material in this country to make such a comparison for himself.

RAUWOLFIA IN HYPERTENSION

The mortality of patients suffering from hypertension, however mild, is greater than in those whose blood pressure may be said to be normal. If there existed a reliable, safe hypotensive drug which could be taken by mouth it should be of benefit to everyone with hypertension. Unfortunately there is no such drug. It hardly needs repetition that the symptoms of hypertension are those of the complications, and headache and anxiety are mainly iatrogenic. Any drug prescribed with sufficient conviction will have a calming effect, without necessarily reducing the blood pressure. Everyone would agree that severe hypertension with papilloedema must be treated, and the best drugs for this purpose are ganglion-blocking agents (notably hexamethonium¹). Until fairly recently they were adminis-

tered by subcutaneous injection several times a day, but now it appears likely that reasonable control can often be obtained with pentolinium tartrate ("ansolysen") by mouth. The dangers of such treatment are not great, but include paralytic ileus, which may be disastrous. The side-effects of postural hypotension, difficulty in accommodation, dry mouth, and constipation, can all be very unpleasant.

For the treatment of hypertension without papilloedema but with diastolic pressures usually ranging from 105 to 125 mm. Hg there are now two drugs available which are safe in moderate dosage and can be taken by mouth. They are the rauwolfia alkaloids and veratrum and its derivatives. Of these two, rauwolfia is probably more satisfactory, having superior hypotensive action with fewer side-effects in the dosage used. In 1582 Leonard Rauwolf, a German botanist, published the results of his investigations of medicinal plants which he had studied during an expedition to Asia and Africa. One of these plants was subsequently named after him and is what we now know as "rauwolfia." Of the many species of rauwolfia the most important is *Rauwolfia serpentina*, which grows mainly in India: extracts from it have been used intermittently for a variety of disorders during the last three or four centuries, but it was not until a few years ago that an alkaloid (reserpine) was isolated which was found in animal experiments to have a hypotensive and sedative action. When given to unanaesthetized animals it causes a reduction of spontaneous activity with no change in the normal electroencephalographic pattern, in contrast to the effect of barbiturate administration. In dogs miosis appears early and is prevented by excision of the ciliary ganglion. In the cardiovascular system sinus bradycardia occurs and varying degrees of hypotension are recorded. The bradycardia is abolished in animals by atropine, and the hypotensive effect is not altered by change of posture. It is unlikely that the action of the drug is related to autonomic blockade, and it has been suggested that its main seat of action is in the region of the hypothalamus.

The papers in this issue by Dr. Inder Singh (p. 813) and Dr. S. Locket (p. 809) describe the clinical use of rauwolfia, and their results confirm the findings of others.^{2,3} The drug brings about a mild or moderate reduction of blood pressure at the expense of only mild toxic effects such as nasal stuffiness, diarrhoea, and depression. In another paper Drs. C. W. Curtis Bain, F. Ashton, and B. P. Jones (p. 817) report that rauwolfia in combination with pentolinium tartrate enables less of the latter very potent but toxic drug to be used. This is a more encouraging use for rauwolfia than in combination with veratrum.⁴ Thus the drug treatment of hypertension is gradually being put on a more satisfactory basis, the subcutaneous ganglion-blocking agents being available for severe hypertension, the oral ganglion-blocking agents together with rauwolfia for moderate hypertension, and rauwolfia alone for mild hypertension.

ASSISTANTS IN GENERAL PRACTICE

Since early in 1953, when the Assistants and Young Practitioners Subcommittee of the General Medical Services Committee first called attention to the difficulties experienced by young doctors in becoming established principals in the National Health Service, the employment of assistants in general practice has been the subject of controversy. That some young doctors have difficulties no one disputes, and it is generally agreed that the chief cause of the trouble is the blocking of promotion by a hard core of principals who make a habit of advertising posts "with a view" and yet take none of a succession of assistants into partnership. It is difficult to say quite how much of this sort of thing there is, and accurate evidence is hard to get. Our correspondence columns in recent months have borne witness to feelings of frustration, and Dr. Leslie Potter, in the Annual Report of the B.M.A.'s Medical Practices Advisory Bureau,¹ says that there are too many "blind alley jobs" being offered to young doctors. Yet he also says that available figures suggest that the number of so-called permanent assistants is falling; and this is in line with the increase in the number of partnerships recorded in the Medical Practices Committee's report.²

As a solution of their problem the young practitioners have consistently advocated proposals aimed, in the main, towards a reduction of the additional list of patients (2,000 in number) allowed to a principal by virtue of his employment of an assistant. They think that, as things are, having an assistant is too profitable financially for a principal and that this is a real deterrent to him to make his assistant a partner. The G.M.S. Committee, although sympathetic towards the unestablished practitioners' difficulties, has been unable to accept their suggested remedy and has made a report which will go before the Annual Conference of Local Medical Committees on May 19.³ Its recommendations must be studied in the whole context of the report of which they are a part. The need to impress on assistants the importance of entering into a formal agreement when taking a post may seem elementary unless it is realized how often this precaution is neglected. The recommendation suggesting that local executive councils should have, in consultation with local medical committees, additional powers to regulate the employment of assistants provides means for selectively dealing with those principals who, as the report puts it, flagrantly disregard the principles of fair treatment.

The report's final recommendation is that a principal who registers with the executive council an agreement with an assistant with a view to partnership should be able to claim retrospective payment on the basis of notional lists for a period up to a maximum of one year when the partnership is implemented; it should be an appropriate incentive to the fair-minded principal who is willing to give a hand to a junior colleague.

¹ Supplement, March 26, p. 120.
² Ibid., September 11, 1954, p. 113.
³ See this week's Supplement, p. 151.

The G.M.S. Committee's proposals are a constructive answer to the problem and would not upset the harmonious relations which exist between the majority of principals and assistants.

ACCURACY IN BIOASSAY

The assay of many therapeutic substances, and the investigation of new substances of possible therapeutic value, entail the use of animals, and such use accounts numerically for by far the greatest number of laboratory animals, most of them being mice. It is plainly important to choose the right sort of mouse, or other species, so that the accuracy of assay should be as great as possible, and in this connexion genetically identical animals have been suggested as a more reliable instrument than mixed strains. Winton¹ reported in 1926 that one inbred Wistar rat was, in the assay of red squill, about as useful as ten rats of mixed breed, and attributed this to genetical uniformity. Over the last twenty years the use of inbred strains has achieved increasing popularity in the interests of accuracy, even though it may be suspected that in not every case of their reported use has the extent of inbreeding been such as to produce near-homozygous animals. But the fact that attention was directed to the pedigree of animals meant that their environment was also under more or less strict control, and, as Lane-Petter² has pointed out, this in itself may contribute much towards uniformity.

Elsewhere in this issue of the *Journal*, Dr. Elizabeth Russell discusses the difference in physiological responses that may exist between inbred strains of mice, and puts forward convincing evidence to support her views. The right inbred strain is a valuable instrument of research, which should therefore make more use of homozygous strains than it does. On the other hand, Grüneberg³ has pointed out that homozygous animals are sometimes less stable developmentally than heterozygotes and may therefore be less uniform, and adds his warning that not all reputed "pure lines" are homozygous. McLaren and Michie⁴ have concluded that, at least for some purposes, a balance has to be struck between homozygosity, which leads to phenotypic variability, and heterozygosity, which may operate in the reverse sense. Moreover, even if genetical identity contributes to uniformity—as it undoubtedly does for very many purposes—homozygous animals are not the only ones available; animals in the first-generation cross between two different homozygous strains are partially heterozygous, but always in the same way, and meet the criterion of genetical identity as fully as homozygous animals, while being less variable. Biggers and Claringbold⁵ have suggested that, for uniformity of response to bioassays, each test should be examined on its merits: for some tests a suitable inbred strain will serve, but for others the first-generation cross between two inbred strains will be preferable, and for yet others randomly bred animals will not only be as accurate but may even be superior as well as being (generally) easier and cheaper to produce. It is for the bioassayist to make the choice in the light of his own requirements.

EMERGENCIES IN GENERAL PRACTICE
AGRICULTURAL PESTICIDES

BY

E. F. EDSON, O.B.E., M.B., Ch.B., M.Sc.

Medical Department, Fisons Pest Control Ltd., Cambridge

This article sets out to help general practitioners, especially those in areas of intensive agriculture or horticulture, to deal with emergencies arising from the use of chemical pesticides. A short article can only emphasize the more important facts, in the hope that interested practitioners will then seek further information.

Chemicals Used

There is now a large and annually increasing range of pesticidal chemicals, with many proprietary brands and special-purpose variants. These chemicals differ so much in toxicity to animals and potential hazard in use that any attempt to divide them into such simple groups as "comparatively safe" and "hazardous," as in the Table, may need revision later. The safest chemical can be dangerous if sufficiently mishandled, while the most hazardous can be safely used so long as adequate precautions are maintained.

Pesticides in Common Use

Purpose	"Comparatively Safe"	"Hazardous"
General herbicides	Borates Sodium chlorate *C.M.U.	Sulphuric acid (corrosive) Arsenites
Selective weed-killers	Sodium trichloroacetate 2,4-D 2,4,5-T M.C.P.A. { hormone- type growth *M.C.P.B. { regulators *Pentachlorophenol	D.N.C. (dinitro- <i>o</i> -cresol) D.N.B.P. (dinoseb, dinitrobutyl phenol)
Fungicides	Copper compounds Sulphur Zineb, Thiram Lime sulphur Dilute D.N.C. or D.N.B.P. Captan	Lead arsenate Organic mercurials, e.g., ethyl, methyl, phenyl, or other mercurial salt. (Also used in seed-dressings)
Crop defoliants	Monochloroacetate	D.N.C. Arsenites
Insecticides and acaricides	Tar oils Derris Pyrethrum "PCPPCBS" D.D.T. B.H.C. and lindane *Aldrin, Dieldrin *Chlordane, Heptachlor Organic phosphorus compounds: *Malathion *Methyl-demeton	Lead arsenate Nicotine Organic phosphorus compounds: Parathion T.E.P.P. (H.E.T.P.) Schradan Dimetox Demeton

* These chemicals are of recent introduction and their comparative safety is provisional.

Over 90% of British pesticide usage involves the comparatively safe chemicals listed above. Many growers still prefer to pay professional spraying contractors to carry out hazardous operations, but the more experienced are now tending to use the hazardous chemicals themselves.

Occupational Hazards

The main occupational risks are unremoved splashes and smears of chemical on the skin, chiefly on the hands, from handling concentrated preparations or contaminated equipment, and the prolonged inhalation of airborne mist or dust whilst spraying. Ingestion may sometimes occur—for example, from blowing or sucking at blocked jets or contamination of food or water. Eye contamination may produce local effects but hardly ever any risk of poisoning. Vapour concentrations out of doors are rarely high enough

to be of toxicological importance; the important inhalational hazard is that of particles, not vapour. Frequently repeated minor over-exposures are markedly cumulative in their effects, but early effects are usually slight and tend to be ignored or misconstrued until acute illness begins to show itself. Risks are dictated not simply by the nature of the chemical used but also by the suitability and serviceability of equipment, the worker's own care and cleanliness, and the duration of his exposure.

The chief users of the hazardous chemicals are spraying contractors and their employees, farm workers, workers in greenhouses, orchards, hopfields, and market gardens, private farmers, workers in seed-dressing establishments, and scientific workers. Deliberate or accidental ingestion may occur in adults or children, as dangerous chemicals are often insecurely stored by purchasers. The hazardous chemicals are not easily available to or much used by amateur gardeners, whose occupational exposure and risk is therefore small.

The period of most intensive use and consequent risk is from early April to August or September, the peak months being May, June, and July. Periods of fine hot weather intensify field spraying and sharply increase risks. Pesticide usage is most concentrated in the Eastern, South-eastern, and Midland counties, but is quickly extending.

As in most other countries, fatalities occurred in England during the early years of use. Eight agricultural deaths occurred between 1946 and 1951, all in contract spraying operators in hot weather, from the intensive use of D.N.C. as weed-killer, obviously without adequate safety precautions. The ninth death occurred in a glasshouse worker in Guernsey in 1954, due to over-absorption of parathion. There have also been a number of cases of mild poisoning, but it is encouraging that there has been no fatality or serious accident from the use of D.N.C. since 1951, despite its wider use.

Emergencies from "Comparatively Safe" Chemicals

With chemicals of comparatively low toxicity, emergencies are only likely from accidental or deliberate ingestion of large single doses. The effects would then probably include violent nausea, prompt severe vomiting, purging, and abdominal pain, leading on to mental confusion, collapse, tremors, stupor, circulatory failure, respiratory distress, cyanosis, convulsions, and death in coma. With such compounds the full severity of the case may not be apparent for some hours or even days. If there is prompt vomiting or a gastric wash-out is performed quickly, a patient may survive the immediate effects, later to show prolonged weakness, or delayed further illness, due to secondary effects on, for example, the liver, kidney, or nervous system. Such effects may at times be due to the solvent, not to the active chemical. The prognosis should be guarded for at least one or two weeks.

General procedures in such medical emergencies are suggested below. The modes of toxic action of the less hazardous chemicals are rarely known, and, with two exceptions, there are no specific antidotes or pharmacological antagonists to be recommended. The most urgent needs are the rapid removal of residual chemical from the stomach, followed by good nursing, symptomatic and supportive treatment, with careful observation during the recovery period for late effects on the liver, kidney, blood, nervous system, or gastro-intestinal tract.

Poisoning by the comparatively safe organic phosphorus insecticides malathion and methyl-demeton should be treated as later advised for the more toxic organic phosphorus compounds. Pentachlorophenol closely resembles D.N.C. and D.N.B.P. in its manner of disrupting carbohydrate metabolism, and acute poisoning should be treated as suggested for the more toxic compounds.

Emergency Procedure in Pesticide Poisoning

Most of the following suggestions are elementary, but they are often forgotten, despite their proved importance in any case of acute poisoning:

1. Make urgent inquiries about what chemicals had been used in the past few days, and examine any available instructional leaflets or container-labels from the immediate place of work. Note that workers often mix a hazardous with a safe chemical—for example, parathion with D.D.T., or T.E.P.P. with a copper fungicide. Treat as for the most dangerous.
2. Start any recommended treatment immediately. Cases with rapid onset tend to deteriorate further, and speed is vital.
3. Unless already done, carefully remove all outer working-clothes and thoroughly wash the exposed skin with soap and water to remove unabsorbed chemical.
4. If the chemical is known or believed to have been swallowed, induce vomiting unless the patient has already vomited repeatedly. In all cases it is preferable to pass a well-lubricated gastric tube, evacuate the stomach contents, and wash out repeatedly with warm water. About one pint (half a litre) of a dilute solution of sodium bicarbonate (1%) may then be left in the stomach. If available, activated charcoal (1 or 2 tablespoonfuls) could be given to conscious patients.
5. If the patient is obviously ill, disturb him as little as is compatible with treatment. Exertion will dramatically increase the severity of effects, especially with the hazardous compounds, and may lead to death.
6. Rapid effective sedation is therefore necessary for restlessness, excitement, or apparent imminence of convulsions—for example, injection of sodium amylbarbitone, 0.4–0.8 g. (7–12 gr.), or sodium phenobarbitone, 100–200 mg. (1½–3 gr.), intravenously in urgent cases, or otherwise intramuscularly. Morphine should not be used.
7. Anticipate coming therapeutic needs—for example, for oxygen supplies, saline, or glucose-saline infusion.
8. Do not send a seriously ill patient off to hospital unless it is quite certain that this will be the best for him, and that he can receive all necessary treatment *en route*.
9. Save vomitus, chemical container, and the worker's clothing, in case of later inquiries.
10. If in doubt about diagnosis, treatment, or procedure seek outside medical help.*
11. The patient's workmates may also be approaching a dangerous degree of over-exposure. They should be examined and not allowed to return to work or home until it is quite certain that they are fit to do so.
12. Ensure that the occurrence is notified to the local Ministry of Agriculture safety inspector.

Their extent of usage and worker-hazards suggests that attention should now be focused on D.N.C. and organic phosphorus compounds, and then on the less widely used arsenical, mercurial, and nicotine compounds.

Dinitroresol Poisoning

Absorbed D.N.C. or D.N.B.P. rapidly upsets carbohydrate metabolism and increases the basal metabolic rate, an effect usually tolerable in cool or cold weather conditions, but liable to cause dangerous effects when heat loss is limited by, for example, hot sultry weather. The general clinical picture is that of a worker with yellow-stained hands, face, or hair, with excessive sweating, thirst, and air-hunger.

Mild cases may show nothing but copious sweating and thirst; the patients are sometimes feeling particularly well, presumably owing to the moderately increased metabolic

rate. Severe cases are likely to show profuse and continuous sweating, fast pulse, nausea, vomiting, weakness, malaise, restlessness, dehydration, yellow sclera, scanty urine of fluorescent yellow hue, albuminuria, and deep rapid breathing. Fulminating cases may be drenched in sweat, dyspnoeic, cyanosed, comatose, or having convulsions even when first seen. There is usually a history of a few days' progressively increasing, but ignored, sweating and tiredness. Body temperature may be raised.

Laboratory tests in severe cases would show a tremendous rise in basal metabolic rate and the presence of D.N.C. in the blood and the urine. Photoabsorptometric methods of determining D.N.C. levels in the blood have been described by V. H. Parker* and D. G. Harvey,† and I have recorded a simple comparator method, eminently suitable for both emergency and routine purposes.‡ All hospitals in the major cereal-growing areas should be equipped to determine blood D.N.C. levels very quickly (see Appendix for details of collection, etc.). Symptoms are likely to be absent below 25–30 µg. of D.N.C. per ml. of whole blood, mild at 30–40 µg. per ml., severe at 45–55 µg. per ml., very severe at 55–65 µg. per ml., and critical at over 65–70 µg. per ml. The analytical methods apply equally well to D.N.C. and D.N.B.P., which are equivalent in hazard and effect. Since serum protein binds most of the circulating D.N.C., serum D.N.C. levels are twice as high as those given above for whole blood: some hospital laboratories quote serum levels. Urinary D.N.C. levels are not a good index of absorption or of the severity of the case. Whole-blood D.N.C. levels normally decrease at about 1 µg. per ml. of blood a day on removal from further exposure. The yellow staining of the skin is a specific persistent dyeing action, extremely difficult to avoid even in careful workers, and needing days or weeks to wear off. It does not therefore reflect the severity of the case, nor even the certainty that the case is one of D.N.C. poisoning.

Treatment

There is as yet no known specific antagonist to the effects of D.N.C. in the body, and treatment is aimed at the rapid promotion of maximum heat loss and the complete relief of anoxia, restlessness, and dehydration. Mild cases require little but a few days' enforced rest, freedom from further exposure, frequent cold sponging, minimum clothing and bedding, and abundant soft drinks. They should not resume work with D.N.C. for a month, or until the blood D.N.C. level is down to 5 µg. per ml. (All users are strongly urged by manufacturers to seek medical advice as soon as they notice unusual sweating.)

The most effective emergency method of cooling the severely affected patient is to remove his clothing and cover him with a wet sheet subjected to vigorous air movement to cause evaporative cooling—for example, by relays of helpers with large fans, electric fans, or a reversed vacuum cleaner acting as a blower, preferably carried out in the shade with free ventilation. Water should periodically be sprinkled on the drying sheet, or a fresh wet sheet used. Cold wet cloths to the head, ice-packs, ice to suck, and abundant cold drinks for the conscious patient, and, if possible, a cold-water rubber-bed or wetted stretcher, all promote further heat loss.

Restlessness demands the use of quick-acting barbiturates. Dehydration is almost certain to exist; conscious patients should drink copiously and often of cold drinks with added glucose (1 oz. per pint—40 g. per litre) and salt (1 teaspoonful per pint). An unconscious patient should ideally have a fast intravenous glucose-saline drip. Failing this, large volumes of rectal saline should be administered. Dyspnoea demands oxygen therapy by nasal tube, oral tube, face-mask, improvised "cellophane" or paper head-tent and open tube, or resuscitator.

*Analyst, 1949, 74, 646.

†Lancet, 1952, 1, 796.

‡Ibid., 1954, 1, 981.

The acute illness may last for 12–24 hours, and the above treatment may be required throughout that time. The prognosis in the fulminating cases is bad despite energetic treatment. Severe cases need a guarded prognosis for the first 24–36 hours, but thereafter the outlook improves. No delayed after-effects have as yet been reported in recovered acute cases. There should be no exposure to D.N.C., D.N.B.P., or other hazardous chemicals for at least two months; this usually means until the next season.

Organic Phosphorus Insecticides

All present-day organic phosphorus (O.P.) insecticides cause similar toxic effects, by inactivating acetylcholinesterase enzyme (ChE) of the tissues and thus permitting acetylcholine to accumulate dangerously. Since ChE regenerates only slowly, frequent small over-exposures are cumulative in their effects but often symptomless until ChE reserves fall to perhaps 5–20% normal. Illness then occurs, first affecting involuntary muscles and secretory glands, then the voluntary muscles, and finally vital brain centres.

Early or mild cases with gradual onset show malaise, fatigue, weakness, cold sweats, pallor, nausea, vomiting, abdominal discomfort, irritability, apprehension, or restlessness. Severe cases develop headaches, visual disturbances, confusion, vomiting, colic, diarrhoea, dyspnoea, and fine fibrillary tremors of hands, lids, face, or tongue. Very serious cases develop salivation, lacrimation, bronchorrhoea, severe diarrhoea, incontinence, basal rales, circulatory collapse, cyanosis, severe dyspnoea with a sense of suffocation, mental confusion passing to stupor, muscular weakness with tremors and convulsions, and coma. Fatal cases end with gross pulmonary oedema, cyanosis, bradycardia, and fall in body temperature.

The pupils may be pinpoint and fixed, and there may also be a sense of asthma-like tightness of the chest. These effects can, however, be misleading, being producible by the local eye or chest effects of exposure to spray mist of T.E.P.P., parathion, or demeton. Where present, they are presumptive of exposure, but not necessarily of poisoning. On the other hand, severe poisoning can occur with some organic phosphorus compounds—for example, schradan or dimefox—without miosis or bronchial constriction. The clinical diagnosis of organic phosphorus poisoning relies on concurrent effects on secretions, muscles, and brain. There are no external indications of contamination, but there will be a history of exposure within the past few days. The confirmation of diagnosis relies on demonstrating reduced ChE activity in the circulating blood. The technique is specialized, but is now available at certain regional laboratories (see Appendix). A simple colorimetric method has recently been introduced, suitable for emergency and routine testing. Activity is usually expressed as percentage of normality of healthy adults. Values above 80% normality imply that no significant absorption has taken place; there is no important upper limit. Cases with values between 50% and 80% normality are usually symptomless, but indicate over-absorption. Slightly early effects, mainly abdominal discomfort and cold sweats, may occur at 20–30% normality. Severe cases would be expected to have very low ChE activity in the blood—for example, 5–10%—but some apparently severe cases of parathion poisoning have had up to 50% normal values, while some cases of over-exposure with ChE levels reduced to 5% normality have proved symptomless. Thus, ChE levels are vitally important for confirmation of the diagnosis of an illness or over-exposure in workers, but low activity results may bear no obvious relationship to the clinical severity of effects.

Treatment

The recommended general emergency procedures should be carried out as they apply. The specific antagonist to organic-phosphorus-induced hypersecretion, involuntary muscle contraction, and some central effects is atropine sulphate. Unfortunately, it does not prevent muscular

tremors or weakness. All but very minor cases should be given atropine sulphate immediately (unless the worker has already had an initial oral dose elsewhere) in high dosage (initially 1–2 mg. (1/50–1/30 gr.)) intramuscularly, or intravenously in very ill patients; then ½–1 mg. (1/100–1/50 gr.) subcutaneously, repeatedly (at intervals of ½–3 hours, depending on the severity of the case) and for a prolonged period (12–48 hours, if the patient's condition remains poor). The atropine dosage needed in organic phosphorus poisoning vastly exceeds orthodox dosage schedules for this drug. The risk is of giving too little in severe cases, rather than too much. In a recent severe case, for example, 45 mg. of atropine (¾ gr.) was given intravenously in three hours, with recovery.

Here a special word of warning must be given:

1. If atropine is given erroneously in D.N.C. poisoning, the patient will stop sweating and may then die. The two types of poisoning must never be confused.

2. Practitioners should send the receiving hospital details of atropine and other drug dosage already given.

Restlessness must be combated immediately by quick-acting barbiturates. Dyspnoea demands continuous oxygen. Pulmonary oedema requires quick recognition and postural drainage. A recent suicidal case in Germany showed dramatic improvement in lung oedema after the injection of a mercurial diuretic; in a severe case injectio mersalyli (2 ml.) should be given intravenously.

Sudden failure of respiration justifies prolonged artificial respiration, preferably with positive pressure. Breathing may be resumed and survival follow. Care should be taken not to overload an already struggling circulatory system by saline infusion or transfusion of plasma or blood. On theoretical grounds, harm would result. Similarly, morphine should not be used. Good nursing is required, and the patient must not be left unattended while acutely ill.

The prognosis in very severe cases is poor, despite treatment. In such cases it is apparently not enough to have dried up the secretions and eased the involuntary muscles and anoxia; central effects dictate survival. Severe cases may be pulled through by intensive treatment. Mild cases usually respond extremely well to atropine. Full recovery can usually be expected, even in severe cases, if the first few days are survived, but careful observation should be kept for delayed effects on the nervous system for some weeks after organic phosphorus poisoning.

Cholinesterase activity returns to normal at the rate of about 1% a day, so a severely affected person should have no further exposure for at least three months. It should be noted that persons with a temporarily low cholinesterase activity may be hypersensitive not only to all organic phosphorus insecticides, but also to anticholinesterase muscle relaxants, procaine, neostigmine, eserine, or D.F.P.

Arsenical Preparations

There is increasing use of arsenites as weed-killers and defoliants. The toxic effects of over-exposures may include reddened eyes, skin rashes, sore throat, hoarseness, coryza, vomiting, diarrhoea, headaches, hallucinations, haematuria, aphasia, and peripheral nerve lesions. Eventual confirmation of the diagnosis is by finding arsenic in the urine in excess of the normal 0.008–0.15 mg. of As per litre of urine. The specific antidote to be used along with the general emergency procedures is dimercaprol in doses of 200 mg. intramuscularly every four hours for two days, and reduced doses for ten days.

Organic Mercurials

Organic mercurials occur in many fungicidal seed-dressings and spraying mixtures. Fatalities have occurred in Europe owing to the volatility of ethyl and methyl compounds, but inhaled dusts are also hazardous. The possible effects include gastric upsets, headaches, trembling, clumsiness, slurred speech, confusion, ataxia, nervous irritability, and

Specialist advice in such cases may be sought from the Medical Research Council's Department for Research in Industrial Medicine, the London Hospital, London, E.1. (Tel.: Bishopsgate 3255); or, when suggested on container labels, from the medical departments of the larger manufacturing concerns.

change in temperament. Rashes or blistering of exposed skin may occur as local effects of primary irritancy. The diagnosis may be confirmed by finding over 20-30 µg. of Hg per litre of urine. Dimercaprol therapy should be carried out in severe cases, although the results are not likely to be as favourable as in arsenical intoxication. The neurotoxic effects of mercurial poisoning tend to persist or slowly increase, and prognosis must be guarded. The skin lesions respond well to orthodox treatment as for thermal or minor chemical burns.

Nicotine Preparations

Nicotine still has considerable use in horticulture. Its toxic effects, most serious in non-smokers, include nausea, vomiting, pallor, vertigo, palpitations, tachycardia, chest pain, excitability, diplopia, incoordination, and collapse. Nicotine is less cumulative as a result of minor over-exposure than are most pesticidal materials. There is no specific antagonist to the effects of absorbed nicotine, treatment being that suggested under general emergency procedures, and symptomatic.

Prevention of Over-exposure to Pesticides

During the coming four to five months over 2,000,000 acres in this country will be sprayed with crop-protection chemicals. About one-tenth of this acreage will involve the use of hazardous pesticides, often under conditions of some risk. The safeguarding of potential worker-casualties from these modern agricultural operations remains a matter of great concern to users, employers, distributors, manufacturers, and Government departments. Many real steps have been taken to ensure safety, so far as this is currently possible, by mutual collaboration between these groups and by legislative measures. The practitioner is himself able to make some important contributions. He should be able to recognize and treat casualties as effectively as present knowledge permits. Medical treatment often stands a poor chance of success in serious cases, however, so whenever an opportunity presents itself he should enjoin on his user-patients the need for care, especially in the prevention and avoidance of contamination. He could also detect unsafe working methods by arranging for periodic analyses of blood D.N.C. levels in major users of dinitro-weed-killers, or for ChE levels in organic phosphorus insecticide users, and could with advantage carry out periodic scrutiny of workers, especially of contract spraying operators, during their season of major risks.

APPENDIX

The following details about laboratories to which specimens may be sent for blood D.N.C. and blood cholinesterase estimations are based on information provided by the Ministry of Health.

Blood D.N.C. Estimation.—Five millilitres of oxalated blood is required for this estimation. Blood must be taken in a dry syringe not previously sterilized with spirit. The specimen, or the patient, should be sent to the hospital to which the practitioner normally refers patients for pathological tests of any kind.

Blood Cholinesterase Estimation.—Five millilitres of oxalated blood, taken under the same conditions as for D.N.C. estimation, is required. Specimens may be sent either direct to Dr. E. N. Allott, Group Laboratory, High Street, Lewisham, London, S.E.13; Dr. E. M. Darmady, Pathological Laboratory, Central Laboratory, Milton Road, Portsmouth; Dr. D. H. Fulton, Memorial Hospital, Peterborough; or Dr. P. Kidd, Pathological Department, Royal Infirmary, Worcester; or, alternatively, the specimen should be sent to the hospital laboratory which the practitioner normally uses. Specimens sent through the post should go by letter post and be marked "Pathological Specimen (Agricultural Poison)."

Next article on Emergencies in General Practice.—"Diabetic and Insulin Coma," by Dr. J. D. N. Nabarro.

SELECTION OF PATIENTS FOR PSYCHOTHERAPY

Which patients with neurosis should be accepted for systematic therapy? This is a question that confronts every psychiatrist, and it is made no easier by the very large number of such patients now coming forward for treatment. In a lecture at the St. Marylebone Hospital for Psychiatry and Child Guidance on March 23, Dr. E. A. BENNET addressed himself to this problem.

Psychotherapy, said Dr. Bennet, took many forms: the kindly interest shown by the family doctor towards his patient; the psychological element accompanying physical treatments in psychiatry; art therapy; and, in particular, the methods ranging from explanation and suggestion to the often rigidly ordered types of analysis employed in the neuroses. Before accepting any patient with neurosis for systematic treatment—their present concern—at least two preliminary interviews were desirable, and these should be therapeutic as well as diagnostic.

Therapist and Patient

Psychotherapy, unlike most methods of treatment in general medicine and surgery, was always conducted upon a personal basis. The therapist was in the treatment, and for better or for worse his personality counted. Patients might select their therapist when treatment was arranged privately, but in hospital or clinic this was rarely possible. Nevertheless, in a department with a big staff it was essential, in the selection of patients, to take note of the personalities, predilections, and preferred methods of the therapists. One therapist might choose patients in the younger age groups, another do his best work with those in the second half of life, a third use supportive methods, and a fourth formal analysis.

Further, in selecting, the psychiatrist must do his best to decide whether a particular patient was likely to respond to the treatment available and so justify the heavy expenditure of medical time involved, before adding his name to the waiting-list. The dull individual with an intelligence below the average should be rejected; likewise those with established psychotic symptoms, and reluctant patients sent (or brought) for treatment they did not want. Although such patients might be treatable, the demand for treatment was so high that the needs of others ruled them out.

The patient's expression of a need for psychological treatment should be taken seriously in the selection. An intelligent person, aware that there was something within his personality which needed attention, was often quite right. He might be successful in life and the antithesis of the "chronics" who frequented every medical out-patient department and became, to the student, the prototype of the "psychological case." Sometimes these patients reported that they had asked their doctor to send them to a psychiatrist and had been told that they did not need to see one—that they were not "the neurotic type." But, eventually, the doctor was persuaded to ask for an appointment. An importunate attitude on the part of a patient might even indicate suitability for psychotherapy.

The value of an affirmative diagnosis was often overlooked by doctors who diagnosed neurosis by the exclusion of organic disease, went on Dr. Bennet. Their medical training was responsible for this, and it was an attitude that frequently bred invalidism. Fruitless and often expensive investigations were disheartening, especially to an anxious patient, and the possibility of psychotherapy might be welcomed. Nor were psychotherapy and physical investigation mutually exclusive, but could well proceed *pari passu*. Likewise, when necessary, sedatives and other medicines should be prescribed by the psychiatrist, whatever type of psychotherapy he might be using. Some analysts would disagree with this and insist that medicine must be prescribed by another doctor, claiming that otherwise the transference

would be interfered with. But to withhold these aids because of a theoretical objection might protract treatment unduly and lead to an uneconomical use of the therapist's time.

Depressives and Obsessionals

Patients with depression formed the largest group of psychiatric invalids, and many of them would respond to psychotherapy. But a careful history was necessary before advising psychotherapy. Involuntional depressives and those with defined endogenous mood swings should be given electric convulsion treatment. Patients with conversion symptoms were often depressed and so were those with morbid anxiety and tension, and both these groups could be helped by psychotherapy. In these patients, and often more definitely in the patient with an obsessional neurosis, the symptoms were more severe when they were depressed, and it might be difficult to separate the reactive and endogenous elements in the depressive features of the illness. However, this was often unnecessary or even impossible to do. The main point of importance here was that during the depression the psychoneurotic features were better defined and hence perhaps more open to treatment.

Certain characteristics in the obsessional patient, when clearly marked, indicated that psychotherapy was desirable. These features were a sense of guilt about the symptom, marked secrecy concerning it, and a dread of growing older—of the passing of time. The sense of guilt might be overwhelming and suicidal impulses difficult to control. Nevertheless, these three characteristics served the purpose of preserving the symptom, and by recognizing this the patient could be helped to see what his symptoms meant.

Transference was an inevitable and essential process in psychotherapy. Yet in selecting patients no one could be prophetic about it, for unconscious elements in both therapist and patient were involved which would only become evident during the treatment. Cure or amelioration was the product of a dynamic situation in which two personalities, working co-operatively, sought to solve the problem set by the neurosis. Hence the selection of patients for psychotherapy could never be a fixed procedure, a technique, which any sensible person could learn and apply. It demanded an "intelligence of the heart" as well as experience and sound judgement.

Reports of Societies

RADIOTHERAPY AND GENERAL PRACTICE

An example of the value of the exchange of ideas between two branches of the profession was the joint meeting of the Sections of Radiotherapy and General Practice at the Royal Society of Medicine on March 18. On this occasion the object was to draw attention to the many ways in which the radiotherapist can help his general-practitioner colleague, and it may have surprised some of those present how wide this field is, particularly outside the obvious territory of malignant disease. But a second and no less important purpose was once again to stress the overriding value of close consultation between specialist and practitioner in planning the treatment of the individual patient.

The opening speaker was Dr. DAVID BROWN, a general practitioner from Liverpool. Although, as he said, both diagnosis and treatment had nowadays come to depend on special techniques, it was still important for the general practitioner to stay in charge of his patients, to decide on their treatment, and to assess the final results. Radiotherapy, continued Dr. Brown, could be used for many non-malignant conditions. It was specially valuable for skin complaints. In disorders giving rise to pruritus, x rays were not always curative, but they allayed symptoms, prevented complications, and brought ease of mind. Radiotherapy was particularly helpful in neurodermatoses, eczema, lichen planus,

and pruritus ani and vulvae. Although with the last two conditions the ideal was to find and treat the underlying cause, this was often far from easy. Radiotherapy also benefited infective skin conditions, such as sycosis barbae, where an antibacterial action was produced without the risk of bacterial resistance so often seen when antibiotics were used. Keloids might be softened, and the cosmetic results in treating radiosensitive naevi were most satisfactory. Radiotherapy could also be used to diminish secretions in seborrhoea and acne.

Many gynaecological disorders were amenable to radiotherapy: ovarian sterilization was simple, and metropathia and other forms of functional bleeding could be relieved safely and without the upset to family life occasioned by surgery. When surgery was contraindicated fibroids could be treated successfully. Among other conditions, osteoarthritis of the spine responded to radiotherapy, and the relentless course of the disease was slowed. Excellent results were achieved in ankylosing spondylitis, but in young women there was a grave risk of damage to the ovaries.

Malignant Disease

Malignant disease of the skin was common, and it was in the treatment of basal and squamous-cell carcinomata of the skin, and of cancer of the lip, that the real triumphs of radiotherapy could be seen. In growths of the tongue and buccal cavity radiotherapy combined with plastic surgery was becoming increasingly successful. In tumours of the nasopharynx and larynx cure was less likely, but distressing symptoms were relieved.

Breast cancer, went on Dr. Brown, was a cause of much anxiety to the family doctor. In the early stages surgery offered the best hope, later on surgery should be used together with irradiation, while in advanced disease radiotherapy alone was indicated. Cancer of the cervix was also dreaded by practitioners, since it afflicted women at an age when they were so essential to their growing families. The disease was probably best treated by panhysterectomy and irradiation. Radiotherapy was unfortunately of little value in carcinoma of the stomach or lung, both of which were becoming so common in practice. In Hodgkin's disease and leukaemia full liaison between the practitioner and the radiotherapist could often lead to prolongation of life, reduction of toxæmia, and the relief of unendurable symptoms. In patients for whom neither surgery nor radiotherapy offered any hope of cure, irradiation was often the best method of giving temporary relief from unpleasant symptoms, particularly ulceration and offensive discharge, thus enabling the patient to be nursed at home.

Co-ordination of Services

Dr. Brown then raised the question of co-ordination between practitioner and radiotherapist in the treatment of patients. He stressed that the family doctor's main responsibility was in early diagnosis, but it was equally important that the radiotherapist should keep the practitioner informed about the subsequent course, since it was on the practitioner that the responsibility of ultimate management would fall. All details of treatment should be sent to the doctor immediately the patient left hospital. When palliative treatment was being considered it was essential that the practitioner should be consulted.

Medical students, said Dr. Brown in conclusion, saw too little of the work of the radiotherapy departments; and the unbalanced amount of time devoted to surgery biased them when they passed into practice. There was a case also for appointing practitioners as clinical assistants to radiotherapy departments.

The Radiotherapist's Viewpoint

Dr. J. S. FULTON, director of the Radiotherapy Service in the Liverpool region, the next speaker, thought that radiotherapy had emerged from its adolescence, and that the

radiotherapist must now be prepared to accept full clinical responsibility for the patient. Though most of his work would concern malignant disease, the radiotherapist could help a great deal in simple conditions. Both plantar warts and keloid scars responded well to irradiation, and good results could be expected in cavernous haemangiomas. In the early stages about two-thirds of patients with osteoarthritis were relieved, and excellent results were found in ankylosing spondylitis. In treating Eustachian-tube deafness substantial benefit was seen in more than three-quarters of the patients. Many skin diseases were amenable to irradiation, and menopausal menorrhagia responded well.

In malignant disorders, radiotherapy was of great value in skin cancer, where good curative and cosmetic results were achieved. In carcinoma of the lip, a disease of smokers, radiotherapy was the best form of treatment, since the whole lip was potentially carcinomatous and could not be dealt with by surgery. Neoplasms of the tongue and mouth were mostly suitable for radiotherapy, and were treated by moulds or dentures containing radium or by radium needles. The Finzi-Harmer technique had proved successful in 73% of patients with intrinsic carcinoma of the larynx; and total laryngectomy should be reserved for patients failing to respond to radium. In cancer of the uterus the best surgical results were never so good as the best results from radiotherapy, especially if radium and x rays were used together. The treatment of breast cancer was still a controversial topic; though there was a place for irradiation in most cases, it was important to treat each patient as an individual problem. The main problem in carcinoma of the lung was that of early diagnosis, since it was only in the early stages that surgery was justified. There was probably a place also for radiotherapy in the treatment of the early case. Wilm's tumours in childhood should always have radiotherapy before surgical removal was attempted. Irradiation played an important part in the treatment of carcinoma of the nasal sinuses.

There was still some doubt, went on Dr. Fulton, about whether the reticulososes were *unifocal* or *multifocal* diseases, but there was no doubt that in Hodgkin's disease it was well worth while to give efficient treatment to the first local group of glands. Palliative treatment should aim not only at prolonging life but at relieving pain and other distressing symptoms. Radioactive isotopes had not justified the early hopes. The best results were to be found in the use of radioactive phosphorus in polycythaemia and of radioactive iodine in the diagnosis of thyroid disorders.

Dr. Fulton was in full agreement that collaboration with practitioners was of the utmost importance. Cancer was an urgent condition; there should be no need to delay the first consultation by an appointment system; new patients should be seen at once by the specialist likely to be responsible for treatment. Progress reports should be sent to the family doctor whenever a course of treatment was concluded, and possible complications should be emphasized. Shortage of beds meant that aftercare would be largely in the hands of the practitioners. There was great benefit to be derived from the domiciliary services both in early consultation and in the care of the reaction phase after treatment.

Discussion

In the subsequent discussion Dr. WALTER LEVITT reminded the meeting that radionecrosis might follow the treatment of plantar warts if adhesive strapping was applied after treatment. Radiotherapy played a most important part in the treatment of uterine haemorrhage. Dr. N. S. FINZI emphasized the importance of collaboration between practitioner and radiotherapist. In the early days of radiotherapy only the hopeless cases had been referred for treatment, and for this reason there had been a tendency for radiotherapy to fall into disrepute. Happily a fairer view was now taken by both the profession and the patient. With regard to gynaecological cases he had seen patients with fibroids up to the ensiform cartilage that had responded well to radiotherapy. Dr. R. J. MINNITT (president of the

Section of General Practice) paid tribute to radiology in the early diagnosis of disease.

Dr. G. F. ABERCROMBIE raised the question whether a patient should be told that he had malignant disease. Among others taking part in the discussion were Dr. LINDSEY BATTEN, Dr. TALBOT ROGERS, Mr. I. G. WILLIAMS, Dr. J. R. NUTTALL, Dr. ANTHONY GREEN, and Dr. J. JACKSON RICHMOND. There was general agreement that a patient should be told the truth about his disease only if the practitioner or specialist was quite sure that he genuinely wanted to know the truth.

LOCAL MEDICAL SOCIETIES

Liverpool Medical Institution

At a meeting on March 10 Mr. DONALD YOUNG, consultant surgeon at Warrington Infirmary, described what surgery could do for the infertile husband. A brief consideration of the anatomy, physiology, and development of the male genital tract showed how an accurate anatomical diagnosis might be reached in cases of azoospermia. For instance, once spermatogenesis had been proved by testicular biopsy, the presence of fructose but not spermatozoa in the ejaculate meant that there must be bilateral obstruction in the vas deferens below the level of the seminal vesicles; if, however, the ejaculate contained neither spermatozoa nor fructose, then there was either bilateral blockage of the ejaculatory ducts or bilateral absence of the vas deferens. Testicular biopsy played an important part in deciding which cases would be amenable to surgery: they were those with azoospermia but proved spermatogenesis in at least one testicle, and those with large varicoceles. Recent work had suggested that removal or ligation of the latter would promote the production of spermatozoa, probably by lowering the temperature of the scrotum.

Obstructive azoospermia, continued Mr. Young, could be caused by several factors in the vas deferens—congenital, traumatic, or infective. The commonest of the congenital abnormalities was absence of the vas deferens. Eight such cases had been found in over 900 patients attending the Liverpool Infertility Clinic. In addition, there had been two cases of unilateral absence and five of incomplete development or stenosis of the vas. Treatment of congenital absence of the vas deferens had been attempted by forming an epididymal fistula and by making an artificial spermatocele. Treatment of traumatic obstruction was by excision and end-to-end anastomosis of the vas. Only two cases of traumatic obstruction had been found in 133 cases of azoospermia investigated. The results from this operation were good. The relief of azoospermia due to bilateral blockage of the vas deferens was by the delicate operation of epididymo-vasostomy.

Manchester Medical Society

The opinion that spinal analgesia in prostatic surgery should now be abandoned was urged by Dr. T. H. CHADWICK, consultant anaesthetist to the North Manchester Group of Hospitals, in an address to the Section of Anaesthetics on February 17. The improvement in spinal analgesics in 1930, he said, had led to their enthusiastic acceptance by surgeons for prostatectomy because they provided for the first time operating conditions previously unattainable. In an attempt to minimize the inevitable serious reduction of blood pressure, with its attendant tissue anoxia, a modified technique combining low spinal and local analgesia was evolved. This technique, though eminently satisfactory to the surgeon, did not preclude the dangers of sepsis. For that reason a technique employing the least toxic drugs, nitrous oxide, thiopentone, curare, and pethidine, was now used, intravenous administration of the non-volatile drugs being imperative in the poor-risk case. Mortality had dropped from 34% for spinal analgesia to less than 1% with this technique.

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Blood Groups in Relation to Peptic Ulceration

SIR,—The paper by Professor Ian Aird *et al.* (*Journal*, August 7, 1954, p. 315) induced us to investigate the ABO blood groups in patients who had been treated for peptic ulceration in the two surgical departments of Ullevål Hospital, Oslo, in the years 1945–54. The results of the investigation will be published elsewhere. They were in full agreement with those of Aird *et al.* In particular, it is of interest to note the difference in the proportion A/A+O between patients with gastric ulcer and patients with duodenal ulcer. The data from both investigations are as follows:

	No. of Patients			
	Gastric Ulcer Blood Group		Duodenal Ulcer Blood Group	
	O	A	O	A
London	314	228	535	311
Manchester .. .	122	90	225	148
Newcastle .. .	102	58	288	157
Oslo	179	189	282	250

The difference between the two ulcer types is not significant if either investigation is considered alone. If, however, we combine the data according to the method recommended by Aird *et al.*, we find χ^2 for the difference = 5.63 with 1 degree of freedom. The probability that such a difference, or an even greater one, will arise by pure chance is less than 1 : 50 ($P = 0.018$). The weighted mean difference in the proportion A/A+O between gastric ulcer and duodenal ulcer is 0.040. A significance test for the combined material according to the method suggested by Cochran¹ gives approximately the same result ($P = 0.021$).

The Norwegian data thus strongly support the observation reported by the British investigators that there seems to be a difference in blood group frequencies between gastric and duodenal ulcer.—We are, etc.,

KNUT WESTLUND,
HELGE HEISTÖ.

Oslo, Norway.
