The Section of Psychiatry of the Royal Society of Medicine held a joint meeting with the Section of Neurology on January 11 to hear papers on three aspects of recent research made possible by modern brain surgery. Professor W. MAYER-GROSS, president of the psychiatry section, was in the chair, and was joined on the platform by Professor F. J. NATTRASS, president of the neurology section. The first paper was by Professor ALFRED MEYER, head of the neuropathology department at the Maudsley Hospital, on "Temporal Lobe Epilepsy and the Hippocampal Region."

Local Sclerosis in Temporal Lobe Epilepsy

The hippocampus, or Ammon's horn, was the most medial part of the temporal lobe of the cerebral hemisphere, said Professor Meyer. In 1927 Spielmeier had shown that interference with its blood supply or anoxia (as in a major epileptic fit, carbon monoxide poisoning, and similar conditions) led to its sclerosis—selective or even total neuronal loss and glial proliferation. The same year had seen the beginning of the overthrow of the traditional theory that the hippocampus is part of the "smell" brain, subserving olfactory function: it was now regarded as part of the "visceral" or limbic brain, concerned with the control of the autonomic functions of the body. In this the hippocampus formed part of a system with the uncus, the adjacent amygdaloid nucleus, the anterior uvula, the anterior cingulate region, and the thalamus and hypothalamus.

Penfield and his collaborators had recently introduced the operation of anterior temporal lobectomy for epileptics who showed no gross focal lesion, continued Professor Meyer. In their series two-thirds of all such cases showed sclerosis of a part of the temporal lobe, where in their view the lobe had at some time, probably at birth, been wedged a little way through the notch or incisura of the tentorium and its blood supply compressed. All cases with "incisural" sclerosis in the removed lobe had clinical or electroencephalographic evidence of temporal lobe epilepsy. Professor Meyer, in collaboration with Dr. Denis Hill, Mr. Murray Falconer, and Mrs. E. Beck, had been making a similar study of the tissue removed at operation for temporal lobe epilepsy. Out of 18 cases of non-focal or "incisural" epilepsy 12 showed the predicted hippocampal sclerosis, but the other 6 had very little specific abnormality in the removed lobes. Of course it was possible that in these last cases the damage lay elsewhere—perhaps in the temporal lobe on the other side, which had not been opened. Study of a comparable group of epileptics with focal lesions of different kinds (four with angiomas, two with oligodendrogliomas, and so on) which produced the well-known uncinate fits showed lesions much more frequently also in the uncus and amygdaloid nucleus and less commonly in the hippocampus. However, a sclerosis of the hippocampus could extend forwards to the uncus and into the amygdaloid nucleus, as had, in fact, been demonstrated by the speaker in four of the few biopsy specimens in which amygdaloid tissue was available. He had also seen in a necropsy on a demented child of 8, who had suffered repeatedly from status epilepticus, sclerosis of the

hippocampus (Sommer sector areas H3 to H5) as well as softening of the amygdaloid nucleus, visible to the naked eye. In a woman of 43, who began to have severe epilepsy six months after prefrontal leucotomy for chronic mania and survived for seven years, the amygdaloid nucleus in addition to the uncus and hippocampus was found sclerosed.

It was interesting that Gastaut and Magnus and their associates had found that electrical or chemical stimulation of the amygdaloid nucleus in animals was the best way to elicit a psychomotor (temporal lobe) fit experimentally. Professor Meyer pointed out that this nucleus, the uncus, and the hippocampus received blood through anterior branches of the anterior choroidal artery, whereas posterior branches of this artery supplied the globus pallidus, which in his post-mortem cases was histologically normal. He doubted whether hippocampal sclerosis occurred always at birth, as proposed by Penfield, but thought it might well be the sequel to anoxia from any cause, and particularly from the onset of severe major epileptic fits, whenever these first occurred.

Results of Cingulectomy

Dr. C. W. M. WHITTY, of the Radcliffe Infirmary, Oxford, spoke on "Cingulectomy," the removal of the anterior part of the cingulate gyrus (area 24 of Brodmann), which, as already mentioned by Professor Meyer, formed a part of the limbic brain.

Bilateral cingulectomy in monkeys produced no neurologically detectable changes but considerable emotional alteration: the animals lost their aggressiveness and became very tame. They lost all normal fear reactions, and their social behaviour with their cage-mates was different. It was thought, therefore, that the operation might be useful in the treatment of psychiatric disorders in man, and since 1944 35 human cases had been studied, the earlier operations done by the late Sir Hume Cairns, the more recent by Mr. Walpole Lewin. A limited subpial suction ablation of the cortex was made, about 4 cm. × 1 cm. × 1 cm. of tissue being removed, great care being taken to preserve branches of the anterior cerebral artery. Necropsy of five patients who later died showed that the intended area had been accurately excised in all but one. Le Beau, of Paris, had published his results on 30 cases, but the excised area was bigger.

The Oxford workers first operated on 18 chronic deteriorated mental cases, 11 of whom were schizophrenics. Aggressive outbursts and obsessional symptoms became fewer, but the relief was only temporary. They then treated 17 patients who were in hospital on account of single severe anxieties or compulsive or obsessional symptoms but whose basic personalities were well preserved. Of 7 cases in the anxiety group 4 were improved—that is, they were happier, able to go home and even work—and 2 greatly improved (all symptoms abolished). Of 10 obsessionals 7 were greatly improved and 2 improved. Improvement was not immediate, but took place gradually over a number of months. As the obsessions faded away, emotional reactions became more open and less persistent, and drive and power of concentration lessened. Follow-up after one to four years showed that patients had lost their tendency to abnormal emotional or cognitive perseveration and also some of their inhibitions. Dr. Whitty thought there was less blunting of personality than after frontal leucotomy or orbital undercutting, but he was very cautious in making any claims for cingulectomy. There seemed to be a tendency to bring out latent epilepsy, at least temporarily; though only one case had persistent fits post-operatively. During the operation electrical stimulation of the area to be excised produced variable results—stomach sensations in some, a drop in blood pressure or sweating attacks in others. Study of blood pressures, pulse rates, and response to adrenaline and mecholyl before and after operation suggested that cingulectomy produced a change in the range of response but not a change in the baseline.

Stereotactic Brain Surgery

Professor H. HASSLER, head of the neuropathology department at Freiburg University (Germany), showed a film on "A New Stereotactic Method of Brain Surgery." Different areas in the thalamic nuclei (or elsewhere in the brain) could be accurately coagulated by means of a specially introduced diathermy needle which could also be used to take electrical recordings from the area, or to stimulate it, before producing the coagulation. A rigid metal ring was fixed round the patient's skull in the plane of the auditory meatus and the root of the nose, and an aiming-bow (a metal half-ring running over the vertex and attached to the base ring) fitted to carry the needle. Air encephalograms of the patient's brain were taken to measure off various dimensions of his brain and compare them with a model brain which could be placed inside a duplicate base-ring and aiming-bow. From the model it was estimated at what angle to set the aiming-bow, and where it should carry the operation needle, and how far this should plunge in. After all this preparation the needle could be simply slid into position through a previously prepared skull defect, and a second air encephalogram would show that it had attained the desired place. This could be confirmed by the effects of electrical stimulation through the needle in the conscious patient. The film showed dramatically the results in one or two chosen cases out of the 140 so far treated, most of them for intractable pain, or for muscular rigidity, tremor, or athetosis. For example, a man with typical Parkinsonian rigidity and intention tremor of a severe degree had the needle introduced into the anterior ventral nucleus of the thalamus first on one side and, three days later, on the other. Electrical stimulation of one nucleus inhibited the rest tremor of limbs on the other side of the body. After coagulation of both nuclei the muscular rigidity was abolished, walking became very much easier, intention tremor almost vanished, but in the right arm tremor at rest persisted, though diminished. A girl with severe athetosis from a birth injury had her spontaneous uncontrollable movements very greatly reduced by coagulation of a segment of the globus pallidus.

Discussion

In the discussion Dr. M. A. PARTRIDGE paid tribute to the extraordinary accuracy of Professor Hassler's technique, and wondered whether cingulectomy would compare favourably with rostral leucotomy. Mrs. A. PETRIE said that patients with rostral leucotomy gave a very different pattern of response to her battery of personality tests from Le Beau's cingulectomy patients whom she had recently tested; the latter resembled patients on chlorpromazine. Dr. J. S. PIPPARD said his study of 240 cases of rostral leucotomy clinically showed only slight personality changes, and these were similar to the changes described by Dr. Whitty. He wondered what Mrs. Petrie's tests were measuring. Dr. STEPHEN SHERWOOD described how they had done 100 cingulotomies at Severalls Hospital, Colchester, the results of which compared favourably with classical leucotomy. He also gave details of their attempts at stereotactic brain surgery.

LOCAL MEDICAL SOCIETIES

Persian Gulf Medical Society

The third annual meeting of the society was held in Bahrain, Persian Gulf, on November 24 and 25, 1954. Over 70 delegates attended, representing governments, oil companies, and the American Mission, from countries extending from Iraq in the north to Muscat in the south of the Gulf.

The Congress was officially opened by the Ruler of Bahrain, SHEIKH SIR SULMAN BIN HAMAD AL-KHALIFAH. The guest speaker was Dr. HOEFNAGELS, of the World Health Organization, who read a paper entitled "The Position of

Tuberculosis Control as Part of a General Health Programme." It has become an established policy of the society to lay emphasis on practical problems of the Persian Gulf area, and this was well shown by the choice of papers. Dr. JOYCE OWEN, of the Kuwait Oil Company, followed Dr. HOEFNAGELS with a paper on "The Out-Patient Treatment of Tuberculosis amongst Arab Women and Children." Dr. JAMES GRANT, of the Bahrain Government, Public Health Department, read a paper on "The Susceptibility of Insects to Insecticides." Dr. WELLS THOMS, of the American Mission, who has spent most of his life in the area, read an interesting paper on his experience in dealing with leprosy in Muscat. During the second day there was a panel composed of surgeons from the various areas discussing fractures of the long bones, presided over by Dr. R. J. BIGGAR of the Bahrain Petroleum Company.

It is planned to hold the next meeting of the society at Kuwait in November, 1955.

Liverpool Medical Institution

On January 13 there was a discussion on "The Medical Education of Patient and Public." Dr. ROBERT KEMP, speaking of the medical education of the patient, emphasized the difficulties and drawbacks in providing patients with complete clinical information. However, there were a number of diseases, such as diabetes mellitus, pulmonary tuberculosis, duodenal ulcer, and epilepsy, where successful management depended almost entirely on the patient understanding his complaint. In such cases a formal educational approach to the patient was required, but the doctor had to be extremely selective both in regard to the material offered to the patient and in the type of illness in which education was undertaken. The approach to the patient differed somewhat from that of the profession itself to the general public.

Dr. I. HARVEY FLACK, editor of *Family Doctor*, said that there was a real need and a real demand for information and education on medical subjects. Ideally it should be met by the individual physician talking to the individual patient. In practice it very frequently had to be met in some other way. There were several possible methods, but one of the most important at the present time was by means of the magazine *Family Doctor*. Doctors had to be realistic and accept the fact that the public at large were not interested in health. They were interested in disease. They were interested in wonder drugs, miracle cures, and remarkable operations, not in the kind of health education that very often the profession wanted to get across to them. However, if one talked or wrote about a disease interest was attracted, and within that framework a good deal of valuable advice could be conveyed on prevention, healthy living, and the avoidance of infection. The only section of the public that was vitally interested in non-disease teaching were the young mothers, who were always anxious for information about the normal physiology of pregnancy and delivery, and about the care of infants, toddlers, and young children. There was a big field of interest here, and it was one that *Family Doctor* consistently tried to meet.

Devon and Exeter Medico-Chirurgical Society

On December 16, 1954, Dr. F. S. W. BRIMBLECOMBE spoke on some common disorders of childhood. Underfeeding was one, he said, but overfeeding very rare. If a baby failed to thrive it was wise to seek the cause in the baby rather than in the feed. Most of the causes of failure to thrive could now be recognized. Wrong feeding was one, but a rare one. Another was hiatus hernia: here the function of the cardiac sphincter was lost and the patient vomited from birth, especially when laid flat. The vomit contained mucus and sooner or later, owing to oesophageal ulceration, blood. Painful swallowing from the same cause produced anorexia, and occult bleeding might give rise to

anaemia. The diagnosis was a clinical one, for confirmation by barium x-ray examination was difficult. Feeds should be thickened and the baby sat upright. Occasional surgery was needed to free a stomach which had ridden up into the chest and become adherent.

Bottle-fed babies, apparently thriving, sometimes started to vomit at the third or fourth month, became costive, and developed unexplained pyrexias. Necropsy showed calcification in the proximal renal tubules which could be demonstrated radiologically during life. In these cases there was acidemia with a urine constantly alkaline. This disorder, persistent renal acidosis, could be treated successfully with large doses of sodium bicarbonate. Another group, clinically similar, was due to hypercalcaemia of unknown origin, which was equally controllable by a calcium-free diet.

Preparations and Appliances

A HANDY OCCLUDER

Dr. G. J. ROMANES (London, W.1) writes: The use of a shield is convenient when assessing the visual acuity of each eye separately. Unless a special instrument is available the occlusion is usually carried out by covering each eye with any object to hand, such as a card or a piece of paper. This tends to give the patient an unfavourable impression. I have therefore evolved for this purpose a suitable occluder (see illustration), the features of which also enable it to fulfil several other functions.

The shape of the "head" allows it to rest comfortably on the bridge of the patient's nose, thereby occluding one eye for visual acuity assessment or for the cover test—that is, the unmasking of a latent squint. Both eyes can be covered simultaneously if desired—for example, during examination of pupil reactions. One side of the handle is

engraved with a millimetre scale enabling it to be used for interpupillary distance measurement. The end of the handle is rounded to allow it to be placed on the zygomatic bone, when a numerical idea of proptosis can be obtained from the scale. The reverse side of the handle incorporates a white spot 5 mm. in diameter, which can be used as a rough scotometry target or as a fixation point to help the patient look in a specific direction. The handle is tapered so that it can be utilized as a pointer to indicate the letters which are to be read on the test type. The whole instrument is designed so that its overall length enables it to fit into the accessory tray of a standard trial case.

I have used a similar occluder for some years now and find that it is a handy and time-saving accessory.

I should like to acknowledge the help which I have had in developing the accessory from the staff of Clement Clarke, Ltd., London, from whom the shield is now available.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Fluoridation of Public Water Supplies

SIR,—We enter with great reluctance the controversy upon this topic mentioned by your correspondent, Dr. C. G. Dobbs (*Journal*, January 8, p. 105). Our reluctance arises partly from our profound ignorance both of the effects upon the human body of the chronic ingestion of low concentrations of fluorides and of the level of intake at which retention in the body occurs in different people. But we believe our ignorance is no greater than that of other members of our profession. Since one of us (D.C.W.) has worked upon the subject for some years, and since the other (H.M.S.) has been publicly and correctly reported as being opposed to fluoridation of public water supplies before further research is done, and has been consulted by Dr. Dobbs and many others, we feel it our duty to state very briefly our views.

It is well established that the ingestion of water containing 1 p.p.m. of fluoride decreases the incidence of dental caries in children up to the age of about 8 years; the effect on adults is much less certain. It is proposed that the public water supply of four places—Anglesey, Darlington, Kilmarnock, and Watford—should be fluoridated to the level of 1 p.p.m., presumably to increase the resistance of the teeth of children to caries during the period of their calcification. This will undoubtedly benefit the teeth of the children, but we do not believe it is without risk to the adults whose teeth may not be improved.

It can be argued that, because some 14 million persons in the U.S. are drinking public water supplies fluoridated to 1 p.p.m. without any demonstrated ill-health, the practice would be without risk to health in this country. But habits differ in the two countries. The two richest dietary sources of fluorine (according to McClure¹) are sea foods, which as consumed may contain 5 to 15 p.p.m., and tea, of which the better grades contain 75 to 100 p.p.m. From these sources communities in the U.S. are likely to derive less fluorine than those in this country, and the consumption of tea may be highest among old people least able to excrete fluorides. It has been argued² that in this country adults who have arrived in West Hartlepool (with a water of natural fluoride content of 2 p.p.m.) or Maldon (5 p.p.m.) after the calcification of their permanent teeth "have drunk water containing 2–5 times the proposed concentration with no ill effect," but we have not seen the evidence for this statement. One of us (D.C.W.) took part in a study in which "severe dental fluorosis" appeared to be associated in some persons living in one village in Oxfordshire with a water supply having fluoride concentrations between 0.3 and 1.2 p.p.m. and in another village with a supply containing 0.8 p.p.m.³ One of us (H.M.S.) quoted this work in a lecture to the Women Public Health Officers' Association last July to which wide publicity has unfortunately been given.

We believe the hazard from atmospheric pollution is greater in this country than in the U.S. Outbreaks of animal fluorosis have occurred from the use in industry in increasing amounts of compounds which naturally contain compounds of fluorine, such as "marine" coals and clays and the phosphatic iron ores; and there are at least 28 industrial processes in which added compounds of fluorine are used as a flux during manufacture. Such atmospheric pollution causing animal fluorosis in the neighbourhood of Stoke-on-Trent was the subject of recent questions in Parliament.

An adult eating ordinary foods (without sea food) with four cups of tea daily and drinking 1½ litres of water containing 1 p.p.m. of fluoride would ingest about 2.2 mg. of fluoride daily. The level at which storage occurs in the body is not known: Machle, Scott, and Largent⁴ found some storage on an intake of 2.0 mg. daily, and in a more recent study Largent⁵ concluded that 1.36 mg. of fluoride daily for 45 weeks led in a healthy adult to storage of about 226 mg. during this period. In the elderly or in those with impaired renal function, storage is likely to be greater. More information is required.

Various authors, including one of us,⁶ have concluded that the toxicity of fluorides depends upon the nutriture of the person concerned; calcium nutriture has been claimed to be particularly relevant.⁸ This problem deserves further study. The United Kingdom Mission on the Fluoridation of Domestic Water Supplies⁹ believed that "in theory any fluorine compound which will ionize in aqueous solution should have the same action on teeth." We take leave to doubt this. First, a solution of stannous fluoride has a greater influence in the rat on experimental dental caries than has a solution of sodium fluoride.¹⁰ Secondly, it is not unreasonable to expect these two compounds to behave differently, at any rate in strong solution: a solution of stannous chloride, unlike a solution of sodium chloride, has a reducing power attributable to its solution containing much SnCl_3^- anions,¹¹ and stannous fluoride might ionize similarly. So even on a simple chemical point there seems to be divergence of opinion. We do not even know how fluorides act on the teeth. There appears to be no protection against caries if they are given parenterally,¹² which would indicate that the effect is one following direct application to the surface of the tooth; but incorporation in dentifrices is alleged to be useless,¹³ though others have claimed results from application to scaled and polished teeth. The effect on the oral flora deserves more attention. But we hasten to add that ignorance of how fluorides increase the resistance of the teeth of children to caries is no argument against their use.

Our argument is, in summary, that we do not consider it to be established beyond reasonable doubt that increasing the fluoride content of public water supplies to 1 p.p.m. is without risk to adults in this country. We consider that more research should first be done, which should include further studies upon storage in the body, particularly of the elderly.—We are, etc.,

H. M. SINCLAIR.

Premedication of Children for Tonsillectomy

SIR,—I have read with interest the article and subsequent letters on this subject (*Journal*, December 11, 1954, p. 1397, and January 1, 1955, p. 44).

During the past five years I have tried the following combinations for guillotine tonsillectomy and adenoidectomy in children: (1) quinalbarbitone premedication followed by pure N_2O from a McKesson machine. This was associated with anoxia and occasional troublesome laryngeal spasm. (2) Syrup of chloral hydrate 5 gr. (0.32 g.) per stone (6.4 kg.) body weight for premedication followed by pure N_2O as above. No cases of laryngeal spasm and no untoward sequelae were seen, but as anoxia rather than anaesthesia formed the basis of the technique it was discontinued. (3) Premedication with atropine only followed by intravenous thiopentone 50 mg. per stone (6.4 kg.) body weight. Post-operative restlessness in the ward rendered this technique unpopular. (4) Premedication with syrup of chloral and atropine followed by ethyl chloride and ether or "neothyl." This proved too time-consuming for a long list. (5) Premedication with atropine only followed by vinyl ether, ethyl chloride, or trichlorethylene in the Oxford inhaler. Induction proved stormy and generally unpopular. (6) Premedication with atropine only followed by 50% cyclopropane in 50% oxygen and a trace of ether. As with the thiopentone series post-operative crying and

restlessness ruled this out. (7) In a recent series of 100 children whose ages ranged from 5–10 years, 50 were pre-medicated with methylpentynol (2–4 teaspoonfuls) one hour pre-operatively and 50 with syrup of chloral 5 gr. (0.32 g.) per stone (6.4 kg.) body weight one hour pre-operatively. Induction was with pure N_2O , followed by N_2O and O_2 (10%) and a trace of trichlorethylene from a McKesson machine.

The nursing staff soon requested the abandonment of methylpentynol in favour of chloral because of pre-operative apprehension and post-operative restlessness. The only point in favour of methylpentynol would appear to be its effectiveness in removing the after-taste of syrup of chloral. While the ideal premedication and anaesthetic technique for guillotine tonsillectomy in children has yet to be found, syrup of chloral correctly given, followed by nitrous oxide, oxygen, and trichlorethylene, correctly administered from a McKesson machine, is at present, I think, the nearest approach to this ideal. My thanks are due to Dr. Kothary and Sister Beal, of the E.N.T. department, for their interest and co-operation.—I am, etc.,

Hull.

W. N. ROLLASON.

Sickling and Malaria

SIR,—The *Journal* of November 13, 1954, has just arrived here and we have seen Dr. A. B. Raper's letter (p. 1162), with much of which we are in complete agreement. The problems presented by the hypothesis that there is an association between malaria and sickling are exceedingly complex and not capable of easy solution. We did not say that we had proved that sickling and malaria are not associated, but stated (*Journal*, September 11, 1954, p. 630): "There is no confirmation of the theory that there is an association of any magnitude, such as that suggested by Allison, between sickling and malaria" (*Journal*, February 6, 1954, p. 290).

The purpose of our survey among the Daruma and Kambe was to discover if very wide variations in sickling were accompanied by differences in malaria rates; we found none. Our determinations of sickling and malaria were done on the same individual. In Allison's work the samples investigated for malaria and sickling consisted of different individuals, in some instances in widely separated areas. Raper says that our numbers were small (302 Daruma and 220 Kambe), but we have since doubled them and have still found no correlation between sickling and parasite or spleen rates.

We are puzzled by Raper's reference to the mixture of adults and children that composed our sample. Since sickle-cell rates do not differ significantly between adults and children the validity of significance tests could not be affected. It is, of course, true that if there were a differential in malarial rates between sicklers and non-sicklers for children, but not for adults, a sample of children only would be more efficient for the purpose of determining associations. However, since our memorandum was published in the *Journal* we have selected a sample of children under six months and have again found no association between malaria and sickling rates. Results of this survey will be published later.

Numerous pitfalls are likely to be encountered in trying to correlate sickling and malaria, since any associations may be seriously influenced by a number of factors, such as population movements, genetic drift, and ecological changes. Any changes in gene frequencies, due to deaths from sickle-cell anaemia, would be very slow. We are, of course, aware that the survival of sickle-cell genes involves some selective advantage, but this advantage might equally well be due to either higher fertility or lower mortality.

We gather that Raper considers that the severity of malaria is less in sicklers than non-sicklers, since he found a lower parasite density in the former, and considers this to be one of the reasons for the persistence of high sickle-cell trait rates in various African tribes. At present we have very little evidence to contribute on this question of parasite density. However, in a survey that we have just completed among a very homogeneous group of Jaluo we have found no evidence that parasite density and sickling were associated. So far the numbers examined have been small and larger samples may reveal a different situation. This work is being continued.

We must emphasize again that we cannot accept any evidence of association where the homogeneity of the sample, with respect to the characteristics studied, is not proved. We have previously shown that sickle-cell trait rates vary very greatly from place to place, even within the same tribe, and this has now been confirmed by other workers. Parasite rates and densities as well as sickling vary even in quite small areas, and the chances of fortuitous associations are therefore high. Under such circumstances the assumptions necessary for tests of significance do not hold; we gave an example of this in our memorandum. Our own experience, and that of others doing medical survey work in Africa, is that such fortuitous associations are common. Our reluctance to accept the results of tests of association at their face value is particularly strong when the sample is a mixture of tribes, as was Dr. Raper's. An association between parasite density and sickling, such as postulated by Raper, can only maintain the sickling gene by ultimately causing a differential mortality. Even if parasite density can be shown to be lower in sicklers, it remains to be proved that this is associated with a lower death rate in the untreated patient.

Further, is parasite density really a measure of malarial severity in African natives? The pyrogenic density or threshold is a factor of great variability in falciparum malaria in immunes as well as non-immunes. Severe clinical symptoms may occur with densities as low as ten parasites per cubic mm., and in other cases large numbers of parasites may be present and give rise to only the slightest illness. The presence of parasites in blood and particularly their density is dependent on a number of complex and, so far, little understood factors. No single entity, such as sickling or immunity, can be regarded as paramount. The high traumatic fragility of blackwater fever red cells is one of the factors that contribute to the scarcity of parasites in this disease. Similarly, in sickle-cell trait the traumatic fragility of the parasitized red cells may result in their being destroyed at an early stage of infection and thus reduce parasite density both by direct destruction of red cells and by limiting the number of parasites that undergo schizogony; we do not, at present, know whether there is a more intense destruction of red cells in cases of malaria in sicklers than in malaria in non-sicklers. This is a question that can only be answered by careful blood studies particularly of pigment metabolism.

There may be a "negative association" between sickling and mortality from malaria, but we cannot agree that it has yet been proved. We are not altogether convinced that an association between parasite density and sickling has been demonstrated, but even if it has we cannot agree that parasite density and mortality from malaria can be equated.—We are, etc.,

Medical Education

SIR,—I was interested to read Professor L. J. Witts's review of the *Proceedings of the First World Conference on Medical Education* (*Journal*, October 9, 1954, p. 853) which has recently arrived here. As Professor Witts says, there are too many thoughts and not enough experiments in medical education. It is heartening to read of the various recent work in medical education in the United States of America.

In Queensland, we have departed from the usual system of written examinations in the final year, and have introduced oral and clinical examinations only; written examinations have been included at the end of the fifth year. This was recommended by Sir William Osler long ago. At the present time, there is an urgent need to make better provision for the requirements for entry to medical schools. All students should have a knowledge of the arts, sciences, and sociological subjects, and thereby would have a good basis for general education.

Now that arrangements for the academic training of those who are going to be specialists of one sort or another follow set lines, the undergraduate curriculum may be considered. Sir A. L. Mudaliar, who presided over the section on the "Aims and Content of the Medical Curriculum," has put the case quite well. There is need for a reduction in the amount of anatomy and physiology taught to undergraduates, and, as Sir A. L. Mudaliar said, "It would be well if the student would occasionally look into the hospital ward,

and be shown what was normal and what was abnormal. . . . Similarly with pathology, "the pathologist would walk into the wards, and tell the students exactly what he felt about pathological conditions. . . ." Years ago Lord Moynihan stressed the importance of the "pathology of the living," and quite recently Lord Horder and Sir Heneage Ogilvie have emphasized that medical students are not going to be professors of these subjects, but should be able to recognize anatomical and physiological conditions as met with in general practice.

The *Proceedings of the Conference on Medical Education* will require careful study, and, as has been said, Dr. Clegg and his colleagues have done well to produce the book so quickly. It seems to me, however, that unless arrangements can be made for universities to exchange views on their efforts to produce a better curriculum from time to time the full benefit of the work of the conference will not be realized.—I am, etc.,

Brisbane, Australia.

E. S. MEYERS.

Reading and Writing about New Diseases

SIR,—For those of us who spend a few week-end hours in trying to keep up to date in new medical discoveries about which we know nothing, it would be most helpful if a preliminary paragraph introduced us as simply as possible to the subject. For instance, I have to-day battled with articles on phenylketonuria (*Journal*, January 8, p. 57) and byssinosis (p. 65) without ever getting my ignorant feet on the ground for a good start in understanding them. I have always told myself and my juniors to kick off with a simple explanatory paragraph relating the past to the new when writing about specialized novelties. I hope you, Sir, will insist on this when your authors tend to neglect it.—I am, etc.,

London, W.1.

R. D. LAWRENCE.

Talc Pneumoconiosis

SIR,—I read with much interest the letter from Dr. David Weitzman (*Journal*, January 8, p. 104). The atomic lattice structure of talc is such as to render its inhalation in powder form unlikely to cause a true pulmonary silicosis. Nevertheless, some unsatisfied valencies may be found at the edges of the platelets in freshly powdered talc, just as they are found at the fractured ends of freshly powdered asbestos fibres, and may possibly produce similar results. For a recent discussion on the chemical surface activities of silica and the silicates your readers are referred to *Tubercle* for September, 1953.—I am, etc.,

Cork.

PATRICK HEFFERNAN.

Treatment of Papilloma of Bladder

SIR,—I have just read with very considerable interest the article by Dr. Frank Ellis and Mr. R. Oliver on the above subject (*Journal*, January 15, p. 136). I do not wish to appear in any way critical, as the treatment of papillomatosis of the bladder has always been notoriously unsatisfactory, and the case described by the authors would have otherwise come to total cystectomy, an operation which must be regarded as a last resort, for, no matter what steps are taken to minimize the subsequent disability, the patient will remain a potential invalid for life.

I feel, however, that one statement should not be allowed to pass without comment, as it may give an entirely false impression of the results of the more common treatment for vesical papilloma. This reads: "The treatment of these lesions by cysto-diathermy has for many years been the method of choice, but the results of such treatment are difficult to find. It is certain, however, that a number of patients develop incurable malignant disease after many years' cystoscopy and diathermy." During the past ten years I have been privileged to see a large number of cases of vesical papilloma treated with cysto-diathermy, and no

single case which was diagnosed clinically as a simple papilloma has later developed characteristics of malignancy. Furthermore, I have seen several cases which had the cystoscopic appearance of malignancy, but in whom radical surgery was contraindicated. Following treatment with cysto-diathermy the growths have regressed permanently, and in some instances have disappeared. Cysto-diathermy is a treatment for these lesions which has, in my humble opinion, successfully stood the test of time, and must not be hastily abandoned for a far more hazardous procedure.—I am, etc.,

Slough.

ROBIN BURKITT.

Epithelioma Due to Tar Ointment

SIR,—We are grateful to Mr. W. H. Bond (*Journal*, November 20, 1954, p. 1226) and Dr. R. E. W. Fisher (*Journal*, December 4, p. 1355) for their comments on our case report (*Journal*, November 6, p. 1089). In his letter Mr. Bond states that "with the solitary exception of the histological report all the reported features are convincingly those of molluscum sebaceum" (the italics are ours). In their original description of molluscum sebaceum MacCormac and Scarff¹ list six features of the condition. They are: (1) The lesion develops rapidly to its maximum in four to six weeks and then remains stationary. (2) In no case has more than one lesion been present. (3) The middle area of the face is the site of election. (4) The lesion is usually of firm consistency but may show central degeneration. (5) In all cases the patients were of mature age—generally over 60. (6) Both sexes were affected. In a further series reported by Beare² only seven out of seventy-six were below the age of 35; the majority were over 50. In other respects the features of Beare's cases conformed to the original description. Mr. Bond puts forward (1) the age of our patient—that is, 31; (2) the apparent absence of other pre-malignant or benign tar tumours on other parts of the body treated with tar (when there were in fact several tar mollusca also present in the treated area); and (3) the appearance of a tumour within a patch of psoriasis, as convincing evidence of molluscum sebaceum. We are quite unable to agree with this view. The short exposure to tar is unusual, but we believe that this feature was compensated for by the patient persisting in its use for a considerable period after signs of tar intolerance had appeared. Incidentally, we are not aware that tar is an aetiological factor in molluscum sebaceum.

Savaterd³ commented on MacCormac and Scarff's cases that the features were those of the well-known button epithelioma, a criticism almost the reverse of what Mr. Bond says about our case. In their reply MacCormac and Scarff⁴ emphasized one point very clearly. They said "... the appearances of the section of the growth are much more nearly matters of fact, and we confess, with all respect, that we can find nothing in those appearances which suggest epithelioma or rodent ulcer either in the slide or the photograph." We have re-examined the sections in our case. The appearances are those of a well-differentiated, keratinizing, squamous carcinoma of low-grade malignancy. There is a hyperplasia of the epithelium around the tumour—a feature not found in molluscum sebaceum.

With respect to Dr. Fisher's comments we agree that tar epithelioma can occur without the presence of other lesions and may even appear in a man who has long since given up working with tar. It was not our intention to suggest that tar acne is an essential precursor of tar epithelioma. On the other hand, it is the repeated stimulation of the skin which results in the malignant change. Other signs of such stimulation or irritation are also very often present. The late onset of epithelioma due to tar in industrial workers, often at a time when they are no longer exposed to tar, may account for tar acne being absent at that time. In passing we would remark that the failure to make a diagnosis of cancer because of the absence of tar acne does not commend the clinical acumen of the examining physician to us. Surely a cancer lesion should be diagnosed or at least suspected on its clinical appearance and not on ancillary findings.

We question whether in fact industrial workers do rub tar into their skin any more than our patient did. The latter used a very strong ointment made up in emulsifying

base, which is expressly designed to secure quick and deep penetration of the skin. This occurs particularly around the hair follicles. Anyone who has used tar ointment extensively knows that this may sometimes produce folliculitis or tar acne, and this is an indication for withdrawal of tar therapy.—We are, etc.,

Kaposi's Varicelliform Eruption

SIR,—I have been prompted to protest against the title, "A Case of Kaposi's Varicelliform Eruption (Accidental Vaccinia)" reported by Dr. A. Fry (*Journal*, January 1, p. 28). The case reported undoubtedly refers to accidental infection with vaccinia, but the lesions described are those well recognized as generalized vaccinia. Dermatologists reserve the title of "Kaposi's varicelliform eruption" for the alarming eruption often associated with severe constitutional disturbance and high fever which occurs when a case of infected eczema also becomes infected with the virus of herpes simplex or vaccinia. In these cases the virus infection is usually a primary one, but it may not be, because recurrences of Kaposi's varicelliform eruption have been reported.

When a virus has been identified most dermatologists would prefer a diagnosis of eczema herpeticum or eczema vaccinatum, but the clinical picture of Kaposi's eruption, as illustrated by the above photograph, is nothing like that of accidental vaccinia. It is probable that a spreading factor such as hyaluronidase, present in infected eczema, accounts for the rapid local spread of the virus in cases of Kaposi's varicelliform eruption. Although the vaccinal cases of this disease may well be described as accidental they can readily be distinguished from vaccinia.—I am, etc.,

London, W.1.

REGINALD T. BRAIN.

A Case of Human Anthrax

SIR,—The authors Mr. M. F. Hunt and Dr. P. Cook (*Journal*, January 8, p. 87) and medical practitioner in charge of this case are to be congratulated for their early diagnosis, treatment, and subsequent investigations. It would be of interest to learn if "bone meal" was a constituent of the "animal manure," and, if not, had the inoculating insect access to this substance in a neighbour's garden. In recent years several writers¹⁻³ have stressed bone meal as a source of *B. anthracis*, as frequently the dried bones are imported from Asiatic countries where anthrax is endemic.—I am, etc.,

London, W.1.

Low Backache

SIR.—The methods of treating disk lesions advocated by Dr. James Cyriax (*Journal*, January 15, p. 140) are, he says, "based on logic." Logical thinking in medicine must always be followed amongst others by the question: Does it work in practice?

Cyriax suggests with all his strength that his methods do work: in one instance "immediate manipulative reduction succeeds in 99% of all cases," and "this simple manoeuvre prevents the later onset of brachial neuritis," presumably in 99% of cases. Again, referring to the dorsal spine, he says, "A protrusion irreducible by manipulation during manual traction is a rarity," and for the lumbar region his summary is, "In backache manipulative reduction, without anaesthetic, is usually successful," although there is a footnote stating that "the pain seldom returns to anything like its previous intensity." These manipulations have been carried out in Dr. Cyriax's department "with manifest success," and physiotherapists, he says, can be trained to do them, "as our experience at St. Thomas's Hospital proves."

The problem set by painful disability from disk degeneration and protrusion is very difficult and troublesome, and we would be inclined to agree with Cyriax's estimate of 20,000 to 50,000 individuals disabled from their work at any one time by these disorders.

If Cyriax really has the answer to both cause and treatment, as his article is meant to suggest, we must learn from him and train doctors and physiotherapists to carry out his methods. But can he really produce the goods? Can he prove that his rather elaborate technique, including manipulation, is more rapidly and surely successful than the established methods of exercise therapy which have always been productive of moderate success?

We must examine closely and objectively any method of treatment for any condition which claims "99% of cures," which is "usually successful," and in which "failure is a rarity." So far Dr. Cyriax has published many statements¹⁻³ but no figures. Many of the syndromes which he treats are apt to resolve spontaneously whether the patients are manipulated or not, and in two or three weeks. Gradual improvement during a series of manipulations at daily or weekly intervals cannot easily be disentangled from the probability of spontaneous cure. Will Cyriax produce rather more concrete evidence of the success of his methods so as to draw them more convincingly from the morass of palliative osteopathy? Will his colleagues at St. Thomas's Hospital or in the specialty of physical medicine support his claims for outstanding success?

Finally, expert medical opinion is at present such that a patient might argue much more successfully in a court of law that a manipulation had done harm than that recovery had been delayed by a negligent failure to manipulate at all.—We are, etc.,

SIR.—All those concerned with the treatment of low backache should make themselves acquainted with the important report published by Romanus.¹ It is based on a careful study of 117 male patients. His data make it quite clear that the bone changes not only of the spine and pelvic girdle but also of more peripheral parts are the result of chronic prostatitis-veniculitis. To establish such a relationship reliable means of demonstrating the presence of prostatic infection must be employed. Certainly the examination of a single prostatic smear is inadequate. It is astonishing at first to find that a prostate which feels quite normal on rectal examination can show granulomata in the prostatic

sinuses or on the verumontanum. To me such findings are evidence of badly draining infective foci—the proof of which can often be shown by improvement in the urinary symptoms (commonly chronic frequency) and backache. In women the regular use of the urethroscope for more than 20 years on all those with disturbances of micturition has revealed to me concealed chronic inflammatory foci in the posterior urethra, often in the presence of a crystal-clear and sterile urine. Treatment of these foci in many cases will cure or improve the accompanying backache.

The appropriate treatment of cervical erosion, and chronic vaginitis, will often have the same effect. Improvement from treatment, however, is not to be expected when the lower urinary tract condition has progressed to an established *Bact. coli* infection or fibrosis of the bladder neck, and chronic changes in the upper urinary tract. The x-ray films of the pelvis and spine which the urologist so commonly examines are constantly reminding him of the presence of osteoarthritic changes in chronic urinary cases.—I am, etc.,

London, W.1.

SIR.—Mr. John Charnley's views on low backache (*Journal*, January 15, p. 163) command respect, but it is doubtful whether they can be adopted as "facts." I find it difficult to accept some of his contentions, and trust I will be forgiven if I examine some of them from the point of view of a peripheral general surgeon who is not exempt from some responsibility for this skeletal disability.

Surely consultants employed by a National Health Service must think twice about withholding treatment unless "there is unanimity that the results . . . are worth the financial outlay." Most sensible patients approach the doctor in order to have some incommensurate symptom removed or mitigated. They are not concerned with abstract (though useful) concepts such as "significant organic causes," "scientifically sound rationale of treatment," or even "diagnosis." The doctor or his wife with backache wants the ache removed. If it is not removed the patient may, in spite of consultations, radiographs, corsets, or even "reassurance without treatment," get the idea that nothing has been done. He may even become "impossible to reassure" and finally resort to a quack who may cure him. I doubt whether, in the present state of knowledge, it is practicable to resolve pain into "organic and functional elements." As far as I am concerned persistent pain is a real thing, even when I cannot see, feel, or x-ray the aetiological lesion. A significant lesion may be physically minute. Mr. Charnley's colleague, Professor Kellgren,¹ demonstrated that the injection of 0.1 ml. of hypertonic saline into an appropriate skeletal structure could cause severe widespread segmental pain. It is easy to conceive of natural lesions so small causing persistent symptoms. The prolapsed disk is a common small yet significant lesion which escaped the attention of our profession for generations. Who can demonstrate the lesion of tennis elbow or facial neuralgia?

The history of our art is rich in examples of skeletal pains ignored by the orthodox only to be successfully treated by the unorthodox.²⁻⁷ Rational physiotherapy is more economical than irrational. Dr. L. S. Calvert (*Journal*, December 18, 1954, p. 1488) rightly drew attention to methods of physical medicine long exploited in the back street and by osteopaths, but now greatly improved and clarified in terms of orthodox medicine by Dr. Cyriax.⁸ Cyriax has described rational and refined methods of examining patients with aches and pains and has based on them a reasonable system of physical medicine⁹ of which the main ingredients are deep friction, manipulation, and traction, accurately applied to the site from which the pain is thought to emanate. *En passant* he has dealt severe blows at that honoured clinical nonentity "fibrositis." In the limited compass of his writings he has described his methods without producing evidence strong enough to compel acceptance of them, but by testing them it is easy to see that they produce benefits in many cases not amenable to traditional physiotherapy, much of which

justifies Mr. Charnley's description of "six weeks' quackery." It is conceded that there is a considerable residuum of incurables, but I share Mr. Charnley's hopes for the future.

The golden age of surgery was preoccupied with visceral disease, and most classical researches on pain, from McKenzie to Morley, were concerned with visceral pain. It is possible that many genuine pains due to obscure skeletal lesions have, in the past, been brushed aside as "not due to significant lesions" or "functional." I encounter many pains which I cannot diagnose or cure, but consider it salutary to attribute this to the limitations of my knowledge and methods. The researches of Kellgren and Lewis¹⁰ have thrown new light on the mechanisms of somatic pain, and I submit that Dr. Cyriax has significantly illuminated the clinical exploitation of this knowledge. We must test, not reject out of hand, all promising ideas. The great Paget,¹¹ in this connexion, said, "*Fas est ab hoste docere*." It is even better to learn from the successes of our less orthodox colleagues. To do so may protect the profession from some public criticism as in the case of Sir Herbert Barker.¹²—I am, etc.,

SIR.—Dr. James Cyriax (*Journal*, January 15, p. 140) performs a great service in pointing out in his paper the value of manipulative procedures in the treatment of low backache, but he does not disclose his diagnostic criteria for the diagnosis of spinal disk lesions.

Harris and McNab,¹ of Toronto, pointed out in 1952 that only a small percentage of the 123 patients then examined at necropsy had disk lesions and that other anatomical deformities and degenerations were probably the basis of both the patients' backache and root pain: thus we may assume that the majority of patients attending the practitioner and hospital clinics will have symptoms not related to disk derangement. Whereas a percentage of the latter will also respond favourably to competent manipulation, a large number would not only make no improvement but may indeed be made far worse by this form of treatment, especially if attempted by the inexperienced.

Prior to advocating widespread manipulative therapy in this country for all cases of backache, would a greater service not be rendered, Sir, by the clarification of the various diagnostic procedures required to make a correct diagnosis in the many sufferers from backache? In low back pain, more than in any other condition, accurate diagnosis is the only safe starting-point for successful treatment.—I am, etc.,

London, S.E.1.

P. HUME KENDALL.

REFERENCE

- ¹ *J. Bone 't Surg.*, 1954, 36B, 304.

SIR.—As a general physician often concerned, and frequently confounded, by the chronic or recurrent lumbar backache problem, I view the diametrically opposed opinions of Dr. James Cyriax (*Journal*, January 15, p. 140) and Mr. John Charnley (p. 163) with baffled and amused wonderment.

As I see it, Dr. Cyriax (the sanguine) considers the majority of chronic backache sufferers to have small posterior disk protrusions, easily cured by manipulation (delegated to the physiotherapist), while Mr. Charnley (the pessimist) considers the vast majority have either no physical disease (presumably psychoneurotics) or have a physical disease he cannot diagnose or treat, and so he reassures them. Where does the truth lie? Has Mr. Charnley previously adopted Dr. Cyriax's methods and abandoned them as ineffective, too reminiscent of osteo-

pathic practice, or as pure psychotherapy, to be classed with E.C.T.? Is the apparent success of Dr. Cyriax really due to the reduction of existing disk protrusions, is it a form of psychotherapy, or perhaps the patients, once subjected to manipulation without anaesthesia, are wise enough to keep their backaches strictly to themselves?

Quite seriously, the low backache problem remains an unsolved mystery in perhaps half the cases we see, for we are uncertain of the diagnosis, and therefore lack confidence in the treatment and management. I write this letter in the hope that the protagonists will take up the cudgels once more in the vertebral no-man's-land, and perhaps, who knows, we shall find that there is a wider common agreement than I imagine.—I am, etc.,

Warrington.

DENIS M. FREEMAN.

SIR.—I have a great admiration for Mr. John Charnley as an inventor of ingenious orthopaedic instruments, but I am considerably shaken by his conception of a "humane and sympathetic Health Service" (*Journal*, January 15, p. 163). It is, of course, apparent that Mr. Charnley has himself had neither sciatica nor lumbago, but if and when his good fortune ceases I wonder how he will react to "reassurance without treatment." I am sure that he is "an intelligent, decent, and sensible" person, but will "sympathetic explanation" be any comfort to him in his suffering? No. He will probably "hand-pick" himself into the select residue who have their spines fused.

Was it by design or chance, Sir, that in the same issue as Mr. Charnley's letter appeared Dr. Cyriax's article (p. 140)? Their mutual contradictions as regards the efficacy of physiotherapy made intriguing and amusing reading. One cannot dismiss Dr. Cyriax's results by the trite phrase "*ad lib.* physiotherapy" and one suspects that Mr. Charnley is begging a big question when he implies that "organic" backache is a matter of "collagen degeneration." It might be an idea for the British Orthopaedic Association to invite Dr. Cyriax to be a member of the panel at their next brains trust. It would certainly dispel the "dog-in-the-manger" attitude which undoubtedly exists, and might even persuade Mr. Charnley to stop bellyaching about the "backaching multitudes."—I am, etc.,

Loughton, Essex.

DONALD V. BATEMAN.

SIR.—As one who has had the opportunity of seeing Dr. James Cyriax's work and hearing the testimony of some of his patients, I feel that its value cannot be doubted, particularly in his insistence on accurate diagnosis before physiotherapy treatment is instituted and in his bringing to our notice the all-too-long-neglected forms of manipulative and traction therapy, which have reached a high standard in his hands. However, I must say that I believe equally firmly that he does his cause a great disservice in his over-simplification of the various intervertebral disk lesions and his insistence that the essence of their treatment is the reduction of the protrusion in all cases. Nothing in fact in a study of the anatomy and pathology of the intervertebral disks, particularly in relation to the effects of ageing on their physiology, lends support to this simple mechanistic theory, and a comparison of the lesion with that of a displaced meniscus of the knee-joint, as Dr. Cyriax has done,¹ is entirely misleading. I have already reviewed some of the reasons for this misrust,² and subsequent work on dissections of the cervical and lumbar regions has merely served to confirm this.

Our ignorance of the exact cause of the symptomatology associated with the various types of spinal disk lesions is profound, but I believe there are reasonable grounds for rejecting the simple organ-stop approach, that is to say, disk out giving a *vox radicularis* or *vox ligamentus* and, alternatively, disk in giving perfect comfort. The spread of this conception is making the work of orthopaedic surgeons interested particularly in this problem difficult. I mention orthopaedic surgeons in order to refute emphatically the

implication of the quotations which precede Dr. Cyriax's article (*Journal*, January 15, p. 140), and to assure him that there are many surgeons concerned with this problem who could have given a great many suggestions for coping with the vast number.

Furthermore, I feel that he is playing also into the hands of the very people whom I know he is anxious to defeat—namely, the unqualified manipulator. For, now this mechanistic concept of the prolapsed disk and its treatment has been given an aura of medical respectability, many doctors find it difficult to understand why they should not advise their patients to attend lay manipulators who are ready to claim they can reduce three or four disks at each session, whether in fact there is any reason to suppose they are displaced or not.—I am, etc.,

Wellington, Salop.

Heel Comfort

SIR,—I have lately had great success with an idea for treating painful heels in crippled or bed-ridden patients. A strip of "latex foam," 8 in. (20.4 cm.) by about 18 in. (45.7 cm.), put upside down between the sheets at the foot of the bed takes the heel or both heels in the squares, the front of which must be cut away. The depth of the squares varies from about 1 in. (2.5 cm.) to about 6 in. (15.2 cm.). I have used 2 in. (5.1 cm.), but where there is a risk of foot-drop the 6 in. (15.2 cm.) depth would help. The comfort has not only been to the heel, but one arthritic who has a pin in the neck of the femur has lost her pain in the hip and back also. She carries the cushion with her to sit on as well.—I am, etc.,

New Milton.

MARY G. H. EDWARDS.

Intramuscular Iron

SIR,—We would correct the impression given in the letter from Drs. Sheila T. Callender and Mary D. Smith (*Journal*, December 18, 1954, p. 1487) that we found the preparation of intramuscular iron to be innocuous when given intravenously. During certain observations made¹ two anaemic and two healthy subjects were given 5 ml. of the iron preparation, first intramuscularly and then, after an interval, intravenously, but "the experiment was then abandoned because the patients developed moderate reactions after intravenous injections." The intravenous use of this preparation is not without risks and in our opinion is unnecessary.

With regard to Dr. Callender's and Dr. Smith's experience of reactions in four patients after injection of the preparation, two in fact received the iron intravenously, and of the two patients given iron intramuscularly one was already known to be of allergic disposition. We found no reactions in the 40 patients treated with an experimental preparation of intramuscular iron, but since publication of our results we have found one batch of iron preparation which, when given intramuscularly to two patients, produced malaise, pyrexia, and shivering. When a further batch of "imferon" was substituted no reaction of any kind was noted in either case to the same dose given intramuscularly. It is evident that certain batches of the iron preparation contain a pyrogenic substance.

The difficulties of assessing "reactions" can be judged from the following case report: A woman aged 64 was admitted to the dermatological department, Royal Infirmary, Sheffield, for treatment of psoriasis, and while in the ward an iron-deficiency anaemia was discovered. After oral treatment with ferrous sulphate and ferrous gluconate severe diarrhoea ensued, so imferon therapy was commenced. After two intramuscular injections of 5 ml. severe diarrhoea and some pyrexia occurred. Two possibilities were considered: (a) this was an allergic response to iron, (b) some iron was being excreted in the faeces—contrary to accepted concepts of iron metabolism. A further injection of 5 ml. of the same batch of imferon caused no diarrhoea and an iron balance experiment revealed no increase of faecal iron

excretion after the injection. The diarrhoea was evidently coincidental to the intramuscular iron therapy.

Further experience is necessary to evaluate the frequency of reactions after intramuscular iron, particularly with regard to the occurrence of pyrogenic batches, and we feel that the published data indicate a useful but restricted place in therapeutics for the preparation, and the occasional occurrence of reactions should not deter from its use in selected cases.—We are, etc.,

Trichomonal Vaginitis

SIR,—I was interested in the article by Drs. S. R. M. Bushby, R. D. Catterall, and Mary Williamson (*Journal*, January 8, p. 78) reporting the results of a clinical trial of yet another drug in the treatment of trichomonal vaginitis. I am prompted to write a few brief comments based on my experience of treating a large number of cases of vaginal discharge.

Over 40% of cases complaining primarily of vaginal discharge are due to infestation with *T. vaginalis*. No age is immune; the disease has been observed in pre-puberty and after the menopause, but is more common during the reproductive years, especially in pregnancy. Clinical diagnosis in the acute phase is easy but should be confirmed by examination under the microscope; swabs are unreliable; pipette specimens examined fresh are essential. Ideally no case should be treated without demonstrating the organism; a week's supply of vaginal pessaries for "leucorrhoea," though giving temporary symptomatic relief, is a potent factor in the production of chronic cases. Acetarsol gives the highest percentage of cures, but it must be realized that to be effective the treatment should start with an initial insertion of 12 tablets and then daily insertions of one for at least 8 weeks, including during the menstrual periods. Weekly vaginal paintings with 2% gentian violet in spirit is a useful adjunct, and all marital relations should be "protected" by a condom for a minimum period of 6 months. The relapse rate with this routine is very small and a further course of treatment is usually effective.—I am, etc.,

Cambridge.

OSWALD LLOYD.

Sequelae of Erythroblastosis

SIR,—In your leading article (*Journal*, January 1, p. 35) you drew attention to the problems of kernicterus. Your suggestion that experimental kernicterus has been produced by bilirubin infusion is, however, a little misleading. Day¹ exposed cerebral tissues to x rays and then demonstrated that the infused pigment stained the damaged portions. Kuster and Krings² appear to have produced little more than a generalized yellow staining of the brain, but in Kuster's original paper³ reference is made to some staining of the basal nuclei when the serum bilirubin concentration rose to 75–100 mg. per 100 ml. In humans the characteristic pathological and clinical feature of the disease is the tendency for certain nuclear masses to be picked out and damaged, and the only experimental work which comes anywhere near achieving this state of affairs is that of Eyquem.⁴ By the injection of anti-cat red cell serum into kittens he produced an acute haemolytic anaemia with jaundice, acute neurological disturbance, and staining of the basal ganglia. Although acceptable as experimental kernicterus, this work does not give any further clue to the pathological processes in the brain; Eyquem himself concluded that a local antigen-antibody reaction was responsible and that bile-staining was secondary. The widespread incidence of kernicterus without any evidence of an antigen-antibody reaction now makes this interpretation untenable; the typical clinical and pathological changes have been reported in prematurity, in acholuric jaundice,^{5,6} and in "congenital familial non-haemolytic jaundice."⁷

There is strong circumstantial evidence pointing to bilirubin itself as the toxic agent, and a rational explanation of the high incidence of kernicterus among premature infants can be put forward when it is remembered that bilirubin levels in the blood of the newborn are inversely related to maturity⁸ and that the "blood-C.S.F. barrier" is less effective in premature than in full-term infants.⁹

Despite these clinical observations, experimental evidence is lacking. Although successful attempts have been made to demonstrate the toxic effects of "bile" in the young animal¹⁰ they cannot be accepted as incriminating bilirubin itself, as the material used was "concentrated bile" and not the pure pigment. To settle the role of pigments in the pathology of kernicterus it would seem necessary to show (1) that pure indirect-reacting bilirubin is toxic to the central nervous system and that if introduced into the cerebrospinal fluid it shows "special affinity" for the nuclear masses; and (2) that in both experimental and clinical kernicterus there are special circumstances which permit bilirubin to reach the cerebrospinal fluid in large amounts. It should not be long before evidence on these points is forthcoming.—We are, etc.,

Changes in the Mental Health Services

SIR,—The recent correspondence on mental observation wards has shown that opinion is divided regarding whether or not their continuance in the future is desirable. Most of your correspondents have, no doubt, been arguing from their knowledge of such units in their own localities, and as there is no clear definition of what constitutes a "mental observation ward" the arguments are tending to become confused.

If by the term "mental observation ward" one is to understand a ward in a general hospital where patients on 3- and 14-day orders are admitted, for the purpose of deciding whether or not treatment in a psychiatric hospital is desirable (as voluntary, temporary, or certified patients as the case may be), or whether the patient can be discharged home, I can see no justification whatever for their existence—except possibly in the very largest centres of population where conditions are somewhat different. In any lesser centre the unit will inevitably be too small to allow of proper classification of the patients, and too small also to be administered and staffed efficiently as an economic proposition. Equally important objections are (a) that the patients requiring admission to the psychiatric hospital at the end of their "observation" will usually have to suffer a change of doctor as well as of nursing staff, and (b) that they will feel that they have failed to make the grade, and will go to the psychiatric hospital with an unnecessary feeling of shame.

On the other hand, it is generally agreed that psychiatric wards of some kind in general hospitals are desirable: such wards, however, should be for the most minor degrees of mental illness (including psychosomatic conditions) for whom admission to a psychiatric hospital might be difficult to arrange. If the Royal Commission recommends that the 3- and 14-day order procedure shall continue, the best place, in my experience, to which patients on such orders should be admitted, is the psychiatric hospital. Apart from many obvious advantages of such an arrangement, it is found in practice that the need for certification hardly ever arises,

as is seen from the following figures for a provincial psychiatric hospital for the year 1954.

Admissions			Disposal					
3-day	14-day	Total	Vol.	Temp.	Cert.	Died	Home	Other Hospital

Cardiac Asthma

SIR,—Congratulations to the *British Medical Journal* for once more publishing outstanding articles which are of so much benefit to general practitioners. I read with great interest the first of the new series written by Dr. J. G. M. Hamilton, of Edinburgh, on cardiac asthma (*Journal*, January 1, p. 39). This condition is not a common emergency seen in general practice, but is one of the most satisfactory to treat. The use of morphine as quoted by the distinguished author as the only treatment in severe cases cannot be overemphasized. May I describe an outstanding case which I attended five months ago to substantiate this statement?

The patient, a man aged 67, had to my knowledge suffered from aortic regurgitation and cardiac hypertrophy for the past six years, having had attacks of breathlessness and been treated with digitalis and aminophylline. I was called to see him in the early hours of the morning and found him sitting by the open door very dyspnoeic. On examination, the patient was cold, clammy, and cyanosed. Neck veins were engorged and frothy sputum exuded from his mouth. Pulse was impossible to estimate, pupils sluggish, and he could not speak. His condition was truly grave.

Owing to the obesity of the patient—18 st. (114.4 kg.)—and urgency of the condition, $\frac{1}{4}$ gr. (32 mg.) morphine was given intramuscularly. Within 25 minutes a dramatic change occurred. The cyanosis and coldness of the skin disappeared although a slight degree of breathlessness remained. Pulse was now countable too. Mental outlook was normal, and he spoke intelligently. One hour later he insisted on returning to bed, and aided by a friend walked to his bedroom.—I am, etc.,

ERIC LODGE.

Treatment of Bronchial Obstruction

SIR,—The reason why the odds given by Dr. J. W. Trevan in his letter (*Journal*, January 8, p. 103) cannot be used to measure our degree of belief in the relative inefficacy of calcium chloride (*Journal*, December 11, 1954, p. 1388) is that, although our patients were chosen "at random," the trial was not concluded at a predetermined point (which would again be "at random" as far as the results were concerned), but at a point determined by the results themselves. This point was then bound to be one at which a clear distinction between the drugs, or a close similarity of them, had been established. The special form of analysis used makes due allowance for this characteristic of a sequential trial, which the simple form of calculation made by Dr. Trevan does not.

It would, of course, have been perfectly possible for us to have planned our trial in such a way as to have enabled us to establish, with calculable risks, the superiority of either calcium chloride or adrenaline. Unfortunately, as it now turns out, we did not plan to test the superiority of adrenaline. It will be understood that the trial would never have been begun had not the claims made for calcium chloride suggested that it was superior to more conventional remedies.

May we hasten to add that common sense has led us to the same opinion as Dr. Trevan's, that calcium chloride is

no good? We cannot, however, use a statistical argument to reinforce this opinion, and it was therefore not claimed as a result of the sequential trial. Nevertheless, there is no conflict between common sense and statistics here; we are all accustomed to act on common-sense opinions for which statistical justification is lacking. Common sense tells us the sun will rise to-morrow; although the odds that it will do so are probably high, they cannot be worked out.—We are, etc.,

Penarth, Glam.

Antibiotic Sensitivity Spectra

SIR,—I have read with interest the article by Dr. E. P. Silberstein (*Journal*, January 15, p. 148) on the use of antibiotic spectra in the investigation of epidemics. It is, however, unfortunate that Dr. Silberstein used both aureomycin and terramycin for his series of tests, since the sensitivity of *Staphylococcus aureus* to these two antibiotics is almost always the same. The development of resistance to one of them automatically confers resistance to the other. Dr. Silberstein's method would have greater powers of differentiation if another antibiotic were used instead of terramycin.—I am etc.,

R. BLOWERS.

Leukaemia and Ankylosing Spondylitis

SIR,—A conference was recently convened by the Medical Research Council to consider new ways of inquiring into the causes underlying the present rise in the death rate from leukaemia. At this conference a memorandum was presented drawing attention to an apparent association between leukaemia and ankylosing spondylitis. This information was based on a rather limited number of instances, and the members of the conference considered it very desirable that further evidence should be collected on this question. The possible association of leukaemia with ankylosing spondylitis is a curious one, but it may well be one that has been noted in individual patients by some of your readers.

Dr. W. M. Court-Brown, a member of the Council's External Scientific Staff, at present working at the Department of Medicine, The Postgraduate Medical School of London, Hammersmith Hospital, London, W.12, is collecting the relevant data on this subject. He would be very grateful if any of your readers who may have witnessed the occurrence of leukaemia in a patient suffering from ankylosing spondylitis would write to him.—I am, etc.,

London, S.W.1.

H. HIMSWORTH.

POINTS FROM LETTERS

Boxing Injuries

Dr. HERBERT SIMON (London, N.3) writes: I have read the conclusions of Drs. J. L. Blonstein and E. Clarke re amateur boxing (*Journal*, December 25, 1954, p. 1523) summing up that "amateur boxing is a useful and justifiable sport." In my opinion boxing is only justified as a weapon of defence. Only six deaths due to boxing among amateurs within the last seven years have occurred, so we are told. I have watched amateur boxing in reality and in good close-up shots on television. What a spectacle watching young men hammering at each other in a more or less skilful way! The principle in boxing is to knock the other fellow out by inflicting injuries to your opponent. The "sport" is designed to win by doing the most possible physical damage to your opponent and to hurt him as severely as possible. It is a sorry tale of the commentator we have to listen to of bleeding noses, wobbly knees, eyes blinded by blood, and the lovely pay-off right on the spot of the jaw. I cannot imagine that cranium, eyes, ears, and the solar plexus are created to be intentionally exposed to punishment which might sooner or later lead to physical or mental harm.

Obituary

GEORGE HALL, C.M.G., M.D., F.R.C.P.

Dr. George Hall, consulting physician to the Royal Victoria Infirmary, Newcastle-upon-Tyne, died on January 10, aged 75.

George Hall was the only son of M. Stokoe Hall, of Bishop Auckland. From Armstrong College, where he took the Durham degree of B.Sc. in 1899, he went on to study medicine at University College, London, where he was Bucknill Scholar and where he won a gold medal and exhibition in physiology at the intermediate M.B. examination in 1901. He also won the Cluff Prize in the same year. Graduating M.B. in 1903, he continued his brilliant student career by winning the Atkinson Morley Scholarship in 1904. He proceeded M.D. in 1905, took the M.R.C.P. in 1907, and was elected F.R.C.P. in 1927.

After qualification Hall held the posts of house-physician and house-surgeon at University College Hospital, and then was junior and senior house-physician at the National Hospital, Queen Square. Returning to Newcastle to take up consultant practice he was elected assistant physician and assistant pathologist at the Royal Victoria Infirmary in 1908. He also became assistant demonstrator of bacteriology at the College of Medicine at Durham University, which he was later to serve as registrar. One of the first papers he published in this *Journal* was on the bacteriology of keratitis. Hall was a Territorial, and during the first world war he served in the R.A.M.C. with the rank of major, being appointed C.M.G. in 1916.

In the years after the war Hall quickly established a large practice as a consulting physician, especially in neurology. He became a full physician on the staff of the Royal Victoria Infirmary in 1927, and lecturer in medicine at King's College. He had previously been lecturer in medical jurisprudence and in materia medica and pharmacy. Among other appointments he held were those of honorary physician at the Ingham Infirmary, South Shields, consulting neurologist to the Home for Crippled Children at Gosforth, and visiting physician to the Ministry of Pensions Hospital, Dunstan Hill. He was also a Fellow of University College, London, a J.P. for Newcastle, and medical visitor for the Durham county magistrates. During the Annual Meeting of the B.M.A. at Glasgow in 1922 he was vice-president of the Section of Medicine; and he was chairman of the Newcastle-upon-Tyne Division of the B.M.A. in 1931-2.

Dr. Hall married Margaret, eldest daughter of Nicholas Mein, of Newcastle. They had one son and one daughter.

J. H. B. writes: I would like to pay a tribute to my old friend Dr. George Hall, who was a very lovable man. He was good-looking, modest and quiet, and a good conversationalist. He had a very kind and friendly disposition and was always ready to help anyone who came to him for advice. He was popular with colleagues, students, and nurses. He was one of the old school and most conscientious in his hospital attendances. In spite of a very busy professional life he found time to indulge in some hobbies. He was fond of music, golf, and cricket, thoroughly enjoying taking part in the annual cricket matches between the staff of the infirmary and the students. For the past few years, after the death of his wife and the departure south of his son and daughter, Dr. Hall was a rather lonely man.

He loved his friends to call in and have a chat by the fire-side. About two years ago he had a serious illness from which he never fully recovered. He will be greatly missed in Newcastle. Our sympathy goes out to his son and daughter.

H. K. WALLER, M.B., F.R.C.O.G.

After a long and distressing illness Dr. H. K. Waller died on January 13, aged 73, at the home of his adopted daughter in Wadhurst. For most of his life he was a general practitioner, but his infant welfare work at the British Hospital for Mothers and Babies, Woolwich, and elsewhere brought him well-deserved renown.

Harold Kirk Waller was born in 1881, the only son of the late Rev. Horace Waller, who was in his early days a companion of David Livingstone in some of his later journeys and after whom Waller's gazelle (*Lithocranius walleri*) was named. Horace Waller came much into contact with Sir John Kirk, British Agent at Zanzibar for many years, the adviser and helper of all the mid-Victorian East African explorers, and for this reason his son was given the name Kirk. Harold Waller was educated at Charterhouse School and at Trinity College, Cambridge; thence he went on to the medical school of University College Hospital, qualified M.R.C.S., F.R.C.P. in 1909, and graduated M.B. in 1911. He was house-physician at his own hospital and at the Shadwell Children's Hospital as well as resident medical officer at Queen Charlotte's Hospital. After service in the R.A.M.C. during the 1914-18 war he was in general practice in Chelsea, and there developed a special interest in infant feeding and infant welfare; but he always insisted that he was primarily a general practitioner, that mother and baby should be treated as a unit, and that it is the family doctor and nurse, provided they are adequately trained, who can best manage and supervise the nursing couple. In 1914 he had been appointed superintendent medical officer at St. Katharine's College, Poplar. This was a child health centre, started with funds provided by the Chapter of London, at which there were infant welfare, dental, and sunlight clinics, as well as eight to ten cots for in-patients. His appointment there continued until the inception of the National Health Service. He always had a warm affection for those who lived in the East End, and during the second world war was placed in charge of the children's ward at the Poplar Hospital, at the same time being appointed physician to the nursing staff.

Waller's association with the British Hospital for Mothers and Babies at Woolwich began in 1913 and continued until 1950. During the years since his retirement he still kept in touch with the hospital, and in the latter part of his illness, when travelling from Tunbridge Wells was a physical strain, made every effort to visit the hospital, which had become a Mecca for all those interested in the subject of lactation and the care of the newborn. He was elected an honorary F.R.C.O.G. in 1953, the second paediatrician in this country to be so honoured, and in 1951 received the Dawson Williams Prize from the British Medical Association in recognition of his original contributions to the clinical study of lactation and infant feeding.

The Chelsea Babies' Club was another institution to which Waller was devoted. He was its first medical adviser when it was started in 1927 with Lady Piercy as its chairman. Here he instituted classes for expectant mothers, instruction on infant care, breast-feeding, suitable clothing, the importance of open air, nursery planning, and so on. He was a shrewd observer and an excellent and discriminating writer. In *Clinical Studies in Lactation* (published in 1938) he described all that he had learnt about lactation—for example, the draught reflex which governs the outflow of milk from the breast, the reasons for early failure of breast-feeding and the re-establishment of lactation. His observations were made at the bedside, in the out-patient clinic, or in the patient's home without resort to esoteric laboratory procedures. His wish was that there should be two rooms at the Woolwich Hospital for "after-care" of mothers and babies. The building of this annexe with money collected from the nursing staff, doctors, and patients is almost complete—an appropriate memorial to him. He had been a widower for a few years and leaves no issue.

Sir EARDLEY HOLLAND writes: It was characteristic of Waller to head his last piece of writing with a quotation from his admired teacher, Wilfred Trotter: "The scientific world is a democracy of facts where the inhabitants are of equal standing and there is no table of precedence. Indeed, the progress of knowledge has been in great part the discovery of the importance of small things and the exaltation of the insignificant." Waller's interest in obstetrics no doubt began as R.M.O. at Queen Charlotte's, and when he went into practice in Chelsea he became in due course what would now be called a general-practitioner obstetrician. The advantage this sort of practitioner has over the obstetric consultant accoucheur is that he has the continuous care of the baby from birth onwards and the welding of the mother-baby unit. He soon became deeply interested in breast-feeding (his "last phase of the reproductive cycle"), the clinical study of which was strangely neglected, and the want of success of which, as conventionally managed, was deplorable. Even a recent survey showed that lactation failed within eight weeks of delivery in nearly one-half of nursing mothers. When Waller began practice the position can have been no better; but instead of passively accepting it he began to dedicate himself to a lifelong clinical study. In such regard did he hold baby welfare that he founded a private infant welfare centre, the Chelsea Babies' Club. His ideas soon became known to leading London midwives and welfare workers, for here was a man who seemed likely to solve one of their most hopeless problems. His work soon gathered impetus: in 1914 he became medical superintendent to the earliest public welfare clinic in London (The Royal College of St. Katharine) and physician to the Home for Mothers and Babies, Woolwich, which led on to his later appointments as paediatrician to Poplar Hospital and to the British Hospital for Mothers and Babies, Woolwich. The secrets of lactation were revealed to Waller by patient and persistent observation, through the years, of babies at the breast and by careful recording, whereby he was able to form conclusions that were convincing and to recommend simple devices that were at once adopted. Groups of devoted midwives and co-workers helped, above all at the Woolwich Hospital, which became the recognized centre of his teaching. Midwife teachers and sisters, and even young obstetricians, were sent there to learn, not only from British centres, but from many parts of the world, and he visited many centres by invitation to show his methods.

Medicine was a vocation to Waller, and from first to last he was a dedicated man. Throughout his life he inspired a feeling of affection in all who came in contact with him. Such an unusual combination of gifts—charm, gentleness, unselfishness, quick sympathy, and devotion—captured all hearts. As a doctor he was great, but he was greater still as a human being. So lived one who was content with the discovery of small things and the exaltation of the

insignificant. But was the bringing of so much happiness and comfort to so many mothers and babies such a very small and insignificant thing?

Mr. T. TWISTINGTON HIGGINS writes: Harold K. Waller was one of the outstanding doctors of my time. Pioneer in the natural feeding and welfare of infants—who can compute the debt owed to him, or yet to be incurred, by babies and their mothers? All who were fortunate to count at need upon his steadfast care and skill in their own homes can never forget this prince of family physicians. To those privileged to enjoy his friendship there will ever remain the inspiring memory of his commanding debonair figure, gentle courtesy, and infinite kindness of heart. His alert mind with its own gifts of insight, quiet humour, and modesty made him a delightful and stimulating companion, whether in a teeming noisy Poplar street, in the charm of his Chelsea house, or among the flowers and peace of his beloved country garden. At Charterhouse he had played football in distinguished company, with some whose names are now a legend—G. O. Smith, Oakley, Cobbold—and much of the boy always remained to temper the dignified distinction of the man. Harold Waller made his world a richer place for many, and those who knew him best are sadly the poorer for his passing.

Dr. DAVID MORRIS writes: Dr. Waller will be most remembered by his pioneer work on breast-feeding. But we who knew him personally know intimately the remarkable quality that lay behind his scientific contribution. Whether on ward round or in lecture-room, at consultation or in social gathering, his special ability was always to establish a warmth of human relationship. His work was much more than a mere method or technique of antenatal preparations or post-natal management of breast-feeding; it was the application of a rich experience and judgment to individual human beings. He was a remarkable example of the old school who learned and taught on the individual case rather than by statistical analysis. Typical of his mode of working was his last series of clinical observations, carried out after his retirement, on a small group of individual nursing mothers whom he visited in their homes; his accurate observations added much information to the natural history of breast-feeding. He was held in high esteem by all who knew him, exemplified in the building of the "Dr. Waller Rooms" at the British Hospital for Mothers and Babies, Woolwich, from a voluntary fund launched after his retirement.

J. D. WHITE, O.B.E., M.B., D.M.R.E.

Dr. J. D. White, director of the radiological department at the Hammersmith Hospital and senior lecturer in radiology at the Postgraduate Medical School, died in London on January 21 at the age of 59. He had suffered for years from the effects of working with radium during his early years as a radiologist.

John Duncan White graduated M.B., Ch.B. at Edinburgh University in 1917 and held the post of resident surgeon at the Royal Infirmary. During the closing stages of the first world war he was a captain in the R.A.M.C. On his return to civilian life he determined on a career in radiology, and served his early years under the guidance of his revered chief, the late Dr. Stanley Melville. In 1921 he took the D.M.R.E. of Cambridge, having held the post of clinical assistant in the x-ray department of King's College Hospital. After working for some years as assistant radiologist at St. George's Hospital and at the Brompton Hospital, and as radiologist at the Hospital of St. John and St. Elizabeth and the Hospital for Tropical Diseases, he was appointed in 1932 as radiologist at the Royal Infirmary, Edinburgh, and also as lecturer in radiology at the University.

Within two years, however, he was back in London as director of the radiological department at Hammersmith Hospital, where he had been working for over 21 years at the time of his death.

Indefatigable in the efforts he made for the good of his specialty, Dr. White served on the councils of many organizations concerned with radiology. For many years he was a member of the council of the British Institute of Radiology, being elected its president in 1934, and serving as honorary treasurer from 1939 to 1945. In 1936 he was vice-president of the Section of Radiology at the Annual Meeting of the B.M.A. in Oxford, and he was a member of the Consultants Board and of the Radiologists Group Committee of the B.M.A. for a number of years. Much of the credit for the high standard of radiography set by the Society of Radiographers must be given to him, for he had been one of its critical and constructive advisers throughout. During the last war he served again in the R.A.M.C., attaining the rank of temporary major. He was appointed O.B.E. in 1953.

Dr. JAMES F. BRAILSFORD writes: With the passing of John Duncan White another doctor joins the roll of x-ray martyrs, and British Medicine has lost one of its greatest exponents in radiology, radiologists a loyal and courageous colleague, and radiographers their best adviser and friend. White rightfully looked with disfavour on that modern appropriation of radiological services in experimental medicine which was activated merely by desire to satisfy the curiosity of the investigator—the risks to the patient being ignored. Though he taught and showed the highest standards of radiology to his students, radiographers, and radiologists, he did not consider the production of a spectacular radiograph his goal, but merely a means to help the patient. The control of a big department, in which the chief so scrupulously and intimately inspected all the work and advised with firm humanitarian principles on all of its most important investigations, may not produce universal approval, but such behaviour did endear all to him who honoured good work. His integrity, enthusiasm, and desire to render to his patients the utmost service radiology could give unfortunately resulted in severe radiation burns which necessitated several amputations. These ominous signs, though associated with much pain, were borne silently with great fortitude. He made light of his sufferings and kept his friends free from any painful reference to them, and by his quiet and courageous facing of an early death put the hall-mark on the enduring love and affection of his devoted wife, Claire, to whom we extend our deepest sympathy. Truly can it be said of him as of other x-ray martyrs:

"But in our hearts they rest
Not less revered than blest
Than those their brothers who in fighting fell,
Nor shall our children hear their names pronounced less dear
When England's roll of gallant deeds we tell."

A colleague writes: Duncan White was a most gallant fellow. No one who knew him and saw him hobbling about, overcoming his physical disabilities and doing his work day after day under circumstances which were often distasteful, would deny him this merit. Thrust into radiology in the urgent days of the 1914-18 war, with little experience and no knowledge of its perils, he sustained damage which ultimately caused his death. Knowing his inevitable end, he faced the long-drawn-out period of waiting with a courage which shamed those who occasionally visited him in those latter days. We may mutter *Ave atque vale* and feel that we have paid some tribute to a man of great heart and cool courage, but until and unless we face the same ordeal we can never evaluate the gallantry which D.W. brought to meet it.

R. J. WILLAN, C.B.E., M.V.O., M.S., F.R.C.S.

Sir GORDON GORDON-TAYLOR writes: Perhaps I may be granted a few lines to add a personal tribute to the late Professor R. J. Willan—"R.J." to his friends—whose obituary notice appeared in the columns of last week's *British Medical Journal*. I have been deeply indebted to Willan on at least two occasions: first during the earlier part of the 1939-45 war when he was consulting surgeon in the north-east region of England and I was busying myself with the collection of abdominal casualties due to air-raid attacks on Britain; and, secondly, I cannot forget the generous help which he afforded me in the preparation of the Rutherford Morison Centenary Lecture with which I was honoured in 1953. Rutherford Morison remained my hero till the very end of life, and, although I should not dare to decide whether Charles Saint, of Capetown, or Willan was Morison's "beloved disciple," the duration of "R.J.'s" friendship and loyalty was inevitably the longer. The numerous letters from Morison to Willan which the latter had preserved and which he kindly permitted me to read showed that the affection was not one-sided: it was to Willan and Hamilton Drummond, assisted by Gordon Irwin, that Morison turned for surgical help in 1923, and their surgery prolonged his life for 15 years. And I have also in my possession a copy of the pathetic letter written in 1938 by Morison, who when 85 years of age was faced with a serious surgical ordeal, dropping "the old pilot": "the old pilot" paid his last tribute to his chief a few days later in the chapel of the R.V.L., the scene of their long comradeship.

Perhaps Willan was more proud of his association with the Royal Navy than almost anything in his long life: many are the surgeons of the Royal Navy who are eternally grateful to him for appointments and surgical registrarships in the R.V.L., Newcastle. The medical department of the Admiralty was not unmindful of this loyal help to the Senior Service, and, when opportunity suddenly offered during the last world war, there was not a moment of delay, and Willan, to his unfeigned delight, donned the uniform of a surgeon rear-admiral. He may not have been one of the world's master surgeons; he may not have even been an eloquent and forceful teacher; but he had a genius for friendship, and, as he wrote of Rutherford Morison, he also overcame obstacles by sheer force of character, merit, and good temper; and to so many, as to his old chief, he will always remain "my old and loyal friend," utterly incapable of any mean or ungenerous action.

J. B. MILLER, M.D., LL.D., D.P.H.

The obituary notice of Dr. J. B. Miller was published in last week's *Journal* (p. 232).

We are indebted to Dr. JOHN LAMBIE for the following appreciation: My first contact with "J.B." was when we were students. He was always a studious chap and paid great attention to his work, but, as the fruits of that are well known and recorded, I would like to make some mention of his other interests.

His earlier interest, other than medicine, was centred in the wild flowers of Scotland, consequently botany in his first year was of great interest: he attended the excursions and collected a herbarium which was the envy of many. Later in life he became a great gardener and never was happier than when pottering in his garden and hot-house. Last year a severe storm reduced his hot-house to the ground and he lost many of his cherished plants, but his philosophy helped him through and he continued his interests in his outdoor plants and shrubs, knowing them as friends and full of knowledge of their special characteristics.

When a student he played Rugby and was a member of the medical team when the interfaculty matches took place. He enjoyed the rough and tumble, and his interest in Rugby remained all his life. He was a keen supporter of his old school F.P. team (Glasgow High School) and attended the matches faithfully on Saturday afternoons religiously wear-

ing his "old school tie." Murrayfield also engaged his attention when the internationals were on. He was also very keen on golf. Apart from playing on his own course, he was for many years a member of the Glasgow Medical Golf Club and attended steadily during that time. Curling in the Glasgow rink claimed his attention when it was possible, and he was very keen, not only for the game, but because he also met his friends. He liked company and was a member of several medical dining clubs. Not only did he enjoy his meal, but his ability as an after-dinner speaker was greatly in demand. He replied to many different toasts in his usual pawky and subtle manner, not forgetting to mix grey matter with humour and often introducing a Latin quotation. As a man he was a kindly, erudite family doctor who was not only sympathetic with his patients as regards their health but also was a great help in private problems. As such, his passing, while being a great loss to his patients and the community, will be keenly felt by his large circle of friends.

Dr. J. W. WILSON, who had been in general practice at Stirling since 1925, died in Edinburgh on December 31, 1954, at the age of 59. John Wight Wilson was born on April 4, 1895, and was educated at Glasgow University. As an undergraduate he left his medical studies in 1914 to serve with the Highland Light Infantry in the first world war, and saw active service as a combatant officer in France and Mesopotamia. He returned to Glasgow after the war, and, after graduating M.B., Ch.B. in 1922, held house appointments for the next eighteen months at the Western Infirmary and the Royal Maternity Hospital. He then spent a year as an assistant at Cumnock, Ayrshire, before moving in 1925 to Stirling, where he was successively assistant, partner, and, later, senior partner in a general practice. In 1936-7 he was president of the Stirling Branch of the British Medical Association. In 1926 he married Miss Catherine A. S. Blair, who graduated M.B., Ch.B. with him in 1922.

W. B. G. A. writes: For 30 years Dr. Wilson's work in Stirling was characterized by an integrity and a thoroughness which were based on a very lively Christian faith. In addition to the work of a large practice he made time and found the strength to give assistance to the Boys' Brigade, and, when need arose, to the Home Guard and the Army Cadet Force. In all his work, and to his family, he gave himself to the utmost, never counting the cost. His spirit lives on, and in our memory of him we have a very precious heritage. He leaves a widow, a son in the Royal Navy, and four daughters, all of whom are in work having some connexion with medicine.

Dr. G. A. WILKES, a well-known Birmingham practitioner, died at his home on January 8 at the age of 84. George Arthur Wilkes was born on July 26, 1870, and was educated at Queen's College, Birmingham, and at Leeds, qualifying M.R.C.S., L.R.C.P. in 1892. Two years later he obtained the D.P.H. of the English Royal Colleges. In 1901 his name appeared in the first list of recipients of the M.B., B.Ch. degrees granted by the newly founded Birmingham University, and he was awarded an Ingleby Scholarship and the senior medical prize. In the following year he proceeded to the M.D. He held the appointment of resident surgical dresser at Queen's Hospital, Birmingham, and was in practice at Bradford, Yorkshire, for a short time before returning to Birmingham some three years before the turn of the century. At Trinity Road, Aston, he quickly established himself as an outstandingly good doctor, and later he added to his work by becoming medical officer and public vaccinator for Aston Manor, medical officer to the Post Office and to the Birmingham Fire Brigade, and police surgeon. Becoming increasingly troubled by deafness, he retired from practice about ten years ago. He leaves a widow, a son who is also in general practice, and a daughter.

We are indebted to Dr. H. GUY DAIN for the following appreciation: With the passing of George Arthur Wilkes, Birmingham loses one of her notable and oldest doctors.

A product of the Birmingham Medical School in the days before the University had come into being, he started practice with the Conjoint qualification in 1892. Although he soon attracted a good general practice, he had the energy to take a D.P.H. and, when they became available, to work for and to take the M.B., B.Ch. degrees of Birmingham and, later, the M.D. in 1902. He took a great interest in medical affairs and in the British Medical Association, holding office as chairman of the Birmingham Central Division from 1916 to 1918. In 1923-4 he was president of the Birmingham Branch. As a member of the local medical and panel committee for many years, he became chairman in the early years of National Health Insurance. He showed the same interest in the academic side of medicine and was president of the Midland Medical Society. He was a sound clinician, and his opinions on cases, or on medico-political problems, were always well considered and showed good judgment. These opinions could be forcibly expressed. He once said that the smallest object that a person should be allowed to put in his ear was his elbow. Perhaps it is hardly necessary to say that he could hold his opinions very firmly in debate. Off duty he enjoyed, until late years, his game of golf, and a game of bridge was always an attraction. During the last war, after an operation which was followed by very dangerous conditions, he made a good recovery and came up smiling to enjoy his retirement.

Mr. L. A. KEY died suddenly at his home at Ascot on January 9 at the age of 55. Leonard Arthur Key was born at Norwich on December 15, 1899. He received his early education at the local grammar school and then served as a midshipman in the R.N.V.R. in the first world war. He went to Cambridge in 1918 and completed his medical studies at St. Thomas's Hospital, qualifying with the London conjoint diploma in 1925. Following a year's appointment as house-surgeon at the East Surrey Hospital, Redhill, he entered general practice at East Grinstead. During 1932 indifferent health, undoubtedly caused by the fact that he never spared himself in the interest of his patients, forced him to take up a less strenuous branch of medicine, and following a year with the late Sir Henry Gauvain at the Lord Mayor Treloar Orthopaedic Hospital, Alton, he developed a great interest in bone and joint tuberculosis and entered the L.C.C. health service in 1934. While in this service he became deputy medical superintendent of Queen Mary's Hospital for Children, Carshalton, and in 1947 was appointed medical superintendent of Heatherwood Orthopaedic Hospital, Ascot. During this time he wrote several papers on bone and joint tuberculosis affecting the hip and knee.

The following appreciation has been jointly written by several colleagues of Mr. Key: At Heatherwood Mr. Key's wide knowledge of medical administration, combined with a sound and broadly based judgment, enabled him to guide the development of the hospital from the treatment only of long-term bone and joint tuberculosis to its present function as a regional orthopaedic centre. The original conception was largely his own, and he worked quietly, tactfully, and unswervingly towards that end. He was a member of the regional orthopaedic committee and was able extensively to influence both policy and detail, always modestly but with clear-sighted and lucid argument. Modern advances in prevention and treatment of tuberculosis reduced his chosen field of work, and, moving with the times and in company with his hospital, he gained the F.R.C.S.Ed. in 1949, and extended his clinical activities into the general range of orthopaedic surgery. He was particularly interested in the problems arising from poliomyelitis, and many young people will walk through life more effectively for having passed through his patient hands. His approach to an orthopaedic problem combined the outlook of a research worker with that of a clinician. Careful dissection in the anatomy school, discussion with colleagues, examination of many cases, critical perusal of current literature, all led to a logically reasoned opinion

and an operation planned in detail beforehand and executed with thought and skill. He gave great encouragement to his registrars and had a way of teaching that was most discreet. No young man could work with him without thereby improving his surgery or realizing that he had a friend with his welfare at heart.

Dr. FRANK BODMAN writes: In your obituary of the late Dr. Elizabeth Casson (*Journal*, January 1, p. 48) no mention was made, among her manifold medical interests, of her membership of the Faculty of Homoeopathy. Dr. Casson joined the British Homoeopathy Society in 1927 and applied the principles of homoeopathic medicine in the medical treatment of her psychiatric patients with considerable success. As late as last summer she made a valuable contribution to a discussion at the British Homoeopathic Congress on homoeopathy and geriatrics, based on many years' clinical experience. She had been a fellow of the Faculty for some years.

Medico-Legal

DEATH FOLLOWING OBLIVON AND NEMBUTAL

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On November 26, 1954, Frank Ronald Preston, aged 23, died after taking about 20 "nembutal" tablets and about 9 "oblivon" capsules.

The post-mortem examination was carried out on the same day by Dr. W. K. Taylor, who found gross oedema and venous congestion of the lungs. A striking feature of the abdomen was the presence of intense venous congestion, causing marked distension of the veins. Dr. Taylor gave the cause of death as acute pulmonary oedema and cardiac failure consistent with narcotic poisoning, pulmonary oedema being sometimes caused by the barbiturates.

The deceased's stomach and duodenal contents, small intestine and caecum, liver, kidneys, and spleen, together with a portion of the lung and a sample of the urine, were sent to the Metropolitan Police Laboratory, where they were examined by the director, Mr. L. C. Nickolls, F.R.I.C. He identified the presence of methylpentynol in quantity equivalent to about 9 oblivon capsules, and about 7½ gr. of a barbiturate the identity of which he could not completely confirm because of the small quantity present, but which he thought to be nembutal.

At the inquest held at Godalming on December 13, 1954, in answer to the coroner, Dr. J. M. Robertson, Mr. Nickolls said in evidence that, while the amounts of oblivon and barbiturate present were not in themselves sufficient to cause death, it had been shown that the two were synergic in action and that similar amounts together had proved fatal. Oblivon was an acetylene alcohol which it was not desirable to take together with barbiturate. The result was similar to that of alcohol and barbiturates taken together.

An open verdict was recorded, the coroner finding that there was insufficient evidence to show why or under what circumstances the oblivon and nembutal had been taken.

SURGEON SUES DOCTOR FOR FEES

Judgment by consent for £183 15s. and costs was entered for a gynaecological and obstetric surgeon in the Queen's Bench Division on January 20 when he sued a doctor for fees alleged to be owing in respect of professional services to the doctor's wife. She died on November 30, 1952, aged 53. The surgeon claimed £265 2s. 6d., which he alleged was owing in respect of professional services up to November, 1952. The husband was sued as executor of his wife's estate. The three people had first met in Berlin before coming to Britain.

The defence was that it was a medical custom for doctors not to charge each other for professional services. There

was said to be an agreement between the surgeon and the doctor's wife that the treatment should be free; and the defence claimed that the fees were excessive and that the surgical operation on the defendant's wife was performed without the defendant's authority and unskillfully. The surgeon denied these allegations.

The doctor's wife consulted the surgeon in November, 1950, and paid him £9 17s. 4d. She never paid anything for subsequent treatment, and the plaintiff did not ask for payment because he did not wish to embarrass her financially, preferring to wait until she was better placed. She was separated from her husband. The surgeon said in evidence that on November 18, 1952, the patient telephoned him, and on examining her he discovered a growth. He decided that an operation was necessary. She refused to go into hospital and said she would prefer to go into a nursing-home under his care, despite the extra expense. She refused to have a second opinion. The surgeon said that when he saw the doctor on December 3, 1952, he did not complain about the treatment nor did he say it was wrong to operate. Later the doctor told him he was surprised at the amount of the fees.

Cross-examined, the surgeon agreed that there was a wide practice among medical men not to charge each other for professional services, but it was not a binding practice. During the cross-examination the defendant received advice from his counsel, and after an adjournment the surgeon agreed to accept judgment for £183 15s. and costs against the doctor. The doctor withdrew unreservedly the allegations of negligence and want of skill, and was satisfied that plaintiff did everything that could be done.

The judge said he could well understand that the surgeon had to fight the case and bring these proceedings. He also thought the doctor had acted wisely having heard what the surgeon had to say, in recognizing that there was no foundation for the allegations.

Vital Statistics

Influenza

Influenza deaths in the 160 great towns of England and Wales increased from 102 in the preceding week to 134 in the week ending January 15. All regions showed increases except the southern, south-western, and Wales, the figures for which remained practically the same. 86.6% of the deaths were of people aged 55 and over and 70% of people aged 65 and over. There is little change in the situation. Many of the outbreaks are due to virus-B influenza, though isolated cases of virus-A infection have been reported in the midlands and Wales. On the whole the prevalence of influenza seems to be waning in many areas and spread elsewhere to be slow.

Record Low Infant Mortality

Provisional figures for England and Wales in 1954 show that the infant mortality rate for the year was the lowest ever recorded. There were 17,098 deaths of children under 1 year of age, giving a rate of 25.5 per thousand related live births. This rate compares with 26.8 in 1953, 27.6 in 1952, 29.7 in 1951, and 52.8 in 1938. Infant deaths in the December quarter numbered 4,067, giving a rate of 25.3. This also is a record figure for a fourth quarter, the previous lowest rate for that quarter being 26.2 in 1953. The total deaths numbered 501,878, giving a rate of 11.3 per thousand population, compared with rates of 11.4 in 1953 and 11.3 in 1952.

There were 16,130 stillbirths, giving a rate of 24.0 per thousand total live and stillbirths. This was higher than the rates for 1953 and 1952 of 22.5 and 22.7 respectively.—Registrar-General's *Weekly Return*, No. 2 (H.M.S.O.).

Week Ending January 15

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 465, whooping-cough 1,769, diphtheria 14, measles 7,800, acute pneumonia 1,121, acute poliomyelitis 22, dysentery 402, paratyphoid fever 2, and typhoid fever 3.

Infectious Diseases

The chief feature of the returns of the notifications of infectious diseases in England and Wales during the week ending January 8 was the large increase of 1,065 for measles, from 8,320 to 9,385. The only other variations of note were a fall of 244 for scarlet fever, from 707 to 463, and a rise of 69 for whooping-cough, from 1,722 to 1,791.

The largest rises in the incidence of measles were 331 in Lancashire, from 2,510 to 2,841, 269 in Yorkshire West Riding, from 703 to 972, 127 in Nottinghamshire, from 215 to 342, and 117 in Cheshire, from 396 to 513, and the largest fall was 54 in Warwickshire, from 327 to 273. No large fluctuations were recorded in the local trends of whooping-cough. The largest decrease in the number of notifications of scarlet fever was 36 in Yorkshire West Riding, from 75 to 39, 13 cases of diphtheria were notified, being the same number as in the preceding week.

25 cases of acute poliomyelitis were notified: these were 1 more for paralytic and 1 more for non-paralytic cases than in the preceding week. The largest returns were Lancashire 6 (Liverpool C.B. 4, Manchester C.B. 2) and London 4.

346 cases of dysentery were notified, being an increase of 6 on the total of the preceding week. The largest centres of infection were Norfolk 60 (Norwich C.B. 35), Lancashire 48 (Oldham C.B. 14), Yorkshire West Riding 43 (Sheffield C.B. 18, Leeds C.B. 11), Cheshire 32 (Marple U.D. 10), Lincolnshire 26 (Scunthorpe M.B. 24), and London 20.

102 deaths were attributed to influenza in the great towns, 20 more than in the preceding week. The largest return was 7 from Exeter C.B.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1945-53 are shown thus ————, the figures for 1954 thus ————. Except for the curves showing notifications in 1954-5, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases in 1954

The incidence of infectious diseases in England and Wales during 1954 was low, and for most of the diseases the number of notifications was the lowest in recent years. The chief exception was dysentery. The number of notifications of this disease was a record, being 15% above the previous high level of 1951. The number of notifications of typhoid and paratyphoid fever, although low, was in excess of the number in 1950 and 1953. The number of notifications of diphtheria was the lowest ever recorded, and was only 1/84 of the number in 1938. The notifications for the past five years were as follows:

England and Wales	1950	1951	1952	1953	1954
Scarlet fever	66,852	49,431	69,091	61,578	43,388
Whooping-cough	157,714	169,394	116,311	157,772	105,628
Measles	366,116	615,332	400,838	534,020	147,076
Acute poliomyelitis	8,699	3,093	4,504	5,251	2,388
Diphtheria	2,858	1,969	1,473	1,022	778
Meningococcal infections	1,745	1,956	1,687	1,783	1,569
Dysentery	18,135	29,488	15,665	19,540	33,976
Acute pneumonia	30,714	43,181	31,403	37,058	26,750
Enteric fevers	654	1,438	1,190	569	751
Great towns: Influenza deaths			996	3,381	947

Smallpox in France

Up to January 14, 44 cases of smallpox had been reported in the Vannes area, including 5 deaths (6 according to press reports).

INFECTIOUS DISEASES AND VITAL STATISTICS
Summary for British Isles for week ending January 8 (No. 1) and corresponding week 1954.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.
A blank space denotes disease not notifiable or no return available.
The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1955					1954

† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Medical News

Princess Louise Children's Hospital.—Medical staff of the Princess Louise (Kensington) Hospital for Children are expected to oppose a recommendation to the board of governors of St. Mary's Hospital that the Princess Louise Hospital should ultimately be converted entirely to adult use. This recommendation is made by a committee appointed by the board of governors to review the services provided by the St. Mary's Teaching Hospital Group. The committee argues that the proportion of children's to adult beds in the group is too high, especially in view of the long waiting-list for adult admissions. The adult waiting-list stands at over 1,600, while that for children was 235 at the beginning of this month, and of these 159 were E.N.T. cases. This disproportion, according to the committee, reflects the notable downward trend throughout the whole country in the demand for hospital accommodation for sick children. There is also the successful start of the experiment in the home care of seriously ill children to be taken into account. The committee suggests as a beginning the temporary conversion of two wards at Princess Louise Hospital to make room for maternity cases from St. Mary's while alterations are being made there to accommodate the new obstetric unit. Earlier the committee recommended the conversion of the Paddington Green Children's Hospital, but now think it simpler to convert the Princess Louise Hospital.

Rockefeller and Dorothy Temple Cross Fellowships.—The Medical Research Council invites applications for the following travelling research fellowships for the academic year 1955-6. Full details and application forms, which must be returned not later than March 15, are obtainable from the Council's headquarters office at 38, Old Queen Street, London, S.W.1.

Rockefeller Travelling Fellowships in Medicine.—These fellowships are intended for graduates resident in Britain with some previous research training in either clinical medicine or one of the basic medical sciences who are likely to benefit from a period of work at a centre in the United States or elsewhere abroad before taking up teaching or research positions in the United Kingdom. Maintenance allowances for fellowships in the United States are normally at the rate of \$2,700 per annum for a single fellow and \$3,900 per annum for a married fellow. Provision is also made for travelling and other approved expenses.

Dorothy Temple Cross Research Fellowships in Tuberculosis.—These fellowships are intended to provide special opportunities for study or research to suitably qualified British subjects "intending to devote themselves to the advancement by teaching or research of curative or preventive treatment of tuberculosis in all or any of its forms." Maintenance allowances are at the rate of £650 per annum for a single fellow and £900 per annum for a married fellow, subject to adjustment for fellows working at centres outside the sterling area. Provision is also made for travelling and other approved expenses.

Lady Tata Memorial Trust.—The trustees invite applications from suitably qualified investigators of any nationality for grants, scholarships, or fellowships for research on leukaemia and allied conditions in the academic year 1955-6. Candidates with programmes of research on any aspect of malignant disease which may throw incidental light on problems of leukaemia will be eligible for consideration. Full details and forms of application (to be returned before March 31) may be obtained from the secretary of the (European) Scientific Advisory Committee, Lady Tata Memorial Trust, 38, Old Queen Street, London, S.W.1.

Grants are available for research expenses or to provide scientific or technical assistants for senior workers. Scholarships (£600 per annum for whole-time research, with proportional adjustment for part-time work) are awarded for the personal remuneration of workers carrying out approved research under suitable direction. In addition one or more Lady Tata Memorial Research Fellowships (£1,000 per annum) may be awarded to workers with considerable research experience.

N.A.P.T. Scholarships.—The National Association for the Prevention of Tuberculosis offers a Hunter scholarship of £350 to enable a graduate of a British medical school who qualified between the years 1936 and 1951 inclusive to study tuberculosis abroad. The association also offers two Hunter scholarships of £150 each for medical students who have developed tuberculosis during their studies. Full details from N.A.P.T., Tavistock House North, Tavistock Square, London, W.C.1. The last date for applications is February 28.

Royal College of Surgeons.—At the council meeting on January 13 Dr. G. J. CUNNINGHAM, senior lecturer in morbid anatomy and histology at St. Bartholomew's Hospital, was appointed Sir William Collins Professor of Human and Comparative Pathology in the College. Dr. JOHN VANE was appointed senior lecturer in the department of pharmacology.

College of General Practitioners.—The Scottish Council of the College of General Practitioners was constituted at a meeting held in Edinburgh on January 13. The members of the Council are: Drs. D. PEEBLES BROWN (Kilmalcolm), MARY ESSLEMONT (Aberdeen), C. M. FLEMING (Edinburgh), W. W. FULTON (Glasgow), W. S. GARDNER (Glasgow), I. D. GRANT (Glasgow), J. M. HENDERSON (Pitlochry), G. W. IRELAND (Pathhead), LOWELL LAMONT (Edinburgh), K. A. MACKAY (Laggan), T. S. McDONALD (Glasgow), J. G. MUNRO (Beaulieu), DAVID MYLES (Forfar), R. A. B. RORIE (Dundee), C. S. SANDEMAN (Duness), RICHARD SCOTT (Edinburgh), J. A. SHEARER (Bucksburn), J. M. STALKER (Dundee), GEORGE SWAPP (Aberdeen). The office bearers appointed were: Dr. J. M. HENDERSON (Chairman), Dr. LOWELL LAMONT (Vice-chairman), Dr. RICHARD SCOTT (Honorary Secretary and Treasurer). The Scottish Office of the College is situated at Livingstone House, 39, Cowgate, Edinburgh, 1.

Refresher Courses for School Medical Officers.—In a memorandum to local education authorities (No. 489, dated January 19), the Minister of Education draws attention to the Postgraduate Medical Federation's refresher courses for general practitioners. "The Minister," says the memorandum, "is prepared to consider for grant expenditure incurred by local education authorities on enabling school medical officers to attend the refresher courses, provided that it is allowed by the district auditor at audit." Details of the courses may be obtained from the Postgraduate Medical Federation, 3, Gordon Square, London, W.C.1.

British Association of Plastic Surgeons.—At the annual general meeting in December the following officers and council were elected for 1955: President, Professor T. POMFRET KILNER (Oxford) (previously president in 1948); hon. treasurer, Mr. R. P. OSBORNE (Liverpool); hon. secretary, Mr. J. P. REIDY (London); council, Mr. J. N. BARRON (Salisbury), Mr. W. HYNES (Sheffield), Mr. P. H. JAYES (London), Mr. D. N. MATTHEWS (London) (immediate past-president), Mr. RAINSFORD MOWLEM (London), Mr. MORTIMER SHAW (Leeds), Mr. J. S. TOUGH (Glasgow), and Mr. A. B. WALLACE (editor) (Edinburgh).

Research on Cerebral Palsy.—The Nuffield Foundation has made grants totalling £17,500 to support a 5-year programme of research at Frenchay Hospital, Bristol, into the neuropathology of cerebral palsy and mental defect. The work is sponsored by the South-Western Regional Hospital Board and the Burden Mental Research Committee, as part of their programme of investigations on mental deficiency, and will be directed by Dr. R. M. NORMAN, lecturer in neuropathology at Bristol University, assisted by Dr. H. URICH. It is intended to examine the brains of those dying from cerebral palsy whose early history and clinical features have been adequately recorded, and a new laboratory is being equipped for this purpose. It is hoped that, when the new laboratory is in operation, material will be sent for detailed neuropathological examination not only from local hospitals but also from hospitals in other regions.

Hull Phonodiary.—Last year (October 2, p. 807) we gave the text of a gramophone record on cancer which was made available to the public over the Hull telephone system. A second record has now been prepared dealing mainly with the method of treatment and the aftercare of cancer patients. The first record resulted in over 5,000 telephone inquiries, at the rate of about 400 a week. This experiment in cancer education is sponsored by the Marie Curie Memorial Foundation.

Family Doctor.—The February issue tells readers how to avoid 'flu and what to do if they do get it. A new departure is headed "*Family Doctor* brings you a chance to listen in." This is selected extracts from a recent article in the *Practitioner*. The idea behind the title is that in the medical journals doctors write for each other, but sometimes they say things "that parents would like to overhear." The subject of the article is "Health and Normality in Childhood." Other articles include the career profile of a remedial gymnast, "How to tell if it is heart disease" by Professor Walter C. Alvarez, and advice on dysmenorrhoea.

COMING EVENTS

Milroy Lectures.—Dr. J. A. SMILEY will deliver the Milroy Lectures at the Royal College of Physicians, Pall Mall East, on February 8 and 10, at 5 p.m. His subject is "Personal Factors in Accident Proneness."

Fédération Internationale Pharmaceutique.—The sixteenth assembly will be held at the Senate House of London University from September 19 to 23. There will be symposia on "The Pharmacy of Blood, Blood products, and Blood Substitutes," "Recent Advances in Pharmaceutical Analysis," "Ion Exchange," and "Tests for the Sterility of Pharmaceutical Preparations." Fuller details from the secretary of the organizing committee, 17, Bloomsbury Square, London, W.C.1.

NEW ISSUES

British Journal of Ophthalmology.—The new issue (Vol. 39 No. 1) is now available. The contents include:

- OCULAR CHANGES IN ACUTE SYSTEMIC LUPUS ERYTHEMATOSUS. F. Clifton and C. H. Greer.
- SIGNIFICANCE OF CONGENITAL CYCLO-VERTICAL MOTOR DEFECTS OF THE EYES. A. Ureus-Zavalala.
- CORNEAL ULCERATION. SENSITIVITY OF BACTERIA TO ANTIBIOTICS. Tulsi Das, M. L. Sur, and M. R. Chaddah.
- DEGENERATIONS OF THE DOG RETINA. VII. CENTRAL NON-PROGRESSIVE DEGENERATION DUE TO AN ANOMALY OF THE GANGLION CELLS AND THEIR AXONS. H. B. Parry.
- EFFECTS OF COCARBOXYLASE ON THE DEVELOPMENT OF GALACTOSE CATARACT IN RATS. R. Van Heyningen, A. Pirie, and J. Blackwell.
- MULTIPLE MYELOMATOSIS WITH PROPTOSIS. A. Handoussa.
- CONGENITAL ECTODERMAL DYSPLASIA. I. D. R. Gregory.
- UNUSUAL CASE OF MYASTHENIA GRAVIS. J. Lloyd.
- INTRACULAR MAGNETIC AIR-GUN SHOT. V. P. S. Tomar.
- SIMPLIFIED NEAR POINT RULE. J. Foster.
- MEASURING STRABISMUS HOOPS. A. B. Moffat.

Issued monthly; annual subscription £4 4s.; single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Journal of Industrial Medicine.—The new issue (Vol. 12, No. 1) will be available in a week's time. The contents include:

- RESEARCH IN INDUSTRIAL HEALTH IN THE CHEMICAL INDUSTRY. M. W. Goldblatt.
- MANGANESE POISONING IN MOROCCAN MINERS. J. Rodier.
- DERMATOSES IN JUTE WORKERS. John Kinnear, John Rogers, and Alexander Mair.
- TALCOSSIS OF UNUSUALLY RAPID DEVELOPMENT. G. P. Alivisatos, A. E. Pontikakis, and B. Terzis.
- RESPIRATORY TRACT INJURY CAUSED BY CERTAIN ISOCYANATES USED IN PRODUCTION OF LACQUERS. Ake Swenson, Carl-Eric Holmqvist, and Karl-David Lundgren.
- DIMETHYL SULPHATE POISONING. T. R. Littler and R. B. McConnell.
- VANADIUM POISONING FROM GAS TURBINES. R. C. Browne.
- THE TOXICITY OF OZONE IN THE PRESENCE OF OXIDES OF NITROGEN. W. M. Diggle and J. C. Gage.
- THE CONSTRUCTION OF CRITICAL ORIFICES WORKING WITH PRESSURE DROPS OF LESS THAN HALF ATMOSPHERIC PRESSURE AND THEIR USE IN CONTROLLING AIRFLOW. H. A. Druehl.
- THE HEALTH HAZARDS OF THE SENIOR EXECUTIVE. A. R. Cooper.
- THE HEALTH OF THE INDUSTRIAL WORKER IN IRAQ. A. Michael Critchley.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Tuesday, February 1

- BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. E. F. Gale: Actions of Antibiotics on Bacteria.
- INSTITUTE OF DERMATOLOGY.—Fifth of a series of semi-permanent exhibitions from February 1 to 25, by Dr. R. T. Brain, on Vascular Naevi (Haemangiomas).
- ROYAL MEDICAL SOCIETY, Edinburgh.—8 p.m., clinical meeting.
- ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Mr. A. W. Bourne: "Functional" Uterine Haemorrhage.

Wednesday, February 2

- EDINBURGH CLINICAL CLUB.—4 p.m., visit to Department of Radiotherapy, Edinburgh Royal Infirmary.
- INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. O. Oliver: Bacteriology of Skin Diseases.
- INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—6 p.m., Professor M. Arslan (Padua): Effects of Ultrasonic Waves on the Ear.
- MIDLAND MEDICAL SOCIETY.—At Birmingham Medical Institute, 154, Great Charles Street, 8.15 p.m., Mr. A. Ruscoe Clarke: Blood Loss and Blood Transfusion in Civilian Trauma.
- OXFORD UNIVERSITY MEDICAL SOCIETY.—At Radcliffe Infirmary, 8.15 p.m., Professor H. A. Krebs, F.R.S.: Role of Biochemical Concepts in Medicine.
- ST. MARYLEBONE HOSPITAL FOR PSYCHIATRY AND CHILD GUIDANCE.—5.30 p.m., Dr. Doris M. Odum: Relationship of Psychiatry to General Medicine.
- YORKSHIRE SOCIETY OF ANAESTHETISTS.—At General Infirmary at Leeds, 8.30 p.m., Dr. G. S. W. Organe: Abuse of Tracheal Intubation.

Thursday, February 3

- BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor P. B. Medawar: Tissue Transplantation Immunity.
- FACULTY OF HOMOEOPATHY.—At Royal London Homoeopathic Hospital, 5 p.m., Dr. W. Lees Templeton and Dr. C. O. Kennedy: Provinces of A.C.T.H. and Cortisone, Including Investigation of Bowel Flora; Dr. L. R. Twinn: Observations on Isoscor Treatment of Cancer.
- INSTITUTE OF PSYCHIATRY.—5 p.m., Professor H. J. Eysenck: Psychology and the Foundations of Psychiatry.
- LIVERPOOL MEDICAL INSTITUTION.—8 p.m., Dr. V. K. Summers: Syndrome of Hypothyroidism; with a note on radioactive iodine tracer studies by Dr. W. Kulke.
- NUFFIELD ORTHOPAEDIC CENTRE.—At Wingfield-Morris Orthopaedic Hospital, 8.30 p.m., Dr. E. G. L. Bywaters: Natural History of Rheumatoid Arthritis.
- ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Professor C. G. Rob: Preservation and Transplantation of Human Blood Vessels (with lantern slides).
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.30 p.m., Otolaryngology Lecture by Sir Gordon Gordon-Taylor: Swellings of the Neck and their Management.
- ST. ANDREWS UNIVERSITY.—At Physiology Department, Medical School, Small's Wynd, Dundee, 5 p.m., Dr. T. Anderson: Unwanted Effects of Chemotherapy.
- ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Sir Paul Mallinson: psychiatry demonstration.

Friday, February 4

- INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. P. J. Harc.
- INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., clinical demonstration by Mr. V. C. Thompson: Tumours of the Lung—II.
- LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.—6.30 p.m., Dr. J. A. Scott: Health.
- POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Professor R. E. Tunbridge: Clinical and Histochemical Study of some of the Disorders of Connective Tissue.
- ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Mr. J. Sloan M. Robertson: Paralysis as a Surgical Problem.
- ROYAL MEDICAL SOCIETY, Edinburgh.—8 p.m., Sir James Learmonth: Some Aspects of Surgery Elsewhere.
- WHIPPS CROSS HOSPITAL MEDICAL SOCIETY.—8.30 p.m., Mr. B. Fairburn: Surgical Treatment of Cerebral Vascular Catastrophes.

Saturday, February 5

- INSTITUTE OF ORTHOPAEDICS.—February 5 and 6, week-end course for Registrars.
- MIDLAND TUBERCULOSIS SOCIETY.—At Birmingham Chest Clinic, 3 p.m., Mr. D. M. E. Thomas: Surgical Treatment of Primary Tuberculosis.

APPOINTMENTS

- LONG, M. C. W., M.B., B.S., Deputy Treasury Medical Adviser.
- MUNKO, T. A. H., M.D., F.R.C.P.Ed., D.Psych., Physician Superintendent, Royal Edinburgh Hospital for Mental and Nervous Disorders, as from November, 1954.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

- Lynn.—On January 15, 1955, to Constance, wife of Dr. C. R. Lynn, of 25, Elgin Avenue, Harold Park, Essex, a son—Jonathan.
- Weber.—On December 29, 1954, at St. Bartholomew's Hospital, London, E.C., to Rosalie, wife of Dr. G. N. Weber, a son—Jonathan Norden.

DEATHS

- Morton.—On January 3, 1955, in London, Harold James Storrs Morton, M.D., of Brinkley, Newmarket, Suffolk, formerly of Bridlington, Yorks, and St. John's Wood, London, N.W., aged 68.
- Rickard.—On October 4, 1954, at "The Firs," Simons Town, South Africa, Cecil Rodney Rickard, M.R.C.S., L.R.C.P., Surgeon Captain, R.N., retired.
- Smith.—On January 4, 1955, at St. Andrews, John Alfred Macdonald Smith, M.B., F.R.C.S.Ed., late of Kalimpong, Bengal, India.
- Stevenson.—On January 3, 1955, Charles Stanley Stevenson, M.B., Ch.B., of Felix House, Middleton St. George, Co. Durham.
- Taylor.—On January 6, 1955, at Downs Cottage, 76, Northwood Road, Tankerton, Kent, Frederic Cecil March Taylor, M.R.C.S., L.R.C.P., D.P.M., aged 55.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Vaccination in Pregnancy

Q.—Is pregnancy a contraindication to the revaccination of a woman (successfully vaccinated as an infant) who now wishes to go abroad? Is primary vaccination contra-indicated?

A.—Vaccination is often stated to be harmless to both the pregnant woman and her foetus. However, MacArthur,¹ who analysed the results of a questionnaire from the West of Scotland, concluded that vaccination during the first trimester of pregnancy increased the risk of abortion; damage to the foetus did not occur after vaccination in the later months. Notwithstanding these findings, severe vaccinia, like any other acute infection, might endanger the foetus at any stage of development. It would seem wise, therefore, not to vaccinate during pregnancy unless there is a likelihood of exposure to smallpox, or good reason to expect the development of a vaccinia or an immediate reaction rather than a typical primary "take." The decision in the present case depends on circumstances; the risks of revaccination after the third month of pregnancy are certainly not great, and postponement of vaccination till after the patient's confinement may not be feasible. Primary vaccination in pregnancy is more likely than revaccination to endanger the life of the foetus. Nevertheless, in the face of smallpox, all vaccination risks must be accepted.

Treatment of Hypogonadism

Q.—A man of 30 with slight hypogonadism has been treated for three months with methyl testosterone, 100 mg. a day, with some success. Is there any danger in this treatment? Is further improvement likely if treatment is continued? To what extent can the improvement be expected to be maintained without further treatment?

A.—In my experience eunuchs can be maintained on a dose of only 25 mg. of methyl testosterone daily, so that a dose of 100 mg. daily for a person with slight hypogonadism seems somewhat high. A daily dose of 100 mg. is unlikely to inhibit pituitary function, but it may cause slight oedema as a result of salt and water retention; this disappears on cessation of therapy, so there is no real danger in this treatment. Improvement in hypogonadism treated with testosterone occurs over a period of six to nine months or more depending on the gravity of the condition. As therapy is merely a replacement of a deficiency, relapse can be expected if treatment is stopped.

Technique of Artificial Insemination

Q.—Could you please give me, briefly, the technique for artificial insemination?

A.—Artificial, or what is better termed therapeutic, insemination can be carried out in various ways. All of them are done at what is judged to be the ovular phase of the menstrual cycle. Intracervical insemination is the commonest technique. To perform this, the cervix is exposed with a speculum and the seminal fluid injected into the cervical canal by means of a suitable syringe and cannula. For intrauterine insemination, the cannula is passed through the internal os and about 0.25 ml. of semen injected into the uterine cavity. After the injection the woman should remain with her legs together and her pelvis slightly elevated for 10 to 30 minutes. A further alternative is to place a

cervical cap, into which the seminal fluid has been introduced, over the cervix, where it remains for 12 hours, the woman having been instructed to remove it at the end of this time.

Where, by reason of impotence or through some mechanical cause, it is impossible for the husband to ejaculate deeply within the vagina, the technique of "self-insemination" may be recommended. For this, the husband produces semen by masturbation into a clean dry glass jar at the ovular phase of the cycle. The seminal specimen is taken up into a special self-insemination syringe (designed by Dr. Joan Malleon and supplied by Messrs. Allen and Hanburys) which the wife then inserts into the vagina to its full extent. By pressing home the plunger the semen is deposited in the place where effective coitus would have left it. If necessary, a non-greasy and non-spermicidal lubricant should be applied to the outside of the syringe before it is inserted. After use, the syringe should be washed in warm soapy water and dried. Sterilization is unnecessary.

Transfusion Problems in a Small Hospital

Q.—Working in a small maternity hospital, I am required occasionally to give blood transfusions. Only group O blood (Rh positive and negative) is stocked here. Group B and group AB blood are almost impossible to obtain. Group A blood is kept at a neighbouring hospital; if this is used it often results in wastage of group O stock. The cross-matching technique is extremely primitive; patient's serum, donor cells from the bottle, and normal saline are mixed and left for 15 minutes on a slide. There is no incubator available. Will you therefore please answer the following questions? Is the risk of incompatible transfusion materially increased by the giving of group O blood to patients of other groups? Is it justifiable to use group O blood to avoid wastage in a small blood bank? Does previous childbirth or transfusion affect the issue? (It is realized that the correct Rhesus type must be used.) Is a cold saline cross-match considered adequate for non-urgent transfusion?

A.—The administration of group O blood to patients of other groups does not, as a rule, give rise to haemolytic reactions. In rare cases—for example, when half or more of the recipient's blood is replaced by group O blood—a reaction may occur; and if the donor has α or β haemolysins in his serum (as occurs after injection of concentrated antibody globulins) these lysins may destroy the recipient's cells.

The exclusive use of group O blood was probably arranged as the least dangerous procedure for a small unit with an "occasional transfusionist" in charge. It has been shown that haemolytic reactions usually result from blunders in ABO grouping by inexperienced or excited workers, or by confusion between two patients of similar name but different ABO group. If this source of error is eliminated, one is left with Rhesus antibodies and the host of irregular antibodies reacting with the antigens M, N, S, P, K, k, Fy^a and Fy^b and others, all of which antibodies are rare; apart from the common Rhesus antibody anti-D, the frequency of irregular antibodies is of the order of 1 in 3,000 recipients; the risk of such an antibody causing a haemolytic reaction is of this order, comparable with the incidence of haemolytic transfusion reactions without demonstrable cause.

Previous childbirth or transfusion makes such antibodies a little more frequent. The frequency of anti-D is, of course, greatly increased by pregnancy or Rh-incompatible transfusion, but the other antigens are weak and rarely initiate the production of antibodies; if one is concerned only with urgent transfusions it is reasonable to subject the patient to this approximately 1 in 3,000 risk of a haemolytic reaction. Even if a reaction does occur, the risk of death is only about 1 in 15, so the overall risk is about 1 in 45,000—a risk far less than that incurred by leaving an exsanguinated patient for two or three hours. Even so, many transfusions can be avoided by the free use of dextran.

There is some argument about the standard of cross-matching which should be adopted for non-urgent transfusions. The expert can use almost any method he likes with safety, but the occasional transfusionist should adopt one of the standard tube methods, since he is less likely to make mistakes with them than with any other. I would suggest a cross-match in saline at about 20° C. (room temperature) and by the Sheffield technique in albumin, at 37° C. A 37° C. incubator and a small centrifuge are essential, and no adequate blood grouping can be done without them. The recommended procedure is:

Place two tubes in each of two racks, labelling one of each pair "test," the other "control." Into each "test" place 3 drops of recipient's serum, into each "control" 3 drops of saline.

Into each tube place 3 drops of an approximately 5% suspension in saline of donor cells which have been removed from the bottle or pilot bottle with a sterile Pasteur pipette and washed once in saline. Leave one rack at room temperature; place the other in the incubator for 1½ hours. After 1½ hours remove from the incubator without shaking, and remove as much as possible of the supernatant serum and saline; replace it with 6 drops of 20% bovine albumin solution without disturbing the sedimented cells. Return to the incubator for half an hour. At the end of a further half-hour—that is, two hours from the beginning—remove samples from the tubes and examine microscopically.

If the tubes marked "test" show even a few clumps of cells, while those marked "control" show more, then the blood should be regarded as incompatible. A number of samples known to be incompatible should be tried at leisure, using smaller proportions of serum, so that the appearance of incompatibility becomes familiar.

But would it not be possible to send all non-urgent transfusions to a large local hospital or to the regional depot for cross-matching? Were I the writer of this question, I should be extremely worried by the lack of facilities, and one of my first actions would be to ask the regional transfusion director to call and advise me on the best use of the facilities which were available. It is definitely not justifiable for an "occasional transfusionist" to use a saline tile cross-match method for "non-urgent" transfusions.

Atropine and Neostigmine after Relaxants

Q.—It is customary when counteracting relaxants at the end of an operation to give intravenous atropine some minutes before intravenous neostigmine. Is there any experimental evidence to suggest that the speed of action of these two drugs is in fact different, so that they may not be given together?

A.—The practice of administering atropine some 10 minutes before neostigmine, when reversing the effects of a curare-like drug, is an attempt to avoid the coincidence of any initial bradycardia due to atropine and the bradycardia due to neostigmine. It is certain that a brief bradycardia generally precedes tachycardia when atropine is administered hypodermically. But there is some doubt whether this happens when the drug is injected intravenously. Indeed, one author¹ is emphatic that it does not. There is therefore some experimental evidence to suggest that the danger of giving atropine and neostigmine together is not a great one.

Any difference in the speed of action between atropine and neostigmine is probably not an important consideration in this connexion, since both take about five minutes to reach their maximum effect when given intravenously.^{1,2}

NOTES AND COMMENTS

Fetishism.—Dr. DORIS ODLUM (London, W.9) writes: I have read with interest the answer to the question on fetishism ("Any Questions?" January 15, p. 178). In the course of the answer, however, it is stated that this appears not to occur in women, but from my own clinical knowledge I can state that in fact it does do so. One of my patients—a woman in the forties of the highest character and a teacher of English—was deeply disturbed by feelings of guilt because she had a definite orgasm whenever she

saw a pair of eye-glasses on a table or in any place where light was reflected on them. She found it a great temptation to put glasses in such a position and from time to time did in fact do so, but her most satisfactory orgasm came when the situation arose by chance. In another case a woman had strong sexual sensations whenever she touched certain types of fur, notably sealskin, moleskin, or squirrel, or when she handled certain types of velvet. In another case orgasm always resulted from the sight of a riding whip or cane, associated with masochistic fantasies. None of these cases was suffering from any kind of emotional disturbance and they were all making a good adjustment to life. I have also known of other cases where the women were happily married and were all well adjusted both to their husbands and children and to life in general. The condition is not necessarily due to any morbid tendency produced by lack of emotional satisfaction, but rather represents an alternative or supplementary form of sexual gratification. I have also had cases where some girl children as well as boys had obvious orgasms when they were sucking a blanket before going to sleep and who insisted on being allowed to suck the blanket before they would settle down at night, and a number of children of both sexes show obvious evidence of rudimentary orgasm when they smack or hug a doll or teddy bear. I have not heard of a case in which a woman has gone so far as to practise fetishism in public, and in the cases that I know of they are extremely loath to speak of it either because they feel guilty about it or because they realize that it would give rise to moral and social condemnation even though they themselves did not feel any guilt. This may be the reason why its existence has not been generally recognized.

Drugs and Fertility.—Mr. HOWARD G. HANLEY (London, W.1) writes: The answer to the question on this subject ("Any Questions?" January 8, p. 118) states, "... there seems good evidence that the sulphonamides in therapeutic doses may suppress temporarily the development of spermatozoa within the testis and so lead to impaired fertility." I have been unable to find the original reference in support of this belief, but have accumulated some evidence to show that it is untrue. I have carefully followed up 21 cases of pyospermia treated with sulphathiazole, "sulphatriad," or "gantrisin" in large and sometimes prolonged dosages, and, although one can expect the sperm motility to improve when the pus cells are cleared, in no case has the count been reduced or impaired in any way. The two cases which have been referred to me as showing reduced spermatogenesis following sulphonamide therapy both gave a clear history of a relatively severe fever (influenza with quinsy; lymphangitis) which necessitated the giving of the sulphonamides, and I suspect that it was the hyperpyrexia or the debility, not the sulphonamides, which were responsible for the temporarily impaired fertility. I also suspect that smoking has been blamed in the same unscientific manner, and whether spermatogenesis can be depressed by nicotine *per se* rather than by the various pathological disturbances attributed to excessive smoking is a debatable point. The opening sentence of the answer to the question contains the crux of the matter. "There have been few, if any (my italics) systematic studies of the effect of drugs on fertility, and consequently knowledge on this subject is scanty."

OUR EXPERT writes: Mr. Hanley's comments may well be quite justified. The first sentence of my answer to which he draws attention was indeed intended to contain the crux of the matter.

Corns Between the Toes.—Dr. C. GUY MILLMAN (Morpeth, Northumberland) writes: May a psychiatrist get down to earth and suggest that animal wool is preferable to the gauze advised in the reply to the question about corns between the toes ("Any Questions?" January 1, p. 56)?

Correction.—In the *Journal* of January 8, p. 111, it was recorded in error that the University of Oxford had granted leave of absence to Professor R. R. Macintosh for three months from January 1, the decree having been withdrawn before Congregation on November 30, 1954.

MEDICAL SCIENCE AND PROBLEMS OF FLYING*

BY

Sir HAROLD E. WHITTINGHAM, K.C.B., K.B.E., LL.D., F.R.C.P., F.R.C.S.Ed.

Director of Medical Services, British Overseas Airways Corporation

In the development of flying, medical science has played a very important though naturally an unobtrusive part in accordance with the traditions of the profession. It has helped to solve problems in the selection and training of aircrew and of air traffic control personnel, the design of such flying equipment as oxygen systems, goggles and glasses to counteract glare, intercommunication sets to obtain good intelligibility, safety harness and other survival devices, including ejection seats and parachutes. Medical science has also contributed to the interior design of aircraft to promote and conserve efficiency of human performance, in particular pressurization, the lay-out of flight decks and gun-turrets, the shape and position of controls, the presentation of instruments to give the best grouping and siting of the most important of them, and to provide legible dials, together with suitable lighting to facilitate dark adaptation as well as map reading by night. In addition, it has aided the development of equipment to prevent blacking-out in aerobatics, of runway lighting for ease of landing and take-off, and of many other matters such as the design of aircraft seats to promote comfort and lessen fatigue, anti-air sickness remedies, and techniques for disinfecting and disinsecting aircraft.

It is impossible in the space at my disposal to deal with this vast subject, so I shall give a brief review of the part played by applied physiology to war in the air, mainly as it concerned the Royal Air Force. During the first world war the work of Flack,^{41,42} Head,⁵² Birley,¹³ and Bazett¹¹ gave us certain selection tests, which ensured that those who passed were alert in body and mind, had accurate vision, good muscle tone, quick reaction time, and a proper sense of balance. These tests did not predict the individual's aptitude to learn to fly or his suitability for high-altitude flying or aerobatics, but they aided in the assessment of general physical fitness to withstand the stress of flying.

Applied physiology in relation to efficiency in flying had only really begun when the first world war finished, and it remained dormant in this country until 1935. During the ensuing four years, tests were introduced to assess suitability for particular aircrew duties, the main ones, which were developed at the R.A.F. Central Medical Establishment, being for power of co-ordination,^{11,2} cardiovascular stability,³⁸ tolerance of rarefied atmospheres,⁷⁴ night visual capacity,^{57,66} and hearing efficiency when operating in aircraft^{29,33,35,74}; this hear-

*A special university lecture in military studies given at the University of London on May 25, 1954.

ing efficiency test was replaced later during the war by one simulating speech sounds as actually transmitted through an electrical communication system with a background noise as encountered in Service aircraft.^{36,37} The problems of glare,³⁴ ocular muscle balance,⁵⁵ and the design of flying goggles³⁶ and helmet^{30,31,32,34} were also investigated.

Early in 1939 the Secretary of State for Air, on the instigation of Air Marshal Sir Victor Richardson, then Director-General of Medical Services, formed the Flying Personnel Research Committee, under the chairmanship of Sir Edward Mellanby. As a result, research was intensified and planned to cover all current medical problems connected with Service flying. Under the aegis of this committee a certain amount of fundamental physiological research was instituted, but, subsequent to the outbreak of war eight months later, many of the researches had to be of an *ad hoc* nature. It is convenient to consider these researches in relation to the main phases of the war—namely, the phony period, the Battle of Britain, the night raids on London and the industrial cities, the retaliation by the R.A.F., the great air offensive in the West, and the air war in the Orient or the setting of the Rising Sun.

The Phony War

In the phony period from October, 1939, to Spring, 1940, the chief physiological problem which demanded attention was an adequate oxygen supply for those engaged in high-altitude reconnaissance when the main shooting was photographic. Though there was little fighting during the first eight months of the war, the Air Force was busy developing the system of photographic reconnaissance which later proved such a great factor in its success. In this work it was important to attain altitudes ever higher than the enemy, in order to escape detection or interference. This necessitated the development of an adequate oxygen system. At the outbreak of war the continuous-flow system of oxygen supply in use allowed two-thirds of the gas to go to waste, and the mask did not fit comfortably with the flying helmet, goggle, and microphone assembly. Work carried out in the laboratory by B. H. C. Matthews and staff,⁷⁵ and in the field by D. A. H. Robson (who later lost his life in an experimental flight of one of the first Boeings used in this country), led to the early development of an improved oxygen mask and an economizer, which prevented the oxygen from going to waste during expiration and was foolproof against

stoppage of the flow of the gas even if the breathing of the wearer became minimal, as during shock or unconsciousness (Fig. 1). This improvement in the oxygen supply more than doubled the operational range of aircraft from an oxygen point of view. The anoxia meter devised by E. A. G. Goldie^{48, 50} was of inestimable value in assessing the relative merits of different types of oxygen masks and revolutionized the study of anoxia, as the amount of oxygen in the blood could be estimated with this apparatus at any moment and for any length of time without puncture of an artery as was necessary hitherto (Fig. 2).

As decompression sickness occurred in some pilots engaged in reconnaissance at altitudes over 25,000 feet (7,600 metres), E. A. Carmichael,¹⁷ B. H. C. Matthews,⁷⁴

Fig. 1.—Oxygen economizer designed to prevent oxygen going to waste during expiration.

and I. de Burgh Daly²⁶ studied this matter and made the first appreciation of its effects. Later, the staff of the R.A.F. Physiological Laboratory at Farnborough, working in liaison with the Royal Canadian Air Force, intensified these researches and, as a result, tests were devised to select those suitable for high-altitude flying, and measures were adopted to alleviate or prevent the occurrence of decompression sickness.^{38 40 92 95 97 119} This pioneer work materially aided in Bomber Command's retaliation on the enemy, which began in 1941.

The aircraft used in these reconnaissance flights were of the single- or two-seater type, had reasonably warm cabins, and were engaged only on flights of relatively short duration, so that the effect of cold on the individual and his flying equipment was not markedly noticeable and did not call for research then.

Work done in connexion with the oxygen supply during this phony period proved of inestimable value for the Battle of Britain.

The Battle of Britain

The enemy, having failed to attain victory by force of numbers, tried to circumvent the air barrier by flying over it. The famous few had therefore to climb to equal or greater altitudes to claw the enemy out of the sky, which would not have been possible without an adequate oxygen supply.

At this time two other problems demanded immediate attention—namely, the temporary loss of vision or blacking-out which resulted from high acceleration during dog-fighting, which was then the vogue; and fatigue consequent on the large number of sorties that had to be flown without a rest.

Fortunately, in the absence of a centrifuge for the fundamental study of blacking-out, a considerable amount of research in this matter had already been carried out by W. K. Stewart and G. E. Watt^{103 106 107} at Farnborough in an aircraft specially fitted for use as a flying laboratory. In this aircraft a cine-camera was suitably mounted to take shots of pilot and passenger, so as to record their physical appearances and visual reactions under various forces of g, together with the readings of the various instruments indicating force of g, time for which applied, air speed, and altitude (Fig. 3).

In this way it was proved that abdominal belts *per se* were of no use as an anti-g device,^{98 109} but that resistance to blacking-out could be increased by $1\frac{1}{2}$ to 2 g if the rudder-bar pedals of the aircraft were raised by 6 in. (15 cm.), and the pilot assumed a crouched position, so as to lessen the amount of blood that pooled in the legs and to reduce the differences in the levels between the brain and the heart (Fig. 4). This minor modification to the aircraft was readily carried out at the airfields without interfering with the operational effort—a most important consideration at a time when every available aircraft had to be in the air or at the alert. The raising of the blacking-out threshold by $1\frac{1}{2}$ to 2 g proved adequate to prevent blacking-out with the centrifugal forces encountered in aerobatics at that period.^{99 108}

The Battle of Britain was such a critical period that little or no rest was possible for our pilots in their all-out effort. Medical aid was sought to give relief from sleeplessness and fatigue without, if possible, loss of performance.⁹ Several drugs were tried, but attention was mainly directed to the use of caffeine¹⁴ and amphetamine ("benzedrine")^{7 14 15 28 99 118 117}; the former was found to stave off fatigue for a short period without interfering with performance. The popular belief at the time was that amphetamine was the wonder

drug to banish fatigue and improve performance—in fact, some thought it would give them a mental acumen that they never possessed.

Professor F. C. Bartlett and his co-workers¹ showed that amphetamine, though it helped to banish sleep, did not im-

prove performance and was mainly a stimulant and acted as a whip to the flagging horse, so that when its effect passed off the need for rest was greater than ever. There was the danger that if it were taken to lessen fatigue prior to a landing its stimulative effect, something like that of alcohol, would so warp judgment that undue risk might be taken, with dire results. The stimulative effect varied according to the type of individual, and in correct dosage the dull appeared somewhat brighter, the average was perceptibly enlivened, while the above average who was normally a "live wire" became "hay-wire" with frayed nerves. Consequently, orders were issued that no drugs were to be given to aircrew, except by the unit medical officer, and then only to individuals in accordance with their known reactions, and that as a general rule no drug should be used except to ward off sleep when the danger of that was greater than any ill effects of the drug. The importance and necessity for natural sleep, even for short periods, was stressed.¹⁰

Night Raids by the Enemy

When, in the last quarter of 1940, the enemy changed tactics from daylight bombing to terror raids at night on London and the industrial cities, anti-measures by the Air Force called for intensive research into the problems of night vision in general, and the protection against searchlight glare, to help our pilots and air gunners to detect the enemy during interception flights.^{92 99} Night-vision-capacity tests were devised to help in the selection of aircrew most suitable for night operations,^{79 85 86} and investigations were carried out to assess the effects of vitamins A and C and various drugs on night vision.^{58 66} At the same time, physiological and psychological aspects of night vision had to be considered in relation to aids for taking-off and landing in the dark. This necessitated improved methods of pre-adapting the eyes for night vision,^{21 24 25} first by wearing dark smoked glasses⁹⁰ to exclude all light, and later by the use of ruby-red glasses⁹² which permitted the user to read white standing by for taking-off.

Cockpit and cabin lighting were studied to ascertain the best type and intensity of illumination that could be used to read instruments and maps without materially interfering with dark adaptation.^{22 25 79 93 111} This led to the development of a satisfactory lighting system whereby fluorescent or red lighting^{91 94} could be used either together or separately, and so controlled that the maximum permissible luminosity could not be overstepped. At the same time, night-vision training schools were established to teach all members of aircrew how to maintain and improve their night vision and how to see or observe, including the value of oxygen in preserving night vision.^{3 4 10} Those mainly concerned in these researches were K. J. W. Craik,^{21 22 92 94} and P. C. Livingston.^{58 59 61 64 65 66} They also played an important part in the development of devices to counteract searchlight glare^{94 110} and in the lay-out of airfield lighting systems to facilitate taking-off and landing in the dark.

Retaliation

Starting in 1941, retaliation bombing by the R.A.F. became ever stronger, and for this purpose the range of flight was increased and operations were carried out at higher altitudes, partly to permit surprise attacks and partly to evade anti-aircraft fire. At the same time, bomber aircraft were provided with more guns for defence, which meant more draughts through the gun apertures. Intense cold was therefore experienced by aircrews, particularly tail-gunners. It was not practicable, owing to operational needs, to install efficient fuselage heating in the aircraft then in use; the immediate necessity was to devise clothing that would keep the aircrews reasonably warm without hampering their movements.⁹⁹ Hot-air suits were tried, but were not a success.⁷⁰ However, as a result of the combined researches of physiologists and material scientists, special flying clothing, consisting of electrically heated suits, boots, and gloves, was devised to apply warmth to those parts of the body most in

need of it; this flying clothing combined lightness and flexibility to facilitate movement, waterproofness against rain, and permeability to air to allow for dispersal of sweat.^{69 71 72}

Another ill-effect of the intense cold encountered was the freezing-up of the oxygen-mask valve under icing conditions.⁷¹ J. C. Gilson¹⁶ tackled this problem and produced an improved type of mask which did not freeze up at high altitudes and had the additional qualities of comfort, smallness, lightness, and perfect fit even during strenuous aerobatics. For these long bombing flights it was necessary to devise a light, portable oxygen set to enable aircrew to move about away from their stations at altitudes over 15,000 feet (4,600 metres), especially when loading guns or moving ammunition.⁶⁹ Before the introduction of this portable set, there were instances of crews collapsing from oxygen want when away from their normal oxygen points.²⁰ A further development of this set was the bale-out bottle to be used either fixed to the person or combined in the parachute pack to ensure an adequate oxygen supply for 10 minutes to enable aircrew to escape from aircraft and descend safely in emergency.^{69 72} These oxygen supply devices were introduced mainly as the result of researches by B. H. C. Matthews and his staff,⁷⁶ and played an important part in maintaining the efficiency and morale of aircrew on hazardous missions.

At this time, anti-submarine activities were intensified and the medical branch was asked to advise on the best visual means of detecting submarines in various waters. This involved camouflage problems and the drawing up of a scheme for teaching aircrew how to look for submarines, and the best means of scanning.⁷⁴ Coupled with this the optimum period of watch and the maximum period permissible to avoid fatigue of such a degree that further watch was useless had to be assessed.^{61 114} Another method of countering submarine and air attacks on our convoys was the use of catapult aircraft on merchantmen. These had often to operate in northern waters, and at the end of the sortie the pilots had to bale out, as they could not land their aircraft on the ships. This meant immersion, perhaps in

FIG. 5.—Original immersion suit made of fabric which allows the passage of water vapour—i.e., perspiration—but is waterproof. It was designed to keep a man's clothing dry after ditching before boarding his dinghy or being picked up. (Air Ministry Crown copyright.)

icy waters, for half an hour or more, before action was broken off and they could be rescued. It was necessary, therefore, to devise an immersion suit which would permit adequate perspiration during standby and still keep the wearer dry and warm enough to remain alive while immersed.¹¹⁶ E. A. Pask^{68 69} was mainly instrumental in the development of such a suit, the principle of which was subsequently adopted by the Royal Navy and the Allied Air Forces (Fig. 5).

Life-jackets were naturally provided for aircrew operating over the Atlantic to escort convoys, spot enemy submarines, and give defence against enemy aircraft, but it was necessary to ascertain whether these life-jackets would keep the nose and mouth of an unconscious individual above water in a rough sea. To test this, E. A. Pask⁷⁴ was anaesthetized on two occasions for several hours while immersed in water wearing various types of life-saving jackets in turn (Fig. 6). It was

found that not only the R.A.F. "Mae West" but also life-saving jackets of other Air Forces and Navies, though adequate in giving safe flotation to a fit person, could not be relied on for an unconscious individual. Following these researches, suitable modifications were made to the life-saving jackets to ensure adequate flotation for the unconscious.

These long, hazardous flights over the ocean and enemy territory were accompanied by considerable fatigue and an increased incidence in nervous breakdown. In connexion with the latter, C. P. Symonds and D. J. Williams⁶ made extensive surveys of the psychological disorders of aircrew, and their findings enabled authoritative advice to be given

FIG. 6.—Assessing flotation properties of life-saving jackets to keep nose and mouth of unconscious individual above water. Subject was anaesthetized through leads to nose. (Air Ministry Crown copyright.)

on operational limits to conserve man-power and maintain efficiency. Researches by physiologists and psychologists into the problem of flying fatigue pointed the way to lesser this by properly designed cockpits and cabins, including seating position, instrument lay-out and dial markings,⁹ lighting to preserve dark adaptation, the best position for all controls so as to obtain the necessary reaction with the minimum of energy, sound-proofing to minimize engine noise, and air-conditioning to maintain a reasonable temperature in all climates and at all altitudes.

This work, and subsequent improvements in the aircraft and flying equipment for maintaining the maximum efficiency of aircrews, proceeded steadily and in parallel with the increasing striking power of the R.A.F. in preparation for the great offensive in the West.

The Great Air Offensive in the West

The air offensive on enemy and enemy-occupied territory was stepped up considerably in 1943, and reached crescendo in 1944 and 1945. Larger and faster bombers were used, flying at still higher altitudes, and these offensives were interspersed with low bombing attacks by much faster-flying aircraft, such as the Mosquito, followed later by the dive-bombing attacks by the very high speed rocket-carrying Typhoons. Operations were carried out both by night and by day, and pin-point bombing became the routine, especially for the "Pathfinders." The physiologists and psychologists were consulted regarding the design of the bomb-aiming apparatus, the best colours for target-markers, and the pattern of the marking.^{6 10 80}

At this time the enemy's anti-aircraft defences were considerably strengthened, and violent evasive action was often necessary to avoid the heavy flak. The enemy's night fighters were frequently concentrated to attack our raiders, so it was essential that both pilot and gunners should have the clearest vision possible to forestall the fighters' attacks. Researches by A. Luczak,⁶⁷ of the Polish Air Force, showed that a clear-vision panel was the ideal, but, failing this, plate

glass set as near the vertical as practicable was to be preferred to "perspex." Goldie¹⁹ demonstrated how markedly visibility was reduced by scratches and dirt on windscreens, and devised an apparatus for measuring the scatter of light and visual loss which resulted from using dirty perspex and other transparent screens: this gadget did much to convince aircrews of the need to maintain clean, unscratched vision panels.

To facilitate the detection and pin-pointing of targets in the dark and through cloud or mist, and to assist in homings under adverse weather conditions, various instrument aids, visual and auditory, were introduced. Physiologists and psychologists collaborated in this work, not only in the laboratory but also in the air in actual operations. The "beam approach" was a good example, as it concerned both visual and auditory aids. The pilot relied on the beam approach device in homing at night or in bad visibility by day at a time when he was likely to be tired and particularly apt to make errors. In addition to this apparatus, the pilot had at least ten instruments on his flying panel which had to be read and their meaning fitted into a whole before he could make a safe landing under blind flying conditions. It was of supreme importance, therefore, that all instruments should present their messages as simply and clearly as possible.

The beam approach consisted of a radio beam which gave two types of clue—one auditory, the other visual. Originally, these were wrongly presented, as the auditory clue did not use the morse letters that could be picked up with least error; the visual clue, consisting of a small luminous plan of the aircraft and its relation to the beam, was confusing, as the pilot had to remember to reverse the signal for right or left turn when approaching the airfield in the opposite direction to the normal. Psychological researches by R. C. Browne¹⁰ showed that the best presentation was that which necessitated the least thought, and as a result correct clues were introduced. The application of this work to the promotion of safety in flying needs no stressing.

Stratosphere Flying

Both sides were striving for the key to victory through mastery in the air, so two projects received high priority—namely, the development of the pressurized cabin and jet-propelled aircraft.

The pressurized cabin aircraft was needed for duration flights at altitudes over 38,000 feet (11,600 metres), and certain physiological aspects of pressure differentials and air-conditioning had to be solved.⁷⁷ An important point that required early clarification was the effect that sudden decompression, following holing by a missile or the blowing of a port, would have on the occupants. It was thought that such an accident would lead to so much distension of the lungs as to cause serious injury or death. R. H. Winfield,¹¹⁶ by personal experiment, demonstrated that explosive decompression at the differential pressures visualized caused no perceptible harm to a fit man provided his glottis was open.^{94 108} Experiments on animals carried out by Professor de Burgh Daly and his team at Edinburgh University gave similar results.^{26 38 39} To meet the enemy's challenge for altitude supremacy, it was necessary to develop some interim measure, and here Professor H. C. Bazett¹² and A. P. Gagge,^{11 43} of U.S.A., with their pressure-breathing waistcoat and mask, respectively, saved the situation, for this equipment so raised the intrapulmonary gas pressure as to maintain sufficient arterial oxygen saturation to enable aircrews to fly

efficiently at altitudes up to 44,000 feet (13,400 metres). This was a requirement of the high-altitude photographic reconnaissance flights, whose work was of the utmost value in deciding on targets and in assessing the result of operations.

Other physiological problems of stratosphere flying concerned ventilation, oxygen needs, visibility, and methods of escape in emergency. In connexion with escape descents by parachute from the stratosphere, physiological aid was sought as to how to guard against the intense cold (-55° C. or less), lack of oxygen, and the high forces of deceleration at the moment of opening of the parachute. Suitable clothing was designed to protect against cold. The problem of oxygen lack was studied by E. A. Pask, W. K. Stewart, and S. L. Cowan,⁶ who carried out a series of experiments in the laboratory to ascertain the length of time the average man could live at altitudes between 44,000 and 25,000 feet (13,400 and 7,600 metres) during a parachute descent, although unconscious. These volunteers were suspended in the air by means of the standard parachute harness and made to breathe nitrogen-air mixtures to simulate the atmospheric conditions from 44,000 feet (13,400 metres) downwards at the rate of descent of an open standard parachute. It was found that man could remain unconscious for 7½ minutes and yet live during such a descent without additional oxygen: the baleout bottle was therefore designed to give a 10- to 12-minute supply of oxygen to allow a sufficient margin of safety to cover the oxygen used by the energy expended in getting out of the aircraft.

Experiments in U.S.A. by R. Lovelace and M. W. Boynton by personal jumps, and by G. A. Hallenbeck,³² using large animals and dummy men fitted with accelerometers, indicated that decelerating forces up to 30 g occurred at altitudes of 35,000 to 40,000 feet (10,700 to 12,200 metres) if the parachute opened almost immediately after baling-out, and this force severely damaged the canopy and its rigging. It was therefore essential to warn all parachutists to allow the speed of fall to slow to a steady rate before pulling the ripcord, and this free-drop time had to be worked out for various altitudes. In one of these very gallant experiments Boynton lost his life. B. J. O. Winfield,¹¹⁷ who personally made many parachute jumps, added considerably to our knowledge of this art, and his observations helped in the design of parachutes and their attachments to the user, and in establishing the best stance to adopt for landing so as to minimize injuries.

Physiological Problems of High Speed

The advent of jet-propelled aircraft with speeds approaching that of sound soon raised other physiological problems,

FIG. 7.—Shows the first successful ejection from aircraft in flight of a dummy man complete with seat following a 40-foot-per-second explosive charge; the airspeed was 250 m.p.h. The parachute, seen in lower photos, operated automatically after ejection. (Air Ministry Crown copyright. Photograph of official test done on October 1, 1945.)

an early and very important one being emergency escape during flight. As a result of a fatality in January, 1944, when a pilot tried to escape from a jet machine which was out of control, it was evident that the force of the slipstream of high-speed aircraft was so great that the unprotected human body could not withstand the air blast for more than a fraction of a second, else limbs were fractured or evulsed against the edge of the escape hatch, the skin of the face torn, and the lungs over-expanded. Researches done on the ground with a Martin-Baker test rig, then in fast-moving aircraft, first with dummies and later with men, showed that it was practicable to eject a pilot, complete with seat and parachute, clear of an aircraft travelling up to speeds of 500 miles (800 km.) an hour (Fig. 7). For safe ejection, however, it was necessary to devise a canopy to prevent undue flexion of the head during the upward thrust, to protect the face and lungs against blast, and to keep the oxygen mask from being torn off by the force of the slipstream.⁴⁷⁻⁵¹ In the final design, the pulling down of the protective canopy automatically activated an explosive charge under the pilot's seat only when the body of the canopy reached nipple level, and the resulting force of ejection ensured that the pilot's hands drew the hood tightly over his head.⁵¹⁻¹⁰⁵

While the war in the air was proceeding apace, important events were taking place in enemy-occupied territory from resistance groups with whom we were in touch by agents dropped by parachute and at times picked up from air. Owing to the difficulty of landing aircraft for this purpose, a technique had to be developed to pick up these agents from the ground while the aircraft was in flight. The physiological and physical problem here was how to accelerate man from rest on the ground to approximately 120 m.p.h. (190 km.p.h.) in the air within half a second. W. K. Stewart and R. H. Winfield¹⁰⁶ did most of the physiological work in connexion with this problem and took part in practising and perfecting the technique (Fig. 8).

Looking ahead to the landing in Normandy and the advance to Germany, it was expected that there would be aerial dog-fights at higher speeds than hitherto, so researches were done in Britain, Australia, Canada, and the United States to develop and perfect anti-g garments that could be rapidly donned and would be comfortable to wear even in hot weather and during long sorties. The combined efforts of these researches led to the production of a very light (3 lb.—1.4 kg.) pneumatic suit or high-waisted trousers fitted with bladders, so designed as to equalize automatically the internal pressure built up in the body fluids by the accelerating forces, thus preventing the blood from pooling in the lower part of the body (Fig. 9). By wearing such a suit the threshold for blacking-out was raised by 2 g or more, and, in addition, by ensuring good circulation of blood to the head, lessened fatigue and helped to maintain quick reaction time during

long and arduous flights.³⁷⁻¹⁰⁶ Much of the credit for this work belonged to those pioneers W. R. Franks,⁴⁴ of Canada, and F. S. Cotton,¹⁰⁷ of Australia, to S. Davidson,³⁷ a medical officer who was test pilot for these anti-g devices, to W. K. Stewart,¹⁰⁰⁻¹⁰²⁻¹⁰⁴ who acted as a guinea-pig in over 200 black-outs, and to our American Allies, particularly the Mayo team—E. J. Baldes, C. F. Code, E. H. Lambert, and E. H. Wood.¹⁰⁸ The Allied air supremacy was so overwhelming, however, that dog-fights did not occur, so these suits were not required by the R.A.F., though they were used in large quantities by the Americans, chiefly to lessen fatigue on long flights under turbulent atmospheric conditions.

FIG. 9.—Pneumatic anti-g suit. A: Shows position of abdominal, thigh, and lower leg bladders as indicated in solid black. The shaded areas are pressurized by tension of the fabric. Pressure cuts in automatically at 2 g. B: Shows how the pressure suit is worn under uniform. (Air Ministry Crown copyright.)

The Air War in the Orient

Following the surrender of Germany in May, 1945, researches in connexion with physiological problems peculiar to the Orient were intensified for the final showdown against the Japs. Special attention was paid to air-conditioning and cooling of aircraft, particularly when on the ground, to protect against the ill-effects of heat, and to the development of escape suits and equipment for survival in the jungle and in warm climates after baling out or crash-landing. The results of these researches were not adequately tested in the field, owing to the abrupt and dramatic end of hostilities in the East, as a result of atomic warfare. Nevertheless, much progress was made and sound foundations were laid for post-war research into problems of climatology, clothing, and human performance in temperature extremes.

Post-War Position

Though there was a lull in researches in connexion with aviation medicine after the first world war, it is most heartening to know that the reverse has been the case since the end of the second world war. Such researches have been intensified as regards both Service and civil aviation, and the R.A.F. Institute of Aviation Medicine at Farnborough has had a considerable increase in staff as well as extension of all its departments, which are fitted with the most up-to-date equipment capable of tackling all current and many future problems. Researches have been actively pursued into space and pace problems of the upper troposphere and the stratosphere, and of supersonic speeds, as well as into the noise and vibration associated with jet-propelled aircraft. Stratosphere investigations include the effect on man of solar and cosmic rays, mesons, and neutrons, and how to protect the body from explosive

FIG. 8.—Initial experiments in pick-up from ground by aircraft in flight at 120 m.p.h. Person to be picked up is crouched facing the oncoming aircraft. Drag from trailing rope of aircraft catches nylon loop fixed between two poles. (Air Ministry Crown copyright.)

decompression should it occur in pressurized aircraft at altitudes over 60,000 feet (18,300 m.), where the blood would boil if some means of compression were not immediately forthcoming.

In addition, the terms of reference of the Flying Personnel Research Committee were extended in 1948 to cover aviation interests other than the R.A.F. and the Fleet Air Arm. The Committee's terms of reference are now to advise the Secretary of State for Air on investigations into the medical aspects of all matters affecting personnel, particularly those which might conduce to safety and efficiency in flying, including research into problems associated with the scientific selection and training of flying personnel and into measures designed to maintain their physiological and psychological efficiency. In addition, the Committee's terms of reference include the following: to advise the Board of Admiralty on these matters in relation to naval aviation; to advise the Ministry of Civil Aviation and the civil corporations on problems of flying staff and passengers of civil aircraft; and to advise the Ministry of Supply on matters in relation to human requirements in flying. The Committee also advises the War Office so far as problems of airborne troops are concerned.

APPRECIATION

This is only a sketchy survey of medical science as applied to the war in the air, but it gives some idea of the part it played in helping to win the war. Those concerned in this work deserve the highest praise for the fine results attained and for the very gallant way in which many of the researches were carried out with great risk to life. Special tribute is due to the excellent work done by physiologists under the guidance of B. H. C. Matthews at Farnborough and to practical psychologists working with Professor F. C. Bartlett at Cambridge, and to those medical officers who were also pilots (termed "flying personnel medical officers") and did liaison duties between aircrews and the laboratory, including two who gave their lives in this great endeavour—Group Captain H. W. Corner and Squadron Leader D. A. H. Robson. These results, however, could not have been attained without the whole-hearted co-operation and pooling of knowledge that existed between biological and material scientists, aircraft designers, and the executive and medical branches of the Allied Air Forces.

The Royal Air Force is greatly indebted to the foresight of Sir Edward Mellanby and Sir Victor Richardson for conceiving and initiating the formation of the Flying Personnel Research Committee, whose activities have proved so valuable in the progress of aviation medicine. Thanks are also due to the Medical Research Council for the help given in certain problems by many of their staff.

EFFECTS OF FLYING ON PATIENTS WITH CARDIOVASCULAR DISEASE*

BY

GEOFFREY BOURNE, M.D., F.R.C.P.
Physician, St. Bartholomew's Hospital, London

The enormous increase in air travel during recent years has, among other results, led to the necessity of considering its effect upon passengers suffering from organic disease. The physical standards insisted upon by Government services and by private air lines in the selection of pilots and air crews of all sorts are naturally very high. This attitude has perhaps led to the parallel conclusion that none but physically fit individuals can safely be subjected, as passengers, to the strains and stresses of this form of transport.

Whittingham, Barbour, and Macgown (1949) surveyed, from the point of view of air-fitness, most of the common medical diseases. They referred to cases of heart disease as follows: "Those suffering from angina pectoris must have the condition adequately controlled with trinitrate, and an electrocardiogram should be done to exclude infarction: such cases can be accepted if the angina is provoked only by a brisk walk of half a mile. Cases with congenital heart lesion can be accepted for low-altitude flights if there is no veno-arterial shunt as evidenced by cyanosis, or if there is no heart-block or severe hypertension resulting from coarctation of the aorta. Cases of high blood pressure are acceptable if the systolic pressure is not over 200 mm. Hg and the diastolic is less than 120, provided they have flown before and there is no pulsus alternans, cardiac asthma, gross albuminuria, or cellular casts in the urine: those who have not flown before may be upset by nervous tension."

Whittingham (1953) states: "Cardiovascular disease of marked degree is present in about three-quarters of those who are taken ill during flight. The low oxygen tension, even at altitudes between 5,000 and 8,000 ft. (1,500 and 2,400 metres), throws a serious strain on the heart. These patients should travel in a pressurized aircraft and limit their movements to the minimum; oxygen and any special drugs prescribed by their doctors should be available; and the medical department of the air line should be made aware of their condition. Patients with angina or coronary occlusion should not fly unless they have been free from symptoms for at least three, preferably six, months. Even then the altitude should be limited to 5,000 ft. (1,500 metres). A test of fitness for anginal patients is whether they can walk briskly for about half a mile (0.8 km.) without symptoms. Patients with valvular disease should not fly while the condition is acute, nor when it is chronic if there are signs of congestive failure or pronounced anaemia. Those with congenital heart disease can be accepted for flights up to 8,000 ft. (2,400 metres) altitude, in the absence of veno-arterial shunt, as evidenced by cyanosis, heart-block, or severe hypertension resulting from coarctation of the aorta. Those suffering from myocardial lesions are unacceptable if there is marked bradycardia or if they have had diphtheria within six months. Cases of high blood pressure can be accepted if there is no pulsus alternans, cardiac or renal asthma, frequent

*A paper read at the Second World Congress of Cardiology in Washington, U.S.A., on September 16, 1954.

headache, much loss of weight, gross albuminuria, cellular casts in the urine, or optic fundus change. They should be given a sedative before flight to prevent nervous tension worsening their condition, particularly if they have not flown before."

Whittingham's paper is naturally written from the point of view of the Director of Medical Services, British Overseas Airways Corporation, and quite rightly is conservative in its approach to the subject. An air line is responsible for the delivery, safe and sound, of its passengers; and from the point of view of its liability it must take stringent measures concerning the safe transportation of individuals known to be suffering from cardiovascular disease.

My own experience has for some time been that this view is ultra-conservative, especially regarding cases whose journey is really necessary. I was therefore led to collect a series of patients suffering from the more serious forms of cardiovascular disease who to my knowledge had safely flown considerable distances.

General Considerations

The chief stresses to which human beings are liable through flying are (1) oxygen lack, (2) excitement, and (3) air-sickness. The oxygen lack is compensated for in modern aeroplanes by pressurization of the aircraft. This is usually so adjusted that the pressure at the altitude flown, whatever this may be, does not surpass 8,000 ft. (2,400 metres). At 8,000 ft. the oxygen saturation of the blood passing through the lungs is about 86%. It is not until an arterial saturation of 83% or less has occurred in the arterial blood that any measurable increase in cardiac output occurs in normal resting individuals. The standard pressurization figure, therefore, is such that there should in ordinary circumstances be no added call upon the heart at the altitude flown normally by passenger aeroplanes properly pressurized. An obvious point is that the pressurization must be known to be adequate before the start of the journey. When Case 3 of the present series (myocardial infarction) was about to fly from New Delhi to London the start of the flight was delayed. Inquiry revealed that the pressurization system was out of order. The journey was put off, being made at a later date when an efficient aeroplane was available.

Certain other general facts are worth remembering. (1) Patients with organic heart disease which is properly compensated are able to increase their cardiac output for considerable periods during the day, remaining free from symptoms. (2) Women with organic heart disease who become pregnant, and who thereby develop a cardiac output of 20% or more above the average, still can remain in a reasonably comfortable physical state. (3) Patients with coronary disease have been safely investigated by reducing the oxygen content of their inspired air. Electrocardiographic changes will only result if the oxygen reduction is in the neighbourhood of 13%. These facts supply additional evidence suggesting that well-compensated cardiac patients flying in properly pressurized aircraft should not be materially influenced for the worse.

Influence of Anaemia

There is one important factor which may intrude upon the problem without being detected unless proper steps are taken in advance, and that is anaemia. It is generally accepted that anaemic patients show an increase in cardiac output. The extent of such an increase is at the moment uncertain, since the experimental methods used are all subject to criticism. The modern view would seem to be that a reduction in the oxygen saturation of an extent resulting from a measurable reduction in the haemoglobin is likely to produce some increase in cardiac output. A proper blood count, therefore, should certainly constitute an essential

preliminary to a prolonged aeroplane flight planned by a patient suffering from organic cardiovascular disease. Anaemia, if present, should be treated. The other factors of air-sickness and nervousness are readily preventable by proper remedies.

The present series consisted of 30 cases—6 with hypertension, 4 with angina of effort, 14 with myocardial infarction, and 6 with other forms of severe organic heart disease. No case in any of these four series was in the slightest extent incommenced by flying.

Hypertension

Details of these cases are given in Table I. The first case provides a good example of the fact that an individual with hypertension can fly without deterioration.

TABLE I.—Hypertension

No.	Age and Sex	Duration and Average B.P.	Heart Enlargement	E.C.G.	Remarks	Miles Flown
1	58 M	230/130 9 years	Slight	T flat I, II, QRS 0.1	Lumbar sympathectomy, 1946	More than 100,000
2	58 M	280/146 248/120 6 years	Moderate	T, I, II, VL, VS, QRS 0.11	Left hemiparesis. Lumbar sympathectomy, 1950	17,000
3	75 M	230/130 190/110 7 years	Slight	Lt. B. Br. QRS 0.13, T, I, V5	Hypertension non-progressive	More than 100,000
4	57 M	194/110 6 years	Moderate	Rt. B. Br. QRS 0.12, S-I, V5, M shaped, V1	Heart size slowly increasing during 6 years	119,000
5	56 F	220/140 5 years	Slight	Left vent. strain, E.C.G. for 10 years	"Benign" hypertension	1,600 one year ago
6	63 M	240/114 4 years	Moderate	T flat in I, V5, R tall in I, V5		7,000

Case 1.—A man of 58 concerned with aeroplane insurance has in the course of his business flown many thousands of miles every year for the last nine years. During the whole of this period his blood pressure has varied between 230/130 and 220/120. In 1946 a lumbar sympathectomy was performed. Whether or not this has influenced the good result is open to doubt. His heart has remained well compensated, but after nine years, during which time electrocardiograms showed flattening of the T waves and a QRS of not more than 0.1 second, changes of a definite left bundle-branch lesion have recently occurred.

Case 2.—A man of 58 had had a blood pressure of 280/146. Six years later it was still 248/120 when taken in the lying position. Lumbar sympathectomy was performed in 1950, and since then he has had a measurable postural hypotension. His electrocardiogram from the first showed the typical changes of left ventricular hypertrophy and left ventricular strain. He suffered a left hemiparesis nine years ago, from which he has made a good recovery. The distance flown is given as 17,000 miles, but it is considerably more than this. Exact figures are not available.

Case 3.—A man of 75 had had hypertension for seven years, the figures varying between 230/130 and 190/110. He has lost count of the number of times he has flown the Atlantic during the past ten years. He has no symptoms and his hypertension has been non-progressive.

Angina of Effort

The history of pain and tightness was typical in all four cases. It involved the upper part of the chest. It was exactly proportional to the amount of exercise taken, causing the individual to stand still. It was in all cases worse in cold weather and was accentuated by hurrying. The details are shown in Table II.

TABLE II.—Angina of Effort

No.	Age and Sex	Duration of Angina of Effort	Heart Size	B.P.	E.C.G.	Miles Flown
7	59 M	10 months	Normal	172/104	Q + I, VL, VS, R + VL, V5	50,000
8	68 M	4 years	Slight increase	132/78	S - and prolonged I, VL, V5	6,230
9	73 M	7 "	Normal	146/80	Normal	12,000
10	53 M	4 "	"	156/90	QRS abnormal and notched II, III, V3, V4	125,000

Myocardial Infarction

In the series of 14 patients with myocardial infarction 12 had suffered one infarct before flying, one had suffered two, and in one patient angina of effort had preceded the aeroplane journey by a year, the infarct occurring three months after the flight. The details are shown in Table III.

TABLE III.—Myocardial Infarct

No.	Age and Sex	Site of Myocardial Infarct	Interval between Infarct and Flight	Remarks	Distance of Flight (Miles)
11	64 M	Posterior T2, T3, TVF	9 years	Now has angina of effort, hypertension, and left ventricular strain, E.C.G. Left bundle-branch lesion also	7,000
12	72 M	Anterior	4 days		5,000
13	56 M	Antero-lateral	2 years 9 months	No hypertension, good recovery	10,000 5,000
14	51 M	Postero-lateral	4 "	Severe angina of effort 4 years	47,000 2,500
15	50 M	Antero-lateral	2 "	B.P. 160/100	1,000
16	53 M	"	5 "	Previous angina with paroxysmal tachycardia. B.P. 160/100	5,000 1,200
17	59 M	Posterior	2 months	B.P. 190/110	470
18	64 M	Antero-septal	7 months	Complete heart-block. Left bundle-branch block. Heart size 16 cm.	300 6,000 total, several journeys
19	38 M	Antero-lateral	3 years	Angina of effort since infarction	1,300
20	65 M	? Left bundle-branch lesion, E.C.G. equivocal	2 months	Angina of effort before and since attack	5,000
21	53 M	Antero-lateral	2 years 18 months	Attack slight. Second severe attack four months later	11,300 3,000
22	58 M	Posterior	—	Infarct three months after flight. Angina of effort	2,000
23	68 M	"	1 year	Flights in war conditions. Angina of effort	100,000
24	66 M	1. Posterior 2. Postero-septal	4 months	Partial heart-block after second infarct	5,100

Hypertension was present in three of these cases. Hypertension had also probably been present previously to some extent in four further cases, since the diastolic blood pressure was 100 or more in these individuals. No hypertension was present in seven of the cases.

The time interval between the occurrence of the infarct and the flight in seven cases was one year or less. In one case the interval was as short as four days; in two cases it was two months, and in one case four months. Two of the patients had flights of considerable stress, one of them (Case 13) flew 5,000 miles nine months after his attack, and 47,000 miles during the next two years, including transit of the Andes between Rio and Lima four separate times. He never suffered any inconvenience from this.

Case 23.—This patient, a man of 68, produced an even more severe test. He did nearly all of his flying during the war years from 1942 onwards. He was an expert with the Australian stock-whip, and flew from England to North

Africa, West Africa, Sudan, Iceland, and other areas under wartime conditions and in whatever aeroplane transport might be available. He entertained the troops by his skill. He always took glyceryl trinitrate tablets before his performances to prevent angina of effort. He flew considerably more than 100,000 miles before the end of the war. In 1945 his electrocardiogram (Fig. 1) showed that auricular

FIG. 1.—Case 23. Electrocardiogram taken after the onset of auricular fibrillation. It shows the typical Q-T changes of a posterior myocardial infarction in Leads II and III.

fibrillation had supervened. He subsequently died at the age of 72.

Case 18.—A man aged 64 had suffered from intermittent claudication for three years. Seven months before his flight he had had a severe myocardial infarct which left him with complete heart-block (Fig. 2). For personal and business

FIG. 2.—Case 18. Electrocardiogram showing changes characteristic of complete heart-block with a left bundle-branch block.

reasons he desired to make a journey to Australia, to which continent he travelled by sea. When there he flew 6,000 miles or more on personal and business errands. Radiologically his heart was much enlarged.

Only one patient (Case 24) in this series had had two infarcts. The first, a posterior lesion, occurred two years before his flight, and the second, a postero-septal lesion, four months before. The second electrocardiogram showed a transitory partial heart-block.

Case 22 illustrates a further point. This patient had suffered from angina of effort of a severe degree a year before his coronary attack. In spite of this he made two aeroplane flights of 1,000 miles, and it was not until three months later that he developed his myocardial infarct. It is reasonable to assume that at the time of his flight he was in a condition when if flying was going to induce myocardial infarction it would have done so.

Miscellaneous

The miscellaneous group (Table IV) includes the following examples: a case of auricular fibrillation, without evidence of coronary disease or of thyrotoxicosis, but asso-

TABLE IV.—Miscellaneous

No.	Age and Sex	Diagnosis	E.C.G.	B.P.	Remarks	Flew (Miles)
25	65 M	Myocardial degeneration	Auricular fibrillation	150/110	Decompensated till digitalized	7,000
26	68 M	Aortic stenosis	T, I, T, VL, T, V5	168/90	Faintness on exertion	5,140
27	35 M	Aortic regurgitation (rheumatic)	QRS=0.12 T, I, T, VL, T, V5	154/62	Large heart	3,540
28	59 M	Aortic regurgitation hypertension. W.R.-ve	QRS=0.12 T, I, T, VL, T, V5	230/102	Class II (N.Y.) failure	9,850
29	19 F	Rheumatic myocardial and mitral disease	Auricular fibrillation QRS+	122/64	Enormous heart	13,000
30	41 F	Mitral stenosis	Normal rhythm	156/94	Paroxysmal dyspnoea attacks	8,500 before valvotomy

ciated with a slightly raised diastolic blood pressure and a history of severe chronic bronchitis and bronchospasm; a case of aortic stenosis with the typical physical signs and electrocardiogram, and with the history of faintness induced by exertion; and a case of well-marked aortic regurgitation, rheumatic in origin, with a blood pressure of 164/62. This patient had been under observation from 1940 to 1953, during which time his heart had shown a progressive increase in size. In 1940 the transverse diameter was 13 cm., in 1949 13 cm., in 1950 16 cm., and in 1953 16.5 cm. He flew 3,540 miles in 1952. Case 28 is of particular interest, and Case 29 is perhaps the most interesting of all.

Case 28.—An Indian business man with hypertension and some aortic incompetence arrived in England, having travelled by sea, complaining of increasing dyspnoea and of attacks of nocturnal paroxysmal dyspnoea. The history also suggested that he had had several attacks of slight pulmonary oedema. The heart was enlarged. The electrocardiogram showed evidence of left ventricular hypertrophy, and while in England he developed congestive heart failure, for which he was taken to hospital. Although far from well, he wished at all costs to make the journey back to India, where his family lived, and to which country his friends had returned. It was decided that this could safely

FIG. 3.—Case 29. Antero-lateral x-ray picture of chest. The heart shadow is typical of advanced rheumatic carditis with enormous dilatation of the heart as a whole.

be done by air, and he made a transit of 9,850 miles by this means. A year later, except for a little weakness, he was keeping reasonably well.

Case 29.—A girl of 19 was first seen in 1949, when she had an extensive rheumatic heart disease. The history suggested the possibility of pericarditis 18 months previously, and physical examination showed very great enlargement of the heart, auricular fibrillation, and systolic and diastolic murmurs at the apex. Broadbent's sign was positive in the interspaces behind on the left. The x-ray film (Fig. 3) showed that the heart was enormous; the transverse diameter of the chest was 23.5 cm. and that of the heart, by orthodiagraph, was 19.5 cm. In spite of the extent of organic change she has remained symptomatically remarkably well, and flew with her father from San Francisco to Australia via the Philippines without symptoms. In recent years she has flown more than 13,000 miles.

Case 30.—A woman aged 41 with mitral stenosis, normal rhythm, and pulmonary hypertension had had increasing shortness of breath with several attacks of severe paroxysmal dyspnoea before her journey from Singapore to London. She was found to have a severe degree of narrowing, the mitral orifice measuring 1.5 by 0.5 cm. at the time of operation. She has now returned to her home in the Far East.

Comment

These examples from many different varieties of cases of organic heart disease would seem to show that flying is perfectly safe when the heart is well compensated, and that it is a reasonable risk in patients whose state of compensation is not perfect, provided that the journey is necessary, or provided it is of such personal importance to the patient that he is prepared to take what can accurately be described as a very moderate risk. Generalizations as to suitability or unsuitability for flying cannot be made. Every case must be considered on its merits.

This opinion is confirmed by figures obtained from a recent survey carried out by the Medical Committee of the International Air Transport Association, which includes figures from 13 different air lines. It seems that on a five-year average one cardiac death has occurred per 1,113,000 passengers carried, and that one cardiac death has occurred per 800,000,000 passenger miles.

Conclusions

Thirty individuals, all with organic cardiovascular disease, are shown to have been able to undertake journeys by air successfully. They comprised most of the common varieties of severe organic heart diseases. In all cases the state of cardiac compensation was good at the time of flying, and in no patient did such air travel deleteriously affect the heart or the hypertension, either at the time or subsequently.

Adequate pressurization of the aeroplane must be assured in such cases. This point must be confirmed with the airport officials as an essential preliminary.

The benefit of the short air journey must be set against the disadvantage of the longer sea transit in such patients as may require to be in close contact with specialized medical care for therapeutic or other purposes, and who yet need, perhaps for personal reasons, to make a long journey.

The establishment of the "American College of Angiology" is announced. This new organization has been formed by physicians and surgeons interested in diseases of the blood vessels. The College, whose official journal will be *Angiology*, is "dedicated to the teaching, research, and dissemination of knowledge concerned with the science and practice of angiology."

GASES ADMINISTERED IN ARTIFICIAL RESPIRATION

WITH PARTICULAR REFERENCE TO THE USE OF CARBON DIOXIDE

A Report to the Medical Research Council by its Committee* for Research on Breathing Apparatus for Protection against Dangerous Fumes and Gases

WRITTEN BY

Dr. K. W. DONALD

AND

Professor W. D. M. PATON

John Hunter suggested, in 1776, that inflation of the lungs with oxygen would be a valuable procedure in resuscitation. In 1780 Chaussier (see Hahn, 1899) administered oxygen in asphyxia of the newborn and later devised a laryngeal tube for this purpose. Early in the present century oxygen was being used increasingly in attempted resuscitation. However, in 1920, Henderson and Haggard reported that 90% oxygen and 10% carbon dioxide caused more rapid elimination of carbon monoxide in experiments on dogs. In later papers they recommended a mixture of 95% oxygen and 5% carbon dioxide for carbon monoxide poisoning, ether or alcohol intoxication, or for respiratory failure due to any cause. These workers also made a great contribution by persuading the authorities concerned that there was no efficient apparatus generally available for the administration of oxygen or other gases and that there was an urgent need for portable apparatus with properly fitting masks. Nicloux *et al.* (1925), Walton *et al.* (1926), and other workers could not confirm the great increase of carbon monoxide elimination with added carbon dioxide reported by Henderson and Haggard, and continued to support the use of pure oxygen only. Nevertheless, mixtures containing carbon dioxide were adopted almost universally for use in resuscitation.

Since this time evidence has accumulated against the use of carbon dioxide for this purpose, and recently the Medical Research Council Committee for Research on Breathing Apparatus for Protection against Dangerous Fumes and Gases recommended (unpublished memorandum) that, in first-aid practice, pure oxygen and not oxygen and carbon dioxide (carbogen) be administered to persons suffering from respiratory failure or respiratory depression and requiring manual artificial respiration. This recommendation was stated in simple terms, and it is now considered desirable that the reasons for abandoning "carbogen" should be given in greater detail. It is to be emphasized that the recommendation applies only to the resuscitation of subjects suffering from respiratory depression or failure and requiring immediate manual artificial respiration.

The urgent decision on whether artificial respiration is required may be very difficult. It is often hard to assess the degree of respiratory failure by looking at the movements of the chest or the colour of the patient.

*Members of the Committee: Professor Sir Bryan Matthews (chairman), Mr. S. H. Clarke, Mr. F. Dann, Professor E. A. Pask, Professor W. D. M. Paton, Dr. J. M. Rogan, Dr. J. S. Weinert, Mr. A. H. A. Wynn, and Dr. K. W. Donald (secretary).

* First-aid workers rightly err on the side of safety, and artificial respiration may be given to patients who are not in respiratory failure.

Causes of Respiratory Failure

The various types of respiratory failure seen by first-aid workers are as follows:

1. There are those persons who have become unable to ventilate their lungs because of drowning, asphyxiation, or strangulation and are suffering from severe oxygen lack and carbon dioxide retention.

2. There are those subjects who have been breathing an atmosphere deficient in oxygen and who have been able to increase their ventilation in response to increasing anoxaemia, thus washing out a considerable amount of carbon dioxide. However, in any dangerous atmosphere, anoxia will subsequently cause central respiratory depression, and these subjects will ultimately suffer from reduced ventilation and carbon dioxide retention.

3. There are those patients who have been able to ventilate their lungs freely with air but are rendered anoxaemic by the combination of haemoglobin with carbon monoxide, with resultant interference with oxygen transport. Animal experiments show that so long as the impaired oxygen transport has not caused respiratory depression there is little immediate danger (Schwerm *et al.*, 1948). But when respiratory failure supervenes, even the limited amount of available haemoglobin will no longer be oxygenated and very grave anoxaemia will occur. It is the first-aid treatment of such subjects requiring artificial respiration which is being considered here. The further treatment of surviving patients after first aid presents a special problem in so far as they may still have large quantities of carboxyhaemoglobin in the blood.

4. There are those persons who have been exposed to irritating gases and have developed pulmonary oedema. Cases of drowning may also have pulmonary oedema as well as water in the lungs. In such instances alveolar ventilation is grossly disturbed, and, added to this, the transfer of oxygen across the pulmonary membrane is impaired.

5. There are those subjects in whom electric shock or gaseous, volatile, or ingested poisons have caused acute central respiratory failure with consequent oxygen lack and carbon dioxide retention in an otherwise normal environment.

In all these instances there is cessation or severe depression of respiration, and urgent danger of permanent asphyxial damage to the vital centres even when the patients are returned to a normal environment. Unless artificial respiration is started very quickly they will die. (It is assumed in this discussion that irreversible circulatory failure has not occurred.) It must be emphasized here that it is *immediate* artificial respiration that is the major life-saving procedure; and that if it is efficiently carried out it will save many lives whether air or oxygen is breathed. The administration of oxygen is a most important ancillary measure, and it is useful to discuss the advantages so obtained before considering the use of carbon dioxide.

Advantages of Oxygen Therapy in Resuscitation

In general terms, the immediate danger is the death or irreparable damage of vital structures (the medullary centres, brain, and myocardium) from lack of oxygen. Even the smallest rises of oxygen tension in the lungs and body must therefore have a favourable effect in the few critical minutes during which the damage may become irreversible.

The efficient distribution of the inspired air to the alveoli may be impaired by secretions, exudates, haemorrhages, or fluid in the air passages and air spaces. Further, the abnormal air movement in and out of the lungs produced by artificial respiration appears to cause serious deficiencies of the proper distribution of inspired air to the individual alveoli; and oxygenation of blood flowing through the lungs may be subnormal even when normal or greater than normal ventilation is being induced (Gordon, Prec, *et al.*, 1951). The administration of high tensions of oxygen will go far to overcome the effects of poor gas distribution and to ensure that blood passing through the alveoli will be adequately oxygenated.

If there is oedema fluid in the alveoli or alveolar walls, then there will be considerable interference with the diffusion of oxygen from the alveoli to the venous blood flowing through the alveolar capillaries. The administration of oxygen will greatly increase the oxygen diffusion gradient, with resultant improvement in the transfer of oxygen to the blood.

Even if distribution and diffusion are not greatly impaired there will be a small but significant increase in the oxygen actually dissolved in the blood which will increase the initial oxygen diffusion gradient to the tissues. Although this effect cannot be great, it may turn the tide in favour of the survival of vital structures in the early critical moments of resuscitation. An extreme example of how small a quantity of oxygen may decide between death and survival is seen in Brucer and Swann's work (1950) on asphyxiated dogs, where 2% oxygen in nitrogen prevented the death of these dogs in the critical period following asphyxia.

In carbon monoxide poisoning, in view of the danger of anoxic brain damage even without respiratory failure, the administration of oxygen is often as urgent a necessity as artificial respiration. A further advantage of the increased tension of oxygen in the blood is that it will favour the dissociation of carboxyhaemoglobin.

The advantages of giving oxygen during resuscitation by artificial respiration are thus unqualified.

Carbon Dioxide Therapy in Resuscitation

Although carbon dioxide has been given with oxygen to subjects with respiratory failure during the last 30 years, there has been a great deal of uncritical thought concerning the use of this gas, and an attempt needs to be made to define with greater care the physiological situation involved. The main problem under consideration is whether the administration of additional carbon dioxide to persons with respiratory failure, who are being artificially ventilated, has any stimulant or other desirable effects.

The most straightforward view is that these subjects are suffering not only from profound anoxaemia but also from carbon dioxide retention; that artificial respiration is instituted to ensure normal or high oxygen tensions in the lungs and to remove both the excess carbon dioxide and that being produced by body metabolism; and that additional carbon dioxide is unnecessary because of the excess already present.

But this view has been questioned. It has been claimed that persons suffering from respiratory failure may have low body tensions of carbon dioxide and that this gas should therefore be administered to such cases. However, this has never been demonstrated under first-aid conditions, and it is clear that any subject who has remained capable of maintaining such efficient ventilation that it causes a lowering of the body pCO_2 is not in respiratory failure. Further, the postulated syndrome of respiratory failure with low levels of carbon dioxide in the living body, in which metabolism continues, implies the removal of carbon dioxide without breathing. There is, however, the remote theoretical possibility that the body metabolism and carbon dioxide production are so immediately and greatly reduced under extremely anoxaemic conditions that complete respiratory failure and abnormally low carbon dioxide levels can occur simultaneously. Reliable and precise evidence on this point is not available in the human subject, but clinical research has always shown normal oxygen uptakes and carbon dioxide production during fairly severe anoxaemia (Donald *et al.*, 1952).

Grodins *et al.* (1946) have studied this point with some care in dogs in which asphyxia was produced by tracheal obstruction or by the inhalation of nitrogen. In the former case an early respiratory acidosis was reinforced by a severe metabolic acidosis, such that, by the time the circulation failed, the arterial pCO_2 was 65 mm. Hg (control value in this series, 36 mm. Hg). In fatal nitrogen asphyxia the early respiratory alkalosis, due to hyperventilation before

respiratory failure, was overcome by a later respiratory and metabolic acidosis, so that both the arterial blood acidity and carbon dioxide tensions were above normal when circulation failed. Another important finding was that, if artificial respiration with air at the animal's control ventilatory volumes was then begun, the arterial pCO_2 and hydrogen-ion concentration continued to rise until spontaneous respiration was resumed. This effect was attributed by these workers to the oxygenation of the haemoglobin releasing carbon dioxide, to the sweeping of metabolic acid products formed during asphyxia in the now restored circulation, and to the resumption of normal aerobic carbon dioxide production. They also showed that, on resumption of spontaneous breathing, hyperventilation occurred in an attempt to lower the pCO_2 and compensate the metabolic acidosis.

Summarizing, the theoretical possibility of such severe and immediate depression of metabolism by anoxia that low carbon dioxide levels could occur with anoxic respiratory failure was not substantiated. Low carbon dioxide levels were found only during hyperventilation due to anoxia before respiratory failure had occurred. After anoxic respiratory failure there was an increase of body pCO_2 and metabolic acidosis even in those animals which had previously hyperventilated considerably. When the respiratory centre recovered, as a result of oxygenation following artificial respiration, it was then able to respond to the increased concentrations of carbon dioxide and hydrogen ions which were already present in the body.

It is not definitely stated by those who advise the use of carbon dioxide in resuscitation whether they wish to induce a rise of the body pCO_2 or not, but one must presume this to be their aim. If this is so, then, if oxygen is available, one could ensure adequate oxygenation and a rise of body pCO_2 by deliberately maintaining low ventilatory volumes; the administration of exogenous carbon dioxide would thus be unnecessary. It is well known that artificial respiration under various circumstances may fail to achieve adequate pulmonary ventilation (Gordon, Affeldt, *et al.*, 1951; Nims *et al.*, 1951), and it is certain that further carbon dioxide retention occurs in many subjects receiving artificial ventilation and breathing only air or pure oxygen.

When a subject receiving artificial ventilation is given added carbon dioxide to the oxygen being administered the following events occur. The addition of 5-7% carbon dioxide to the inspired gas without any simultaneous increase in ventilatory volumes will cause an almost immediate rise of the pCO_2 in the alveoli of the same order—that is, with 5-7% carbon dioxide = 36-50 mm. Hg (Fenn *et al.*, 1946). In those subjects who are receiving adequate ventilation to begin with, the initial alveolar pCO_2 would be about 40 mm. Hg (5.5%). Thus the alveolar pCO_2 will rise to 76-90 mm. Hg (10.6-12.6%). If the subject is not being adequately ventilated or is still suffering from gaseous acidosis, then the alveolar pCO_2 will rise to far higher figures (15-25%). The arterial pCO_2 and that in the well-circulated organs, including the central nervous system, will also rise to these levels. Evidence is presented that such tensions in the body, particularly in subjects who have suffered nearly fatal anoxaemia, so far from being beneficial, are in fact harmful.

The advocates of carbon dioxide administration may argue that the artificial ventilation should be appropriately increased to avoid an undesirable rise of carbon dioxide tension in the body. The simultaneous administration and vigorous removal of a therapeutic agent is treatment reduced to absurdity. It has been suggested that enough carbon dioxide should be given with the oxygen so that with carefully judged artificial ventilation there is a "slight" rise of pCO_2 which will act as a "respiratory tonic." Granting this was desirable, it would be most difficult to achieve even by a team of respiratory experts with all the aids of modern science, and certainly impossible in first-aid conditions.

From all these considerations it is evident that the administration of carbon dioxide under first-aid conditions to a subject in respiratory failure who is receiving artificial respir-

ation is an uncertain and uncontrolled form of therapy with grave risk of high and dangerous tensions of carbon dioxide being induced in the subject.

Possible Dangers of Overventilation

It has been argued that efficient artificial ventilation may wash out such large quantities of carbon dioxide that it causes a depression of the body pCO_2 to below normal levels (acarbica), and that carbon dioxide should be administered to counteract this. Overventilation can certainly occur with mechanical respirators of the Drinker type. It has also been reported in patients with severe poliomyelitis under treatment, but there are always several important factors contributing to these sustained high ventilatory volumes—muscular paralysis, tracheotomy with intubation, and air or oxygen given at positive pressure (Astrup *et al.*, 1954). Indeed, the assisted respiration in such cases is very similar to the "controlled" respiration used in modern anaesthesia.

However, overventilation is most unlikely to occur for any period when manual methods of artificial respiration are used under first-aid conditions on unconscious persons who have been rescued from nearly fatal asphyxia and who not only have severe carbon dioxide retention but may also have some degree of respiratory obstruction and other lung damage. Nims *et al.* (1951), who studied the very effective "push-pull" methods, strongly support this view, and emphasize that the high ventilatory volumes obtained cannot be maintained for very long periods under first-aid conditions. Further, even if overventilation occurred occasionally, there can be no doubt that such efficient washing out of carbon dioxide would be too unusual to warrant the administration of carbon dioxide to raise the body pCO_2 in all cases. Even if such instances could be diagnosed, and carbon dioxide given, then a gaseous acidosis would be rapidly induced unless the volumes being ventilated were even further increased—an improbable event under first-aid conditions.

Finally, it may be pointed out that if a patient is "acarbica" while receiving artificial ventilation the resulting lack of respiratory stimulus will have no significant effect on the volumes being artificially ventilated or on the oxygenation of the blood, and the cessation of artificial respiration for a short time will cause the alveolar and arterial pCO_2 to rise to stimulating levels. There is no evidence that a period of low body pCO_2 will cause any damage to the centre, or any other part of the body, provided that oxygenation is adequate, and, in the presence of continued metabolism, such a state of affairs can only be short-lived under first-aid conditions. It is underventilation that is the main danger in resuscitation.

Carbon Dioxide as a Respiratory Stimulant

Although it has been shown that the administration of carbon dioxide during artificial respiration is an uncontrolled and uncertain form of therapy, it is still important to consider whether an induced rise in body carbon dioxide will increase the likelihood and degree of spontaneous activity of the respiratory centre. The effect of increased levels of carbon dioxide on humans or animals in respiratory failure not being artificially ventilated must therefore be reviewed.

If a normal subject is given 5% carbon dioxide then his respiratory centre will increase its activity, with a resultant increase in ventilation that will maintain nearly normal tensions of carbon dioxide in the lungs and body. Thus, although there is an increase of activity of the centre, it is a defensive increase and there is no evidence that it improves the condition of the centre or organism. It merely avoids an undesirable gaseous acidosis. This increase of normal respiratory activity due to carbon dioxide is loosely termed "stimulation." Stimulation is a vague term which has erroneously implied, to many people, that the exhibition of carbon dioxide will cause an increase of viability or efficiency of a failed or failing respiratory centre under all

circumstances. Yet it has long been known that the depressed respiratory centre becomes less and less able to respond, or actually incapable of response, to increased tensions of carbon dioxide. Many physiologists assess the degree of depression of the centre by drugs (such as ether, chloroform, morphine, pentobarbitone, chloralose, urethane, cyclopropane, polamidone, and pethidine) by the diminution of this response (Trevan and Boock, 1921; Schmidt, 1924; Dripps, 1947; Wang and Nims, 1948; Remy, 1950). The administration of carbon dioxide to a person with respiratory depression who is not being artificially ventilated will therefore inevitably result in further carbon dioxide retention.

In experiments on the effect of these increased tensions of carbon dioxide in respiratory failure, Schmidt (1924) showed that the administration of carbon dioxide to dogs with respiratory depression due to morphine and heroin actually reduced their minute-volume in many instances. Frequently carbon dioxide inhalation was followed by permanent respiratory failure even in animals with previously adequate ventilation. Ivy *et al.* (1947) gave 5% carbon dioxide to animals with developing respiratory failure due to anoxia, and showed a progressive decrease of the response to this gas. In a number of instances, as in Schmidt's experiments, the volumes ventilated were decreased and the gas not only increased the degree of respiratory failure but also precipitated circulatory failure.

Not all these experiments are feasible or desirable in the human subject, but there is a great deal of evidence emphasizing the dangers of increased tensions of carbon dioxide in the body of humans.

Effects of High Levels of Carbon Dioxide

Anaesthetic and Narcotic Effects

Carbon dioxide was, in fact, the first gaseous anaesthetic used surgically, and Hickman performed surgical operations on animals under its influence as long ago as 1824 (see Duncum, 1947). Paul Bert (1878) subsequently confirmed that high concentrations of carbon dioxide (15% upwards) rendered normal animals unconscious, and again suggested its use as an anaesthetic during surgical procedures. Since that time many workers have described the depressant narcotic effect and the antagonism to anaesthetics produced by high concentrations of carbon dioxide in animals (Gellhorn and Heymans, 1948; Stein *et al.*, 1949; Pollock, 1949); and in man (Richardson, 1885; Brown, 1930; Seever, 1944; Dripps and Comroe, 1947). Stein *et al.* (1949) reported that 30% carbon dioxide for 30 minutes would prevent electrically induced convulsions in man. This implies, incidentally, that the administration of carbon dioxide is likely to weaken the effectiveness of any anaesthetics given during resuscitation. These reports concern the inhalations of high percentages of carbon dioxide by normal subjects, in whom even a normal response to carbon dioxide was unable to prevent severe gaseous acidosis with its attendant dangers.

Over 40 years ago Krogh and Lindhard (1913) noted that the administration of oxygen with carbon dioxide appeared to reduce the ventilatory response to the latter gas. Work during the recent war (Barlow *et al.*, 1945; Donald, 1945) showed that in the absence of efficient carbon dioxide absorption in respiratory apparatus, exercising subjects breathing oxygen could readily become anaesthetized by carbon dioxide without appreciating any preliminary respiratory stimulation, and that, in resting subjects, concentrations of 10% or more carbon dioxide in oxygen readily induce unconsciousness.

In controlled respiration, with high oxygen tensions, as used in modern anaesthesia, it has been shown that a relatively small decrease of minute-volume will cause the body pCO_2 to rise to narcotic levels (Orton, 1952; Dripps, 1952), and levels of up to 20% carbon dioxide have been recorded (Dripps, 1947; Buckley *et al.*, 1953); this may cause considerable delay in return of consciousness (cf. Scurr, 1954; Gray and Fenton, 1954). All anaesthetics and narcotics will,

if given in larger doses, finally cause medullary failure, and there is no reason to believe that carbon dioxide is an exception.

It has only recently been appreciated that carbon dioxide narcosis, far from being an academic curiosity, is not uncommon in routine clinical practice (Barach, 1948; Donald, 1949; Comroe *et al.*, 1950). If patients with very severely damaged lungs (emphysema, extensive tuberculosis, bronchiectasis) develop bronchopneumonia, severe bronchitis, or status asthmaticus, they frequently suffer extreme and fairly sudden anoxaemia—that is, arterial blood saturation of 20 to 40%. The body pCO_2 of these very ill patients rises considerably as anoxaemia develops, and this would suggest the development of some degree of anoxic central respiratory failure (Donald, 1953) with resultant depression of ventilation. In this state the respiratory centre appears to be insensitive to carbon dioxide, but still responds to some extent to anoxaemic stimuli from the sino-aortic zones. The administration of oxygen to such patients, although life-saving, does not cause an immediate return to normal respiratory behaviour, and, as the main effective stimulus to the damaged centre under these conditions is now removed, the patient ventilates even less, with the retention of increasing amounts of carbon dioxide and, frequently, resulting loss of consciousness. Removal of the oxygen under these conditions will often cause marked increase in ventilation and reduction of carbon dioxide levels with return of consciousness even though the extreme anoxaemia returns. It is to be emphasized that these very ill patients are not receiving artificial ventilation. Recently a Drinker respirator has been employed to allow improvement of oxygenation in such cases without dangerous carbon dioxide narcosis (Boutourline-Young and Whittenberger, 1951; Stone, 1953; Lovejoy, 1954).

Even very grave respiratory infections rarely cause such a severe degree of anoxaemia in previously healthy persons with hitherto normal lungs. Further, they do not have the initial respiratory acidosis and increased body base which is usually found in the patients described above. However, Engström (1954) and Christie (1954), workers of great experience in the field of poliomyelitis, state that carbon dioxide intoxication does occur in the acute phases of the disease, particularly with oxygen therapy and inadequate ventilation. Although it is still uncertain whether a similar syndrome would occur in a healthy subject who has been exposed to acute and nearly fatal anoxaemia due to drowning or asphyxiation, it would seem very likely, and animal experiments strongly support this view. Marshall and Rosenfeld (1936) caused partial respiratory failure in healthy dogs by severe anoxia and showed that the administration of oxygen appeared to remove the only remaining effective drive of spontaneous respiration and resulted in a further reduction of respiratory volumes with retention of carbon dioxide.

These clinical observations, and the experiments of Schmidt (1924), Ivy *et al.* (1947), and Marshall and Rosenfeld (1936), all suggest that a respiratory centre which is depressed either by drugs or anoxaemia, although still capable of a considerable response to the anoxaemic stimulus, may no longer respond to increased carbon dioxide or hydrogen-ion concentration, and that any attempt to increase the body carbon dioxide tension further will not only be ineffective but also dangerous. They also emphasize that efficient artificial ventilation is the keystone of resuscitation even when oxygen is being administered.

Vascular Effects

Low concentrations of carbon dioxide have, initially, a stimulant effect on the vasomotor centre with peripheral vasoconstriction. However, concentrations of 15% or greater appear to cause vasomotor depression (Nowak and Samaan, 1935; Liljestrand, 1948). There is also a direct capillary-dilating action which may well contribute to peripheral failure. Rats and guinea-pigs exposed to a cold environment fail to maintain their body temperature

normally when exposed to 3% carbon dioxide. This may be due not only to the peripheral circulatory changes but also to depression of the thermo-regulatory centres (Gellhorn, 1937). Although it is not intended to discuss this in detail here, circulatory failure is often the critical cause of death even in persons with respiratory failure (Swann, 1953), and any contributory cause of peripheral vasodilatation and fall in blood pressure must be avoided.

MacDonald and Simonson (1953) have reported considerable abnormalities of cardiac rhythm in human subjects after very brief periods (23 to 63 seconds) of acute respiratory acidosis (30% carbon dioxide). Altschule and Sulzbach (1947) describe electrocardiographic signs of reversible myocardial injury in subjects receiving 5% carbon dioxide in 95% oxygen by intratracheal tube. Under anaesthesia vagal action is said to be potentiated by hypercapnia (Campbell, 1950), with the danger that usually harmless manipulations in the respiratory tract may stop the heart. These adverse effects on the heart are highly undesirable when life is, in any case, threatened by the possible onset of irreversible cardiac failure or acute ventricular fibrillation.

Carbon dioxide administration, even in small concentrations, causes dilatation of the cerebral vessels (Wolff and Lennox, 1930; Kety and Schmidt, 1948). Further, there is a considerable rise of cerebrospinal fluid pressure—that is, up to 350 mm. of water with 10% carbon dioxide (Cobb and Fremont-Smith, 1931). A similar rise of cerebrospinal fluid pressure was demonstrated in patients who become unconscious with oxygen therapy (Davies and MacKinnon, 1949), and later was attributed (Donald, 1949) to carbon dioxide narcosis and associated cerebral vasodilatation. It has been suggested that this cerebral vasodilatation will cause a beneficial increase of blood flow to the whole cerebrospinal axis; and yet the fact that many such patients are unconscious, are hypoventilating, probably because of respiratory failure, and have a great increase of intracranial pressure, often with papilloedema, would emphasize that such high tensions of carbon dioxide in the body are, if possible, best avoided.

"Off Effect"

Even in normal subjects the sudden cessation of 5% carbon dioxide inhalation, after exposure for periods of half an hour or more, causes "shock-like" symptoms such as pallor, shivering, vomiting, and severe malaise (Alexander *et al.*, 1939). Miller *et al.* (1952) reported serious or fatal cardiac irregularities in 18 out of 19 dogs on returning to air-breathing after several hours' carbon dioxide (30 to 40%) administration; 15 of these animals died, 12 from ventricular fibrillation. Cyclopropane anaesthesia has been found, if respiration is not assisted, to cause alveolar carbon dioxide tensions of up to 20%. Abrupt withdrawal of the anaesthetic mixture, and hence also of the high levels of carbon dioxide, produces the condition originally called "cyclopropane shock" but now recognized to be caused by the removal of a severe hypercapnia. It is accompanied by a dangerous fall in blood pressure, cold clammy skin, bradycardia, and sometimes delirium (Dripps, 1947; Buckley *et al.*, 1953).

Summary and Conclusions

The value of the administration of oxygen and carbon dioxide to subjects in respiratory failure and receiving artificial respiration is reviewed. It is emphasized that without immediate artificial respiration all other measures will be useless. However, the administration of oxygen to patients receiving artificial respiration is given unqualified support.

The value of the administration of carbon dioxide under these conditions is considered in greater detail. The possibility of low levels of body pCO_2 in the presence of respiratory failure prior to resuscitation is discussed, and reasons are given why it is thought that this syndrome does not occur. If carbon dioxide is administered during

artificial respiration, then the partial pressure of carbon dioxide in the lungs and well-circulated organs will be raised to highly abnormal levels unless a considerable further increase of ventilation can be induced. Under first-aid conditions the rescue worker will never know the initial levels of carbon dioxide in the body of the subject, nor the ventilatory volumes he is producing. The administration of carbon dioxide under these conditions is therefore uncontrolled and uncontrollable, and in many cases is apt to cause a dangerous intensification of carbon dioxide accumulation and intoxication.

The question of possible overventilation and the lowering of the body pCO_2 by manual methods under first-aid conditions is considered. It is concluded that this is very unlikely to occur for any significant period, that it would not alter the prognosis, and that, even in the most improbable event of its being diagnosed by a first-aid worker, carbon dioxide therapy would be unnecessary and undesirable.

The ability of even slight-to-moderate rises of body pCO_2 to increase the viability and promote further spontaneous activity of a failed or failing respiratory centre is also questioned.

The dangers of high concentrations of carbon dioxide in the body are emphasized. These include depression of the central nervous system and respiratory centre, vasomotor depression with peripheral vasodilatation, dangerous cardiac arrhythmias, and fall in body temperature. The sudden removal of the gaseous acidosis also causes severe symptoms. Barcroft and Margaria (1931) said of even normal subjects that "the breathing of 7.5% carbon dioxide for 20 minutes produces a shock from which the system does not wholly escape for some hours or perhaps even a longer time."

For these reasons it is recommended that in first-aid practice carbon dioxide should not be administered with oxygen in the resuscitation of subjects requiring and receiving artificial respiration.

CAN WARD ROUNDS BE A DANGER TO PATIENTS WITH MYOCARDIAL INFARCTION?

BY

KLAUS A. J. JÄRVINEN, M.D.

Lecturer in Internal Medicine, Assistant Physician-in-Chief at the First Medical Clinic of the University of Helsinki, Finland

Like physical effort, emotional stress may bring on anginal pain in a patient suffering from a disease of the coronary arteries. The contributory effect of mental tension can often be shown even in cases of myocardial infarction. Besides physical rest, complete mental rest is a fundamental requirement in the treatment of myocardial infarction (Miller, 1942; Stroud, 1945; White, 1945; Scherf and Boyd, 1947; Friedberg, 1950; Levine, 1951). Physical rest is usually easy to organize: bed rest in itself guarantees it. A more difficult factor to control is mental rest. Internal mental stresses may affect the patient to such a degree that it is difficult to control them. This makes it all the more necessary that attention should be devoted to the external factors disturbing the patient's peace of mind.

Contacts in Hospital

For the in-patient, contact with others doubtless causes the strongest psychological stresses to which he is exposed. The persons with whom the patients come into contact are the patient's relations and friends, other patients, and hospital personnel.

Relations and Friends.—It is often found that the visit of a certain relative or friend to a patient with myocardial infarction does not have the desired effect of soothing him. On the contrary, one result of such a visit may be increased pain. This is an occurrence that can, of course, be avoided

if the attending physician, in serious cases, decides which visitors may be allowed to see the patient, and how often.

Other Patients.—The patient with myocardial infarction reacts differently towards his fellow-patients than towards his relations. The influence of the patient in the next bed may be soothing, that of another irritating. By choosing the patient's bed the mental stress arising in this way may be eliminated. In serious cases of myocardial infarction the practice in our clinic is often to place the patient in a single-bed room to start with.

Hospital Personnel.—Of the hospital personnel, only nurses and physicians come into close contact with cases of myocardial infarction. In selection and training of the nurses emphasis is placed upon those qualities that have a reassuring effect on the patient. It may be taken as read that credit for preserving the patient's peace of mind must go to the nurses. What is more difficult to assess is whether the attending physician may not introduce emotional stresses deleterious to the patient. Calmness of the doctor and wisely worded pronouncements by him may have a beneficial influence on the patient's worried state of mind. On the other hand the patient with myocardial infarction, knowing that his condition is dangerous, is probably anxious about the doctor's verdict. This may induce a harmful state of excitement. My personal experience has been that on several occasions, just as the ward round has advanced to the patient suffering from coronary disease, or, more often still, to the patient preceding him, he gets an attack of angina pectoris, in some cases fatal.

The present paper is an attempt to ascertain, by analysing the fatalities from sudden myocardial infarctions, whether the ward round may be a danger to such patients. No analysis of the anginal pain felt by these patients and possibly associated with the doctor's round has been included, for the simple reason that it is generally impossible to show these pains objectively.

Material

The material investigated is taken from the 373 patients with myocardial infarction treated in 1950-3 at the Third Medical Clinic of Helsinki University, and comprises those who died of acute myocardial infarction while in hospital. Where the death occurred later than six weeks after the acute myocardial infarction the case is not included. The series consists of 84 cases in which death occurred—69 male and 15 female. The average age of the male patients at the time of death was 57.4 years, and of the female patients 66.5 years. In 47 cases the diagnosis was confirmed

TABLE I.—Analysis of 84 Deaths from Acute Myocardial Infarction

Age Group	Male	Female	Lapse of Time from Onset of Infarction to the Moment of Death		
			24 Hours	7 Days	8 Days-6 Weeks
30-39	1	0	—	—	1
40-49	12	0	7	2	3
50-59	26	1	6	6	15
60-69	24	2	7	8	18
70-79	5	5	3	5	2
80+	1	0	1	—	—

at necropsy. Table I gives details of the age and sex distribution of the 84 cases and the lapse of time between the onset of infarction and death. It shows that the first 24 hours accounted for a considerable proportion of the total deaths. A probable contributing factor is that all the patients lived in the neighbourhood of the clinic; this means that serious cases were admitted to hospital more or less immediately after the attack of infarction. In hopeless cases therefore, death occurred in the hospital more often than would have been the case had the distance of transportation been longer. In addition, Table I shows that 45 of the patients died within seven days of the attack. As the first week must be regarded as a very critical period for these patients, it was thought undesirable to draw conclusions

from them even when a ward round coincided with death. Only when the patients survived for more than seven days have the cases been analysed.

Results

The 39 patients who died more than seven days (but less than six weeks) after a sudden attack of myocardial infarction included six whose death was closely associated with a ward round. Table II gives details of these six cases. As the

TABLE II

6	68 F	..	12	9	+

factors associated with the last ward round are important in these cases detailed histories are given below.

Case 1.—A chief accountant aged 58 had had a severe attack of angina pectoris at home. Twenty-one days later, as the pain persisted, he entered hospital. Examination indicated a myocardial infarction of the posterior wall. There was no pyrexia. The E.S.R. was 36 mm. in one hour. The customary anticoagulant treatment was not given. From the beginning he was allowed to sit daily in an easy chair. Slight cardiac insufficiency disappeared with mild digitalis treatment. Emotionally he was abnormally labile. Up to the sixteenth day in the ward his condition had been satisfactory, both subjectively and objectively. That day, however, the physician-in-chief was on his round; the patient became more excited than usual, and when the round reached him he began to feel nausea, which soon developed into severe thoracic pain. In spite of the doctor's efforts, death ensued in approximately two hours (at 12.35 p.m.). **Findings at Necropsy.**—Thrombosis of right coronary artery. Thrombosis of superficial anterior descending branch and of left circumflex coronary artery, with myocardial infarction. Congestion of the lungs. Mild congestion of the liver. Mild nephrosclerosis.

Case 2.—A switchman aged 61 had had a severe anginal attack two days before admission, followed by slighter but persistent pain. Repeated E.C.G.s gave no positive indication of a fresh myocardial infarction, although signs of myonecrosis were seen. On the basis of the clinical picture, however, the diagnosis was regarded as clear. A temperature of 100.4° F. (38° C.) persisted for five days, and his E.S.R. rose to 99 mm. After the temperature had subsided slight signs of cardiac insufficiency were noted. Careful digitalis treatment was started, and bed rest and anticoagulant treatment were continued throughout his stay in hospital. The patient seemed calm but slept poorly. On the seventeenth day, as the ward doctor approached his bed, he had a severe attack of pain and died immediately (at 9.15 a.m.). **Findings at Necropsy.**—Thrombosis of left coronary artery. Myocardial infarction and cardiac hypertrophy and dilatation. Thrombosis of left ventricle. Pulmonary congestion, oedema, and emphysema. Small right-sided pleural effusion. Congestion of liver and kidneys. Some softening of the cerebral cortex on the left side. Strawberry gall-bladder.

Case 3.—A works foreman's wife aged 62 two weeks before admission to hospital had had an attack of thoracic pain which did not completely subside with nitroglycerin. An E.C.G. taken on admission showed no clear signs of a fresh myocardial infarction. However, the clinical picture was clear enough to warrant the diagnosis, and the customary treatment with anticoagulants was given. There was no rise in temperature. The E.S.R. reached its peak, 35 mm., at the beginning. Forty-one days after the assumed infarction

the patient died while the physician-in-chief was on his rounds. She had been out of bed for eight days and was impatiently awaiting her discharge from hospital. For several days she had been informed that the physician-in-chief would decide about her discharge on that very round. While he was at the bedside of the patient next to her (at 9.20 a.m.) she began to pant, and jerks were observed in the extremities. Respiration continued for a while, but heart action could not be restored. **Findings at Necropsy.**—Thrombosis of left coronary artery. Myocardial infarction. Apical aneurysm of left ventricle. Thrombosis of left iliac and femoral arteries. Pulmonary oedema.

Case 4.—A painter aged 65 had had a severe attack of thoracic pain three weeks before admission to hospital, followed by persistent distress. The E.C.G. taken in hospital showed signs of an extensive myocardial lesion. Myocardial infarction was considered to have occurred in connexion with the pain. His E.S.R. was 45 mm. in one hour. There was no rise in temperature. Seroreactions for syphilis were positive. The medical history was not indicative of syphilis. Mesaortitis was suspected. He received treatment for cardiac insufficiency, and was given penicillin. After ten days in the ward the patient suddenly fell from his bed when the ward doctor on his round reached the room (at 9.45 a.m.). Cardiac action could not be restored. **Findings at Necropsy.**—Thrombosis of right coronary artery. Cardiac hypertrophy and dilatation. Myocardial infarction. Mural thromboses in left ventricle. Pulmonary congestion, oedema, and emphysema. Congestion of the liver. Specific aortitis. Gall-stones.

Case 5.—A business man aged 67 was admitted to hospital on the day of his attack of myocardial infarction. An E.C.G. showed indications of posterior wall infarction. His temperature rose to 99.2° F. (37.3° C.), and the E.S.R. to 45 mm. in one hour. Apart from the first 24 hours he had no pain while in hospital. He was given the customary treatment with anticoagulants. Recovery seemed to proceed well. The E.S.R. dropped evenly. After four weeks it was 10 mm. in one hour. As the patient insisted, he was promised discharge after 32 days in hospital, treatment to be continued at home. He had waited for the round during which the discharge was to be decided on finally—so much so that he had had his clothes brought to the ward. Immediately after the doctor on the round had granted him permission to go home he began to dress, but collapsed and died by the side of his bed (at 11.35 a.m.). Permission for necropsy was refused.

Case 6.—A female Post Office clerk aged 68 was admitted to hospital for thoracic pain, which had started the night before in connexion with an emotional disturbance. Previously, too, anginal pain was associated almost exclusively with a feeling of resentment. An E.C.G. indicated myocardial infarction of the posterior wall. Her temperature rose in hospital to 99.5° F. (37.5° C.), and the E.S.R. to 58 mm. in one hour. Subjective complaints rapidly subsided in the ward. The customary anticoagulant treatment was given. She was psychically very labile and grew excited over trivialities. After nine days in hospital, and when the physician-in-chief was on his round in the eight-bed room in which she lay sixth, she grew restless as he reached the patient preceding her. On being asked how she felt she began to reply, but suddenly she went highly cyanotic, started to pant, and the heart ceased to function (at 9.30 a.m.). **Findings at Necropsy.**—Right coronary thrombosis. Myocardial infarction. Rupture of left ventricle. Haemopericardium. Congestion of the lungs.

Discussion

Six of the patients who had survived the first seven days but died while still in hospital before six weeks had elapsed from the acute myocardial infarction, died in connexion with the ward round. The occurrence of such a remarkable accumulation of fatalities simultaneously with the ward round cannot be ascribed to coincidence. If the 24 hours

of a day and night are divided into six-hour periods beginning from midnight, the fatalities are distributed over these periods as follows: 11, 10, 7, and 11—thus fairly evenly. In our clinic the ward round in each room takes from a half to one hour. Had the 39 fatalities not occurred during a ward round more frequently than at other hours, only 0.8 to 1.6 fatalities should have occurred during them. But these deaths totalled 5. (In Case 1 death did not occur until two hours after the round, although the fatal attack began during it.)

A closer association between these fatalities than is provided by mere coincidence is strongly suggested by the course of several individual cases. It also seems that the explanation for this phenomenon can be found in the state of excitement that may be brought on in some patients by the doctor's visit. Two deaths occurred when the patients were told that the time for their discharge, so eagerly awaited, had come (Cases 3 and 5). In two cases (Cases 1 and 6) the patient habitually got excited during the visit. Perhaps it was no coincidence that three deaths occurred in connexion with the round of the physician-in-chief, repeated only weekly or bi-weekly in each ward.

On the basis of the foregoing it is possible that there may be a serious hidden risk in ward rounds for the patient with myocardial infarction, since on these occasions he is subjected to an unusually severe emotional stress. This danger is clearly very difficult to avoid in the case of an unusually labile patient, but it is always possible to reduce it. The adoption of the following precautions may lead to improvement in this respect.

(1) To ensure that the attending doctor is aware of the risk, and takes heed of it in his attitude to the patient. According to Stroud (1945), the most important point in treatment is a sympathetic attitude on the part of the doctor towards his patient. (2) It is advisable not to emphasize excessively the importance of ward rounds to a patient with myocardial infarction. Where such emphasis is made it may not be the doctor's fault so much as owing to the attitude of the nursing staff. The patient may well have been told of the great importance of the round of the physician-in-chief, the beds may have been made with great care and speed, and other special preparations made for the expected visit. Presumably the patient's state of mind, susceptible to excitement, receives an added stimulus from this general state of bustle in the ward. This is by no means the case everywhere, but, so far as I can see, these disadvantages increase as the "formal" side of hospital life becomes more pronounced. (3) The administration of sedatives when any signs of a state of excitement are observed in a patient with myocardial infarction is naturally very important. But, obviously, the mental rest secured by this means is not the same as that resulting from a successful removal of the factor accounting for the development of mental excitement.

Summary

Six out of 39 hospital patients affected with acute myocardial infarction who died more than seven days but less than six weeks after the onset of the infarction did so during or shortly after ward rounds. This cannot be dismissed as a coincidence. Four of the ward rounds in connexion with which the deaths occurred involved, even to the casual observer, an unusually heavy mental stress to the patient. In two cases discharge from hospital, eagerly awaited by the patient, was to be decided upon at that very occasion. In another two cases the round was that of the physician-in-chief, made only once or twice a week.

The conclusion is that the ward round may sometimes constitute such a heavy strain on the patient that in cases in which this stress may be deleterious, as in myocardial infarction, it may constitute a danger. Means of reducing this risk are discussed.

ARRESTED MENTAL DEVELOPMENT INDUCED BY LEAD-POISONING

BY

J. W. G. GIBB, M.B., Ch.B., D.C.H.

AND

J. F. MacMAHON, M.A., M.D., D.P.M.

Physician-Superintendent, the Manor Hospital, Epsom, Surrey

This paper is based on the clinical history of a boy aged 7½ who, as result of lead ingestion, suffered arrested mental development and is now a mentally defective person in institutional care. The data on which his case history has been compiled are derived from the interim reports of clinicians who attended him at various stages of his long illness and his mother's account of the sequence of events and their attendant circumstances. The case is reported in part chronologically, and in part in the order in which relevant information materialized, so that the diagnostic problems which arose may be appreciated as they were presented to the physicians concerned and so that the importance of early and adequate diagnosis in such cases may be emphasized.

Case History

The patient's mother, a woman of apparently average intelligence, reported that her son was an only child. His birth weight was 6½ lb. (2.9 kg.), and both pregnancy and delivery were uncomplicated. He developed normally in infancy, sitting up at 7 months, walking at 17 months, and talking at 18 months. By the age of 2 years he had achieved sphincteric control and was repeating nursery rhymes. He was duly inoculated against diphtheria and whooping-cough and the family doctor confirms that he was a normal infant. The mother states quite definitely that the child was more than 3 years old when he had an illness, diagnosed as "food-poisoning" and associated with intestinal symptoms and an itchy rash. In the course of about six weeks the latter faded; but thereafter he developed a cough, worse at night, accompanied with almost continuous vomiting. She says that whooping-cough was prevalent at the time and the illness was so diagnosed, although the child did not "whoop."

A neurologist, consulted when the patient was aged 5, reported that the severe illness, believed to have been whooping-cough, occurred when the child was 2½; but in all other matters confirmed the mother's version of the past history. His opinion was that the severe illness may have been encephalitis, following or complicating whooping-cough, and that its sequelae were regression and an acquired aphasia (both receptive and executive). Thus the child's performance I.Q. was only 58. The mother was therefore advised to send this ineducable boy to an occupation centre while he was kept under observation at the out-patient department. He was given a course of glutamic acid.

The third medical report relates to the patient's condition when he was 5½ and under observation at another hospital. He had been referred because he was unable to talk, ignored

people, and was very fearful. The father, aged 33, was described as being emotionally immature, solitary, and like his son in his inability to form emotional relationships. It seems that incompatibility and housing difficulties caused the parents to separate by mutual consent for a period of a year in 1951-2. On examination the patient was found to be a sturdy child with incontinence of faeces but not of urine. Mentally he was withdrawn, preoccupied, and unable to talk. On the Merrill-Palmer scale his mental age was 3½ years, but full testing proved impossible. During his six weeks in hospital he was noisy at first, but later quieted down; his play activities were simple and he delighted in sand and water. He played with faeces when opportunity offered and he tended to place everything that he handled in his mouth. He did not associate with the other children, and seemed to be so sensitive to the noise they made that he sought comfort from the nurses. On January 31, 1953, he was transferred to a fever hospital with varicella. The diagnosis of his mental condition was "infantile autism." His prognosis was "poor."

The fourth medical report describes the patient's condition when he was seen at his parents' home in October, 1953 (aged 6½). His parents complained that they could not cope with the child because of his extreme restlessness, screaming fits at night, and constant overactivity indoors and out. It was noted that in his restless phases he appeared to be extraordinarily sensitive to noise and covered his ears with his hands to exclude it. As he had become unsuitable for further care at the occupation centre, the parents were at their wits' end and begged for assistance. Ultimately they agreed that the child might be admitted temporarily to a mental deficiency hospital so that they might have a rest.

Developments after Admission to the Manor Hospital

The patient was admitted (without an order) in January, 1954, for a period of seven weeks. His general condition and behaviour were as already reported, and he was found to be very constipated—however, enemata proved to be effective, and after no more than a few weeks on a liberal diet his screaming fits ceased; his general condition improved considerably and he became more co-operative, even regaining the ability to dress himself. He returned home in March, but on April 9 the health visitor reported that his restlessness and his screaming fits had recurred. He was accordingly "dealt with" under section 3 of the Mental Deficiency Act, 1913, and was "placed" at the Manor on May 28.

Clinically, the sequence of events which had attended his earlier short stay was repeated, and after a month he was transferred to the children's ward. Thereafter his condition deteriorated: from being almost hyperkinetic he became dull and languid. He refused food, and his only solace appeared to be tasting rubbish and eating paint scratched from the walls. Appropriate investigations were undertaken and the positive results were: blood Hb. 88%; R.B.C., 4,700,000 per c.mm.—the red cells were hypochromic and punctate basophilia was conspicuous. X-ray examination of the long bones revealed areas of increased opacity, most marked at the lower ends of the femur, radius, and ulna, and the upper end of the tibia.

In the light of these significant findings the mother agreed to give a more detailed account of her son's history at a clinical meeting. She confirmed the details already reported, but not until leading questions were put to her did she state that, before the boy had "food-poisoning" at the age of 3½ years, a set of very old toy lead soldiers had been resurrected for his delectation. These toys left grey dust on his hands, and it was then that he became so constipated and developed cough and vomiting. Although he was very ill there were no convulsions, coma, or paralysis. After a few weeks his physical condition improved, but he ceased to speak and became withdrawn and asocial. By the time he was 4 he had a marked craving for oil, fat, and paint, and discovered discarded (leaded) paint pots and brushes which had been used to decorate the kitchen; *pari passu*, his constipation became complicated with bleeding piles. He lost

previously acquired skills and interests, and took to hiding in cupboards and behind walls of toy bricks. Noise seemed to irritate him and he lost all affection for his parents. At this stage she sought specialist aid, but as treatment had not effected a lasting improvement she reluctantly accepted the inevitable and "placed" her son at the Manor.

Thus the diagnosis of lead-poisoning was made, and it was confirmed beyond all doubt by the further report that a 24-hour specimen of urine contained 435 µg. of lead as compared with 24 µg. in controls of the patient's age group.

Treatment and Progress

Steps were taken to free the circulation of lead. A high-calcium diet supplemented with calcium lactate, iron, and preparations of vitamins D and C was provided; within a week the colic ceased and the constipation was relieved. The child's appetite is now healthy and his complexion positively ruddy. He is more interested in his companions and attempts to join in their games. Noise no longer disturbs him and he is attracted to strangers. He welcomes his mother's visits and sometimes seems to anticipate them. He obeys simple instructions conveyed through the media of voice and gesture. His mutism persists, but he phonates when he hums and croons. He sleeps well and restless overactive behaviour is not so marked, except when he is in strange surroundings. In brief, he is a happier child, but there has been no measurable increase in his cognitive ability. Pica persists, but the casual desultory way he attempts to indulge it is in marked contrast to the drive and energy which attended it some months ago.

In an effort to determine if the patient is an indiscriminate oral experimenter or has certain predilections, a board daubed with eight different items (including fatty, salty, bitter, and sweet substances, together with leaded and non-leaded paints of similar appearance) was placed before him while discreet observation was maintained. In the course of eight minutes he tasted seven different items (he ignored one non-leaded paint) and concentrated almost entirely on just two—fat and lead paint. Three controls of the same age and grading proved to be quite uninterested in the experiment. The very tentative conclusion was reached that he is to a certain extent selective in his taste and has a partiality for fats; but, whether it is the lead or the fat (linseed oil) in the paint and whether "deprivity" or depravity is the motivating factor remains an open question.

Discussion

In the light of after-events it is tempting to speculate about the series of interim diagnoses which marked the progress of this case. Food-poisoning, pertussis, encephalitis, infantile autism, and amentia were, in that order, provisionally postulated to account for the symptomatology; but as the parents seem to have failed to appreciate the relevance of the essential causal factors—pica and lead—it is questionable whether they reported them with due emphasis when they sought advice. Moreover, as children's diets in hospital usually have high calcium and vitamin values it may be assumed that, as occurred at the Manor, once the patient had been under care for a short time the more urgent symptoms were relieved by good feeding. It may be thought that pica was the sequel to pertussis encephalitis and plumbism was its outcome; but, if this contention is correct, encephalitis must have occurred when the patient was about 2½ years old (as reported by the neurologist) and thus before the lead soldiers were "resurrected." The mother, however, insists that the child was more than 3½ years old when he had "food-poisoning" and "whooping-cough," and she is quite certain that he was playing with lead soldiers before he became ill. In the light of this and the implications of other circumstantial evidence that she has adduced, it seems reasonable to infer that the actual sequence of events was as she now describes it.

The signs, symptoms, and treatment of plumbism in children have been described so comprehensively in the literature

that further comment on them is scarcely necessary. It may be observed, however, that hyperacrusis, which so tormented this child, seems to have determined, in part at any rate, his rather hyperkinetic behaviour. Its origin must nevertheless remain a matter for speculation.

Only a score of cases of lead-poisoning in children have been reported during the present century in this country, and, of these, 10 have been described by Burrows *et al.* (1951) and Millichap *et al.* (1952) during the post-war period. They have certain features in common which indicate the need—indeed, the urgent necessity—for appropriate consideration and action by public authorities, medical practitioners, parents, and others concerned with child health.

Pica

Pica is certainly one of these features. Almost indiscriminate oral sampling is of course a characteristic developmental phenomenon in children of less than 2 years; but, if parental management is prudent and well-informed no harm is done. In some, the habit may persist until the sixth or eighth year; in others it may recur, in a more selective fashion, after it has been outgrown: in such cases it may be interpreted as failure to emerge from, or as regression to, the so-called "oral-erotic" phase. As stated by Sheldon (1951) it may be due to "chronic intestinal indigestion" with or without associated enuresis, temper tantrums, or night terrors. It may follow encephalitis, or point towards amentia; but even in low-grade aments it is met less frequently than might be expected. There is no doubt, however, that more often than not it precedes plumbism in children, and, as its serious implications are not always realized, diagnoses may be inadequate unless the relevant questions are asked.

Legislation has certainly served to protect workmen from lead-poisoning, and propaganda appears to be effective in ensuring that painted toys and nursery equipment are lead-free when they leave the factory; but, in this day and age when there is a premium on self-help in the home, the "handyman," and the "handy-woman" too, may unwittingly imperil their children's prospects of normal mental growth and general well-being through carelessly leaving lead-paint containers about the home and applying lead paint to household fittings. Lead paint is still often used on exterior wooden surfaces, and this, in point of fact, was found to be the case at the Manor; formerly it was used much more extensively, and thus may lie (unsuspected) on interior surfaces, masked by more recently applied lead-free coats. The amateur home decorator is, however, apt to believe that the best paints are leaded, and in his enthusiasm he is prone to buy them, perhaps from surplus war stocks sold cheaply in street markets, and then proceed to apply them, with more zeal than discretion, to the new baby's cot or perambulator, toys or play-pen, the kitchen walls, or the dingy recesses around the scullery sink. Millichap *et al.* (1952) listed the sources of plumbism in childhood as follows: painted woodwork, 9; nipple shields, 4; toy soldiers, 2; fumes from burning battery casings, 2; drinking-water, 1; and toilet powder, 1. Thus paint and toy soldiers account for more than half the cases reported in this country during the present century, and the patient described adds to their number.

Mental Sequelae

The grave consequences of lead-poisoning, in terms of mortality, paralysis, paresis, optic atrophy, and epilepsy, are widely recognized, but it is clear that its disastrous effects on the progress of mental development are generally underestimated. Levinson and Zeldes (1939) studied 26 Chicago cases and found that 5 of the patients had died in the acute stage; they followed up only 9 of the survivors for periods not exceeding 3½ years and graded 1 as blind, mute, and helpless, 2 as being epileptic and mentally subnormal, and no more than 3 as being normal, mentally and physically. McKhann and Vogt (1933) reviewed 89 hospital cases at Boston and found that 12 were latent and 77 showed signs of lead intoxication. Of the latter, 11 died, 45 had

"encephalitis," and 4 neuritis; 12 had permanent sequelae, half being mentally retarded. McKhann (1932) suggested that the neurological manifestations of lead-poisoning usually subside without serious consequences if the ingestion of lead is stopped and its removal from the circulation hastened by securing its deposition in the bones in an inert form. No doubt this view is correct, so far as the most urgent and dramatic symptoms are concerned: but it is unlikely that if follow-up techniques had then been practised he would have made quite so sweeping a statement—indeed, Byers and Lord (1943) have shown that, of 20 cases discharged from hospital as "cured," favourable prognoses, even in "mild" cases, were almost invariably falsified by the event. Lord's reports on the mental sequelae of plumbism are admittedly incomplete (Byers explains that after Lord's death he prepared her records for publication); nevertheless, they merit earnest consideration, because they are the only available published data on the important question of prognosis in terms of mental growth.

Lord screened the records of 71 children who had plumbism, and, having eliminated 12 with gross brain damage on discharge, found that the remaining 59 left hospital "recovered." Of these it seems that only 20 (perhaps the élite) entered the school system and became the subjects of her follow-up studies. From the reports of the medical staff in attendance on these children on their first admission to hospital and from her own inquiries, Lord concluded that they had progressed normally prior to developing plumbism. On their initial admission they were in the age range of 10 months to 7½ years (the mean age being almost 2½ years, with a standard deviation of 17.3 months), and, as regards involvement of the nervous system, 8 presented more or less conclusive signs of encephalopathy and 12 did not. When the whole group was finally reviewed, the age range was 6–15 years and their I.Q.s (mostly on the Stanford-Binet scale) were in the range of 67–109 points (with a mean of 91 and a standard deviation of 12 points).

When the size of the sample is considered, the mean I.Q. of 91 is not really exceptional; but it is highly significant that only one of these patients did passably well at school (she was the only "nipple shield" case in the group and had an I.Q. of 103—the next best was a girl with an I.Q. of 82).

The comparative progress of the encephalopathic and non-encephalopathic cases is shown in Table I.

TABLE I

	No. of Cases	Age Range		I.Q.s	
		On First Admission (Months)	On Last Test (Years)	Average	Range
Encephalopathic	8	11–55	6–12	91	69–109
Non-encephalopathic	12	10–81	6½–15	91	67–105

It may be inferred that the presence or absence of encephalopathy made no material difference to the course of mental development in this group.

As already stated, only one child did passably well at school. I.Q.s of less than 85 no doubt contributed to the failure of five others. In her analysis of the remaining 14 cases Lord made her major contribution to our knowledge of the mental sequelae of plumbism: she showed that "sensorimotor" defects and temperamental anomalies were responsible for their social and educational failure despite the fact that in many instances their I.Q. ratings were in the average range of the general population. Thus, while some were verbally facile, they could not learn to read, write, or do number work, and, when the appropriate battery of tests was applied, their "sensorimotor" disabilities were exposed in terms of their inability to deal with shape, direction, space, and projected imagery. Some also exhibited behaviour disorders which seem (from Lord's account of them) to have resembled some of the sequelae of encephalitis lethargica.

A further point of prognostic significance also emerges. The occurrence of more or less complete arrest of mental development may have typified some cases. The relevant data in terms of declining I.Q.s are given in Table II.

TABLE II

Age when First Admitted (Years)	Intermediate Follow-up Test		Final Follow-up Test	
	Age	I.Q.	Age	I.Q.
4½	5	90	12½	65
6½	6½	100	12½	82
1½	6½	102	7½	91
2½	5½	106	7	92

Lord concluded that plumbism, whether characterized by evidence of encephalopathy or not, leads, even in those cases discharged from hospital as completely recovered, to failure or impairment of the normal processes of growth and development of the cerebral cortex. Support for this conclusion is also to be found in the fact that air encephalography, as indicated by McKhann and Vogt (1933), Levinson and Zeldes (1939), and others, reveals the existence of cortical atrophy in lead-poisoning victims.

There can, indeed, be no doubt about the gravity of the aftermath of plumbism in children, and in the few instances in which adequate follow-up techniques have been applied its consequences have been, even in so-called "cured" cases, deleterious to the progress of mental growth. Hence prognoses must be guarded until the age of at least 16 years has been reached, as it is not until then that intellectual development normally approaches its peak. Moreover, as successful therapy merely diverts lead to the bones, the patient remains, during childhood and adolescence, in a precarious plight. Trifling intercurrent indispositions, missed meals, or temper tantrums may suffice to disturb the acid-base equilibrium of the circulating media and so release lead to do further brain damage.

The mental defective described in this paper is aged 7½, but his mental age is only 3 to 4 years. Whether his mental development has been arrested partially or completely, temporarily or permanently, only time will tell—moreover, regression complicates the prognostic problem. Hence, lacking data about the ultimate fate of such cases in late childhood and adolescence, we can only speculate about his future prospects.

Screening and Follow-up Procedures

According to Levinson and Zeldes (1939), correct diagnoses were made only in 10 out of 26 cases when first admitted to hospital, and then only because plumbism had been recorded in other members of the families concerned. Bearing their observations in mind and considering also the implications of the case under discussion—the diagnostic problems it presented, the long period of lead ingestion and illness; the naïveté of the parental attitudes towards pica in general and lead in particular; the fact that the patient is now a mental defective; and the tenuous theoretical foundations on which much of our knowledge of the aetiology of mental subnormality is based—it is impossible to escape making certain obvious inferences.

It must surely follow that many others are naïve, ill informed, or careless about the risks to which they expose their children; therefore the real incidence of plumbism must be far greater than hitherto envisaged. No doubt, too, an unknown number of children are now in special schools and mental-deficiency establishments handicapped in various ways because of undiagnosed plumbism. It is hoped that, in particular, those responsible for the care and training of subnormal and "maladjusted" children will consider the advisability of applying screening procedures to their charges. Past or present association of pica, constipation, and colic might serve as preliminary criteria; thereafter, fuller investigations should be carried out on those who satisfied them. Particular attention might also be given to cases with "sensorimotor" disabilities and those with symptoms suggestive of primitive schizophrenia or hyperkinetic

disease. Lay (1938) indicated that symptoms sometimes regarded as characteristic of the two last-mentioned conditions may be caused by encephalitis, and it is relevant that the patient described was thought by different observers to be the subject of encephalitis, infantile autism, and an approximation to hyperkineticism.

Summary and Conclusions

A case of arrested mental development caused by lead-poisoning has been described and its implications and those of others in the literature have been discussed with particular reference to the following considerations.

1. The diagnosis of plumbism may be delayed over long periods during which serious and possibly irreversible brain damage may be done, with resultant arrest of mental growth, the appearance of "sensorimotor" defects, and both social and educational disabilities.
2. Pica, more often than not, precedes plumbism in children, and, as its implications are not always recognized, its occurrence may not be reported with appropriate emphasis. Hence there is the possibility that lead ingestion is not considered when the presenting symptomatology suggests such conditions as food-poisoning, pertussis, infantile autism, amentia, sensorimotor defects, educational subnormality, hyperkinetic disease, and behaviour disorders.
3. The need for appropriate screening and follow-up procedures has been indicated in light of the probability that the real incidence of plumbism is much greater than hitherto envisaged.
4. It is hoped that the Ministry of Health, local authorities, medical practitioners, parents, and all concerned with child welfare will take appropriate action to safeguard children from exposure to the risks of plumbism.

We wish to thank Drs. W. W. Kay and M. K. Beattie for the pathological report, Dr. I. L. McKelvie for the radiological report, and Drs. C. I. A. D. B. Clarke, and A. M. Clarke for their very helpful advice.

Discussing postal treatment in his latest quarterly report, Mr. H. H. BAGNALL, Birmingham's City Analyst, writes: "If a person goes to a pharmacist's shop, as many people hoping for quick and semi-miraculous cures still do, and demands a bottle of 'indigestion mixture,' he must, by the provisions of the Pharmacy and Medicines Act, be supplied with a printed list of the constituents of the medicine, and there is thus some sort of control, although admittedly not nearly enough, over such sales. The same Act, however, allows for the omission even of this simple precaution if an article is made up and supplied for the use of a particular person, being an article prescribed by reference to the needs of that person. The postal quack relies on this provision to avoid giving the composition of his remedies, for, as he sends out a typewritten chart of questions asking for answers to certain stock questions by his prospective patients, it can be said that in a sense he is prescribing for their particular needs. Is it not possible, as a slight check on these long-distance cures and as a preliminary to more thorough action, to require that all stock mixtures, powders, pills, and so on should be labelled with a list of ingredients, unless they are supplied on prescription by a properly qualified medical man?"

LEAD-POISONING IN CHILDREN

CORRELATION OF CLINICAL AND PATHOLOGICAL FINDINGS

BY

H. B. MARSDEN, M.B., D.C.H., D.Path.

Pathologist, Royal Manchester Children's Hospital

AND

V. K. WILSON, M.Sc.

Biochemist, Royal Manchester Children's Hospital

Lead-poisoning in childhood is not a rare disease. The danger of ingestion of the metal exists from infancy, as shown by Clark (1950). Two fatal cases have been investigated at this hospital during the past year, and this paper is devoted to a description of the clinical and pathological findings. The changes in the kidney have received particular attention, as fatty vacuolation, which does not appear to have been a prominent feature in previously recorded cases, was found at both necropsies and an attempt has been made to correlate the biochemical findings in one case with the microscopical changes in the kidney.

The difficulty in making a diagnosis of lead-poisoning in infants is emphasized. Anderson (1948) points out that the central nervous system is particularly susceptible at this age, and states that after a relatively short period of ingestion of the metal the picture of encephalitis may develop in the absence of such well-recognized features as anaemia or colic. In both the cases described in this paper vague symptoms were present towards the end of the second year of life, and in neither was the diagnosis made at that time. In one case the child lived to the age of 4 years, when the presence of anaemia, constipation, abdominal colic, and punctate basophilia readily suggested the possibility of lead-poisoning, while in the other the diagnosis was made at necropsy.

The gross and microscopical pathological findings, notably the presence of intranuclear inclusions in the liver and kidneys, are described to assist in the rapid post-mortem diagnosis, and histochemical methods for detecting the presence of lead in the tissues are discussed.

Case 1

A white male child aged 4 years was first seen at the age of 2 years, when he appeared to be unsteady and tended to fall. No physical abnormality was detected at the time. He was again seen at the age of 4 years, when there was pain in the lower abdomen, pallor, and unsteadiness of six weeks' duration. Vomiting ensued and also frontal headache. The child was admitted to hospital and at this time was unconscious. The parents, when questioned, stated that, as long as they could remember, there had been a tendency to bite and chew the furniture and other articles, including toys.

Examination on admission showed a peculiar state of unconsciousness with widely staring eyes and continuous nystagmus. The skin had a grey colour, with a reddish tinge over the cheeks. There was excessive salivation, but the teeth were good and no lead line was detected. The tongue had a constant tremor, being protruded every few seconds, and there was twitching of the right cheek and the left side of the body. The blood pressure was 140/85 mm. Hg, and the pulse was rapid. Difficulty in seeing the fundi was experienced, but the veins were noted to be engorged.

The blood haemoglobin was found to be 60% (Haldane) and there was a leucocytosis with predominance of poly-

morphonuclear cells. Marked punctate basophilia was present. The urine contained a reducing substance which was identified as glucose by chromatography. A one-way chromatogram in phenol was made, taking the volume of protein free urine corresponding to 250 µg. of total nitrogen. After drying the strip and spraying with ninhydrin, excessive amino-aciduria was seen to be present. Two-way chromatograms were then run on Whatman No. 1 filter paper 18 b.

Diagram of chromatogram of urine from Case 1. The sample has been placed at the bottom right-hand corner of the paper. Phenol has been run from right to left as first solvent and tetrahydrofurfural alcohol upwards as second solvent. The convention is used of representing the strength of the ninhydrin colour reaction by means of the size of the spot, using an arbitrary scale: 1, cysteine (from cystine); 2, serine; 3, glycine; 4, taurine; 5, alanine; 6, glutamine; 7, β -amino-iso-butyric acid; 8, leucine; 9, lysine.

22 in. (46 by 56 cm.), using phenol as first solvent followed by tetrahydrofurfural alcohol as second solvent. The result is shown in the diagram. The pattern shows an excess of cystine, taurine, and especially β -amino-iso-butyric acid. The identity of the latter two was confirmed by the copper method of Crumpler and Dent (1949). Cystine and β -amino-iso-butyric acid were the strongest spots on the square.

The other biochemical findings in this case were serum sodium 315 mg. per 100 ml.; potassium 16 mg. per 100 ml.; phosphorus, 5.8 mg. per 100 ml.; chlorides, 594 mg. NaCl per 100 ml.; bicarbonate, 41 vols. CO₂%. Blood urea, 60 mg. per 100 ml.; blood sugar, 0.127% glucose.

In the small quantity of urine obtained no porphyrins were detected.

X-ray examination of the long bones showed increased density of the metaphyses. Lumbar puncture yielded a clear fluid under increased pressure with a protein of 70 mg. per 100 ml., but no cells.

Death took place shortly after admission in spite of sedatives, surgical decompression, and attempts to lower the intracranial pressure by the use of hypertonic solutions.

Post-mortem Examination

Gross Findings.—The external features were not remarkable. There were ten teeth in the upper and lower jaws in good condition. The lungs were red, fleshy, and oedematous, the right weighing 163 g. (normal 90 g.), and the left 167 g. (normal 85 g.). The liver weighed 540 g. (normal 516 g.) and had a smooth yellow-brown capsule and a greasy yellow cut surface. The right kidney weighed 66 g. (normal 58 g.), and the left kidney 71 g. (normal 56 g.).

both organs having yellow-tinged cortical regions with poorly defined markings. Examination of the bones included the ribs, vertebrae, and lower end of the left femur. In the ribs and femur a dense white band several millimetres in width was seen in the diaphyses at the bone-cartilage junction. The brain weighed 1,330 g. (normal 1,190 g.), and was moderately engorged and tense. The white matter tended to swell on incision.

Microscopical Findings.—The principal changes were noted in the liver, kidney, and bones. In the liver the peripheral portions of the lobules were relatively intact, while the remainder showed extensive fatty vacuolation. Many of the hepatic cell nuclei were swollen and had a glassy appearance with wisps of chromatin below the nuclear membranes. Inclusions filling the greater part of the nuclei or several small inclusions were sometimes seen, and it was noted that the nuclear changes were most prominent in the neighbourhood of the portal regions, where there was less vacuolation. The smaller inclusions, in particular, showed variable acid-fast properties and stained orange with Masson's trichrome stain, as has been described by Wachstein (1949b), but for their detection it was felt that haematoxylin and eosin gave the best results. There was no cellular infiltration and the Kupffer cells were not mobilized.

The changes in the kidney were seen in the convoluted tubules, where the proximal portions appeared to be damaged, and in the medullary rays and outer portions of the medulla, where the looped tubules were thought to be involved. Fine vacuolation could readily be seen in the cytoplasm of the tubular cells, this feature being most marked near the basement membrane. Stains with Sudan black showed that the vacuoles contained fat. Some of the nuclei in the looped tubules were greatly enlarged and occasional inclusions were seen in this situation, but the latter were abundant in the proximal convoluted tubules.

The bone changes were studied in the rib and femur. The cartilage columns at the growing ends of the bones were short and regular. There was, however, inadequate erosion at the bone-cartilage junction, and broad, close-packed trabeculae were present for a distance of several millimetres along the shaft. This area corresponded with the white band noted in the gross specimen, and also with the zone of increased density noted in the x-ray films. There were numerous giant cells between the trabeculae, some of which had the appearance of typical osteoclasts, while others had swollen nuclei with clumped chromatin and a vacuolated or granular cytoplasm.

Demonstration of lead in the femur was found to be most satisfactory by the sulphide method described by Timm (1936). The tissues were fixed in absolute alcohol and decalcified in 30% formic acid. Excess acid was removed by 5% sodium sulphate and then washing in water. All the solutions were saturated with hydrogen sulphide. Frozen sections were cut and treated with potassium cyanide and yellow ammonium sulphide to remove copper, silver, and tin. The deposits of lead sulphide could readily be seen with the naked eye, and under the microscope fine black-brown granules were noted in the trabeculae. These granules were most abundant in the compact region close to the cartilage, but their presence could be detected for some centimetres along the shaft. Bismuth was excluded by staining with a 4% aqueous solution of potassium iodide and a 2% acidified aqueous solution of quinine sulphate as described by Lillie (1954).

Chemical analysis, using the method of Irving and Butler (1953), showed the presence of 158 mg. of lead per kg. of fresh bone in the femur. The total lead content of the liver was 9.205 mg.

The microscopical findings in the brain consisted of evidence of oedema with swollen glial cells in the white matter and lymphocytic infiltration in the meninges. A portion of the left popliteal nerve showed no unusual feature and there were no significant changes in the remaining organs, including the pancreas and parathyroids.

Case 2

A white male child aged 1 year 10 months gave a history of vomiting, anorexia, and constipation of one month's duration. He screamed and doubled up before vomiting, and was irritable, rubbing the back of his head and pulling at his ears. The mother stated that he appeared to be frightened, and constantly called out during the night. No history suggesting the possibility of lead ingestion was obtained. On admission to hospital he was very difficult to examine. He was ataxic and there was marked pallor. The fundi showed advanced papilloedema and engorgement of the retinal veins.

The blood haemoglobin was found to be 66% (Haldane), but there was no punctate basophilia. Sugar was present in the urine, and the spinal fluid contained 8 lymphocytes per c.mm. and had a protein content of 40 mg. per 100 ml. Ventricular taps were performed, but there was a great increase of intracranial pressure and convulsions developed. Death took place in spite of all measures, including operative decompression to relieve the intracranial tension.

Post-mortem Examination

Gross Findings.—The body was that of a well-nourished white male child. There were eight teeth in the upper and lower jaws with no evidence of a lead line on the gums. The right lung weighed 105 g. (normal 83 g.) and the left 93 g. (normal 74 g.), both organs being red, haemorrhagic, and fleshy. The liver weighed 411 g. (normal 345 g.) and was pink and yellow in colour with a rather greasy cut surface. The right kidney weighed 42 g. (normal 40 g.) and the left 45 g. (normal 43 g.), both organs being pink in colour with rather faint cortical markings. Examination of the bones, including the ribs, vertebral bodies, and the lower end of the left femur, was carried out. In the long bones a white thickened band several millimetres in width was noted at the growing end of the shaft. X-ray examination of the long bones *post mortem* showed zones of increased density. The brain weighed 1,360 g. (normal 1,050 g.) and was swollen with flattened gyri. The white matter was watery and tended to bulge above the cut surface.

Microscopical Findings.—The principal changes showed a similar distribution to those noted in Case 1. They were not so obvious in the liver, where the degree of fatty vacuolation was less and the intranuclear inclusions were smaller. The nuclear changes were, however, more widespread throughout the lobule, and the inclusions, though small, were more frequently seen. In the kidney the distribution of the lesions was again confined to the cortex and outer portion of the medulla, the proximal convoluted and looped tubules being involved. In the former the fatty vacuolation was finer and less prominent and there were no inclusions, while in the latter there were abundant inclusions and giant nuclei were readily noted.

The bone changes were similar to those seen in Case 1. The band of closely packed broad trabeculae was present with numerous typical and atypical osteoclasts. The lead was demonstrated in the lower end of the left femur by the sulphide method. The deposits of lead sulphide were much finer and less profuse than those in Case 1, and with the exception of the cortex they could be detected only for a distance of less than 1 cm. along the shaft. The changes in the brain were, by contrast, more marked. There was lymphocytic and large mononuclear cellular infiltration in the meninges. Large numbers of swollen glial cells were present in the white matter, and the latter showed evidence of oedema and softening, with focal accumulations of small glial cells and lymphocytes. The nerve cells in the brain stem showed fine cytoplasmic vacuolation and their nuclei had clumped chromatin with swollen eosinophilic but not acid-fast nucleoli.

No significant changes were found in the remaining organs, including the pancreas and parathyroid. The peripheral nerves were not examined. The lead content of bone (femur) was 101 mg. per kg. of fresh bone.

Discussion

The two cases described showed symptoms at the end of the second year of life. In the first case the patient was at that time restless and unsteady, and although his urine was not examined it seems probable that the cause of the symptoms was lead-poisoning. In both cases the clinical picture suggested cerebral damage, and it is of interest that the microscopical findings in the brain were more prominent in the younger child. Anderson (1948) emphasizes that the symptoms in young children may be confined to those indicating central nervous system involvement, and in the above cases ataxia, irritability, and restlessness at night would appear to be of importance. The symptoms, however, were vague, and it is felt that reliance must be placed upon the mother's statement that there is a change in the child's behaviour.

Punctate basophilia was present in only one of the two cases and, as shown by McKhann and Vogt (1933), too much reliance should not be placed on the presence or absence of this finding in arriving at a diagnosis. Abdominal pain was a feature in both cases, as was constipation, but in Case 1 these symptoms were not found when the child was first examined.

The gross necropsy findings were not striking in the cases described in this paper. There was some increase in weight in the liver and kidneys, this feature being attributed by some authors to the toxic effect of lead on mitosis (Chiodi and Cardeza, 1949; Finner and Calvery, 1939). This toxic effect would account for the giant nuclei shown in the renal tubules in the present cases. In order to arrive at a correct diagnosis in the necropsy room, a rib should be examined by dividing the bone longitudinally, when the white band close to the cartilage can be seen. For confirmation frozen sections of the liver and kidney may reveal the presence of intranuclear inclusions.

These inclusions were first described, in the livers of 21 children dying from lead-poisoning, by Blackman (1936), who showed that they could be produced in rats by the addition of lead to the diet. Similar inclusions have been found by Pappenheimer and Maechling (1934) in the cells of the renal tubules in a patient treated with bismuth, and Olitsky and Harford (1937) have shown that they occur after the injection of aluminium and ferric compounds. Wachstein (1949a) found that the metal-inducing inclusions were acid-fast, thus differing from other types of inclusions examined. This latter property was not a marked feature in the present cases, although this could be attributed to formalin fixation. Nuclear enlargement was, however, a prominent feature in the liver and kidney, some of the nuclei having a glassy appearance and others an apparently normal structure.

Previous reports of the kidney changes in lead-poisoning have described intranuclear inclusions in the tubular cells with nuclear hypertrophy. Wachstein (1949b) has found necrosis and calcification of the cells of the cortical tubules with foci of chronic inflammation in experimental work in rats. Fatty vacuolation does not appear to have been a feature.

In both of the present cases there was damage to the cortex and outer portion of the medulla involving the proximal convoluted and looped tubules. The findings consisted of fatty vacuolation of cytoplasm and swelling of nuclei with intranuclear inclusions. There was no evidence of cellular infiltration, and the collecting tubules and vessels were not remarkable.

The pattern of the urine chromatogram in Case 1 is similar to the one described previously by Wilson *et al.* (1953), especially as regards the large excess of β -amino-iso-butyric acid, which was the strongest spot on the square in this recent case. This amino-acid was originally discovered by Crumpler *et al.* (1951), who found that 5% of normal people excrete large amounts, and as the blood level of β -amino-iso-butyric acid in these people is no higher than in the rest of the population they assume that its excretion is probably due to a defective absorption in the renal tubules.

More recently, Sandler and Pare (1954) have made a study of this amino-acid and found that an increased excretion followed starvation. In a later paper (Pare and Sandler, 1954) these authors showed that cystine and β -amino-iso-butyric acid were excreted in excess in march haemoglobinuria and suggested that these two amino-acids together with haemoglobin are reabsorbed in the same or adjacent sections of the renal tubules.

Fanconi (1951) maintained that dextrose, phosphate, and amino-acids were absorbed in the proximal renal convoluted tubule. Wilson *et al.* (1953) showed that the amino-aciduria in lead-poisoning was renal in origin, as the level of plasma amino-acids was normal. The glycosuria and amino-aciduria which are a most frequent finding in cases of lead-poisoning have been concluded to be the result of injury to the proximal convoluted tubule. In both of the present cases the proximal tubules showed marked evidence of damage, thus confirming the work of Fanconi on the physiology of the kidney.

Summary

The clinical and post-mortem findings of two cases of lead-poisoning are reported.

The possibility of this disease must be borne in mind in all children with vague cerebral symptoms or evidence of increased intracranial tension.

Post mortem it is possible to make the diagnosis by examining the cut end of a rib or by examining frozen sections of liver and kidney for intranuclear inclusions and nuclear changes.

Fanconi's theory concerning the absorption of dextrose and amino-acids in the proximal renal tubules has been confirmed.

We are indebted to Dr. A. Holzel for much helpful advice and criticism. We wish to thank Mr. F. G. Ralphs, H.M. Coroner for permission to publish these cases, also Dr. M. L. Thomson and Mr. H. Maslowski for allowing us to use the clinical records.

The latest addition to the Medical Research Council's *Memorandum* series is called "Indices of Heat Stress" (No. 29, price 2s. net). Written by a statistician, it compares two indices used in measuring heat stress under hot and humid environmental conditions. The first, the "effective temperature," takes account of the temperature and humidity of the atmosphere, the rate of air movement, and radiation from the surroundings; the second is based on the rate of sweating. An earlier *Memorandum*, No. 17, describes the measurement of effective temperature. These memoranda will interest primarily those concerned with the well-being of workers in hot conditions. Both memoranda are published by Her Majesty's Stationery Office.

SIGNIFICANCE OF INITIAL
CONDITION OF CERVIX UTERI TO
SUBSEQUENT COURSE OF LABOUR

BY

DENIS PELLIS COCKS, M.D., M.R.C.O.G.

(From the Obstetric Hospital, University College Hospital, London)

Prolonged labour in the absence of cephalo-pelvic disproportion, where the cervix uteri fails to become fully dilated twenty-four hours or more from the onset of contractions, remains one of the great problems of obstetrics. Much research has been carried out into the causes responsible for this delay, and it was during one such departmental investigation into the problem at University College Hospital, London, that Nixon (1952) gave a preliminary report upon the correlation of the initial condition or type of the cervix and the subsequent course of labour. This investigation has been continued and 133 cases have now been studied.

It was decided to note carefully the condition of the cervix before the onset of labour at the time of surgical induction. In the great majority of cases pre-eclamptic toxæmia was the indication for induction in primigravidae at or near term with the vertex presenting. Cases of cephalo-pelvic disproportion were excluded from this study.

The diagram shows the way in which the cervix has been typed at the time of induction of labour. Types 1 and 2 represent the condition most commonly and

Diagram showing types of cervix uteri. 1. Soft, effacing; canal admits one finger. 2. Soft, long, and closed; whole canal admits one finger. 3. Firm, long, and closed; external os will not admit one finger. 4. Firm and short external os admits one finger; internal os rigid. 5. Cervical anomalies: pinhole os, duplication, etc. A—Sacral os, anterior sacculum occurring in any of the previous types.

types 3 and 4 the condition least commonly found. Cervical anomalies are included in type 5. It will be seen that there is an increasing hardness of the cervix as well as increasing difficulty in inserting the examining finger through the cervical canal as one passes from types 1 to 5. Other authors have noted differences in texture of the cervix. Arthur (1949) describes certain characteristics, such as hardness and tenseness, in his observations on the cervix in cases of cervical dystocia; and MacRae (1949) refers to a similar rigidity of the tissues in cervical achalasia in certain cases of primary uterine inertia. Dieckmann and McCready (1947) classify the cervix somewhat similarly by the degree of softening, effacement, and estimated amount of dilatation. Calkins (1954) also has drawn attention to the importance of the firm cervix in prolonged labour.

The diagram also depicts a special position of the cervix that has been found in types 1 to 4. This is the "sacral" position, or "sacral" os, in which there is posterior displacement of the cervix, with the external os pointing backwards towards the hollow of the sacrum in such a manner that if the presenting part is engaged in the maternal pelvis its lower part is at a deeper level in the birth canal than the external os. In order to enter the cervix the examining finger will first have to hook it down below the presenting part and thus bring the cervical canal back into its normal axis. Greenhill (1951) has described this position, and states that "the location of the cervix at term varies. . . . Most often it is in the middle of the pelvis, many times it is back in the hollow of the sacrum. . . . If it is near the sacrum and hard to reach with the finger it is pathological."

Kerr and Moir (1949) also discuss this backward displacement of the cervix in association with anterior sacculum and abnormal stretching of the anterior wall of the lower uterine segment. Presumably, the degree of posterior or sacral position depends upon the amount of stretching of the anterior uterine wall.

Present Investigation

In this study 133 cases have been observed—99 cases without and 34 cases with a sacral os. The distribution of these types of cervix is shown in Table I, where the numbers of the "ripe" cervix (types 1 and 2) and "unripe" cervix (types 3, 4, and 5) are also shown.

By typing the cervix from the condition found at the time of surgical induction and by noting the course of labour that followed, it has been possible to investigate whether any particular type of cervix, especially if combined with a sacral os, is associated with a long labour, a long latent interval prior to the onset of labour, or an increased interference rate by forceps or by caesarean section in the ultimate delivery.

Table II sets out the findings of the course of labour studied for the average time of the induction-to-delivery interval (I.D.I.), average duration of labour, and average latent interval in relation to the condition of the cervix with a sacral os. It is evident that the average latent interval before labour starts in the "ripe" types of cervix (types 1 and 2) is significantly less than in the "unripe" types of cervix (types 3, 4, and 5), confirming previous clinical observations. The average duration of labour is also less in types 1 and 2.

Dr. D. E. Barton, of the statistical department of University College, London, has kindly investigated the figures in

TABLE I.—Distribution of the 133 Cases According to Type of Cervix

Type	Cases Without Sacral Os	Cases With Sacral Os
1	66	17
2	23	14
3	4	1
4	5	2
5	1	0
Total	99	34

TABLE II.—Types of Cervix Uteri Without a Sacral Os, Showing the Subsequent Course of Labour (99 Cases)

Type of Cervix	Average I.D.I. in Hours	Average Duration of Labour in Hours	Average Latent Interval in Hours (i.e., Induction to Onset of Labour)	No. of Cases
1	19.7	10.7	9.0	66
2	27.0	16.0	11.0	23
3	71.7	22.0	49.7	4
4	53.2	21.5	31.7	5
5	One case delivered by caesarean section after being 9 hours in labour with a pin-hole os			

these tables as well as the individual figures of the cases, and has shown them to be statistically significant.

The course of labour with the various types of cervix complicated by a sacral os has also been analysed, and is shown in Table III. It will be seen that, compared with

TABLE III.—*Course of Labour in Cases of Sacral Os (34 Cases)*

Type of Cervix	Average I.D.I. in Hours	Average Duration of Labour in Hours	Average Latent Interval in Hours	No. of Cases
1	61.1	16.0	45.1	17
2	44.8	34.2	10.6	14
3	One case only.	This patient was 72 hours in labour, and was subsequently delivered by caesarean section		
4	46.0	17.0	29.0	2

Table II, the induction delivery interval is strikingly prolonged in types 1 and 2 and the average duration of labour is also increased, especially in type 2. The increased latent interval in type 1 cervix with a sacral os is also of great interest. The difference in the mean times of these cases compared with the same type of cervix without the sacral os is highly significant statistically.

Table IV compares the relative rates of forceps delivery and caesarean section in the different types of cervix and gives the figures for the total number of deliveries (1,232)

TABLE IV

Type of Cervix	Forceps Delivery	Caesarean Section	No. of Cases
Ripe cervix (types 1 and 2) . .	15 (16.8%)	4 (4.4%)	89
Unripe cervix (types 3, 4, and 5) . .	2 (20%)	3 (30%)	10
All types with sacral os . .	4 (11.7%)	6 (17.6%)	34
Total deliveries in 1951 . .	11%	5.4%	1,232

for the year 1951. The increased interference rate in the unripe types as compared with the ripe types of cervix is statistically significant, as is also the increased caesarean section rate in cases of sacral os found in all types of cervix.

Table V shows the numbers of cases in which labour lasted over 24 hours or in which labour was terminated before this time for reasons associated with delay in cervical

TABLE V.—*Course of Labour in Relation to Type of Cervix (133 Cases)*

Type	No. of Labours over 24 Hours or Terminated Earlier by Caesarean Section		No. of Cases

1	7	5	66	17
2	9	7	23	14
3	1	1	4	1
4	3	1	5	2
5	1	—	1	—

dilatation by caesarean section. The latter operation was performed in these cases for such reasons as increasing pre-eclamptic toxæmia if deterioration in the maternal condition was directly associated with a long latent interval. The sacral os is especially seen to be responsible for a higher incidence of prolonged labour and surgical intervention.

A typical example is shown by the following case, in which a high rupture of membranes was performed for a mild pre-eclamptic toxæmia near term. The cervix was found to be firm, long, and closed, and admitted a finger only with difficulty (type 2). It was also sacral in position and required hooking down digitally—a difficult procedure—before a Drew-Smythe catheter could be introduced. Eighteen ounces (510 ml.) of liquor amnii was withdrawn, but 5½ hours passed before contractions began. After a further 29½ hours caesarean section had to be performed on account of an increasing degree of toxæmia and a rising foetal heart rate.

Discussion

By a careful examination of the condition of the cervix at the time of induction of labour or, for that matter, at the spontaneous onset of labour, it should be possible to classify the cervix according to its degree of "ripeness" and so give a reasonable estimate of the likely course of labour that will follow. If there is a soft open and partially effaced or an early onset of labour and a spontaneous delivery are to be expected. If, however, the cervix is firm and difficult is experienced in inserting the finger, then a prolonged latent interval and a somewhat longer labour are likely.

If a sacral position of the cervix is found, even in the case of a type 1 cervix, a longer latent interval is to be expected, although once labour starts it may well be of average duration.

Intervention either by forceps or by caesarean section is also more likely in the unripe type of cervix, and caesarean section is more likely to be required in cases in which the sacral os is present.

As well as the risk of deterioration in cases of severe pre-eclampsia, there is an increasing risk of infection and foetal death when the membranes have been ruptured for 24 hours. In certain cases, therefore, in which the type of cervix is unfavourable and the latent interval likely to be prolonged, it may well be advisable to perform caesarean section without awaiting the onset of contractions.

In cases of sacral os in which time is not so pressing it may be possible to hook down the cervix and sweep the membranes digitally without actually rupturing them. Forty-eight hours later the cervix may be found to have become much easier to enter, and rupture of the membranes can then be more effectively performed. Faris and Kahlenberg (1954) suggest the use of a dilute oxytocin drip to soften certain cases of the hard unripe cervix. It is given during the day for two days. This may well be tried in such cases of sacral os following a digital sweep, provided the uterus is not hypertonic, although in such cases proper tographic control is advisable.

In the light of these findings, a special plea is made for a more careful assessment of the cervix uteri at the time of surgical induction than is often the case. By so doing the clinician can learn much that will help him in the subsequent care of his cases, and at the same time increase his interest in what is often, quite incorrectly, thought to be a somewhat prosaic obstetric procedure.

Summary

The cervix has been classified into five types at the time of the induction of labour in 133 cases.

The course of labour in regard to the induction delivery interval, the duration of labour, and the latent interval prior to the onset of contractions has been studied. Special reference is made to the "sacral" position of the cervix.

The relative interference rate by forceps or caesarean section in relation to the various types of cervix has been noted.

The significance of certain types of cervix in labour and their management is discussed.

I should like to pay tribute to the help and encouragement given to me by Professor W. C. W. Nixon, for the time and trouble taken by Dr. D. E. Barton in checking the statistical aspect, and to the unfailing co-operation of Sister Billing, who is in charge of the labour wards at University College Hospital, London.

CHLOROQUINE SULPHATE IN TREATMENT OF CHRONIC DISCOID LUPUS ERYTHEMATOSUS

BY

H. J. LEWIS, M.R.C.S., L.R.C.P.

(From the Department of Dermatology, Radcliffe Infirmary, Oxford)

For some years mepacrine has been used in the treatment of chronic discoid lupus erythematosus (Prokoptchouk, 1940; Popoff and Kutinscheff, 1943; Page, 1951). From 1952 to May, 1954, a group of cases have been treated with chloroquine sulphate in this department. This drug has the advantage of being less toxic than mepacrine and does not lead to yellow discoloration of the skin.

Since the course of the disease is variable, with seasonal exacerbations, the patients were followed through the four seasons before coming to any conclusion. Routine investigations carried out included: (a) Hb, R.B.C., W.B.C. differential count, E.S.R.; (b) plasma proteins; (c) chest x-ray examination.

The following complications, as noted by Alving *et al.* (1948), were looked for: pruritus, anorexia, vertigo, tinnitus, visual disturbance, diarrhoea, malaise, urticaria. The possibility of agranulocytosis was kept constantly in mind and patients were warned to report any untoward symptoms, such as lassitude and sore throat.

Dosage.—The dosage of chloroquine sulphate used initially was 0.1 g. thrice daily by mouth (tablet, not base dose). If the clinical response was rapid the dosage was dropped to 0.1 g. twice daily.

Results

Eighteen cases have been under treatment (see Table). Ten showed clinical cure (scaling disappeared and the skin was either normal in appearance or atrophic); five improved—slight scaling remained; one (B) was subjectively improved; one (A) was unchanged; and in one (O) the condition continued to spread. No complications occurred.

The following points were noted with three of the 10 clinical cures while under treatment. Case K relapsed under treatment. The relapse occurred after the patient had stood in the sun without protection. There was also a relationship between the E.S.R. and clinical response, there being no response to treatment when the rate was raised. Case M

complained of indigestion, but, on questioning, he said he was "a martyr to attacks of indigestion." Case T found that his rheumatic pains, for which he had had many medical remedies, cleared "miraculously" while he was under treatment, but they returned as soon as the treatment was stopped.

The patients who were under observation for less than six months were asked to communicate with us should there be a relapse, but as yet we have had no response.

Two cases of subacute disseminated lupus erythematosus were also treated with chloroquine sulphate with no satisfactory clinical response.

Summary and Conclusions

Eighteen cases of chronic discoid lupus erythematosus were treated with chloroquine sulphate by mouth. The results are tabulated and discussed.

It is considered that chloroquine sulphate is as efficient a form of palliative therapy as any previously used, though not as yet the answer for the chronic disease. There is still a place for CO₂ snow treatment where there is a single discoid lesion.

I have to thank Dr. Alice Carleton, consulting dermatologist, the Radcliffe Infirmary, Oxford, for her guidance and for permission to publish this article. I am much indebted to Sister Burbridge and Dr. S. O'Reilly, of the skin department, for their help. I am also grateful to Miss Donaldson, secretary, for all her work.

CHRISTMAS DISEASE ASSOCIATED WITH FACTOR VII DEFICIENCY CASE REPORT WITH FAMILY SURVEY

BY

W. N. BELL, M.D., M.Sc.Med., F.R.C.P.C.

AND

H. G. ALTON, M.B.

(From the Department of Medicine, Cambridge University)

Reports of congenital deficiencies of isolated blood coagulation factors have become common. Instances of more than one such deficiency occurring simultaneously in the same individual have been much less frequently reported. Koller (1954) has drawn attention to this possibility by describing a case of combined haemophilia and Factor V deficiency. Soulier and Larrieu (1953) have reported a case of combined haemophilia and Christmas disease, the diagnosis being based on the failure of the patient's plasma to correct the clotting defect of either haemophilia or Christmas disease. To our knowledge, no association of Factor VII deficiency with Christmas disease has previously been reported. Such a combination has recently come to our notice in a family, some of whose members suffer from haemorrhagic manifestations.

Case Report

A 29-year-old man was admitted to Addenbrooke's Hospital following a road accident in April, 1954, when he received a cut over the right eye which had continued to bleed intermittently for two weeks. He had had excessive bleeding from traumatic cuts since childhood, and recurrent haemarthroses of the elbows and knees had resulted in

partial flexion deformities of these joints. In 1951, following an appendectomy, he had required 6 pints (3.4 litres) of blood, and the wound had healed by secondary intention (occasionally sutures had been sloughed out since then). In November, 1953, a dental extraction had required three weeks' hospitalization and 6 pints (3.4 litres) of blood. He had received 6 pints of blood at another hospital just before this latest admission in an attempt to control the bleeding from his forehead, with only moderate success.

General physical examination was unremarkable. Both wrists showed impairment of dorsiflexion, and there was 20 to 30 degrees limitation of extension in both knees and elbows. The cut in the forehead had been sutured, but a large subcutaneous haematoma had caused the wound edges to gape. Oozing from the wound was moderate. There was a nylon suture protruding from the appendectomy wound in the abdominal wall, surrounded by a small area of granulation tissue. X-ray examination of the knees showed loss of articular cartilage, subarticular cyst formation, and sclerosis and osteophytes of both knees, particularly on the right side. The changes were regarded as compatible with those of repeated haemarthroses.

Laboratory investigation of the urine and routine haematological examination revealed nothing abnormal. Coagulation studies are shown in Table I.

TABLE I

Test	Method	Result	Normal Values
Clotting-time	Modified Lee-White	17.5 mins.	5-10 mins.
Platelet count	Rees-Ecker	670,000/c.mm.	2-400,000/c.mm.
Oil-suspended clot retraction	Budtz-Olsen (1951)	13% in 4 hr.	20% in 4 hr.
Prothrombin consumption	Quick et al. (1949)	22.9 sec. in 1 hr.	Over 30 sec. in 1 hr.
One-stage prothrombin time	Quick	22.3 sec. (40%)	80-100%
Factor V	Stefanini (1950)	95%	90-100%
Two-stage prothrombin	Biggs and Douglas (1953a)	104%	85-100%
Factor VII	Koller et al. (1951)	44%	90-100%
Thromboplastin generation test—fully corrected by normal serum but unchanged by normal plasma	Biggs and Douglas (1953b)	27%	100%

These tests indicated a defect in thromboplastin generation compatible with the diagnosis of Christmas disease, and a prolonged one-stage prothrombin time due to a marked reduction in Factor VII. By definition, Christmas disease is characterized by a normal one-stage prothrombin time (Biggs et al., 1952), and Factor VII deficiency alone produces a defect in the thromboplastin generation test only if less than 10% of normal (Biggs and Marfaland, 1953). Thus there appeared to be two separate deficiencies present in this patient. No evidence of liver disease existed to explain the reduced Factor VII level.

Clinical Course

He was given by intravenous drip 80 ml. of compatible 10-day-old serum, which reduced his clotting-time to 8.5 minutes, raised his prothrombin consumption to 26.2 seconds in one hour, shortened the one-stage prothrombin time to 17.2 seconds (58% of normal), and improved the clot retraction to 20% in four hours. Under cover of this treatment, the haematoma of the forehead was evacuated and resutured, and covered with a pressure bandage. At the same time the nylon suture was removed from the abdominal wound and a pressure bandage also applied. There was no excess haemorrhage as a result of these procedures. He was given a further 40 ml. of serum immediately post-operatively. His tests had returned to their pre-treatment level by 18 hours post-operatively. The sutures were removed without trouble 10 days later under cover of more serum intravenously. Traction to the right leg produced some improvement in the degree of flexion contracture. He was discharged after an uneventful convalescence.

Our use of serum, rather than plasma or whole blood, may call for brief comment here. Both Christmas factor and Factor VII are stable in stored blood, plasma, or serum for considerable periods (Biggs et al., 1952). We have found Christmas factor to be stable in stored oxalated plasma and normal serum for three weeks. Therefore, any of these fractions may be used in the treatment of Christmas disease, Factor VII deficiency, or a combination of these defects. In the course of work carried out by us on another patient with uncomplicated Christmas disease, we have found that 1 ml. of serum is approximately equivalent in therapeutic effect to 10 ml. of A.C.D.-stored plasma. Because of this finding, and because serum provided a supply of both deficient factors in this patient, it was used exclusively in this case, with good results.

Family History

The presence in this patient of a combined deficiency, apparently of a congenital nature, called for an effort to test all available members of his family. This proved only

Family tree of patient. The numbers refer to the subjects (see Table II). Male, non-bleeder; ■ Male, bleeder; ○ Female, non-bleeder; ● Female, reported bleeder, not studied.

moderately successful owing to distant residence, unwillingness on the part of some members, and death of others. The accompanying genealogical tree is based on information received from several members of the family. The patient's maternal grandmother could not be tested; his grandfather and both his father and stepfather were dead. An apparently unaffected uncle, a bleeder brother, and two sisters were not available for testing. Only males showed a bleeding diathesis. The principal clinical manifestations in all affected males were haemarthroses and subcutaneous haematomata.

In Table II are summarized the results of tests performed on the members identified in the family tree by numerals. Since these tests had to be done either in the patient's home

TABLE II.—Results of Tests in Members of Family

Subject	Bleeder	Clotting-time (min.)	Prothrombin Consumption (3 Hours)	1-Stage Prothrombin Time (sec.)	Factor VII (% of Normal)	Peak Thromboplastin Generation (% of Normal)	Correction by Plasma or Serum
1	—	8	(sec.) 48.2	65	65	98	—

8	+	17	28.2	48	50	11	—

or two hours later on return to the laboratory, their range had to be limited, and normal controls were subjected to similar conditions.

Discussion

This investigation is reported in order to draw attention to the existence of combination forms of isolated coagulation factor deficiencies. In this family the most striking

feature seems to be that, whereas both sexes showed deficiencies of Factor VII, only some of the males had Christmas disease as well; all of the clinical "bleeders" belonged to this latter group. From these results it would appear that the critical haemorrhagic level of Factor VII is less than 40% of normal and that it was the deficiency of Christmas factor which determined the tendency to bleed. It is interesting to note that the serum of the mother (a female carrier of Christmas disease) was as effective in the correction of the abnormal thromboplastin generation tests as normal human serum, providing further evidence of the inability to demonstrate a laboratory defect in the female carrier of this disease.

Summary

A survey is made of a family, some of whose members exhibit a combination of Christmas disease and Factor VII deficiency. Pathological bleeding was confined to those showing both defects.

The advantage of serum in the clinical management of such patients is illustrated.

We wish to thank Sir Lionel Whitby for providing the facilities for this study, and Miss S. C. Tomlin for valuable technical assistance. We are indebted to Mr. D. J. Martin for referring to us the patient whose case is reported in detail.

A CASE OF PHAEOCHROMOCYTOMA

BY

R. A. C. OWEN, F.R.C.S.

AND

G. H. MURRAY, M.R.C.P.Ed.

From Walton Hospital, Liverpool

As comparatively few cases of phaeochromocytoma are described in the literature of this country the following case is recorded. The number of cases of successful removal of the chromaffin tumour of the adrenal is smaller still, many of the reported cases having been found at necropsy (Crowther, 1951; Jellicoe, 1952; Davies, 1952; Priest, 1952). A review of the world literature up to 1949 is given by Graham (1951).

Phaeochromocytoma is probably a commoner condition than the literature would lead one to believe, and it is likely that many cases remain undiagnosed. By publishing details of these cases the condition will become better known and take its proper place in the diagnostic field. An additional reason for publication is that most new cases still present special difficulties in diagnosis and surgical treatment.

Case Record

A married woman aged 52 was admitted to hospital with sweating attacks following a respiratory infection. There were few signs in the chest, however, no pyrexia, and x-ray examination showed that her chest was normal. She then volunteered that she had suffered from these sweating

attacks for some two years. During these attacks, many of which occurred during her stay in hospital, there was no associated headache, dizziness, or definite pallor of the skin. She had no other complaints, but it is interesting to note that she had been treated at home for the past seven or eight years for high blood pressure. There was no other significant illness.

On examination she presented a normal appearance for a woman of her age, and her general condition was average. There was a sense of fullness in the right lumbar region, but no definite tumour could be felt. Manipulation of this region did not produce an attack of sweating. Her blood pressure at the time of admission was 180/110, but frequent estimations showed that it varied between 250/150 and 160/100.

Unresolved pneumonia was at first thought to be a possible diagnosis. Thyrotoxicosis was considered and the B.M.R. at this time was +39%. In view of this it is of interest that Davies's case (1952) simulated thyrotoxicosis. At this stage, however, a sweating attack was observed by one of us and the possibility of a phaeochromocytoma was considered. Special investigations were undertaken with this diagnosis in mind.

Special Investigations.—A straight renal and intravenous pyelogram showed some broadening of the lower pole of the right kidney but no other abnormality. A perirenal air insufflation followed by x-ray examination did not show any definite tumour in either kidney region, but, as is usual in our experience, the x-ray films proved difficult to interpret. A piperoxane test showed a definite response, with lowering of the blood pressure from 180/110 to 145/90. This was subsequently repeated, and the blood pressure was lowered from 170/110 to 125/80. The pharmacological tests were reviewed by Swan (1951), who described an illustrative case. In the present case the amount of adrenaline and noradrenaline excreted in the urine before and after operation was ascertained. The pre-operative specimen contained a considerably greater quantity than the post-operative. The pre-operative urine contained 1 mg. of L-noradrenaline per 24-hour output. Three days after operation it fell to the equivalent of 0.5 mg. of L-noradrenaline. Ten days after operation it had fallen to 0.25 mg. An amylobarbitone sedation test, an electrocardiogram, and an x-ray film of the skull showed no significant abnormality.

On the above evidence a diagnosis of phaeochromocytoma was confirmed, and it was thought most likely that the tumour was on the right side, although this was by no means certain. It was decided that if at operation no tumour was found on the right side, then the left side would be explored.

Operation

A right lumbar incision was used, excising the twelfth rib subperiosteally. A spherical tumour about 3 in. (7.5 cm.) in diameter was immediately found in the position of the right suprarenal gland. There was a well-marked line of cleavage between the tumour and the surrounding structures and it was freed along this line without difficulty. The pedicle was then ligated and the tumour removed. The wound was closed in layers with rubber drainage.

Technically, the removal of this tumour presented no problems, but, as is usual with these cases, the problem was to deal with fluctuations of blood pressure throughout the operation. At the beginning of the operation it was 170/90. On incision of the skin it rose to 215/140, and it continued to rise to 235/145 when the tumour was being handled.

Piperoxane, 10 ml., was given immediately before the start of the operation, and this was repeated after 10 minutes. When the blood supply to the tumour had been arrested by ligation the pressure remained unchanged for a period of 15 minutes and then fell to 135/80. It remained at this level until the end of the operation and, coincident with the postural change of the patient, dropped to 60/40. It remained at this level for over an hour, when it rose to 95/65, and continued to rise slowly thereafter. Noradren-

aline was given into the drip as soon as the vascular pedicle of the tumour was clamped, and a noradrenaline drip was continued until the next day.

Throughout the operation there was a marked degree of sweating. Oxygen was given and continued for 1½ hours after the end of the operation. Convalescence from the operation was uneventful and the blood-pressure readings were 120/80 eight days after the operation, and remained round about this figure until her discharge. The piperoxane test was repeated before her discharge and did not demonstrate the previously noted fall in blood pressure, and indeed there was a rise in blood pressure from 125/70 to 160/85.

When seen in the out-patients' department a few weeks after discharge the patient was symptom-free and her sweating attacks had been completely abolished. Her blood-pressure on this occasion was 180/110.

Although she readily agreed to the operation, one interesting personal sidelight was that she was obviously unconvinced that the operation would benefit her. It was not until some little time after the operation that she realized with pleasure that she had indeed been cured of her sweating attacks.

Pathology

The specimen was reported on as a typical chromaffinoma weighing 425 g. The cells were more pleomorphic than usual, and the cytoplasm was plentiful and slightly granular. The nuclei were often large, pale, and with many chromatin dots and an inconspicuous membrane. An estimation of the amount of adrenaline and noradrenaline in the medulla of the tumour was made. The amount of L-noradrenaline was equivalent to 0.46 mg., and the amount of L-noradrenaline was equivalent to 0.85 mg. per g. of medulla.

Summary

A case of phaeochromocytoma is described, illustrating the difficulty in diagnosis of these tumours. Some of the diagnostic investigations are described, together with some of the important points for successful surgical removal of the tumour, which was undertaken in this case.

Our thanks are due to Dr. J. D. Loughrey for the administration of the anaesthetic and the control of the blood pressure during the operation, to Dr. H. E. Vickers for the pathological reports, and to Dr. H. Wilson, of the department of pharmacology, University of Liverpool, for the pharmacological estimations on the urine and tumour.

"In view of modern knowledge on leprosy, countries have revised their laws against lepers. The present trend in dealing with leper patients does not seem to favour compulsory segregation; this method is becoming obsolete; it has its utility as a check on the spread of disease, but it has also many drawbacks—social, ethical, and administrative—and it certainly does not seem to agree with the modern outlook. It has been ascertained that the ancient system of compulsory segregation may do more harm than good, in causing the early cases to be hidden for fear of lifelong imprisonment, until it is too late for effective treatment and they have already infected members of the household. With modern drugs and modern methods of treatment the course of the disease may be favourably altered, especially if patients seek medical advice early. Forcible segregation has been tried in many countries, but it has given poor results. In the Philippines it was adopted at a great expenditure of money, but it has not proved capable of controlling leprosy, and now the law is being reviewed and amended."—Report of the Chief Government Medical Officer, Malta.

Medical Memoranda

Bact. Coli Meningitis in Adults

Bact. coli is a rare cause of meningitis. Most of the recorded cases of meningitis due to this organism have occurred in newborn infants and young children. There have been few reports of adult cases. The rarity of the disease is confirmed by Neal (1924), Barrett *et al.* (1942), MacGregor (1943), and Fraser (1952). Ravid (1935) points out that *Bact. coli* agglutinins are absent from neonatal blood though present in the blood of adults, thus suggesting a possible explanation of the age incidence of this condition.

Previous reports of *Bact. coli* meningitis in adults and older children show that the condition has generally been associated with a septic focus, not infrequently in the genito-urinary tract, or has been a sequel of compound fractures of the skull or vertebral column.

The importance of infections by Gram-negative organisms in head wounds was stressed by Lewin (1948). Ecker (1945), Johnson (1947), and Cairns *et al.* (1947) also record cases of coliform meningitis complicating penetrating war injuries. *Bact. coli* infections have also been noted following spinal analgesia (Kremer, 1945; Evans, 1945), and a case of *Bact. coli* meningitis described by Mayers (1937) followed an intraurethral prostatic resection. Two further cases were recorded by Stallworthy (1943), both in male mental patients, in one of whom evidence of extensive suppuration in the liver and biliary tract was found at necropsy.

Previous accounts of *Bact. coli* meningitis in women show that the disease may follow the surgical induction of abortion (Theys and Gehrcke, 1923; Tesdal, 1934; Magarey *et al.*, 1935; and Crawley, 1946). We therefore thought it of interest to report two further adult cases of meningitis due to *Bact. coli*, both affecting women following induced abortion, and both successfully treated.

CASE 1

An unmarried woman aged 31 was admitted to hospital in semicomatose on October 24, 1952. Previously healthy, she became pregnant for the first time in June, 1952. During the latter half of the pregnancy vaginal douching with hot soapy water was performed twice daily with a syringe. She remained well until October 10, when she developed coryza and stayed off work. On the 16th she had an intense rigor lasting several hours, followed next day by a miscarriage. After this, slight frontal headaches and nausea were experienced until October 21, when she first noticed neck stiffness and increase in headache. The neck stiffness became severe on the 22nd, and was accompanied by tinnitus and backache. Later next day she abruptly collapsed and developed fever. From then onwards she became confused, irrational, and difficult to control, and speech was unintelligible. She had complete amnesia for the later phases of her illness.

On examination she was pale, of normal physique, stuporous, and febrile (temperature 102° F.—38.9° C.), with neck rigidity and marked trismus. The tongue was dry and furred and sordes was present. Pulse regular, rate 96; blood pressure 140/80. Heart sounds normal. Chest, N.A.D. Spleen and liver not palpable. Cranial nerves unaffected, pupils normal. Limbs flaccid. Bilateral extensor plantar responses. Tendon reflexes present and equal. Kernig's sign positive. Urine: specific gravity 1028; reaction acid; slight glycosuria.

Investigation.—A lumbar puncture was performed on admission. The C.S.F. was turbid; pressure over 300 mm.; total white cells 1,700 per c.mm. (polymorphs 80%, lymphocytes 20%); protein, 188 mg. per 100 ml.; chlorides, 680 mg. per 100 ml. *Bact. coli* was isolated in pure culture, sensitive to chlortetracycline ("aureomycin"), chloramphenicol, streptomycin, and "sulphatriad." *Bact. coli* was also isolated from blood culture and from a high vaginal swab on admission. Hb, 11 g. per 100 ml. (74%).

Treatment was started immediately with sulphatriad, 2 g., orally followed by 1 g. four-hourly. The drug was discontinued on October 31. Symptomatic improvement was prompt. The patient was rational on the 25th and the plantar responses were then flexor. Neck stiffness had disappeared by October 27, on which day the temperature fell to normal. Evening pyrexia (99° F.—37.2° C.) persisted, and was associated with vaginal discharge. *Bact. coli* was cultured from a high vaginal swab taken on November 7. The pyrexia and discharge cleared after a course of chlormphenicol, 10 g. in divided dosage, from November 11 to 14. Lumbar puncture repeated on October 31 revealed clear C.S.F.; pressure normal; cells, 56 per c.mm. (predominantly lymphocytes); protein, 67 mg. per 100 ml.; chlorides, 710 mg. per 100 ml.; sterile on culture. A final lumbar puncture on November 17 revealed normal C.S.F., and the patient was discharged well on November 26.

CASE 2

A married woman aged 34 was admitted to hospital on December 3, 1952, as an emergency following a self-induced abortion. There was a history of three previous abortions in 1947, 1949, and 1950. Three earlier pregnancies went to term.

On admission the patient was shocked and afebrile, with a pulse rate of 120. Vaginal examination revealed an enlarged uterus. The cervix was lacerated and bruised. Haemoglobin was 89%; white cells numbered 15,000 per c.mm. (polymorphs 96%). Albuminuria was present. Urine and blood cultures proved sterile. *Bact. coli* was isolated from a high vaginal swab taken on admission.

An intravenous dextran infusion was begun immediately and intramuscular penicillin was given. On December 4 her condition had deteriorated. Fever and neck rigidity developed. Lumbar puncture yielded turbid C.S.F. under pressure. Pending the result of C.S.F. culture, penicillin was given intrathecally and oral administration of chlormphenicol was started.

During the next 24 hours she rapidly became worse, and lapsed into coma. Marked neck rigidity was by now associated with bilateral proptosis, strabismus, subconjunctival haemorrhages, and blurring of the optic disks, suggesting the presence of cavernous sinus thrombosis. Splinter haemorrhages in the nail-beds were also noted. *Bact. coli* in pure growth was isolated from the C.S.F. on culture. The organisms were sensitive to chlortetracycline, chloramphenicol, streptomycin, and sulphatriad. Streptomycin was chosen for subsequent treatment and other antibiotics were discontinued. The drug was administered intramuscularly (1 g. t.d.s.) and intrathecally (100 mg. daily). Heparin, 10,000 units four-hourly, was introduced into the dextran infusion. Lumbar puncture was performed daily (December 5, 6, and 7) under thiopentone anaesthesia, 10 ml. of C.S.F. being withdrawn and replaced by streptomycin. *Bact. coli* was isolated on culture on each occasion though the turbidity of the C.S.F. had decreased, and the cell count fell from 12,360 (polymorphs 100%) to 1,215 (polymorphs 88%). Simultaneously there was progressive improvement in the general condition. On December 8 the patient regained consciousness. The proptosis and neck rigidity were less and strabismus was no longer evident. Streptomycin and the intravenous infusion were discontinued on December 8.

Pelvic examination revealed no retained products of conception, but a low-grade pyrexia was associated with a persistent offensive vaginal discharge, necessitating further treatment. Oral sulphatriad (1 g. four-hourly) was begun. A lumbar puncture on December 10 yielded faintly opalescent C.S.F. (cells 183 per c.mm., polymorphs 75%) which was sterile on culture. Sulphatriad was discontinued on December 15, when recovery was complete, the temperature normal, and the C.S.F. clear and sterile on culture.

COMMENT

Before the advent of chemotherapy, *Bact. coli* meningitis was nearly always fatal, the gross fatality rate in the series of Barrett *et al.* (1942) being 78%. Although there have

been reports of cases recovering without specific chemotherapy (Tesdal, 1934; Magarey *et al.*, 1935), the availability of antibacterial drugs has greatly altered the prognosis and improved the chance of cure. Nevertheless, *Bact. coli* meningitis remains a serious infection.

We are grateful to Dr. M. M. Deane, Dr. R. P. L. Coe, and Mr. C. W. F. Burnett for their kind permission to publish these cases.

Acute Renal Failure After Phenylbutazone

Of the many toxic actions of phenylbutazone ("butazolidin"), its renal effects have received scant attention, although most published series include isolated instances of haematuria and proteinuria. It is not easy to ascribe oliguria or anuria to a drug the toxic side-effects of which already include diarrhoea, vomiting, and salt retention, but the clinical evidence in the following case is strongly suggestive of this complication.

CASE REPORT

A woman aged 61, who had had rheumatoid arthritis for 15 years, was admitted to hospital at 9 p.m. in a state of collapse. She complained of severe vomiting, diarrhoea, and colicky abdominal pain for twelve hours and had had nausea, anorexia, and giddiness for two weeks.

On admission she was very drowsy and distressed from nausea and vomiting. Her temperature, pulse, and respiration were all normal. Her tongue was dry and the throat red, but hydration was otherwise good. There were no abnormal signs in the chest, abdomen, or central nervous system, and the blood pressure was 175/90.

Anuria became obvious the following morning, by which time an uncharted amount of fluid had been allowed. She was still drowsy and appeared overhydrated, with basal crepitations, raised jugular venous pressure, and palpable liver edge, but no pitting oedema. The bladder was empty. A cause for anuria was sought, and on further questioning it transpired that she had passed no urine since 1 p.m. of the day before admission. Moreover, she normally passed urine frequently, usually getting up four times nightly, but had voided very little for two days. She maintained adamantly that scant micturition had preceded the vomiting, and also that it could not be accounted for entirely by a decreased fluid intake from nausea.

Past treatment for arthritis, which had failed to provide substantial benefit, included aspirin, physiotherapy, and over one hundred injections of gold, but no injections had been given for three years. Phenylbutazone, 1,200 mg. daily, was begun two years ago, the dose being reduced to 600 mg. daily after three months, and for six weeks until the time of admission she had been taking 200 mg. daily. The original effect was described as miraculous, and, whereas before taking the drug she had been crippled to a bed-and-

chair existence, only the day after starting phenylbutazone, to the intense delight of her family and herself, she was able to walk downstairs free from pain.

A diagnosis of acute renal failure related to phenylbutazone administration seemed likely, and treatment with an intragastric drip of glucose and arachis oil emulsion was instituted on the morning after admission, to be discontinued after six days, when the urinary output was satisfactory. Catheterization of the bladder on the second day yielded 12 oz. (340 ml.) of dark brown acid urine containing red cells, epithelial cells, and albumin ++; the chloride content was 2 g. per litre and the urea concentration 0.7 g.%; culture was sterile. A blood count showed a haemoglobin of 77% and total leucocytes of 22,000 per c.mm. (polymorphs 93%, lymphocytes 7%). The other investigations are summarized in the Table. Before the patient left hos-

* By catheterization.

pital her urine contained albumin +, no red cells, and the reaction was neutral. On follow-up one month later she felt well and her arthritic condition had not relapsed. Frequency of micturition had returned, the urine contained no albumin, and the blood chemistry was normal.

COMMENT

Bruck *et al.* (1954) described a fatal outcome in an elderly patient in whom oliguria might have been precipitated by phenylbutazone, and histological examination of the kidneys showed degenerative changes in the tubules. They attributed oliguria to salt retention. C. Thornton (1954, personal communication) has had a similar experience in a 7-year-old child with Still's disease, who developed a rash after nine days' treatment with phenylbutazone, 200 mg. daily. Although the drug was discontinued immediately, the child became oliguric, with a blood urea of 128 mg. per 100 ml.

Evidence that phenylbutazone was the cause of acute renal failure in the patient described here can only be circumstantial. The presence of proteinuria and haematuria indicates renal damage. It might be argued that vomiting from some other cause resulted in an extrarenal uraemia, but this is unlikely because dehydration was absent, the blood pressure was not lowered, and the onset of oliguria preceded that of emesis. The alternative explanation of salt and water retention is equally unlikely in view of the normal serum sodium levels and the normal state of hydration on admission. We therefore suggest that, in addition to salt and water retention, oliguria or anuria from phenylbutazone may be due to renal damage, and that such toxicity may become manifest after small doses or prolonged administration.

Fatal Pulmonary Embolism in a Psychiatric Patient
After a Journey by Air

Thanks to modern methods of treatment, pulmonary embolism is no longer the dreaded complication of major surgery that it used to be. Nevertheless it is still responsible for sporadic tragic fatalities, apart from major surgery, and this report concerns one such case. It is published in the hope that it will enable appropriate measures to be taken to avoid similar incidents in the future.

The climatic conditions and the comparatively poor facilities for the treatment of psychiatric illnesses are factors which make it desirable to transfer some patients by air from tropical regions to the United Kingdom as rapidly as possible. The total number of cases is not large, and the patients usually respond favourably to appropriate treatment in the cooler environment of this country. It is to such a patient that I now refer.

CASE REPORT

A woman aged 30, with no previous serious psychiatric illness, was thought to have been very anxious and worried and to have taken sedation for several weeks before the onset of acute symptoms (which occurred at night)—insomnia, confusion, hallucinosis. The day after the onset she was moved to a general hospital. Her physical condition was good, but her temperature was 99.8° F. (37.7° C.), pulse 118, and respirations 26. She was restless, agitated, garrulous, rather muddled, and confused. During the next few days symptoms strongly suggestive of manic-depressive psychosis developed. Sometimes she was very agitated and aggressive, and heavy sedation was necessary—a mixture containing 5 gr. (0.32 g.) of sodium barbitone and 1 gr. (65 mg.) of phenobarbitone as required, and occasionally "somniafine."

As her condition did not improve it was decided to transfer her to the United Kingdom by air. She travelled with a female nurse on the seventh day of her illness. Her condition then was one of hypomania.

During the flight she was very talkative and somewhat noisy. She required three doses of the above mixture, and one dose, 30 min. (1.7 ml.), of "somniafine." Despite sedation she slept very little. She took a light tea and dinner and breakfast. She travelled in a semi-recumbent position, the back of the chair being lowered fully, and her feet elevated on cushions. During the two stops on the journey she remained in the plane because of her mental condition. On the flight she went to the toilet three times, but had to be aided by the nurse and air hostess owing to her unsteadiness. On one occasion she suddenly complained of feeling cold, especially in her feet, and she collapsed. She was wrapped in blankets, and hot-water bottles were provided. Her respiration remained normal, and her colour was very good throughout the flight, apart from the attack just mentioned.

On arrival at an airport in this country she was obviously psychotic, and was sent to the nearest mental hospital. On her admission there she was still mentally rather confused and was prone to ramble incoherently. Physically she seemed well nourished and in good general health. Her pulse was regular and strong. No evidence of any thrombosis was noted. Her blood pressure was 146/100, temperature 98.8° F. (37.1° C.), pulse 80, respirations 18. During the course of the next two days her mental condition improved. The general picture favoured the diagnosis of a "manic-depressive psychosis." Her illness appeared to be reactive in origin, and I formed the opinion that the prognosis for therapy was good.

Two days after admission she complained of pain in the back all the afternoon, and at about 6 p.m., when in a wheel-chair, she suddenly became rigid, cyanosed, and stertorous in her breathing, with signs of syncope and collapse. She now complained of pain in the back and ankles. Her pulse was weak and irregular, and her general condition

poor. A tentative diagnosis of coronary infarct was made. She gradually weakened, dying next morning.

Post-mortem Report.—A well-nourished healthy woman with no physical lesions discernible other than the following: (1) all the veins of both calves were thrombosed; (2) one acute infarct at base of right lung; (3) lungs, numerous rather soft *ante mortem* clots. Cause of death: pulmonary embolism.

COMMENT

This patient, well nourished and of good physique, was examined physically before embarkation, on arrival at the airport, and on arrival at the hospital in this country. No evidence of any physical lesion was found. The blood pressure, temperature, pulse, and respirations were normal at each examination. There was no negligence, and in such a case thrombosis and embolism could not be anticipated. Many patients in much worse physical condition have made the journey without mishap. However, being wise after the event and reviewing the case in retrospect, the following points are relevant.

It is recorded that the commonest site of venous thrombosis leading to pulmonary embolism is the veins of the calves (Willis, 1950). Such thrombosis is not likely to be discerned by physical examination. The facts that might have led to thrombosis in this case are: (1) Bed treatment with possibly insufficient mobility for seven days prior to embarkation. (2) Some exhaustion due to her hypomanic excitability. (3) Sedation necessary to try to combat her excitability. (4) Prolonged immobility on the plane for reasons stated (the journey took approximately 18 hours). (5) Pressure on the calves from the mere weight of her legs against the pillows supporting them. (6) The plane was, of course, "pressurized," but even this precaution does not supply exact ground atmospheric pressure of oxygen, and in her condition this may have had some slight effect. (7) The collapse on the plane was probably due to a small infarct, and had it been possible to realize this preventive measures might have been taken to avoid further infarction (Evans, 1951).

The occurrence of the rare advent of thrombosis in a psychiatric case is no more a contraindication to the transport of such cases by air than a similar possibility is a contraindication to a major operation in surgical patients. There are certain cases in which it is essential to take the risk. Moreover, thrombosis of this type is not peculiar to air travel and might equally well occur in any other method of travel involving prolonged immobilization.

Whenever possible the following prophylactic precautions against this complication are indicated: (1) Adequate mobility prior to embarkation. (2) Ordinarily patients should not be transported by air unless they are well enough to walk by themselves and to take walking exercise at each intermediate stop. (3) The question of sedative treatment should receive very careful consideration, and wherever it is at all possible the patient should be moved to the nearest centre where E.C.T. is available, and treated there until she is well enough to make the journey with the minimum of sedation and able to walk about at intermediate stops and regularly during the journey. (4) It is obvious that if thrombosis can occur in a patient of this type, apparently in very good physical health, it must be guarded against even more in patients suffering from physical illness. (5) In all cases in which the above precautions are not practicable and in those patients having for one reason or another to remain recumbent, special prophylactic measures should be taken—for example, breathing exercises, massage, frequent changes of position, active movements of the legs, and appropriate use of heparin (Evans, 1951).

Reviews

STREPTOCOCCAL INFECTIONS

Streptococcal Infections. Edited by Maclyn McCarty. (Pp. 218. 40s.) New York: Columbia University Press. London: Oxford University Press. 1954.

Scarlet fever is nowadays a mild disease, deaths from puerperal sepsis are rare, erysipelas has lost its terrors, and the E.N.T. surgeon is bereft of radical mastoidectomies, while rheumatic fever and acute glomerulonephritis seem also to be "on the run." Yet haemolytic streptococcal infections still contribute a sizable quota to the total morbidity among communities in temperate climates. For example, it is estimated that there are over 7,000,000 illnesses from streptococcal infections in the U.S.A. every year, and acute rheumatic fever is a sequel in approximately 3% of such cases. In Great Britain cases and outbreaks of streptococcal sore throat in child communities are an everyday occurrence, acute otitis media is not uncommon in young children, and skin and surgical infections due to the haemolytic streptococcus still plague us. A stocktaking in the form of a symposium by experts on our present-day knowledge of *Streptococcus pyogenes*, the ravages it produces, and the means for dealing with or preventing streptococcal infection is therefore opportune.

There is perhaps no pathogen which is so complex in its antigenic make-up and in the variety of substances which it secretes as *Streptococcus pyogenes*, and this aspect of the problem is fully explored in the opening chapters of this book with many stimulating indications for further studies. Particularly interesting at the present time because of its possible practical applications is Dr. L. B. Christensen's review of the streptokinase-plasminogen system, while the chapter on host factors in streptococcal infections by Dr. Dennis Watson may shed fresh light on the pathogenesis of acute rheumatic fever. On the more applied side the last four chapters provide most interesting reading. Dr. Louis Wannamaker discusses the epidemiology of streptococcal infections in the light of an extensive experience of the behaviour of streptococcal pharyngitis at a U.S. Army Training Centre in Wyoming, and concludes that direct contact plays a more important part than air-borne spread by either dust or droplet media. Dr. Floyd Denny deals with prophylaxis by such diverse procedures as tonsillectomy, active immunization, and chemoprophylaxis with sulphonamides or penicillin. The latter drug seems, in adequate doses, to be effective in curing streptococcus carriers and in preventing relapses of rheumatic fever. Dr. C. H. Rammelkamp tells the interesting story, based initially on epidemiological data, of the occurrence of acute glomerulonephritis following infection with one or two specific streptococcal types, particularly Type 12; and Dr. C. A. Stetson shows most convincingly, again from data collected at the Army Training Centre in Wyoming, that rheumatic subjects develop higher antibody titres to streptolysin than do patients with uncomplicated streptococcal infections; indeed, the attack rate for rheumatic fever bears a direct relationship to the antistreptolysin titre.

Altogether this is a most readable and stimulating collection of essays on streptococcal infections, and should have a wide appeal.

ROBERT CRUICKSHANK.

BÖHLER ON FRACTURES

Die Technik der Knochenbruchbehandlung. By Dr. Lorenz Böhler. Band II/1. (Pp. i-xi, 1133-1569; illustrated. D.M. 70; \$16.80.) Vienna and Bonn: Wilhelm Maudrich. 1954.

"The technique of handling fractures of the bones" owes more to Lorenz Böhler than to any other individual, and that his great textbook should now have passed through 13

German editions and 15 in other languages will be no surprise to those who are familiar with its contents. The present volume deals with fractures of the femur; by far the greater part is devoted to the head and neck of that bone, and the difficult problems which occur in that region are fully discussed. The author places at the disposal of other surgeons an experience to which there is no parallel, and this he succeeds in accomplishing with perfect lucidity and precision.

Full illustrations from photographs, radiographs, and diagrams give one an immediate grasp of even complex fractures and of the elaborate procedures required for their correction, but the personal interest aroused in every case which is described marks the genius of the great teacher as well as the great surgeon. Most original of all are the series of questions which are suggested for the surgeon to consider in each case he visits. As the author says, the memory of these questions would avoid many disasters, and it is perhaps consoling that after 45 years of experience he does sometimes forget some little point himself.

It is a wonderful book—a record of surgery on the highest plane, of brilliant work instinct with deep human interest. It is pleasing to know that an English edition will appear in the spring.

HENRY SOUTTAR.

PROGRESS IN ALLERGY

Progress in Allergy, IV. Edited by Paul Kallos. (Pp. 520; illustrated. Swiss francs 68.65.) Basle, New York: S. Karger Ag. 1954.

The arrangement of this fourth volume is similar to that of the previous ones. All articles are in English. Paul Kallos, the editor, gives an introductory survey of the present state of allergy, and his article is followed by eight monographs on aspects of it by authors who have been carrying out research in the actual fields they are reviewing. The first consists of 48 pages on the histology of allergy lesions by M. C. Bohrod; the second, of almost 100 pages by R. L. Mayer, covers group sensitization to compounds of quinone structure. He considers, on experimental evidence, that the allergic manifestations are caused by the metabolic formation of oxidation or reduction products, probably compounds of quinone structure, rather than that the original amines, nitro compounds, azo dyes, sulphonamides, and *p*-aminobenzoic acid derivatives represent direct active antigens.

A short review of delayed hypersensitivities by S. Raffel is followed by three articles on adrenal hormones. The first is by G. Pincus on the biosynthesis of adrenal steroids, the second by F. L. Engel on the functional relationships of the anterior pituitary and adrenal cortex, and the third by T. F. Dougherty on the mechanism of action of the adrenocortical hormones in allergy. These are essential articles in a world where these hormones are being experimented with in allergic and other diseases with varying degrees of success, but they demonstrate that we are far from being certain of the mechanisms involved. The next article is by Noelpp-Eschenhagen and Noelpp, and covers in detail their own experimental work on guinea-pig asthma and a discussion of their working hypothesis of the mechanics of normal and asthmatic breathing. The final review is by K. Maunsell on respiratory allergy to fungus spores: there is nothing really new in this contribution, but it is a very sound and practical one and should be read by all clinical allergists.

To sum up, this volume continues the high standard and excellence of the previous three volumes. The articles are authoritative and all contain first-rate bibliographies. The whole format and printing of the book are excellent, and it can be warmly welcomed as an essential part of the library of all interested in allergic diseases.

C. J. C. BRITTON.

AMOEBIASIS

Amoebiasis. By Ernest Carroll Faust, A.B., M.A., Ph.D. (Pp. 154+xi; illustrated. 34s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications Ltd. Toronto: The Ryerson Press. 1954.

In this small monograph of the American Lecture Series in Internal Medicine the well-known American parasitologist, Dr. Faust, who is a recognized authority on amoebiasis, provides an up-to-date synopsis covering the clinical and public-health aspects of this disease. The six chapters into which the book is divided deal respectively with the aetiology, epidemiology, pathology, clinical manifestations, diagnosis and treatment, and control of amoebic infections. The account is clear and precise throughout, and will serve the needs of the practising physician by providing a concise guide to the recognition and management of amoebiasis. However, the didactic approach to the subject has its drawbacks, for the author's insistence that *Entamoeba histolytica* is invariably virulent leads him to dismiss the existence of healthy carriers, with the result that in dealing with the geographical distribution of amoebiasis no distinction is made between the incidence of symptomless infections—which are in the majority everywhere—and that of clinical cases. The reader of this book will therefore form an exaggerated picture of the incidence of amoebiasis as a disease, especially in temperate regions, and particularly when he is told that "amoebiasis in the United States is as serious a public health liability as tuberculosis." Nowadays this view will hardly be acceptable in Europe, where the host-parasite relations and epidemiology of amoebic infections are beginning to be seen in correct perspective.

For the parasitological diagnosis of amoebiasis reliance is placed on the somewhat imperfect figures of *E. histolytica*, the morphology of which is not adequately described in the text. The photographs illustrating the pathological changes are, however, good. The bibliography occupies 17 pages, and there are author and subject indexes.

C. A. HOARE.

CONNECTIVE TISSUE

Connective Tissue in Health and Disease. Edited by G. Asboe-Hansen, M.D. (Pp. 321; illustrated. \$7.50; Danish kroner 50.) Copenhagen: Ejnar Munksgaard. 1954.

This is a useful symposium dealing with a rapidly developing field. There are 23 authors (14 from the United States, 5 from Denmark, and one each from Italy, Sweden, Finland, and Britain), most of whom have made major contributions to the subject. The scope and quality can best be indicated by listing the various contributions.

After an introduction by the editor, the first half, which is the better one, starts with a review of the morphological aspects by Robb Smith. He is followed by McManus on histochemistry, Meyer on mucopolysaccharides, Dorfman on the metabolism of mucopolysaccharides and hyaluronidase inhibitors, Kulonen on collagen, Bostrom on sulphate exchange, Duran Reynals on the spreading reaction, and Iversen on hormones; other articles follow on ageing (Banfield), wound healing (Howes), pathology (Altschuler and Angevine), infection (Sprunt and Cavallero), arteriosclerosis (Rinehart), and cancer (Simpson), and on cortisone, ascorbic acid, and amyloid (Teitlum).

The book ends with sections on miscellaneous clinical aspects, of which the best is Klemperer's masterly review and defence of the unfortunate term "collagen disease." Ragan's section on the clinical, aetiological, and therapeutic aspects of arthritis and the rheumatic diseases is a triumph of compression. Other sections, on traumatic, ophthalmological, and dermatological conditions, show considerable overlap: it is difficult to understand for what reader such potted descriptions of well-known diseases could be intended. The earlier chapters of this book will, however, be found invaluable to workers in this and related fields as an up-to-date and authoritative assessment of the present situation.

E. G. L. BYWATERS.

ALLEN AND HANBURY, 1715-1954

Through a City Archway: The Story of Allen and Hanbury, 1715-1954. By Desmond Chapman-Huston and Ernest C. Cripps. (Pp. 326+xv; illustrated. 25s.) London: John Murray. 1954.

Many generations of doctors have known and had dealings with the well-known firm of Allen and Hanbury, but probably very few know much of its history. It was founded in 1715 by Silvanus Bevan in an old house in Plough Court, off Lombard Street. Bevan was a Quaker and possessed the reliability and shrewd business acumen which so many of that persuasion have. From small beginnings the firm soon grew to be an important pharmaceutical centre, and had many dealings with doctors in North America both before and after the War of Independence.

William Allen joined the firm in 1792, and within a few years became the controlling personality of the growing business. Allen was a most extraordinary person. He was a devout Quaker with strong humanitarian sympathies. He was the friend of Thomas Clarkson, William Wilberforce, Robert Owen, and many more philanthropists and educational reformers; he lectured at the Royal Institution and at Guy's Hospital on natural philosophy; he was a master of many languages, studied botany and astronomy, and was elected a Fellow of the Royal Society; yet he managed to travel widely while keeping a superintending eye on the affairs of the firm. He was on friendly terms with the Czar of Russia and many crowned heads of Europe, and with the Royal Family in England. He took the lead in many philanthropic enterprises and gave generously to various charities. Yet we could not find in this account how such a comparatively small enterprise could provide him with the wherewithal to do all these things. He certainly must have been a good business man. Allen's second wife was a Hanbury, and after his death the firm was for many years controlled by members of that family. This section of the book would have been more easy to follow if a genealogical table had been inserted. Some of the Hanburys, particularly Daniel (1825-75), were very learned scientists.

The final section of the book gives an account of the modern expansion of the business and relates graphically how the Bethnal Green factory was destroyed by bombs in the second world war. We found the book interesting, but not so easy to read as it would have been if the story had been better knit together. We do not remember ever previously meeting a book with 32 appendices.

ZACHARY COPE.

Dr. F. Kauffmann's book *Enterobacteriaceae* (Copenhagen: Ejnar Munksgaard; 62s.) is still the most complete source of information on laboratory investigations leading to the classification of this family of organisms. Certain changes in classification have been made, notably of two new genera—*Cloaca*, which was known in Britain as *Bacterium cloacae*, and *Hafnia*, which includes many intermediate types of *Escherichia coli* and some paracolons. Generic rank is now given to the *Escherichia* group, which includes *E. coli* and *E. freundii*, to *Klebsiella*, which includes *K. pneumoniae* and *K. rhinoscleromatis*, to *Providencia*, and other well-known groups. The sections on *Salmonella*, *Arizona*, *Shigella*, and *Proteus* include descriptions of new serotypes. Many of the classifications used are not wholly accepted in Britain, but, being based on the work of this well-known author and his colleagues, they are worthy of most careful consideration. The author rather emphasizes the work carried out in Scandinavia. It would have been interesting to have the opinion of Dr. Kauffmann, an acknowledged expert in most branches of this field, on contemporary work carried out in other laboratories.

Treatment with Penicillin and Other Antibiotics. by J. G. BATE, with a foreword by Sir ALEXANDER FLEMING (Faber and Faber. 1954. Pp. 100, 7s. 6d.), is a simple account of chemotherapy intended mainly for nurses. It describes the properties of antibiotics and of some other drugs, including sulphonamides, and their use in the treatment of different forms of disease. In an appendix on precautions against skin reactions is reprinted the memorandum recently issued by the Ministry of Health on how to handle antibiotics without inducing skin sensitivity.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY FEBRUARY 5 1955

CHLORPROMAZINE

Chlorpromazine is a substance which is a near relation chemically of promethazine ("phenegan"). It was introduced by Laborit and Huguenard¹ as a drug to prepare patients for operation, being given together with promethazine and pethidine. Chlorpromazine then was found to produce not only a condition practically equivalent to anaesthesia but also a fall in body temperature, and much interest was taken in what was called a state of "artificial hibernation," as being conducive to the avoidance of post-operative shock. Chlorpromazine ("largactil") has also been increasingly used in psychiatry, having a quietening effect on chronically agitated patients.²

The question is, What does chlorpromazine do? Its action in causing a fall of body temperature was said to depend on a block of the autonomic system, and this view has been repeated by various authors, despite the well-established evidence that the main control of body temperature is due to the tonic impulses passing down the voluntary nerves to skeletal muscle. Recently Holzbauer and Vogt³ have shown that one form of sympathetic activity which is originated centrally is not affected by chlorpromazine—namely, that which follows the administration of morphine. When morphine is given to a cat in a dose of 40 mg./kg. Vogt⁴ has shown that the noradrenaline which is present in the tissue of the hypothalamus diminishes in amount, and in addition, as Elliott⁵ found, impulses pass from the centres along the splanchnic nerves, causing a discharge of adrenaline from the adrenal medulla. Holzbauer and Vogt have observed no diminution in the central stimulant action of morphine as a result of the previous administration of chlorpromazine in such a large amount as 25 mg./kg. There was the same fall in hypothalamic noradrenaline and in the adrenaline and noradrenaline in

the adrenal medulla as occurred without chlorpromazine. As a control for this observation the previous injection of "nalorphine" completely inhibited the action of morphine. There are not many ways in which the hypothesis that chlorpromazine causes central autonomic block can be tested, and in one clear case in which the test is possible a negative answer has been given.

The same workers³ have also demolished the suggestion⁶ that chlorpromazine prevents A.C.T.H. being released after the trauma of an operation and so diminishes the effect of stress. As evidence of the release of A.C.T.H. they determined the ascorbic acid content of the adrenals of rats. The "stress" consisted in administering urethane, exposing the viscera, and handling the mesentery. The fall in ascorbic acid in the adrenal glands was the same whether chlorpromazine (10 mg./kg.) was administered or not. Furthermore, they showed not only that chlorpromazine itself caused some release of A.C.T.H. but also that it did not modify the release of A.C.T.H. by adrenaline. The view, therefore, that chlorpromazine causes either a chemical hypophysectomy⁶ or a chemical adrenalectomy⁷ thus falls to the ground.

Dasgupta and Werner⁸ have studied the effect of stimulating areas in the hypothalamus and in the medulla from which a rise of blood pressure can be elicited, and found that the pressor response was abolished by chlorpromazine provided that the observations were made in the decorticated cat. The significance of the observations seems doubtful, since they could not be repeated in cats anaesthetized with chloralose and since the chlorpromazine caused a large fall of blood pressure in the decorticated cat; such a fall might contribute to the disappearance of the pressor response. They also observed that the pressor response to clamping the carotids was abolished by chlorpromazine injected intracisternally in monkeys. This result, however, does not distinguish the action of chlorpromazine from that of a barbiturate, since that has the same effect.

So far as the important central effect of chlorpromazine is concerned, knowledge is still lacking about how it differs in its site of action from other depressant substances. Kopera and Armitage⁹ have demonstrated a peripheral action on skeletal muscle and shown that injection of the drug into the iliac artery leads to a gradual depression of the contraction of the gastrocnemius muscle of the cat in response to stimulation through the nerve or even directly; this depression develops in the course of 30–60 minutes. An action of this kind exerted even to a small extent on all the skeletal muscles would

appear to be the most likely explanation of the temperature-lowering property.

The effects of chlorpromazine are prolonged and for the most part cannot be reversed. This fact and the evidence that some patients become jaundiced owing to a toxic action on the liver^{10–13} seem the strongest reasons for caution in its use.

INTRACRANIAL GLIOMATA

A statistical analysis of the records of 298 patients with intracranial gliomata has recently been published by the Medical Research Council, and it is to the credit of the authors, Drs. John Penman and Marion C. Smith, that there is so much of interest to be found in this report.¹ Of the verified gliomata in this series, 54% were glioblastomata, 33% astrocytomata, 6% medulloblastomata, 5% oligodendrogliomata, and less than 1% ependymomata. The two most common tumours—glioblastoma multiforme and astrocytoma—were twice as common in males as in females, this sex incidence being observed in early adult life and middle age. A graph giving the numbers of cases at different ages shows peaks at 0–9 and again at 45–54 for the whole series. The curve for astrocytoma alone is similar, while those for medulloblastoma and glioblastoma have single peaks only, at the younger and older ages respectively. The left cerebral hemisphere was more often involved than the right, in the proportion 4 to 3. Two hundred and thirty of the tumours were supratentorial and 68 infratentorial—though in the first decade infratentorial tumours are four times as common as supratentorial. When allowance was made for the varying volumes of the cerebral lobes, it was found that the temporal lobe was affected almost two and a half times as often as the occipital, the frontal and parietal lobes occupying an intermediate position of frequency of involvement.

Analysing the symptoms, Penman and Smith found that at the time of admission 80% of the patients had headache, 69% papilloedema, 57% vomiting, and 43% epilepsy. But the frequency of epilepsy as an initial symptom was almost as great as that of headache and greater than that of vomiting: it was the symptom which most often preceded all others, usually in the form of multiple major fits. The value of radiological investigations emerges clearly from the report, abnormality being seen in 60% of the cases: in half, the films showed evidence of raised intracranial pressure. Pineal calcification of such density as to be readily demonstrable on antero-

posterior films was seen in only one-fifth of the adult patients, and it is noteworthy that in a third of this group there was no displacement of the pineal body in spite of the presence of a tumour. In only 4 out of 247 cases subjected to ventriculography was an abnormality not apparent.

The natural history of these tumours in general has been studied by tabulating the period of survival after the onset of illness. Of the 89 patients receiving no treatment, all had died within seven years of the onset of symptoms—over one-half within three months and almost another two-fifths within three years. In the whole series, where the age at onset of symptoms was under 15, as many as 50% of the patients survived for more than three years, whereas where the age at onset was over 15 only 25% survived for this period. The site of the tumour also affected the survival period, which diminished progressively from the cerebellar tumours, associated with the longest survival, through cerebral and brain-stem tumours to those of the corpus callosum, which were associated with the shortest period of survival. Thus the histology of the neoplasm is plainly not the only factor affecting the fate of the patient.

The figures show all too clearly that treatment favourably influenced the disease in but a minority of cases. Thus over half the patients in Penman and Smith's series were excluded from consideration in the section of the report devoted to the results of treatment, since they either received no surgical treatment or did not survive such treatment for a sufficient period to permit irradiation. Of the remaining 131 patients, nothing can be said about the value of radiotherapy alone, since it was used as a sequel to surgery. Total excision of cerebellar astrocytomata is often curative in the patients surviving operation. In tumours of the cerebral hemispheres total excision is, in the opinion of many neurosurgeons, rarely possible: but, if the neoplasm is so placed as to permit it, attempts at radical excision may prolong the patient's life more than conservative surgery would do. Of the 85 patients who were alive a year or more after admission to hospital and who had been treated by surgery or irradiation or both, in only 52 (18%) was the survival considered to be worth while.

The advances in neurosurgery of the last quarter of a century have thus brought little improvement in outlook for the patient with an intracranial glioma. It is not surprising that intrinsic tumours of the brain should carry a grave threat to life and function. Perhaps in time some satisfactory form of therapy will be developed, and until then treatment by surgery and irradiation must continue—not only because of the relief from symptoms and prolongation of life which

it may provide, but also in order that other less fatal morbid swellings wrongly suspected to be gliomata may be discovered and treated.

ANTICOAGULANTS IN CORONARY DISEASE

In the past ten years anticoagulant therapy in disease of the coronary arteries has become an important feature of cardiological practice. Many physicians have now gained practical experience of it, but there has been much difficulty in determining its true value and indications. Anticoagulant therapy is laborious, uncomfortable, expensive, and potentially dangerous. It is therefore hardly surprising that it is an unpopular form of treatment which would have been abandoned with joy if it had proved of little worth. Indeed, there are some who plead with vigour that there is no justification for its use in any form of coronary arterial disease.¹ Others share the more moderate view of Schnur² that anticoagulants should be used only in severely ill, "poor risk" cases of myocardial infarction. Schnur³ has recently published his views in the form of an interesting catechism, in which he suggests that only about 10% of cases of acute myocardial infarction are likely to benefit from anticoagulant therapy. This is the group of patients who are liable to develop thromboembolic complications, and Schnur appeals for research into the methods by which such patients may be recognized.

A paper from Gilchrist and Tulloch published recently in this *Journal*⁴ gives valuable aid to readers who have been confused by the subject. These authors summarize the pathology of coronary arterial disease, include a reminder of the confusion which arises from slipshod nomenclature, and present a concise account of their experience. They reaffirm their faith in the value of anticoagulant therapy in all cases of acute myocardial infarction, except for patients who suffer from complications such as anaemia, peptic ulcer, and gross hepatic or renal disease. They add to the increasing body of evidence that such treatment reduces both the mortality and the complication rates in the first six weeks after an acute infarction, and they stress the danger of coming to a decision early in the course of treatment that any particular case is a "good risk." On the other hand Russek and Zohman⁵ consider that deterioration of the condition of a good-risk case is relatively uncommon, though they agree that such a deterioration is an indication for the immediate use of anticoagulants. These authors give their criteria for the selection of good-risk cases and record a series of 489 treated without anticoagulants with a mortality rate of 3.1%. They estimate that about 30% of all cases of acute myocardial infarction require anticoagulant therapy and stress its value in the poor-risk case. Hill⁶ expresses a widely held view that it is not justifiable to withhold anticoagulant treatment from any patient with an acute myocardial

infarct unless specific contraindications exist. Indeed, if it is true that anticoagulants are capable of preventing thrombosis in the coronary vessels, there is an excellent argument for their use in the milder case. The less the initial damage, the greater is the scope for the prevention of further infarction. More work is required to determine the effect on prognosis of anticoagulant therapy for about four weeks after an acute myocardial infarction. It might well prove difficult to justify the expense, labour, danger, and discomfort of the treatment if it should be shown that the patients are spared only to fall victim to recurrent infarcts when their treatment is withheld.

Long-term anticoagulant therapy as a preventive measure in patients who have previously had an acute infarct or are suffering from increasing angina raises interesting problems. Its value is not yet established, but there have been some encouraging reports. Nicholson *et al.*⁷ have treated 177 patients with "impending myocardial infarction" or acute coronary insufficiency. Nine (5%) suffered from myocardial infarction while under treatment and 10 out of 27 patients who stopped treatment had an "acute coronary attack" within one month, and 8 of them died.

Gilchrist and Tulloch give an excellent account of the practical difficulties and the dangers of anticoagulant therapy. It is clear that such treatment should never be instituted unless it is possible to control it with daily estimations of the prothrombin activity by a competent technician and daily examination of the patient for signs of haemorrhage, including microscopical haematuria. Opportunities for the use of anticoagulants in general practice are necessarily limited by these inescapable requirements. With the increasing, though still experimental, use of anticoagulants for long-term preventive therapy, many patients will be taking these drugs at home. In such cases it is likely that the doses will be adjusted at the out-patient clinic, but the danger of haemorrhage is always present and the general practitioner may well be consulted in such an emergency. Under these circumstances the administration of 25 to 50 mg. of vitamin K₁ is the most appropriate counter-measure in addition to the necessary local treatment. Finally it is necessary to remember that the use of anticoagulants in no way removes the need for applying all the more established and traditional methods of treatment which have proved of value in the past.

A NEW MYCOBACTERIUM

An interesting story told by F. Linell and Å. Nordén¹ begins with the occurrence of skin lesions on the elbows of children in the town of Örebro, Sweden. Large-scale inspection revealed the existence of 75 children so affected, and a few adults were found with the same condition. The site was always the same, and the lesion began as a papule which slowly enlarged and eventually ulcerated; there was some enlargement of neighbouring lymph nodes. All the patients were swimmers, and, since the histological features of the lesion resembled

those of tuberculosis, it was at first suspected that the water of the swimming-bath had been contaminated from an ulcer produced by B.C.G. vaccination. The swimming-bath was indeed the source, and the site of the lesion was due to scratching of the elbow skin against a rough cement wall when pushing off after holding a rail, but the acid-fast bacillus responsible, which was found in the water itself, was not *Myco. tuberculosis*. Several strains were cultivated both from the bath and from lesions, and their characters, which are fully described, were constant. The organism is strongly acid- and alcohol-fast, and indistinguishable from *Myco. tuberculosis* in morphology. It fails to grow on Löwenstein-Jensen medium at 37° C., a fact which apparently accounts for some delay in isolating it, the temperature for optimum growth being about 31° C.; on the other hand, growth at 37° C. was obtained on glycerol agar. Pathogenicity tests were made in eight species of animal: the organism proved to be almost non-pathogenic to the guinea-pig, which accounted for the failure of diagnostic inoculations with human material made in the early stages of the investigation. The mouse was the most susceptible mammal, and hamsters also developed progressive lesions; chickens were entirely unaffected; in frogs the organism survived and a large inoculum produced lesions; the few tests in tortoises gave results of doubtful significance. It is not clear how far temperature requirements affect pathogenicity for different species; it would be interesting to inoculate reptiles which could be maintained at about the optimum temperature for *in vitro* growth.

Not only did the characters of the organism as determined by the authors appear to indicate that it was a new species, but authorities in other countries to whom cultures were sent verified this. They included A. Q. Wells in Britain and F. Fenner in Australia, who confirmed that it is distinct from *Mycobacterium ulcerans*, another recently described acid-fast bacillus which causes skin lesions. It was accordingly and appropriately named *Mycobacterium balnei*, and the discovery by Zettergren of a second identical epidemic in the town of Västerås, Sweden, provides confirmation that infection by this organism may be acquired in swimming-baths, and thus further justifies the choice of name. The authors have proved the responsibility of the organism for the skin lesions observed by inoculating themselves with living cultures. They have also thoroughly investigated the effect of infection with *Myco. balnei* on sensitivity to tuberculin, and, with assistance from the Ministry of Agriculture Research Laboratories at Weybridge, where a P.P.D. (purified protein derivative) was prepared from their organism and cross-sensitization tests were done in guinea-pigs, have shown that *Myco. balnei* infection produces sensitivity to human tuberculin. Conversely, inoculation with B.C.G. sensitizes to tuberculin from *Myco. balnei*. Whether infection with the latter has any influence on subsequent infection with tubercle bacilli is not yet known. The fact that this trivial lesion produces tuberculin sensitivity is an additional reason for watching for the occurrence of the infection elsewhere. There is no reason for supposing that *Myco. balnei* is confined to Sweden. On the other

hand, it is unlikely to cause trouble in any swimming-bath where the water is chlorinated, since efficient chlorination put a stop to both Swedish epidemics.

VULVAR FLUORESCENCE

The human female does not plainly display by the colour of her pudendal skin the state of her ovarian function as does the female monkey. Under ultraviolet light, however, the vulva exhibits a fluorescence the variations in the colours of which are said to reflect changes in the amounts of ovarian hormones in the blood. Since Margolese¹ reported on vulval fluorescence or luminescence some six years ago, he and several other workers²⁻⁵ have added further comments on its implications in gynaecology. Most recently Morton⁶ has reviewed these earlier reports, and added his own observations based on examinations made over a period of three years. He states that there is general agreement on certain basic findings. There is no fluorescence of the vulva in childhood. About the time of puberty a brown-green background fluorescence appears and continues to be seen after castration and the menopause. During the reproductive phase this brown-green background is replaced to a varying extent and intensity by purple fluorescence. A much darker, but also variable, purple colour is seen during pregnancy, only to fade rapidly within hours or days of delivery. Morton himself found that the administration of oestrogens to women after the menopause was followed by the re-appearance of the purple colour within 48 hours, which faded again after the withdrawal of the hormone. He therefore believes that purple fluorescence is closely associated with oestrogen activity, as originally suggested by Margolese. The latter described a gradual increase in the extent and intensity of the purple fluorescence during the menstrual cycle and a fading away just before menstruation, paralleling the oestrogen levels during the cycle, but Benson³ did not find the variations sufficiently distinct to allow such a precise correlation.

Whereas the significance of purple fluorescence of the vulva seems to be generally agreed, the cause of the appearance of a bright red luminescence, a phenomenon associated with vaginal bleeding, is the subject of argument. Benson believes that this red colour is an extrinsic fluorescence largely due to surface deposition of porphyrins from decomposed red cells, which can be wiped off. Morton, however, supports those who say that there is also a true, intrinsic red fluorescence. Greenblatt⁴ suggests that at present vulval fluorescence has its most useful clinical application in differentiating hormonal from other causes of threatened abortion. He claims that if in threatened abortion the purple colour is replaced by red this is evidence of hormonal deficiency and is an indication for administering large doses of oestrogen and progesterone. He found that where a return to the purple coloration followed this

therapy, the pregnancy nearly always continued. However, many would consider this a case of *post hoc*, not *propter hoc*.

It remains to be seen exactly what advantages this phenomenon of vulvar fluorescence will offer the clinician. When account is taken of differences in techniques and variations in the appreciation by human eyes of colour shades and their intensity, the published reports show surprising unanimity. Morton suggests speculatively that the purple colour is due to the specific effect of a metabolite of oestrogen on certain cells or pigments in the vulval skin, and that if this is proved the knowledge so gained might help to throw some light on the mode of action of oestrogens. For the present, however, he wisely concludes that the nature of the phenomenon is still not clear and that the exact site of the fluorescent material still remains to be determined.

MALNUTRITION IN AFRICA

During recent years the group of symptoms best known as "kwashiorkor" has been recognized as one of the most important and widespread diseases of dietary origin throughout the world. Infants or young children are the victims, and the picture includes a selection of abnormalities from a long list. Thus the child fails to thrive and is weak, lethargic, and miserable. The abdomen is usually distended, and the liver enlarged and fatty. Failures in the digestive system, and particularly the pancreas, give rise to frequent, foul-smelling motions. There is invariably hypoproteinaemia and sometimes oedema. The skin may become dry and cracked, and the curly black hair of the negro may lose its normal texture and become grey or reddish. The condition is generally fatal unless careful dietary treatment is given. The fundamental cause, doubtless complicated by various forms of secondary stress, is a severe deficiency of dietary protein. Several official bodies, including the World Health Organization, have concluded that the problem of preventing kwashiorkor has passed beyond the province of the pathologist, and can be solved on a large scale only by experts in sociology and agriculture. Food adequate in protein must be provided after weaning to replace diets containing excessive amounts of cassava, plantains, or other foods which consist mainly of carbohydrates.

Two years ago an inter-African conference on malnutrition in African mothers, infants, and young children was held at the Medical Research Council's field research station at Fajara, Gambia. Professor B. S. Platt was president, and delegates from many nations attended. The proceedings of the numerous sessions, which have recently been published,¹ indicate the broad field which was covered. Thus most of the seventy communications were on kwashiorkor—its clinical features, pathology, biochemistry, and dietetics—while others discussed the related problem of the effects of malnutrition on pregnancy and lactation.

¹ *Malnutrition in African Mothers, Infants and Young Children*, 1954, London, H.M.S.O., 25s.

Reports from the Gambia, Nigeria, the Bechuanaland Protectorate, Basutoland, Uganda, and French West Africa confirmed the scattered incidence of kwashiorkor throughout Africa. H. C. Trowell and A. J. Howe demonstrated examples of the disease, and J. N. P. Davies discussed its pathology. Animal experiments bearing on the problem of dietary liver injury were described by O. Lindan, and a paper by P. R. Payne, B. S. Platt, and D. F. White got down to the practical problem of avoiding "streaking" in the paper electrophoresis of plasma proteins. Perhaps the most hope for conquering the disease, however, was raised by Professor Platt's account of experiments to prevent malnutrition in Gambian villages by improving agricultural methods and by eradicating malaria. At the same time the conference recognized that in spite of preventive measures cases of kwashiorkor would continue to occur. Information on the diagnosis and treatment of the condition should therefore be made widely available.

ACTIVITY IN PROSTATIC CANCER

"Current trends in cancer therapy are such that the early detection of adenocarcinoma of the prostate is receiving renewed interest and attention." Thus Hudson and his colleagues¹ draw attention to the merits of open perineal biopsy in the belief that other diagnostic measures are often ineffectual until the disease has become inoperable. Their observations follow a previous study² aimed at the detection (and treatment) of unsuspected prostatic cancer in the ageing male population. In this, their material was obtained mainly from the Men's Shelter, operated by the New York City Department of Welfare. One hundred cases were selected at random from 1,657 men, from whom cursory histories were taken and on whom rectal palpation of the prostate was performed. None of the patients had sought medical attention spontaneously (nor presumably examination) but each was submitted to full in-patient investigation and open perineal biopsy. Histological evidence of cancer was detected in eighteen, but showed little correspondence with the pre-operative clinical findings. Since all these growths were regarded as within the limits of operability, immediate radical perineal prostatectomy was performed. The authors claim that a wide utilization of open perineal biopsy would increase the number of prostatic carcinomas detected at an operable stage of the disease.

While such investigations might not find favour in Britain, they are directed at what has generally been regarded as a progressive and lethal condition, and consequently any effort to improve the chance of its early detection and extirpation should not be lightly discouraged. It is probable, however, from records of the high post-mortem incidence of occult prostatic cancer that many growths exhibit a low degree of malignancy, and thus the mere histological diagnosis of an unsuspected focus during life may give little indication of

¹ Hudson, P. B., et al., *Surgery*, 1954, 35, 897.

⁴ Roth, R. B., et al., *J. Amer. med. Ass.*, 1954, 155, 302.

its activity. In these circumstances recourse to unrestricted radical surgery in symptom-free cases would seem indicated only if it were established that a majority of tumours pursued a course which was rapidly detrimental to the patient's well-being. No method at present exists for determining the growth potential in such silent tumours, but it is clear from the effect of oestrogen therapy in the manifest disease that activity may often be restrained merely by alteration of the hormone balance. Indeed, the ability to live in symbiosis with cancer may, in the case of the prostate, be largely determined by a natural reduction of the amount or effect of circulating male hormone.

The possibility of such a physiological decline in testicular function has also been considered in a recent contribution to this *Journal* by Spence on the "male climacteric."³ From this it would appear that some of the symptoms of the condition may be explained by lack of the anabolic action of testosterone. On this theme Roth and his colleagues⁴ draw attention to the superfluity of pharmaceutical advertisements advocating hormone preparations in geriatric practice. Since, they point out, histological evidence of prostatic cancer may be found in 20% of all men aged over 50 years of age, the potential risk of administering androgens and thus stimulating a latent growth may be considerable. Despite the prospect of bolstering up a few flagging metabolic processes for their ageing patients they are therefore disinclined to reach for the prescription pad in response to the sweeping claims sometimes made for these preparations.

UNIT NOTATION FOR AGGLUTINATING SERA

The practice of measuring the activity of drugs in terms of units, when either the complex nature of the preparation or lack of knowledge of the active principle make the use of conventional measures impracticable, is to-day accepted without question. Probably the widespread use of antibiotics in the last decade has brought familiarity in the use of this convenient measure. By enabling the same yardstick to be used in different countries the World Health Organization, continuing the work of the League of Nations, performs a valuable service. It makes possible an intelligent comparison of experience gained in different parts of the world—and indeed in different parts within one country—in the use of complex biologically active drugs for therapy and research. Some idea of the work which is continually in progress to set up and maintain the international standard preparations with their defined activities, and of the important part played by the Medical Research Council in this work, is given in a recent number of the *Bulletin of the World Health Organization*.

A new trend in international biological standardization is shown by the establishment of an international standard for anti-*Brucella-abortus* serum, described by Stableforth,¹ and the account by Felix and Bensted² of the proposed international standard for antityphoid sera. International standards for therapeutic sera have a well-established use—in fact, the first international biological standard was that for diphtheria antitoxin,

set up by Ehrlich in 1897 and later taken over by the League of Nations in 1922. These new standard antisera are, however, intended for use in serodiagnostic work, using agglutination techniques. The results obtained in agglutination tests are affected by many variable factors, such as the agglutinating suspension, and the end-point itself is quite arbitrary; so it is not surprising that the comparison of results obtained in different laboratories is difficult. The provision of standard sera of known agglutinin content will provide a means of overcoming some of these difficulties.

The traditional method of measuring agglutinin contents is by "agglutinin titre." This method is criticized independently by Stableforth,¹ Jerne,³ and Miles,⁴ and the advantages to be gained by changing to a system using units are cogently put. A lead in this direction has actually been given by assigning a unitage to the international standard for anti-*Brucella-abortus* serum, so that now the *Brucella abortus* agglutinin contents of sera from man can be reported in international units, and serum levels measured in this way in different laboratories will be directly comparable.

It might be thought that if unknown sera are all compared with the same standard, unit notation is unnecessary, and the present method of agglutinin titre would still be satisfactory. As is pointed out by Miles, however, once comparison with the standard is accepted, agglutinin titres become themselves unit measurements, but very inconvenient ones—inconvenient because they are awkward fractions and because they vary in value with the method of titration. A change to unit notation from agglutinin titres would mean that the results obtained would be more amenable to statistical examination by the biometrician. The advantage of this might appear doubtful to the busy pathologist in routine practice, since few pathologists are biometricians, and statistical examination takes time. But the methods pathologists use are based on those developed in the research field, in which there is every advantage in using measurements whose accuracy and validity can be defined.

The discovery that a well-used procedure for comparing activities is invalid may be disconcerting, but it often points the way to new facts and, of course, to more reliable methods. This is illustrated in the description of the assay of tuberculin in the sensitized guinea-pig by Long, Miles, and Perry.⁵ The old method was based on the "matching" of skin reactions in sensitized animals—which did not lend itself to statistical analysis. The measurement of activity based on the linear relationship between diameter of skin reaction and logarithm of the dose of tuberculin gives a precise assay which can easily be analysed. Experience with this method has shown clearly what was in fact already suspected, that different tuberculoproteins are heterogeneous, so that a comparison of their activities becomes very difficult. This may seem of negative value, but it does at least show when potency estimations are not to be trusted, and consequently the danger of making false conclusions is less.

EMERGENCIES IN GENERAL PRACTICE

ACUTE LUMBAGO AND SCIATICA

BY

JOHN CHARNLEY, M.B., B.Sc., F.R.C.S.

Orthopaedic Surgeon, Manchester Royal Infirmary

In revision or refresher courses it is customary to stick stolidly to traditional textbook ideas, but in the case of lumbago or sciatica nothing could be less helpful to the general practitioner than the standard textbooks. In the following account I make no apology for putting forward some decidedly bold and unorthodox statements in the management of an acute case of lumbago or sciatica; only by stimulating some clear thinking on this fascinating subject can theories be put to the test and progress made.

The domestic management of an acute attack of lumbago or sciatica is a confidence trick, and the confident practitioner wins the trick by imparting to the patient the feeling that he is in the hands of someone who understands what is happening inside his spine. If we try to visualize what a patient's mental image of a "slipped disk" must be, it is not very difficult to appreciate his anxiety and lack of faith during the conservative treatment of an intensely painful attack of lumbago. If in imagination a patient thinks his disk is in a state varying in degree from Fig. 1 to Fig. 2, how can he expect aspirin, hot bottles, and bed rest to "put it back again"? This,

FIG. 1

FIG. 2

of course, is the source of the whole trouble, because the true pathology is nothing like what the term "slipped disk" suggests, and it is well to remember that the medical profession never invented this term, which seems to have grown up in the popular press.

Unfortunately the teaching of the average general practitioner is at the moment inadequate to enable him to offer any other mental image to take the place of the "slipped disk." This is where time spent in describing the probable pathology of lumbago and sciatica will provide the practitioner with the ability to handle this type of case by reassurance far more successfully than by any practical hints or tips. The medical profession ought to present a united front on a basic theory and leave the argument of scientific details to their own conclaves. Can one blame the patient who is dissatisfied when diagnosed by different doctors as suffering from fibrositis, lumbago, sacro-iliac strain, lumbosacral strain, fatty herniations, sciatica, and, finally, a "slipped disk"?

It is the purpose of this account to show that in the first three or four weeks of an acute attack of lumbago a consultant can do no better for a patient than can any conscientious general practitioner, for the simple reason

that the only sensible therapeutic measures are aspirin, bed rest, and hot bottles. The trouble starts when someone suggests that the patient might have a "slipped disk." No sooner has the question been put than the patient knows instantly that the practitioner's answers are contradictory and lacking in conviction; a consultant must be sent for immediately.

The Identity of Fibrositis

It is only about ten years since most physicians were quite sceptical of the theory of disk protrusion as a common cause of sciatica, and clung to the belief that sciatica was most probably some form of neuritis or radiculitis. So far as sciatica is concerned, ten years have completely changed this attitude; but there is still fierce and heated argument if anyone suggests that the common condition of acute "fibrositis" or acute "fibromyositis" is produced by a disk lesion. Here is the crux of the matter. If one refuses to believe that acute lumbago—that is, acute "fibromyositis" of the lumbar muscles—is due to a disk lesion, then it is impossible to make sense of the clinical facts and to construct from the observed facts a story which will stand the tests of close questioning by intelligent patients. The layman accustomed to assessing evidence can make a doctor look a very sorry expert when the "slipped disk" is being discussed.

Doubtless it will be said that to demand, in the interests of unity, the acceptance of a dogma that fibrositis is due to a disk lesion is not in the spirit of science. To this I would reply that it is better for the public and more constructive for science to have some sort of working theory, which will be proved or disproved by practice, rather than to drag along in the present unhelpful chaos.

The principal evidence which connects fibrositis (acute lumbago) with a disk lesion is threefold: (1) Acute lumbago is often followed by acute sciatica with signs of compression of a nerve root. At operation a protrusion can then be demonstrated. (2) The fulminating onset of some cases of acute lumbago cannot be explained by an inflammatory theory. Onset "out of the blue," often in healthy young athletes, suggests a mechanical cause like the locking of a knee by a loose cartilage. (3) Repeated examination of muscles by the biopsy of "fibrositic nodules" has failed to reveal any histological abnormality. These so-called "nodules" are almost certainly areas of muscle spasm.

The feature of fibrositis which at first sight appears difficult to explain by disk protrusion is that acute fibrositis often appears spontaneously or follows exposure to wet or cold. Though fibrositis certainly can follow trauma it does not always do so, and even after trauma there is often a latent interval. This difficulty seems less formidable now that there is evidence to show that the nucleus pulposus can swell by the uptake of fluid and that in this process it can generate internal pressures probably high enough to cause pain.

A Theory of Disk Pathology

The following is a reconstruction of the stages of a disk lesion, and in support of it I believe there is more evidence for it than against it. I shall give the description in terms which can be used when talking to an intelligent patient:

(1) The normal disk is a hydraulic cushion consisting of a tough, but flexible, outer casing which is inflated to a considerable tension by the property of imbibing water possessed

by the soft pulpy centre (Fig. 3). A mechanism exists to govern the access of fluid to the chemical substances which form the pulpy centre, and thus the tension inside the disk is automatically adjusted to the load imposed on it by the activities of the subject.

FIG. 3

(2) For reasons as yet unknown the pulpy nucleus can sometimes suddenly acquire access to more fluid than normal, and the rise of internal tension so produced is felt by the patient as a stiffness of the

back. If the condition is acute the back muscles may go into guarding spasm and a moderately severe attack of lumbago or fibrositis is produced.

(3) This episode of raised disk tension can now settle to leave a relatively normal disk. There may be a parallel to this sequence in acute glaucoma in which the raised intra-ocular pressure is easily detected but still unexplained. In other cases it is probable that when the tension episode subsides it leaves behind a molecular change in some of the mucopolysaccharides (chondroitin sulphate), which appears to be the essential water-attracting substance of the nucleus. After each new tension episode one presumes that more and more of this changed substance is left behind, and that this process of denaturing of the nucleus is the same process which occurs slowly and without acute episodes in the normal ageing process of the disk. It must be emphasized that this process, when evenly distributed through the disk, results in what is correctly termed a "degenerated" or "desiccated" disk (as distinct from a "slipped" or "protruded" disk).

FIG. 4

I prefer to tell patients that the degenerated disk, to keep up the analogy of the hydraulic cushion, is one in which the substance of the disk has "perished" and has simply lost its original flexibility. In the later stages of degeneration the edges of the vertebral bodies above and below the "perished" disk show osteophytic lipping as a result of the localized areas of mechanical trauma to which they are exposed now that the hydraulic mechanism no longer distributes the body load evenly over the end-plates of the bony bodies (Fig. 4). The symptoms produced by this condition are those of chronic backache, not acute fibrositis.

FIG. 5

(4) If in the course of an acute episode of raised internal tension (lumbago) some of the deep fibres of the annulus are ruptured and penetrated by the swollen nucleus, we now have the start of a disk herniation. The annulus is very thick, and it may take several acute pressure episodes before the nucleus works its way through the numerous layers of the annulus till it comes to lie immediately under the surface of the disk

(Fig. 5). This process of moving up to the surface is usually to one side of the midline, and in right-handed people is decidedly more common on the left than on the right. When this happens the pain referred to the muscles acquires a unilateral element, and pain and tenderness may be localized first to the region of the sacro-iliac joint, later to the fold of the buttock, and later still to the back of the thigh. This is a "referred sciatica," and is distinguished from true sciatica by the fact that there is no evidence of root compression and straight-leg raising is not seriously impaired, because there is as yet no external protrusion of the nucleus through the annulus.

(5) These leakages of the nucleus to the surface may terminate in a true disk hernia or protrusion which now for the first time will stretch a nerve root and produce true acute sciatica (Fig. 6). The pain now will pass down below the knee and into the foot, and it will be associated with a marked degree of limitation of straight-leg raising, indicating the direct stretching of the nerve root. There may or may not be signs of impaired nerve conduction.

It is to be noted that in this condition the disk has not "slipped." The disk has swelled to an abnormal volume and the excess has bulged out to form the protrusion. It will now be obvious to the patient why there is no possibility of manipulating the protruded excess back into the interior. It is here that the patient can understand the necessity for removing excessive body weight from the disk and the need to wait till the episode subsides and shrinkage of the nucleus withdraws the protrusion spontaneously. In these cases there will be no narrowing of the disk space in the radiograph.

(6) So far, the process has merely concerned the hydraulic bulging of the swollen disk, but there is almost certainly a second kind of mechanical element present. This is the production of a sequestrum of degenerated nucleus (or even possibly of degenerated annulus). Crudely speaking these sequestra are lumps of coagulated nuclear substance. Localized degeneration can produce a sequestrum lying in a track passing from the centre of the nucleus to the threatened point of penetration of the annulus (Fig. 7). This can actually be seen at necropsy. The sudden movement of such a sequestrum may be the cause of those fulminating attacks of very acute lumbago which come on, without warning, in patients who have been quite normal a few minutes before. In these cases the patient may actually feel or hear a "click" in the back at the moment of onset of the pain. The swollen disk type of lumbago described in (3) is slower in development than the sequestrum type, or, if sudden, the attack is heralded by slight discomfort present some hours or days before the main attack. The sequestrum type of lumbago is the one which has sometimes been relieved by manipulation or which sometimes clears up quite suddenly, and in this the clinical features are very similar to the recurrent locking of a knee by loose meniscus.

(7) This process of moving up to the surface is usually to one side of the midline, and in right-handed people is decidedly more common on the left than on the right. When this happens the pain referred to the muscles acquires a unilateral element, and pain and tenderness may be localized first to the region of the sacro-iliac joint, later to the fold of the buttock, and later still to the back of the thigh. This is a "referred sciatica," and is distinguished from true sciatica by the fact that there is no evidence of root compression and straight-leg raising is not seriously impaired, because there is as yet no external protrusion of the nucleus through the annulus.

(8) These leakages of the nucleus to the surface may terminate in a true disk hernia or protrusion which now for the first time will stretch a nerve root and produce true acute sciatica (Fig. 6). The pain now will pass down below the knee and into the foot, and it will be associated with a marked degree of limitation of straight-leg raising, indicating the direct stretching of the nerve root. There may or may not be signs of impaired nerve conduction.

It is to be noted that in this condition the disk has not "slipped." The disk has swelled to an abnormal volume and the excess has bulged out to form the protrusion. It will now be obvious to the patient why there is no possibility of manipulating the protruded excess back into the interior. It is here that the patient can understand the necessity for removing excessive body weight from the disk and the need to wait till the episode subsides and shrinkage of the nucleus withdraws the protrusion spontaneously. In these cases there will be no narrowing of the disk space in the radiograph.

(9) So far, the process has merely concerned the hydraulic bulging of the swollen disk, but there is almost certainly a second kind of mechanical element present. This is the production of a sequestrum of degenerated nucleus (or even possibly of degenerated annulus). Crudely speaking these sequestra are lumps of coagulated nuclear substance. Localized degeneration can produce a sequestrum lying in a track passing from the centre of the nucleus to the threatened point of penetration of the annulus (Fig. 7). This can actually be seen at necropsy. The sudden movement of such a sequestrum may be the cause of those fulminating attacks of very acute lumbago which come on, without warning, in patients who have been quite normal a few minutes before. In these cases the patient may actually feel or hear a "click" in the back at the moment of onset of the pain. The swollen disk type of lumbago described in (3) is slower in development than the sequestrum type, or, if sudden, the attack is heralded by slight discomfort present some hours or days before the main attack. The sequestrum type of lumbago is the one which has sometimes been relieved by manipulation or which sometimes clears up quite suddenly, and in this the clinical features are very similar to the recurrent locking of a knee by loose meniscus.

FIG. 6

FIG. 7

(7) If the localized disk sequestrum becomes displaced so that it protrudes from the exterior of the disk (Fig. 8), the classical picture of acute sciatica is produced in exactly the same way as in (5), and it can only be distinguished from the

FIG. 8

the internal pressure of the disk. The sequestrum is a tough fibrous wedge which is permanently jammed between the bodies and stretching a root. In this case there may be narrowing of the intervertebral disk space in the radiograph. These are the cases which eventually have to be operated upon and which, incidentally, give the best results, because, if the sequestration of the disk is sufficiently well advanced, the removal of the protrusion leaves behind no more material to give trouble at a later date. When considering operation there is a lot to be said for not operating too early and for leaving the disk till it is fully "ripe" for picking out the sequestrum. In some very severe cases a sequestered disk can be completely extruded to lie free in the spinal canal. Sequestered disk substance can easily be recognized by the naked eye, because it has none of the pasty, semi-translucent quality of a normal disk, but has the opaque-white, shredded appearance of boiled lobster meat.

(8) Finally, to complete this account of the different types of disk disorder the true "acute back strain" must be added. This is frequently encountered in labourers lifting weights when a sudden additional load is thrown on them, as when a mate drops his end of the load. Immediate intense pain and rigidity is experienced, and severe symptoms may persist for at least three weeks before they start to clear up. There seems every reason to believe that these are ruptures of the deep layers of the annulus without actual protrusion of the nucleus. The subsequent course is indistinguishable from that of any severe fulminating lumbago.

Treatment

From these considerations of the probable pathology, certain points emerge in the handling of acute cases of lumbago or sciatica which need stating with considerable emphasis.

It is not well enough realized that the substance of the intervertebral disk is a unique tissue and that there is no reason to believe that its swelling, shrinkage, degeneration, and rupture are governed by the ordinary processes of inflammation and repair. It is a totally avascular substance, and, like the meniscus of the knee-joint, once ruptured it is probably incapable of repair. Though we customarily prescribe rest, and often fixation (by analogy with ordinary processes of inflammation), there is no proof that this shortens the period of three or four weeks which is often needed before symptoms of an acute disk episode subside. I have never been convinced that a patient who stays in bed any longer than he is forced to by the mere intensity of the pain thereby shortens the total duration of the attack. Indeed, there is evidence to suggest that movement is favoured by nature, because many patients in very severe pain cannot tolerate immobilization and prefer to be constantly changing their position, never remaining quite still for more than a few minutes at a time. Once the acute episode has truly started to regress (that is, after three weeks) it is not likely that activity will bring it back again; in this respect it is quite unlike ordinary inflammation.

Cases for Surgery or Special Treatment

The acute tension episodes, no matter how painful, or whether associated with sciatica and neurological signs, in

the majority of cases will settle merely by the passage of two, three, or four weeks. The commonest error is to underestimate the duration of acute pain—far more often than is realized an acute attack will persist for over three weeks. During this time all that can be done is to sedate, apply heat, and recommend rest.

On being called to the initial violent attack of pain an immediate hypodermic injection of morphine, $\frac{1}{4}$ gr. (16 mg.), will often be necessary. Thereafter this drug should not be needed more than once or twice and should then be reserved for the night, in order to procure sleep. It is at night that the pain, which may be tolerable during the day, seems to exhaust the patient and cause panic. Pethidine in 50-mg. tablets is useful after the first two or three nights. During the daytime two codeine compound tablets (N.F.) every two hours are usually adequate if combined with heat. Heat is best applied by relays of hot-water bottles to the affected buttock and back of thigh. If there is a localized area of extreme tenderness in the loin or buttock, it is often tempting to inject a local analgesic (20–50 ml. of 1% procaine hydrochloride), especially as the patient expects the good physician "to do something." Some transient relief sometimes follows this procedure, but, as it cannot shorten the attack, it is doubtful whether it is worth the trouble, except on psychological grounds.

If, after three to four weeks, pain and disability are still persisting the possibility becomes a probability that a solid sequestrum has been displaced and that the patient may eventually become a candidate for surgery. The initial intensity of the pain is no measure of the need for surgery; and in any case, speaking generally, in a first or second attack one would never recommend surgery until at least three months of disability had been present. In hospital the best results of disk surgery are produced by a long waiting-list. During the subacute phase, after the initial three to four weeks, a plaster jacket is perhaps the best method of encouraging a certain amount of activity while watching the progress with a view to surgery at a later date, but there is not much point in applying plaster before the expiration of the first three or four weeks. In the early acute phase bed rest, taking the load of body weight off the disk, is infinitely better than to try to fix the spine and at the same time keep the body weight on the disk.

Prophylaxis

I will take the risk of saying quite categorically that there is no evidence to suggest that an attack of lumbago which has been "untreated" or "neglected" in its early stages could have been prevented from later passing into a full disk protrusion by "treatment." It is the fear of being responsible for this which causes many practitioners unnecessary worry and imposes such a strain and expense on the Health Service. With the obvious exception of attempting to lift heavy weights or to work too early in a fully bent position, I believe this opinion should be firmly and widely voiced in the popular press.

Conclusion

The importance of a cheerful and even a light-hearted approach by the physician cannot be too strongly emphasized. It is much healthier for the patient's attitude to future recurrences of back trouble, which in some measure is almost certain to occur from time to time, to try to regard lumbago as the sort of music-hall joke it used to be ten or twenty years ago. This does not mean that the practitioner need be insensitive and heartless, but that well-meaning but over-conscientious worry about "slipped disks" does not help the patient in the early stages of an acute attack.

I am indebted to the Department of Medical Illustration Manchester Royal Infirmary, for the illustrations.

OSBORNE HOUSE

The Jubilee of King Edward VII Convalescent Home for Officers at Osborne House, in the Isle of Wight, was celebrated this year, and it is appropriate to review the 50 years which have passed since its inauguration in 1904, and to draw attention to the facilities for convalescence which Osborne affords.

King Edward VII's gift of Osborne House to the nation was made known at his Coronation, and the *British Medical Journal* for January 30, 1904, contained an account of the opening of the convalescent home, when accommodation for 50 officers from the Royal Navy and the Army was made available. In course of time the scope was extended, and members of the Colonial Service, and then officers of the Royal Air Force and members of the Civil Service and Foreign Office, were made eligible, so that the convalescent home now serves a large group of the servants of the Crown. It may be helpful, therefore, for doctors to know the principal classes who are now eligible for admission.

Men.—(a) Serving and retired regular officers of the Royal Navy, Army, and Royal Air Force, and officers of the Commonwealth Forces serving in the United Kingdom. (b) Serving officers of the R.N.V.R., Territorial Army, and R.A.F.V.R. (c) Ex-officers—that is, officers who have ever held a temporary commission in the Forces. (d) Established and permanent unestablished members of the Civil Service. (e) Serving members of the Foreign Office and the Colonial Service.

Women.—Serving regular women officers of the Forces and women members of the Civil Service and Foreign Service.

Attention is drawn to paragraph (c) above, for it may not be generally known that any male officer who has held a commission at any time in the Forces is eligible for admission. For serving officers and those recommended by the Ministry of Pensions there is no charge; for others it is 10s. a day.

The staff comprises a nursing staff, a remedial gymnast, an occupational therapist, and a physiotherapist. The emphasis is on rehabilitation, and there is a hot pool for the treatment of rheumatic diseases, fractures, and poliomyelitis. Cases strictly confined to bed are not suitable, and no cases of incurable illness, mental illness, or tuberculosis are accepted. Convalescents are accepted in the early stage of convalescence, but must be capable of dressing and looking after themselves. Simple surgical dressings can be carried out and certain dietetic treatment arranged. The average stay is for three weeks.

A staff of London consultants visit Osborne each month to advise the House Governor, who is also the medical

superintendent. For officers serving with the Forces contact is maintained with the Naval, Military, and Air Force hospitals, and visits are paid regularly by Service consultants of the three Services.

Osborne House, as Queen Victoria's favourite residence, has a strong historical appeal, and the house and grounds are maintained as a memorial to her. The views from the house over the Solent are superb, and the setting, with its terraces and fountains, its fine trees of many varieties, and its woods and lawns, makes the convalescent home an ideal one for a quiet and peaceful convalescence. The public are admitted to the State apartments during the summer months, and in 1955 the private apartments are also to be thrown open. These apartments show in a unique setting the furnishings and bric-à-brac of the Victorian age.

There are grounds of up to 400 acres, with a private golf course and a bathing-beach; and facilities are provided for tennis, croquet, sailing, and boating. At a hostel in the grounds, about half a mile from Osborne, wives and relatives can be accommodated while officers are in residence. During the past 50 years some 18,000 convalescents have enjoyed the beautiful surroundings of the home, the excellent facilities of which should be widely known. Requests for admission should be made to the House Governor and Medical Superintendent, Osborne House, East Cowes, Isle of Wight.

NEIL CANTLIE, Lieut.-General,
House Governor.

Reports of Societies

LOCAL MEDICAL SOCIETIES

Manchester Medical Society

While showing a film on "Foot Faults related to Form and Function" to the Section of General Practice on December 20, Mr. W. SAYLE-CREER, F.R.C.S., said that they were all conscious of the muscle control of the foot from back to front and the reason why there was stability in that axis, but the lateral stability of the foot was not so well appreciated. It depended on the width and integrity of the fore-foot and was impaired by a narrow foot or incompetence of the first metatarsal segment. A strong foot could be likened to a pair of roller skates calling for minimal muscular control; a defective foot resembled an ice skate and required maximal muscular control to stop inversion or eversion. It was this overwork and consequent early fatigue of the muscles that were responsible for the symptoms of aching and tiredness.

London County Medical Society

On November 16 the society met at the Queen Victoria Hospital, East Grinstead, where Sir ARCHIBALD MCINDOE showed members round the plastic unit.

Sir Archibald and his assistants demonstrated various types of plastic repair, including those of hypospadias, cleft palate, and Dupuytren's contracture, and corneal grafting. These were carried out simultaneously in a theatre suite where the activities of all four theatres could be viewed through large glass windows from a central corridor; galleries inside the theatres also allowed a perfect view from above. Sir Archibald pointed out that the biggest bugbear of the plastic surgeon was not sepsis but the formation of a haematoma; this could completely nullify the result of his work. In that connexion modern hypotensive drugs were invaluable in securing a comparatively bloodless field.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Influenza

SIR.—Your leading article (*Journal*, January 22, p. 211) calls for comment because of its confusion between epidemiological and clinical phenomena. It is admittedly true that influenza B does not appear to cause the mortality and disruption of life occasioned by influenza A. Indeed, its periods of prevalence appear to be characterized by a succession of localized outbreaks rather than a tendency to sweep across the whole country as with influenza A. But does influenza B really cause a "less severe form of illness" as stated in your leader and as is often repeated in the newspapers? Medical officers who may have experienced recent influenza B outbreaks in school-children, the parents of children affected, and even those concerned with the occasional adult with the disease may well be inclined to question the statement.

There are, in fact, few clinical points of difference between attacks of influenza A and B, and the gravest form of illness due to synchronous virus and staphylococcal tracheo-bronchitis occurs with either virus. It might also be said that influenza A is clinically milder than influenza B because of the frequent febricula of one- and two-day fevers and of subclinical attacks with virus A. As, however, the clinical spectrum of illness either in influenza A or B is extremely wide it is fruitless to attempt to draw comparisons between the two.

In view of the frequent long lapses of six or more years between influenza B epidemics, it would indeed be surprising if the infection when it did occur was characterized by its mildness. Certainly the outbreaks in schools are often as explosive as any epidemics can be. It seems more reasonable to attribute our rather contemptuous attitude towards this infection to its lesser tendency to involve the adult and to spread rapidly. Perhaps the immunity engendered by this virus is in fact more durable than that following influenza A, or is the virus less cunningly mutable and thus more readily defeated?—I am, etc.,

Sheffield, 1.

C. H. STUART-HARRIS.

Low Backache

SIR.—It is regrettable that Dr. James Cyriax (*Journal*, January 15, p. 140) has taken the occasion of a negative answer to a silly question at a meeting of the British Orthopaedic Association to put forward again his supposition of posterior disk protrusion as "the common cause" of local and radiating pain in the neck, back, and limbs, his panacea for relief, and his suggestion that the application of the panacea should be entrusted to physiotherapists. Dr. Cyriax believes that relief of such pain is simple, the supposed protrusion of the disk being reduced by manipulation or stretching of the spine. That protrusion of a disk is a cause of local and radiating pain of spinal origin is certain. What is far from certain is that it is the common cause for such symptoms and that, when it is, manipulation and/or stretching by traction are safe and lastingly effective ways of treatment.

It may be noted that recognition of the importance of disk lesions in spinal pathology and symptomatology does not date, as Dr. Cyriax implies, from the paper by Mixter and Barr in 1934.¹ As those authors themselves acknowledge, others in Europe and U.S.A. had published articles on the subject in previous years. A monograph by Mauric in 1933² gave a full account of the large amount of knowledge accumulated by that date, including details of operations for removal of posterior disk protrusions by

Alajouanine and Petit-Datallis from 1928. It is appropriate at this time to record that it was the late Sir Arthur Keith who was the first in this country to realize the importance of the disks. It was at his suggestion that in 1926, with a B.M.A. research grant, I made a study of the disks, published in 1931.³ Later in the same year was published the Medical Research Council report by Beadle,⁴ making available in English the results of Schmorl's great post-mortem study of spines, begun in 1925, upon which our knowledge of this subject is mainly based.

It is a pity to spoil the case of a cause of symptoms by over-emphasis of its importance or of a method of treatment by claiming too much for it. To infer without proof either of their presence or disappearance that posterior disk protrusions are common at all levels of the spine, and that they can be reduced by manipulation or traction, is dangerous and savours of the practice of the unqualified practitioners of whose existence Dr. Cyriax warns us. A disk rupture can be determined with certainty by myelography or at operation; otherwise it can only be supposed to exist. Anyone who has seen this lesion at operation or necropsy will doubt whether it can be reduced, except perhaps temporarily, by manipulation or traction. Indeed, these procedures have been known to aggravate the symptoms; and there must be some danger of traction actually causing rupture of a disk, at any rate in persons over 40 years of age, in whom some kind of degeneration of the disks is usual. In Schmorl's material posterior disk protrusions were found in only a small percentage of spines, the common lesions being protrusion into the vertebral bodies and degenerative states, which indeed appear from radiographic and clinical observations to be by far the most common lesions of the disks from which symptoms may arise.

The old rule that accurate diagnosis precedes treatment should prevail with pain in the neck and back, as with other symptoms. Incomplete as our knowledge of the origin of such pain is, there should be hesitation in accepting a general cause or method of treatment or of delegating treatment to ancillaries. Nor should there be anxiety that unqualified persons practise in this field. Despite the limitations of facilities, over which they have little or no control, in the National Health Service, orthopaedic surgeons, in association with other members of the hospital staffs and the patients' doctors, are indeed coping with these cases and on the sensible lines of assessment for diagnosis of all factors, physical and psychological, and of treatment by the methods, according to these factors, of reassurance, adjustment of activities, physiotherapy, splintage or mobilization by manipulation, and occasionally by operation. Further aggrandizement of departments of physical medicine would only aggravate the problem at much increased cost to the hospitals.—I am, etc.,

Bournemouth.

SIR.—Dr. L. S. Calvert suggests in his letter (*Journal*, December 18, 1954, p. 1488) there are few cases of backache that cannot be cured by manipulation, and pleads for the establishment of more departments of physical medicine to treat such cases. As a gynaecologist, I have been studying for many years the problem of low backache in women, and the result of these studies is now in process of publication. Admitting that manipulation can help in many cases I do not agree that it can cure the majority of these. About 70% of all cases of low backache in women are either postural or gynaecological, or a combination of both. Treatment consists in first removing the cause, and then reassuring the patient. Instead of increasing the number of departments of physical medicine, more attention should be given to the prevention of backache.

In a memorandum in the *Journal* (January 2, 1954, p. 28) I suggested measures to prevent post-operative backache. In addition to the above, I would like to draw attention to a further group which can be prevented—namely, that of backache in connexion with childbirth. Some women date their backache to their first confinement. During the next

pregnancy the pains are usually absent, but often reappear after the next confinement. Recent research has shown that under hormonal influence the pelvic joints become movable during pregnancy and stretched during labour, which is a natural process to facilitate labour. These pelvic changes usually disappear after delivery, but in some cases a residual instability persists. If a woman gets up too early after a confinement and has to do her usual housework, these joints have no chance to consolidate, and lead to postural changes and consequent backache.

I have designed a simple girdle (made for me by F. C. Gould, 12, Wimpole Street, London, W.1) to keep these joints firmly together. This girdle consists of a band about 3 in. (7.6 cm.) wide with a small pad over the symphysis pubis, and another over the lower part of the sacrum. The girdle keeps the pelvic bones firmly together, and should be worn from the first day of getting out of bed for four to six weeks. All patients using this girdle like wearing it and appear to have no backache after the confinement.—I am, etc.,

London, W.1.

E. SCHLEYER-SAUNDERS.

SIR.—It was of interest to read the views of Dr. James Cyriax (*Journal*, January 15, p. 140) and Mr. John Charnley (p. 163) on certain aspects of back pain. On the one hand, an orthopaedic surgeon makes a plea for the accurate diagnosis of back pain and the application of rational treatment. He stresses the fact that this is only possible in a small proportion of the total number of cases and suggests further research by all concerned to shed light on the subject. On the other hand, a physical medicine specialist claims to relieve a large proportion of cases of "lumbago and fibrositis" by manipulation, the rationale for his treatment being that a displaced disk is responsible for the painful condition and that it is reduced by the manipulator's efforts. Where does the truth lie? Many orthopaedic surgeons, I think, feel that Dr. Cyriax is rather optimistic in his claims. While it is true to say that some patients suffering from back pain are relieved by manipulation, a great many are not, and indeed there are cases where manipulation can be positively dangerous, especially in the cervical region.

All concerned, however, must realize how inconclusive the administration of physiotherapy can be to patients suffering from back pain. In many cases it is simply a means of getting rid of a troublesome and sometimes an undiagnosed patient. During the recent wintry spell in the north-east of England out-patients could be seen passing through the portals of the physiotherapy department from the cold outer atmosphere. They were chilled and shivering. Half an hour later they emerged partially thawed, and prepared to face the elements on their homeward journey. How much good their treatment did can be well imagined.—I am, etc.,

Newcastle-upon-Tyne, 2.

ALAN E. BREMNER.

Pancreatitis following Pregnancy

SIR.—I have been interested in these two conditions for some time. In his interesting discussion on the association between pancreatitis and pregnancy (*Journal*, January 15, p. 124) Dr. R. A. Joske attempted to explain the aetiology of the pancreatitis in terms of an exacerbation of an underlying chronic relapsing pancreatitis. This possibility cannot be ruled out, but its importance and, indeed, its probability can only be evaluated in light of the following observations which I have made (in over 90 estimations of both amylase and lipase in 50 cases) in the course of the past year. I was stimulated to this by the observation in a jaundiced pregnant woman of an almost complete absence of serum amylase and lipase. This observation was confirmed in that patient, who, incidentally, was not suffering from obstructive jaundice apparently but from infective hepatitis. From this isolated observation we were led to the study of the levels of serum amylase and lipase in pregnancy, and we confirmed on many occasions that these

levels (especially of serum amylase) were often extremely low. Figures of below 15 units were quite frequent, the mean normal being 100 units. However, these low figures do not occur all through pregnancy but are most frequent between the 8th and 16th week. Apparently, for we have only limited observations on this point, they have fallen from the mean normal range at the beginning of pregnancy but they rise steadily in the later months, reaching the normal range at full term. On occasions figures quite definitely above the normal have been reached at term and in the puerperium, though no patient exhibited clinical evidence of pancreatitis. The curve of serum activity might be described as eccentrically concave, the point of maximal depression being early and that of maximal rise being late. The patients studied were attending the antenatal clinics of two of the Dublin maternity hospitals. Duodenal intubation was considered but decided against owing to the danger of affecting the pregnancy.

How may these observations be related to the paper of Dr. Joske? Pancreatitis following pregnancy might be due to an exaggeration of the physiological rebound of pancreatic enzyme rather than to a preceding pathological inflammation of the gland. Such a deduction assumes that the serum amylase and lipase are altogether of pancreatic origin, and that their level is an index of the activity of the gland. The former deduction is hardly correct, but the second is a moderately fair deduction, though by no means entirely true. It would hardly be pushing the argument too far, however, if we held that a steady rise in the level of serum amylase and lipase to above the normal range could be mentioned. When we sought for previous observations on the pancreas in pregnancy we found no relevant information on the histology, physiology, and biochemistry of the pancreas of the pregnant animal. The relationship also of pancreatic insufficiency (or physiological hypofunction) to a fatty liver in pregnancy is worthy of consideration. Finally, in association with Dr. A. P. Barry, master of the National Maternity Hospital, we have had hopeful results from pancreatic replacement therapy in the dyspepsias of early pregnancy. The observations referred to in the first paragraph are in course of preparation for publication. I wish to acknowledge receipt of grant for laboratory expenses from the Medical Research Council of Ireland.—I am, etc.,

Dublin.

OLIVER FITZGERALD.

SIR.—I was much interested in Dr. R. A. Joske's very complete article (*Journal*, January 15, p. 124), where he discusses six cases of post-partum pancreatitis in young women. In his summary he states that the aetiology of the pancreatitis is considered to be related to the preceding pregnancy, although the mechanism of this is unknown. In spite of the fact that he agrees with Hughes and Kernutt¹ that in his experience the relationship of biliary reflux to pancreatitis in man is thought to be slight, I would suggest that there is a considerable case for suggesting that the pancreatitis was in the main due to a rise in the abdominal pressure. I have had two cases of pancreatitis, one with gall-stones and one without, where the only factor in common was that the patients suffered badly from hay-fever and that they dreaded the incessant attacks of sneezing, as it brought on the epigastric pain.

I myself experienced nine attacks of pancreatitis. In my first operation the head of the pancreas was found to be stony hard, blocking the common duct. Six large stones were found in the gall-bladder, which was anastomosed to the stomach. A year later, because I was still having the severe pain with vomiting and slight jaundice, the surgeon operated again. He opened and cleaned the common bile duct, put a probe down through the ampulla, and inserted a drainage tube. This tube remained *in situ* for 16 weeks. I have remained well since and managed to play 52 rounds of golf last year. In the *British Medical Journal* of December 5, 1953, there was an article on pancreatitis² where the authors stated categorically: "It is our opinion that the findings of biliary calculi are coincidental, and that the

pathological changes in the gland can be explained wholly in terms of a vascular catastrophe." This has not been my personal experience.

In an article in the *British Medical Journal* of December 19, 1953, the authors¹ classified their cases of pancreatitis into three groups: (1) associated with gall-stones; (2) associated with alcoholism; and (3) due to primary infection. I would suggest that it might be better (if we must have a classification for pancreatitis) to make it as follows: (1) due to a rise in abdominal pressure from whatever cause—gall-stones, undue prolongation of the second stage in labour, continual sneezing, continual hiccups, continual coughing; (2) primary infection in the pancreas; and (3) mechanical blockage of pancreatic duct by cysts or tumour. I do not think alcoholism is a primary cause of pancreatitis. It may be that the chronic alcoholic may hiccup his merry way into a pancreatic attack, by fixing his diaphragm and sending his bile juice up the pancreatic duct, but the pain from the resultant explosion of the pancreatic and bile juices is such that he would forswear alcohol for ever and a day.—I am, etc.,

Glasgow, C.3.

SIR,—I was surprised that, in his discussion of post-partum pancreatitis, Dr. R. A. Joske (*Journal*, January 15, p. 124) did not mention the possibility that spasm of the sphincter of Oddi might play some part in the aetiology of this condition. Lagerlof¹ showed that such functional obstruction of the duct of Wirsung can lead to pancreatitis. It is noteworthy that four of Dr. Joske's cases showed evidence of biliary stasis which might also, of course, have followed spasm of the sphincter of Oddi.

The problem remains as to what causes the spasm in these cases. Many substances have been used to produce spasm experimentally. These include morphine,² which is not indicated in patients with pancreatitis (it does not seem to have harmed Joske's fifth case, however). Perhaps one could investigate those biochemical changes during the puerperium which might cause spasm of the sphincter of Oddi. Meanwhile, anti-spasmodic treatment, such as with atropine as in Joske's third case, or with banthine as suggested by Shingleton and Anlyan,³ seems to be indicated if this functional mechanism is of any importance in the aetiology of pancreatitis.—I am, etc.,

Coarctation of the Aorta and Pregnancy

SIR,—The request by Dr. Leonard Rosenthal (*Journal*, January 1, p. 16) for further cases of coarctation of the aorta associated with pregnancy prompts the recording of the following particularly interesting one. The patient has been attending out-patients for the past 12 years, during which time she has had eight uneventful deliveries and three miscarriages.

The patient, now aged 32, was first seen 12 years ago, and was found to have a blood pressure of 185/105, so she was admitted and induced at 36 weeks. Prior to this she had had "toxaemia" in association with a breech presentation, but, despite this unfavourable combination in a primigravida (as she was then), the child had survived. Subsequent pregnancies continued to be characterized by the presence of a hypertension which ranged between 150 and 170 systolic and 90 and 110 diastolic, yet did not worsen at any stage and was never associated with oedema or albuminuria. Blood pressure readings taken on a few occasions between pregnancies were at the same level. After her last delivery (November, 1954) the medical condition was reassessed, and it was found that, although the blood pressure readings in the arms were equal, no pulses were palpable in the legs even though she is a thin woman. In addition, while she was relaxed during an anaesthetic the abdominal aorta was not palpable. The left ventricle was not enlarged clinically or radiologically. On auscultation there was a loud basal systolic murmur which could also be

heard over most of the back including along the axillary border of the right scapula. X-ray of the chest showed definite notching of the 3rd left rib and probably early notching of the 4th and 5th on the same side. Her blood pressure one month after delivery was 210/110.

This case is of particular interest in several respects. The patient has been quite symptom-free during the whole period of observation, and her hypertension has for all practical purposes remained unchanged. In addition, despite the apparently high blood pressure, not, of course, transmitted to the uterine arteries, she never had any albuminuria, and the placentas have apparently been always quite healthy. I would like to thank Professor W. Kearney for allowing me to publish this case and Dr. T. O'Keefe, radiologist, South Infirmary, Cork, for his co-operation.—I am, etc.,

Cork.

W. R. SHANAHAN.

Sterilization Methods

SIR,—The British Standards Institution has recently circulated for comment a Draft British Standard for Bed-pan and Urine Bottle Washers. In an apparatus conforming to this specification a bed-pan may be washed successively with any of three combinations of cold water, hot water, and steam for periods which are not specified. It is required that the words "This apparatus is not a sterilizer" be "permanently inscribed in bold red lettering" upon it.

For the past eighteen years many of the wards in this hospital have been fitted with bed-pan washers which automatically flush successively with cold water, hot water, and finally with steam for 30 seconds, this sequence being started simply by pushing a button. I have received so many inquiries from different sources about the performance of this apparatus and what it may be expected to do that I shall be grateful for an opportunity to answer such questions publicly. I have carried out many bacteriological tests with different models of this apparatus, always with the same results—namely, that any vegetative bacteria, however applied—for example, in the form of a dried film of faeces or pus—whether within the pan or on its rim, are invariably killed; sporogenous bacteria such as *B. subtilis*, of course, are not.

It is therefore quite correct to say that such an apparatus, even if it applies steam for an adequate time, is not a "sterilizer." But how often are bed-pans really "sterilized"? Boiling will not do it, unless some chemical is added to the water, nor will immersion in commonly used disinfectants. And is it necessary? I can imagine no circumstances in which the presence of bacterial spores in a bed-pan can be of any significance in relation to the health of the user. It is only necessary that bacteria causing intestinal or septic infections shall be destroyed, and exposure to steam will ensure this.

I write this letter with the main object of defending the apparatus devised and used in this hospital against a mistaken charge of inefficiency, and to suggest that the indications for sterilization (elimination of all forms of microbial life) and disinfection (elimination of those which in the circumstances are potentially harmful) need to be more clearly distinguished. The apparatus specified in the Draft British Standard is much inferior to ours in that automatic operation is not provided for. If this project is to go forward, I suggest that the apparatus be a simple washer, only using water. The use of steam is pointless unless for the purpose of disinfection.—I am, etc.,

London, E.C.1.

LAWRENCE P. GARROD.

SIR,—In connexion with the perspicuous leading article on this subject (*Journal*, January 15, p. 156) your reader may be interested to know something of the state of sterilizing apparatus in hospitals in a number of typical British hospitals.

During the last two years 64 dressing sterilizers (autoclaves with vacuum attachments) in 45 surgical charges were examined. Details of the defects found in design, installation, maintenance, and operation were drawn up and reported together with diagrams of the steam circuits involved. Only

5 (8%) of the instruments, and these were all of American manufacture, were found to be above reasonable criticism. The criterion was efficiency in sterilization with minimal damage to the load. Some examples of the more common or interesting faults in design or installation were as follows: lacking automatic air and condensate discharge from floor of chamber, 41 (63%); pressure in jacket sufficiently in excess of that in chamber to cause serious superheating, 11 (17%); lacking thermometer, 55 (85%); steam introduced at bottom of chamber under the perforated tray, 40 (63%); connexion between floor of chamber and main water supply of hospital, 11 (17%); connexion between chamber and underground drains (definitely no air break), 3 (4%); connexion between underground drains and main water supply of hospital via chamber, 2 (3%). In 16 hospital laboratories and pharmacies in the same area 32 hot-air ovens were examined; none had fans or turbo-blowers. Of the 26 main autoclaves (without vacuum attachment) used in the 16 units, only one withstood really searching criticism.

The report by the Central Pathology Committee of the Ministry of Health on the sterilization of hospital equipment, issued to hospitals on December 31, 1954, countenances this condition of affairs and goes even so far as to give directions concerning the operation of obsolete and demonstrably ineffective steam pressure apparatus to the total exclusion of efficient design. If perpetration of past faults sanctioned by this retrogressive report leads to criticism and thence to correction or replacement by the Ministry of inefficient sterilizing apparatus in hospitals, this official publication would, in retrospect, become justifiable.—I am, etc.,

Edinburgh.

J. H. BOWIE.

Aetiology of Kwashiorkor

SIR,—The very interesting and significant case of kwashiorkor occurring in a breast-fed infant of three months of age described by Dr. L. G. MacDougall (*Journal*, November 13, 1954, p. 1150) raises again the question of aetiology of this syndrome. The difficulty in reconciling this and other cases of kwashiorkor seen in adequately breast-fed infants^{1,2} with the common view that kwashiorkor is due to a deficiency of animal protein (or of some constituent(s) thereof) led to the introduction of another assumption—namely, that in such cases the mother's milk may be deficient in an essential factor.³ There is no evidence, however, to support this assumption.

It seems surprising that so little attention has been devoted to another concept—namely, to the possibility that it is not the absence, but rather the presence, of some factor(s) which is the cause of kwashiorkor. This concept has been suggested on the basis of experimental studies with senecio alkaloids in young rats.^{4,5} These hepatotoxic pyrrolizidine alkaloids are known to be present in certain plants of the botanical families Compositae Boraginaceae, and Leguminosae,⁶ many of which are being used as traditional herbal medicines by the African negroes and in other under-developed countries.^{7,8} Interesting examples of herbal treatment of mothers and infants have been recently published from Ibadan⁹ and from Tanganika.¹⁰ These authors, however, do not specify the exact composition of the complex concoctions used as drinks, bathing fluids, or porridge admixtures. These probably vary depending on the region, the season, and the availability of the plants. The point of great importance would be to ascertain the constituents of the particular herbal mixtures which have been used in kwashiorkor cases by the mothers during pregnancy or lactation, as well as those given to the babies.

The following points relevant in such an inquiry may be worth recalling: (1) The alkaloid content of plants varies with the season. In young plants pyrrolizidine alkaloids are present mainly in the form of N-oxides which, being more palatable, are likely to be ingested in larger quantities, and induce various degrees of poisoning. (2) The action of the alkaloids in doses not immediately toxic may manifest itself only after an induction period of several

weeks or months or even years. (3) Treatment with the alkaloids of females during pregnancy may affect the foetus *in utero*. (4) The alkaloids induce similar effects regardless of the route of their application, whether by feeding or to the skin. (5) Young animals in the course of rapid growth are more susceptible than adults to the action of these alkaloids. Gastro-intestinal disorders, pancreatic and splenic changes, stunted growth, haemorrhage, anaemia, respiratory disorders, and liver damage (necrosis, fatty infiltration, fibrosis, hyperplasia, and neoplasia) have occurred in response to appropriate treatment with the alkaloids. However, even litter mates show a great variability in response to the same treatment; while some may remain unaffected in good health, other siblings may succumb at various stages of the pathological chain of events. (6) The effects of these alkaloids manifest themselves in animals given an adequate diet, but are aggravated if superimposed on dietary protein deficiency.—I am, etc.,

Operator and Anaesthetist

SIR,—I am somewhat perturbed that the letters which have appeared in the *Journal* on this subject may be used to establish a legal precedent. Surely it is time that this subject was considered from a common-sense point of view. Ideally all dental anaesthetics should be administered by specialist anaesthetists, either with medical or dental qualifications who have had special experience in dental work. However, such men are scarce, and outside London and one or two other centres they do not exist, even if the average patient could afford the fees that such men rightly command.

It is, and has been for the last 25 years, a common practice among dental surgeons to act as operator-anaesthetist when dealing with emergency extractions. They are usually helped by well-trained chairside assistants. This practice, far from being negligent, is safer and more efficient than getting the average general medical practitioner to give the anaesthetic, and is the only economic possibility under the N.H.S. scale of fees. I have been concerned in three anaesthetic deaths. At two I was a spectator, and I arrived at the third shortly after the tragedy had occurred. In each of these cases the anaesthetic was administered by a medical practitioner—one a specialist anaesthetist.

The average medical practitioner has never been taught to give dental anaesthetics. For many years I worked in the dental department of a teaching hospital, and I can count on the fingers of one hand the occasions when medical students visited the department for instruction in dental anaesthesia. Similar conditions exist in most medical schools. It is unreasonable to assume that most medical men trained under these conditions will give efficient dental anaesthetics without special training. In domiciliary midwifery no objection is raised when a medical practitioner induces anaesthesia and then hands over to the midwife while he continues the work of delivery. This, however, is a much more dangerous procedure than that carried out by the dental operator-anaesthetist, who is working on the airway all the time and can readily observe any abnormality of respiration.

These are the facts, and apply as much to thiopentone as to nitrous oxide, provided the dentist has had experience in administering the former. There are occasions when it is safer for the dental operator-anaesthetist to give thiopentone in preference to nitrous oxide.

As to getting a certificate in every emergency case from the patient's own doctor, this is impracticable, whatever a "learned judge" may have laid down. If carried to its logical conclusion, no anaesthetics should be given in the casualty department of a

general hospital without these certificates. I do, however, feel that more careful inquiries should be made into the patients' medical histories, and if any are undergoing medical treatment every reasonable effort should be made to consult with the medical practitioner concerned.

Every anaesthetic is a serious responsibility, and I would stress that I do not consider it ideal for a dentist to act as operator-anaesthetist, but that under existing conditions it is legitimate for him to do so for short emergency procedures. For longer operations he would be wise to get one of his colleagues to work with him. If it becomes established that the operator-anaesthetist practice is abolished, many thousands of working-class patients, and their children, will be denied the advantages of general anaesthetics for tooth extractions.—I am, etc.,

St. Albans.

ERIC SCHOFIELD.

Herpes Zoster Treated with Vitamin B₁₂

SIR,—I am afraid that I cannot endorse Dr. K. E. Jolles's wholehearted enthusiasm for vitamin B₁₂ in the treatment of herpes zoster (*Journal*, January 15, p. 166). For several years I had used injections of liver extract in this condition with very variable results, some apparently benefitting and others running an apparently unrestricted course. So much so that I had abandoned it prior to the advent of B₁₂, considering that the apparently improved patients might have had less severe infections. When B₁₂ was introduced I started treating cases with increasing doses up to 100 µg. daily on three successive days, with equally variable results. For the past six months I have employed 1,000-µg. doses and am convinced that either cases vary greatly in their natural course, or that, to be of benefit, vitamin B₁₂ must be given very early in the course of the disease.

Two cases may help to illustrate.

Case 1.—Married woman. December 11, 1954, herpes zoster ophthalmicus (left) lesions present for 36 hours. "Cytamen" 1,000 µg. injected. December 13, lesions more extensive and eye almost closed. Cytamen 1,000 µg. injected. December 18, eye completely closed. More widespread lesions in scalp and forehead. Progress apparently unrestricted. Pain severe. January 1, 1955, eye open. Neuralgic pain severe. January 15, neuralgic pain still severe.

Case 2.—Married woman. October 10, 1954, complaining of pain right side of head. No lesions present. ? Herpes zoster. October 13, Cytamen 100 µg. injected. Definite herpes on forehead. Eyelid swollen but not closed. October 15, cytamen, 1,000 µg. injected. Very few lesions. Pain slightly more marked. October 18, practically settled. October 23, smarting only at times.

Almost parallel results could be quoted for herpes zoster of the body. The main difficulty in my practice is that patients do not usually attend until the lesions are well established, by which time I find great difficulty in convincing myself that vitamin B₁₂ influences the subsequent course in any degree whatsoever.—I am, etc.,

Holland-on-Sea.

JOHN C. SKELLEY.

Dyspareunia

SIR,—I should like to support the several points made by Mr. Oswald Lloyd in his letter (*Journal*, January 22, p. 228), particularly his statement that cases of introital dyspareunia can be treated successfully in a gynaecological out-patient clinic. I think it is important that when local lesions have been excluded the remaining cases, in which muscle spasm is the cause of difficulty, should be treated forthwith. To refer them to another clinic, where the process of history-taking and examination will be repeated at a later date, is likely to increase the anxiety and apprehension which underly this condition. Treatment by explanation and reassurance, aided by the use of vaginal dilators introduced by the patient herself, is almost always successful. I have recently been impressed by the value of methylpentynol ("oblivon") in doses of 500 mg. taken about 30 minutes before intercourse and repeated on four or five occasions till confidence is established.—I am, etc.,

Newton, Lincoln.

R. F. LAWRENCE.

Kaposi's Varicelliform Eruption

SIR,—Dr. Allan Bigham and Dr. Brian Russell in their letters (*Journal*, January 15, p. 167) rightly suggest that the diagnosis in the case reported by Dr. A. Fry (*Journal*, January 1, p. 28) should be one of accidental vaccinia. But it may be worth commenting on their suggestion that Kaposi's varicelliform eruption arises only on a basis of "eczema" (Dr. Bigham) or of "asthma-prurigo" (Dr. Brian Russell).

Kaposi's varicelliform eruption may appear in the presence of various pathological conditions of the epidermis, and, although a basic chronic eczema is the predominant finding, we have seen herpetic forms in association with impetigo contagiosa and with seborrhoeic eczema, and vaccinal forms in association with infectious eczematoid dermatitis and with ichthyosis. We would therefore define Kaposi's varicelliform eruption as a virus infection (herpes simplex, vaccinia and perhaps other viruses) arising in patients with a damaged skin, and would suggest that precautions against virus contamination are necessary in such subjects.—We are, etc.,

Glasgow, W.2.

A. GIRDWOOD FERGUSON.
W. A. DEWAR.

SIR,—I was very interested to read the case of accidental vaccinia in the *Journal* (January 1, p. 28). I enclose a photograph (Fig. 1) of a case I had in 1902. The lesion was on the right cheek.

FIG. 1

FIG. 2

I also send you a photograph (Fig. 2) of a case of confluent smallpox I had about the same time, which I am sure will interest you.

The patient got quite well, thanks to the skill and care of the nurses.—I am, etc.,

Newark.

ERNEST RINGROSE.

A Foreign Body in the Kidney

SIR,—The paper on "A Foreign Body in the Kidney" in your issue of January 22 (p. 205) seems to demand a world conference on the "kirbigrip." This aid to female beauty is a small smooth object, chemically harmless, without projections or points, ideally shaped to go round intestinal curves; yet of all swallowed foreign bodies it appears to be the most noxious. Why? It is significant that all cases collected by Dr. Duncan Macaulay and Mr. Thomas Moore implicate this gadget, and in all except one it was impacted in the duodenum. How many surgeons have had a similar experience?

I have been forced to remove a foreign body from the alimentary canal once only, though I have often been tempted to do so. I have seen bits of chain, lengths of wire, six-inch (15.2 cm.) nails, and open safety-pins in plenty

(and, of course, Souttar's tubes) passed through the alimentary canal without damage. My one "kirbigrip" remained for a fortnight so fixed at the duodeno-jejunal flexure that I had to remove it in order to preserve the mother's sanity.—I am, etc.,

London, W.1.

HENEAGE OGILVIE.

Lactation from Axillary Tail of Breast

SIR,—I was interested to read Dr. J. P. Roux's case report of lactation from the axillary tail of the breast (*Journal*, January 1, p. 28). I have seen a similar case also in a primigravida, but, unlike Dr. Roux's case, milk excretion continued from the axillary pore both during and between breast feeds, and for the comfort of the mother lactation was suppressed.—I am, etc.,

London, S.E.1.

M. C. JOSEPH.

SIR,—After noting the case reported by Dr. J. P. Roux (*Journal*, January 1, p. 28) I am prompted to report a similar case. It rather confirms the remark that this abnormality has been somewhat neglected by medical writers.

A 23-year-old primigravida in 1952 noticed enlargement of both axillary tails of her breasts. These protruded above the level of the brassière, and caused some embarrassment and slight discomfort, especially when she was cold. Following delivery on December 9, 1952, she had two very full breasts and an abundant supply of milk which leaked freely prior to feeds. The left axillary tail was found to have a small opening which leaked under her arm, and was a source of considerable nuisance. The baby was fed until six months, but she conceived again in April, and the breasts were never free from milk during her second pregnancy. There was, however, very little discharge of milk after feeding ceased. The right axillary tail was also enlarged but less uncomfortable and never had a separate opening. The second baby was born on January 14, 1954. The breasts did not secrete so prolifically, although satisfactory feeding was achieved for six months. The left axillary tail leaked again but to a lesser extent. Even now the axillary tails are still visible above the brassière, and the left is more conspicuous than the right.

It is interesting to note that this patient also had a rigid cervix which did not dilate beyond two fingers after 28 hours in the first stage of labour with her first confinement. This was successfully divided by Mr. F. H. Finlaison, of Windsor, whereupon the cervix immediately dilated fully. An immediate forceps delivery secured a live baby. The second pregnancy and confinement was normal in every way.—I am, etc.,

Ashford, Middlesex.

N. G. NICHOLSON.

Tuberculous Mesenteric Adenitis in Children

SIR,—I read Dr. Hugh R. E. Wallis's article on this subject (*Journal*, January 15, p. 128) with great interest, and I should like to make some observations on the treatment with calciferol. I agree that large doses of calciferol are a logical and effective means of assisting healing by calcification. The dangers of this form of therapy, however, need to be stressed. Dr. Wallis recommends a dose of 50,000 units of calciferol daily, which, I feel, requires qualification, as it is too large for small children. The dose of a potentially toxic drug should be calculated by the weight of the child. I do not agree with his observation that with a dose of this size there need be no fear of toxic symptoms.

In 1948-9 I treated a series of 25 children (aged 3-12 years) in hospital suffering from bone and joint tuberculosis with calciferol in propylene glycol. Symptoms of toxicity were carefully watched for and weekly records were kept of blood pressure, urine analysis, excess calcium secretion, monthly serum calcium and proteins, and urea clearances. At first I used a dose of approximately 2,000 units per kg. body weight daily (equivalent to 150,000 i.u. daily for an adult). Symptoms of toxicity such as loss of appetite, vomiting, and drowsiness accompanied by excess calcium in the urine were found in about half the cases in four to six weeks, and some of these showed albuminuria, depressed renal function, and raised serum calcium. I was not able to estimate the diffusible serum-calcium,

which is said to be a surer method of determining the onset of calciferol toxicity. The dose was then reduced in all patients to 1,100 units of calciferol per kg. daily. With this dose no symptoms or biochemical evidence of toxicity were discovered during two to six months of treatment.

My findings agreed with those of Anning and his associates,¹ who have made a detailed study of the toxic effects of calciferol in 200 patients. The majority of their cases were adults under treatment for skin diseases, but they also found that children were not more resistant to vitamin D unless rickets or other states of vitamin D deficiency pre-existed. They found that toxic symptoms were liable to develop if more than 1,100 i.u. per kg. of body weight was given daily. In treating a mild disease such as tuberculous mesenteric adenitis, there is, in my opinion, no justification for using larger doses.—I am, etc.,

Newcastle, Staffs.

Tuberculin Testing

SIR,—In the Army B.C.G. scheme it has been considered very desirable to have available a single test, simple to execute and interpret, as Professor J. Crofton and Dr. J. Maher-Loughnan have recommended (*Journal*, January 8, p. 105). It may interest your readers to learn that a comparative trial of the Mantoux and Heaf tests was carried out at the Depot and Training Establishment, Royal Army Medical Corps, by Lieutenant-Colonel R. L. Townsend and Captain R. MacDonald from July to September, 1954. A report on this trial has been prepared for publication.—I am, etc.,

London, S.W.1.

G. T. L. ARCHER.

"Rugger"

SIR,—Surely Mr. O'Connell's figures¹ as given in your leading article (*Journal*, January 15, p. 154) show that this game, a usurper of football in our public schools and universities, is more barbaric than professional boxing. The boxer's chief aim during a contest is to cause the maximum amount of severe injury to his opponent, and he reaches the highest peak of his art when he damages his opponent's brain. Although Rugger players make no claim (is it modesty?) that one of the chief objects of their game is to inflict injury, yet Mr. O'Connell's figures show that they surpass the boxer, even, in their most destructive triumphs.

This new game, which dates only from 1823, was started by a silly little boy who was ignorant of the rules of football and lacked the skill to control a round ball. If he had been suitably chastised by his house master this immature horse-play of lower school might still have been played by little boys but would not have been adopted into a game by grown men: *Vis bruta et inscientia cruenta* (usually translated B.F. and B.L.); it might still have been practised by thugs.

Rugger is injurious in ways other than physical. I have heard it whispered that there is one sure way for a young man to gain entry into the medical schools of some hospitals. Oddly enough this acceptance is not gained by showing an interest in the practice of medicine, nor by achieving some academic distinction, but by winning a place in the first XV before leaving school. I hope, Sir, that it still does not obtain in many hospitals that a "sweatband round the forehead to protect the ears" is more helpful during the curriculum and in qualifying than the cold wet towel which some students used to wear.

Despite the second paragraph of your leading article, reminiscent of "What's My Line?" and unctuously phrased to appease not so much employers as devotees of this game, Rugger is essentially a game of the public schools and the universities and, alas, of other schools with social ambitions. Who can assess the dire impetus which this schism in our national game has given to the present calamitous class war?

Finally, Sir, I suggest that it would have been more becoming in a serious and erudite journal if, in your leading

article, you had not dissimulated but had given honest and sound advice to Rugger players. You should have advised them to adopt one of two alternatives. (1) If they feel that they must continue to play this game, then let them remember that attack is the best form of defence, advise them to fit metal studs to their scrum-caps and shoulders as well as to their boots, and carry an Irish shillelagh for emergencies. (2) Abandon this misshapen ball and this puerile form of horse-play and return to our ancient, chivalrous, and noble national game—Association football.—I am, etc.,

London, S.E.7.

JOHN MONTGOMERY.

Tests of Hearing

SIR.—There is an undoubted need for the early diagnosis of deafness, not only because of the need for early treatment but also that provision may be made for suitable education, early training in lip-reading, and the provision of a hearing-aid. As Miss Edith Whetnall suggests (*Journal*, January 22, p. 227), the age of 5 years is too late. Professor and Mrs. Ewing have shown in their pioneer work in Manchester, and in the clinics with which they have been associated in Leicester and Birmingham, that it is possible to diagnose deafness at a year to 18 months. A considerable number of other local authorities are now taking up this suggestion, and clinics may be expected to arise in a considerable number of centres.

However, it does not appear to me that the post-natal clinic is at all a satisfactory venue in which to "increase the mother's awareness of the possibility and implications of partial deafness." The post-natal clinic is a valuable agency in which health education may be given to the mother, who is highly suggestible at this period but tends to be over-anxious about the normality of her infant. If stress is laid upon the possibility of deafness or partial deafness, a great deal of needless anxiety and distress would be caused.

The method now being adopted in Birmingham is routine screening tests of hearing at the local health authority's child welfare clinics by health visitors at the age of 9 months. By this time the mother already has a shrewd idea whether or not her child has any defect of hearing and a two-minute test causes no apprehension. Children in whom there is any suspicion of deafness are then referred to the medical officer for further testing. Such tests are simple and quick to administer and should be attempted on any child who is not beginning to speak, or does not appear to understand the spoken word, by the age of 18 months.—I am, etc.,

Stafford.

HARRY BINYSH.

Acute Thyroiditis from Potassium Iodide

SIR.—In acute iodism it is unusual to have symptoms directly connected with the thyroid gland, and so the following four cases, taken over a period of some years, may be of interest.

Case 1.—A man aged 25 complained of weakness of his wrists, and was found to be a plumber suffering from mild musculo-spiral neuritis. In addition to other treatment he was given a simple mixture containing 7½ gr. (0.5 g.) potassium iodide three times a day. Two days later he came back complaining of agonizing pain in his throat. This was found to be due to a tightly distended thyroid gland which stood out from the front of his neck in sharp relief. The swollen lobes on each side, joined by a swollen isthmus, looked like a pair of miniature swimming wings. The gland was very painful and very tense on palpation, having somewhat the feel of an over-filled rubber hot-water bottle. He said that he had been awake all night with intense pain in his throat, but no other symptoms. The iodide mixture was stopped, and in two or three days the swelling had quite gone and he had completely recovered.

Case 2.—A man aged 35 suffered from rheumatism, for which he was given potassium iodide 7½ gr. (0.5 g.) three times a day. Within 24 hours he had intense pain in his throat, and, as in the previous case, his thyroid gland stood out in marked relief. It was tense and extremely tender to touch, but normal in shape.

As before, it gave the impression of distension rather than growth of new tissue, its outline being approximately normal in size, but having an increased rotundity in a forward direction. On the potassium iodide being stopped, the condition very quickly subsided, and in three days his neck looked and felt normal. It is interesting to note that this man has a slight tendency to asthma and eczema from time to time.

Case 3.—A woman aged 70, who had rheumatism in her hand, was given a mixture containing 7½ gr. (0.5 g.) each of sodium salicylate and potassium iodide in each dose. She took the first dose of medicine after lunch, about 1 p.m., and the second dose after tea at 4.30 p.m. About 7.30 p.m. she noticed her nose was running slightly, and she began to feel unwell. At 11.30 p.m. her throat felt swollen and painful, and became progressively worse during the night. At 6 a.m. she was found to have an oedematous face with swollen eyelids, neck, and soft palate. In addition her thyroid gland was swollen, tense, and very painful, not having the soft characteristics of the other swollen tissues. The pot. iod. mixture was stopped and she was given sodium bicarbonate drinks, and phenindamine hydrogen tartrate ("theophorin"), and later mepyramine maleate ("anthisan"). In just over two days all these swellings had gone, and her throat and face felt normal.

Case 4.—A girl aged 21 had pleurisy with effusion, and was given doses of 7½ gr. (0.5 g.) potassium iodide in a mixture three times a day. She progressed satisfactorily for a fortnight, then suddenly had an acute thyroiditis, with extreme pain and tension in the gland, having similar characteristics to the previous cases. The swelling, however, was rather more than in the others, which was probably owing to the fact that she had had a mild symptomless, parenchymatous goitre for a few years. At the same time as the acute throat symptoms she developed an iodide rash all over her body. The pot. iod. was stopped, and the condition rapidly subsided in about three days.

The special features common to these four cases of (a) sudden onset without inflammation or signs of infection, (b) acute generalized tension within the capsule of the gland, causing great pain, but no distortion of normal shape, and (c) association in each case with administration of normal doses of potassium iodide, and rapid subsidence when the latter was stopped, all point to an allergic condition due to the drug.—I am, etc.,

Slough.

H. TUDOR EDMUNDS.

Treatment of Vitiligo

SIR.—Reference "Any Questions" (*Journal*, February 6, 1954, p. 346), I think the following case may be of interest.

A severe case of vitiligo in a Sikh male of 54 years came to me for treatment in April, 1953; general health and diet good; Kahn negative. A small patch of depigmentation on the left side of the face was first noticed in April, 1950. This rapidly spread over face, neck, arms, hands, and lower limbs. Disfigurement was considerable, as there was complete depigmentation of supraorbital regions, nose, ears, lateral aspects of both cheeks and neck. The patient had tried many treatments, but spread of the depigmentation continued. Treatment with "meladinine" was begun on April 8, 1953—1 tablet orally three times a day (a tablet contains 7.5 mg. ammoidine and 2.5 mg. amidine). On April 19 one local application with meladinine paint (ammoidine 7.5 mg. and amidine 2.5 mg. in 1 ml.) was made to a small area on the dorsum of the left hand. This was exposed as recommended to 10 minutes' direct sunlight. Severe erythema and vesiculation of left hand and forearm occurred and all treatment was stopped. The patient was persuaded to start oral treatment again on May 25 in the same dosage. On June 10 small scattered areas of pigment on the dorsum of left hand appeared; on July 14 many small scattered areas of pigmentation on face, ears, hands, and elsewhere. On July 16 small area flexor surface right forearm painted with meladinine. This became only slightly inflamed. Oral medication was continued, and by October pigmented areas had so enlarged and coalesced that the face was nearly uniformly its normal brown colour, and there were large areas of pigmentation of both arms and elsewhere. Medication has continued intermittently until the present date, and, although pigmentation is not completely normal, the disease is no longer an unsightly one.

This reasonable success with a single patient, I think, makes the drug worthy of further trials. The patient is most satisfied with the cosmetic improvement.—I am, etc.,

Ipoh, Malaya.

F. A. ADAM-THOMSON.

Obituary

Sir EDWARD MELLANBY, G.B.E., K.C.B., M.D.
F.R.C.P., F.R.S.

We record with regret the sudden death on January 30 of Sir Edward Mellanby at the age of 70 years. He was secretary of the Medical Research Council from 1934 to 1949, and held this highly responsible administrative post in the years of stress before, during, and after the second world war: yet he managed to continue to carry out important research himself, chiefly in his own field of nutrition. From Mellanby's early days at Cambridge each distinction gained and each office held was a stepping-stone in the upward climb of a man marked out from the beginning for high achievement. He devoted himself to science, submitting gladly to its disciplines—and understanding by science not only the acquisition but, as Herbert Spencer said, the organization of knowledge.

Edward Mellanby was born on April 8, 1884, the son of John Mellanby, of West Hartlepool. His brother, Professor John Mellanby, died in 1939, three years after succeeding Sir Charles Sherrington as Waynflete Professor of Physiology at Oxford. Another brother—the late Professor Alexander Mellanby—was Professor of Civil and Mechanical Engineering at the Royal Technical College, Glasgow. From Barnard Castle School, in County Durham, Edward Mellanby won a scholarship to Emmanuel College, Cambridge. After taking his B.A. in 1905 he spent two years, as research student of Emmanuel, at St. Thomas's Hospital, London. From 1909 to 1911 he was demonstrator in physiology at St. Thomas's; and in 1913 he became lecturer and later professor of physiology at King's College for Women, an appointment which he retained until he took up his work in Sheffield in 1920. His career at Cambridge had been highly distinguished. He took his M.A. and M.B. in 1910 and his M.D. in 1915, and his Cambridge prizes included the Walsingham Medal (1907), the Gedge Prize (1908), and the Raymond Horton-Smith Prize (1915).

His attention at an early stage in his career was attracted to experiments in nutrition. Hopkins had lately published the full reports of his vitamin experiments. Many facts had been elicited, but explanations were hard to find. In the years from 1915 to 1919 Mellanby pursued researches which resulted in the discovery—published in the *Journal of Physiology* in 1918—that some foodstuffs containing a fat-soluble substance which controlled the deposition of calcium in the bones

were effective in preventing the onset of rickets in puppies kept on certain special diets and in curing the condition both in dogs and in man. There were, however, discrepancies in the observations which were ultimately resolved by the elucidation of the separate parts played by the two fat-soluble vitamins A and D. For many years it remained a mystery why dogs even on an adequate diet developed rickets on being fed with certain cereals, but 20 years after his earlier discovery Mellanby himself, working with D. C. Harrison, showed the rickets-producing substance in the cereals to be phytic acid, which acted by forming an insoluble compound with the calcium in the food—an action which could be overcome by giving an excess of calcium or adding vitamin D to the diet. It was this discovery

which paved the way to the recent conception of "anti-vitamins." His later work in this field demonstrated how vitamin A influenced the growth and shape of bones, and how a deficiency might cause neurological disturbances due to the pressure on nerves of abnormally growing bone. Right up to the time of his death he was continuing his work on vitamin A, and with his colleagues had published a paper in this *Journal* last September describing recent research.

Much other work was carried out by Mellanby during those early years. One of his first contributions to the *Proceedings of the Royal Society* was on the metabolism of lactating women: another, to the *Quarterly Journal of Medicine*, was on diarrhoea and vomiting in children. During the first world war drunkenness was still a serious social problem, and Mellanby was asked by the Government to investigate the action of

alcohol. His observations were summarized in a Special Report of the Medical Research Council, published in 1919, entitled, "Alcohol: Its Absorption Into and Disappearance From the Blood."

In 1920 a chair of pharmacology was founded in the University of Sheffield, and Mellanby was appointed its first occupant. He held it until 1934, together with the appointment of honorary physician to the Sheffield Royal Infirmary. Here some of his most noteworthy work was done. He was recognized by this time as one of the outstanding experts in the biochemical and physiological field. His special reports for the Medical Research Council on experimental rickets appeared in 1921 and 1928 and on nutrition and disease in 1934. In 1924 he was awarded the Stewart Prize (for original medical research) of the British Medical Association. In 1929 he received the Bissett Hawkins Medal and a few years later the Moxon Medal of the Royal College of Physicians for highly important additions to practical therapeutics. In 1932 he was the recipient of the

(Barratt's Photo Press)

Cameron Prize of the University of Edinburgh, and in the same year the Royal Medal of the Royal Society was awarded him. At the Royal College of Physicians he was Oliver-Sharpey Lecturer in 1922, Croonian Lecturer in 1933, and Harveian Orator in 1938. He gave the Linacre Lecture at Cambridge in 1933 and Rede Lecture in 1939—published under the title "Recent Advances in Medical Science: A Study of Social and Economic Implications."

During this period he came into international prominence as chairman of two International Conferences for Standardization of Vitamins, one in 1931 and the other in 1934, and chairman of the International Technical Commission on Nutrition. His connexion with the Health Section of the League of Nations dated from 1930. He was the driving force behind the movement for international standardization. The atmosphere of Geneva during those years was not always stimulating, but this was not evident in the work on nutrition, thanks largely to the energy and determination of the experts who represented Britain. By common consent whatever success was achieved was due in no small measure to Mellanby's patience, assiduity, and ability to reconcile different viewpoints.

In 1934 Mellanby, who had been a member of the Medical Research Council since 1931, succeeded the late Sir Walter Fletcher as secretary of that body and *ex officio* secretary of the Committee of the Privy Council for Medical Research. At the same time he relinquished the Sheffield chair and became professor emeritus. The appointment proved to be an excellent one, for Mellanby not only had the imagination and brilliance of the successful research worker, but he had the gift of inspiring others. His office became more important as the European situation became graver, and brought a multitude of problems concerning the health and nutrition of the fighting and of the civil population in the event of war. A member of the Scientific Food Policy Committee of the War Cabinet, Mellanby exerted a strong influence in the discussions on the medical aspects of food policy, including the prevention of ill-health by dietetic measures—for instance, by the fortification of margarine with vitamins A and D and the inclusion of extra calcium in National flour. He was also chairman of the Food Rationing (Special Diets) Advisory Committee, which had the difficult task of deciding how the rations should be modified or supplemented for patients with certain diseases. In 1939 Mellanby became chairman of a standing committee appointed by the Secretary of State for Air to investigate and advise on the medical aspects of all matters concerning personnel which might affect safety and efficiency in flying; and he also took a prominent part in industrial health research. Yet another of his duties was the chairmanship of the Colonial Medical Research Committee, and it was largely due to his efforts that the organization of research in colonial territories has been put on a sound basis. He also supported the work of the British Council and was chairman of its medical panel.

Shortly after becoming secretary of the Medical Research Council he added to his labours by accepting the Fullerian professorship of physiology at the Royal Institution in succession to Sir Grafton Elliot Smith. In 1937 he became honorary physician to the King, retaining this appointment until 1941. He retired from the position of secretary of the Medical Research Council in 1949, being succeeded by Professor (now Sir Harold) Himsworth. In the year after his retire-

ment the new Institute for Medical Research, with the planning of which Mellanby had been closely concerned, was opened at Mill Hill by King George VI.

It was in this *Journal*, in 1946, that Mellanby published his observation that agenized bread is a cause of canine hysteria. Four years later he and his colleagues succeeded in isolating a crystalline toxic factor from agenized flour which caused severe epileptiform fits in ferrets. Though it has not been proved that this factor is harmful to man, the Government has decided that the agene process for "improving" flour must not be used after the end of 1955. In the Sanderson-Wells Lecture (published in the *British Medical Journal* in 1951) Mellanby gave a general warning about the chemical manipulation of food.

Sir Edward Mellanby was created K.C.B. in 1937 and G.B.E. in 1948. He had been a Fellow of the Royal Society since 1925 and of the Royal College of Physicians since 1928. Elected an Honorary Fellow of Emmanuel College, Cambridge, in 1946, he received the honorary doctorate of science of Sheffield University in 1933 on leaving that city after his 13 years' professorship; the Honorary D.Sc. of Oxford in 1939 and of Cambridge in 1947; and the Honorary LL.D. of St. Andrews, Birmingham, and Durham in 1938, and of Glasgow in 1946, and the Honorary F.R.C.S.Ed. in 1946. An honorary member of numerous foreign academies, he was also a Charles Mickle Fellow of Toronto University, a Nuffield Trustee for medical research, and a Beit Memorial Fellow. In 1935 he delivered the Halley Stewart and the Huxley Lectures, both of them dealing with the progress of science; in 1939 the Stephen Paget Memorial Lecture to the Research Defence Society; and in 1943 the Croonian Lecture to the Royal Society. From time to time he rendered useful services to the British Medical Association. He was honorary secretary of the Section of Physiology at the Annual Meeting at Cambridge in 1920, and vice-president of the same section in 1922 and again at the Centenary Meeting in 1932. From 1933 to 1937 he was a member of the Science Committee, and afterwards of the special committee which was set up to consider the policy to govern the awards of the Association's scholarships and grants.

As a lecturer and speaker Sir Edward Mellanby was plain, direct, and matter-of-fact. Those who knew him intimately were aware of a man of most charming personality, very approachable, interested in the work of others, and eager to express appreciation of the work of colleagues and subordinates when that work was well done. He was unaffected and direct in manner, and a certain boyishness of attitude was an endearing characteristic.

In his early work on nutritional problems Mellanby found a valued colleague in May Tweedy, research scholar and lecturer at Bedford College, London, and they were married in 1914. Lady Mellanby has herself carried out highly important and original work on nutritional conditions affecting the structure of the teeth: the heart-felt sympathy of her many friends and colleagues is extended to her in her loss.

Sir LANDSBOROUGH THOMSON writes: Sir Edward Mellanby was secretary of the Medical Research Council, and of the Committee of Privy Council for Medical Research, during 16 years of great activity and progress in their affairs. These years included the emergency period, 1939-45, in which the scientific resources available to the Council had to be deployed in support of the war effort. This was followed by the period of reconstruction, in which a

notable expansion of the organization was effected. Tasks of such magnitude and difficulty called for direction by a man cast in a large mould; in both of them Mellanby's achievement has had lasting results.

Mellanby's acceptance of the post involved a complete change in the pattern of his life. Hitherto he had devoted himself to his own investigations, in association with his wife and a few other chosen colleagues and personal assistants; the assumption of a wider responsibility towards the work of many others was something new, and administrative problems were frankly uncongenial. He regarded it as a duty, however, to take over the direction of an organization to which he felt indebted for his own early opportunities as a research worker; he had in fact been one of the first small band of investigators supported by the original Medical Research Committee. His aim as secretary was always to bring like help to those younger men, and women, who showed special ability for research and ideas likely to lead to real discovery. To the performance of this responsibility he brought his own intense scientific spirit, his immensely wide knowledge of medical problems, and his great intellectual grasp. Those who worked closely with him especially admired his flair for seeing what was genuine and important in any research project, or any scientific result, that came before him.

Of particular developments for which he was largely responsible, two may be singled out. One was the initiation of "personnel research" for the Defence Services—the application of physiological knowledge and methods of investigation to problems of the airman, soldier, and sailor in relation to operational conditions and the use of specialized equipment. He was himself the first chairman of the Flying Personnel Research Committee, set up by the Air Ministry at his instigation before the war; and on this model there followed two analogous committees for the other Services. The second was an arrangement with the Colonial Office for co-operation in the promotion of research in tropical medicine; and he himself became the first chairman of the jointly appointed Colonial Medical Research Committee.

By the time of his retirement Mellanby's task as an organizer had been done, and administrative shackles were beginning to chafe. It was a source of pleasure to his former official associates that he was thereafter able to return to the personal research work which he had never wholly abandoned, and—with Lady Mellanby as his colleague—to spend some happy years in the undisturbed pursuit of his own still fruitful scientific ideas.

Professor B. S. PLATT writes: Sir Edward's paramount interest was in discoveries; none of us will forget that disconcerting question with which we were often greeted, "Well, young man—what have you discovered to-day?" He prized new knowledge, and he particularly appreciated the scientific worker who had a biological sense. Inspiring as his devotion was to research, he was by no means "academic"; indeed, no one in the present century has contributed so much in so many ways in the application of medical science to human well-being. Search in support of this statement need go no further than the reports of the Medical Research Council, particularly that for the immediate post-war years (*Medical Research in War—Report of the Medical Research Council for the years 1939-45*). He played a distinguished part in international nutrition in the early 'thirties in his work with the Health Section of the League of Nations.

The main function of the Medical Research Council was in his view the promotion of "scientific investigations for the acquisition of knowledge likely to be of value for the prevention, diagnosis, and treatment of disease, and for the maintenance of health and full human efficiency" (Report of the M.R.C., 1945-8). The translation of these objectives is finely illustrated by the application of the knowledge of nutrition to the feeding of the nation in wartime. The work recorded in the report on *Medical Research in War* is alone a monument of which any man might be proud, and one with which most men would be more than con-

tent. This record is only a part of the tale, the whole of which has not yet been told; it states that, great as is the credit deserved by the various Ministries concerned in the feeding of the nation, "credit is due in no smaller measure to those research workers in nutritional science—many of them workers for the Council—who provided the solid structure of knowledge upon which a sound food policy could be based." Sir Edward himself contributed many planks to this structure.

Wise as he was in a wide field, statesmanly as he was in dealing with men and affairs, effective as he has been in the application of knowledge, it was research in nutritional science which was nearest to his heart and for which he will be long and best remembered. Before his service as secretary of the Medical Research Council, throughout his period of office, and since his retirement, his work has been productive of results with any one of which most research workers would be glad to have been associated. As I was leaving him one day last week after a visit to his laboratories, he turned to enter a room with the words, "I must go in here. Something exciting is happening—I am on to something new." Nothing would, I think, have pleased him better than to be remembered for his love of new knowledge, and he would be happy to be known for the way he gave pre-eminence to the need for "having the facts right."

In nutrition research, Sir Edward Mellanby's name will continue to be coupled with that of Lady Mellanby: theirs was a partnership in research which has benefited mankind more than most of its members will ever know.

Professor H. N. GREEN writes: For a former student, personal assistant, scientific colleague, and friend during 30 years, it is difficult immediately to express more than personal grief at Sir Edward's unexpected death. His enormous range of activities, performed with such dynamic energy, makes it difficult to focus them sharply at this stage. A biography is necessary for justice to be done, for he was a great leader in scientific medicine during those eventful years when it attained to glory. His life was dedicated to the advancement of medicine, and he never doubted how best to achieve this. He was a pioneer in bringing the scientific approach of the laboratory into the ward, and he and Sir Thomas Lewis came to be regarded as the first two great clinical scientists in the modern sense. Mellanby's method was to use the lessons learned from the patient as a source of inspiration for laboratory work. So numerous were his ideas that many will never be recorded, but those who knew him during his lively and provocative years as physician at the Sheffield Royal Infirmary will recall the controversies they engendered in the ward and staff-room. As with many great men, ideas flowed from his mind unceasingly, but he curbed them ruthlessly.

This is a purely personal tribute to a great man. Since I was perhaps more intimately aware than any but his wife of his continuous stream of scientific work, it would be an impossible task to summarize his 30 years and more of scientific discovery here. The discovery of the cause of rickets will always remain the landmark in his career, because it had such tremendous practical results on infantile morbidity and mortality; but this is only one of many discoveries with important repercussions in preventive medicine.

Sir Edward's endearing personal qualities were sometimes superficially hidden by his bold and forthright personality which made him say what he thought without apparent fear or favour. In this he really expressed his intense desire to stimulate a strong reaction in whoever was seeking his help or advice and thus to assist them in the most practical way he knew. What his listener thought about him temporarily did not matter so long as medical science was advanced or a new scientist born. Of course one had only to know Mellanby more than slightly to realize that he was warm-hearted and eager to help in medical causes. His sometimes apparent aloofness was merely an expression of a somewhat shy and mentally preoccupied nature. Actually he had a great sense of fun, being very youthful, even boyish, at

heart. Only his lifelong devotion to science, and later also to administration, prevented him from becoming not only a scientific but also a social giant.

Lady Mellanby has been a devoted wife, friend, counsellor, and scientific colleague throughout their long married life. Such a completely happy personal and scientific companionship as theirs is rare, and no one realized the debt he owed to his wife more than Sir Edward. On this theme everything remains yet to be said, and we can only now express our deepest sympathy at the breaking of such a perfect partnership.

C. H. HAMPSHIRE, C.M.G., M.B., Ph.C.

Dr. C. H. Hampshire, who died in London on January 25, was secretary of the British Pharmacopoeia Commission from 1929 to 1950. He was not only a renowned pharmacist but also skilled in a highly specialized form of editing. Probably his greatest achievement—not his achievement alone, but predominantly his—was embodied in the *Pharmacopoea Internationalis*, the first international pharmacopoeia, which came forth, after a prolonged gestation of some 14 years, in 1951.

Charles Herbert Hampshire was born at Ilkley, Yorkshire, in 1885, and educated at Ilkley Grammar School, to which he won a foundation scholarship from Ilkley National School. On leaving school he was apprenticed to a local pharmacist. When he was 20 he gained the Jacob Bell scholarship of the Pharmaceutical Society and entered the Society's school of pharmacy in London. There he showed great promise. In 1906 he obtained the bronze medals in chemistry and botany and the Martindale memorial medal, and in the following year the

(Elliott & Fry)

silver medals in chemistry, botany, and materia medica, the first certificate in practical chemistry, and the Pereira medal. Having qualified as a pharmaceutical chemist, he became demonstrator in chemistry and later lecturer in physics at the school of pharmacy. In 1914 he was appointed pharmacist to University College Hospital, a post which he held until 1929. During that time, with the permission of the hospital and to the great advantage of his future career, he became a student in medicine, obtaining the Conjoint diploma in 1925, followed in 1927 by the M.B., B.S. of London.

For 10 years he acted as honorary secretary of the British Pharmaceutical Conference (being chairman of the conference in 1933 and 1934) and as honorary joint editor of the *Yearbook of Pharmacy*. Later on he was appointed editor of the supplement of the *Yearbook*, known as the *Quarterly Journal of Pharmacy*, which later became the monthly *Journal of Pharmacy and Pharmacology* and which he continued to edit until his death. While still at University College Hospital he was invited by the General Medical Council to organize the revision of the *British Pharmacopoeia* on the lines laid down by Lord Macmillan's subcommittee of the Committee of Civil Research, and in four years the formidable task of producing an entirely new *Pharmacopoeia* was completed.

In 1929 he gave up his appointment at University College Hospital to become the first secretary of the Pharmacopoeia Commission, and two editions of the *Pharmacopoeia* (1932 and 1948) with the various *Addenda*, were carried through under his most expert supervision. Preparations for the *Pharmacopoea Internationalis* began before the last war, when the Health Organization of the League of Nations set up a technical committee of seven pharmacopoeial experts, of which Hampshire, the only British member, was chairman. It held two meetings in Geneva before war began. Then, after the war, in 1946, the World Health Organization returned to the work of setting up standards for the safety, purity, and potency of biological, pharmaceutical, and similar products in international use. Again an expert committee of seven was set up, of which again Hampshire, the only British member, was chairman, and the work of preparing an international pharmacopoeia with a unified nomenclature was completed in New York in 1950. Special mention is made in this book, quite monumental in its detail, of the work which Hampshire had undertaken as chairman. It must have called for extraordinary patience, as well as that scrupulous accuracy for which all Hampshire's work was so notable. Israel was the first State to recognize the *Pharmacopoea Internationalis* as its own official pharmacopoeia.

As anyone seeking information at his room in the General Medical Council offices had reason to know, Dr. Hampshire was not only a very approachable man but able to interpret for the benefit of the less learned the highly technical matters with which he dealt. He was the author of several papers in the journals of the Chemical Society and other bodies. His *Volumetric Analysis for Students of Pharmaceutical and General Chemistry* passed through several editions. He was examiner to the Pharmaceutical Society and to the Royal Institute of Chemistry, of which he was a Fellow. He was made a Commander of the Order of St. Michael and St. George in 1946.

Dr. Hampshire's wife died a year ago, and he is survived by his daughter.

We are indebted to Professor D. M. DUNLOP for the following appreciation. The majority of men, like motor-cars, are mass-produced: a few are hand-made. Dr. Hampshire belonged to the latter category. Perhaps he will be remembered chiefly as secretary of the British Pharmacopoeia Commission, which he served faithfully for twenty-one years until his retirement from it in 1950. He brought a variety of gifts to this work—a knowledge of chemistry; a medical qualification; a great experience of pharmacy, ripened by years of service as chief pharmacist to University College Hospital; and a love of grammatical precision, so that Browning's Grammarian was no more conversant with the enclitic *De* than was Hampshire with the intricacies of pharmaceutical and analytical punctuation and italics. He was the ideal scrupulous editor not only of the *Pharmacopoeia* but of the *Quarterly Journal of Pharmacy*, the perfect draughtsman of concise minutes, and a veritable storehouse of pharmaceutical knowledge. In fact he was for a long time the *British Pharmacopoeia* incarnate in the flesh: he had identified himself so closely with it that he had assumed many of its attributes—solid, dignified, impressive, authoritative, and rather splendid. In his latter years he was no longer just a great British pharmacist, but an international one, and walked with ease in the councils of the World Health Organization at Geneva, where he played a dominant part in the production of the *Pharmacopoea Internationalis*. In spite of his long residence in London and his cosmopolitan activities Hampshire remained uncompromisingly a Yorkshireman from the Brontë country; in

fact he might almost have stepped out of the pages of *Shirley*. Ilkley Moor always had a robust determining influence on his career. Those of us who were associated with him in the work of the Pharmacopoeia Commission, and a great many of his other associates, will remember his long and devoted service with warm gratitude and will think of his achievements with pride. Our inevitable sadness at his death must be tinged with relief that he was spared a long illness and that to within a few hours of his death he remained his erect, erudite, formidable self.

JAMES WHILLIS, M.D., M.S., F.R.C.S.

Professor James Whillis, professor of anatomy at Guy's Hospital Medical School, died in London on January 27, aged 54. He underwent an operation last May, and had to have hospital treatment again last November.

James Whillis was born at Newcastle-upon-Tyne on September 8, 1900. From Carlisle Grammar School he went on to study medicine at Durham University, where

(Lalaye)

he was Philipson Scholar. Graduating M.B., B.S. in 1922 with first-class honours, he was shortly afterwards appointed lecturer in anatomy at the College of Medicine, Newcastle-upon-Tyne. He obtained the degrees of M.S. in 1925 and M.D. (with commendation) in 1930, and was elected F.R.C.S. in 1932. As his qualifications show, Whillis was not content to remain in the dissecting-room, and he co-operated closely with the clinical teachers at the

Royal Victoria Infirmary. He was an advocate of visual methods of education, and he made a number of films for teaching purposes. At Newcastle Whillis was in command of the medical unit of the Officers Training Corps, and towards the end of the second world war he served as a major (T.A.) in the R.A.M.C.

In 1935 Whillis was appointed to the readership of anatomy tenable at Guy's Hospital, and he succeeded Professor T. B. Johnston as professor there in 1943. It was under the co-editorship of Professors Johnston and Whillis that the last three editions of *Gray's Anatomy* have been published. Whillis was also the author of a textbook, *Elementary Anatomy and Physiology*, first published in 1938, and co-author, with Professor Lucas Keene, of *Anatomy for Dental Students* (published in 1950).

For many years Professor Whillis took an active interest in the work of the Chartered Society of Physiotherapy, and he succeeded Dr. W. S. C. Copeman as chairman of the council of the Society in 1950. He was chairman of the negotiating committee which considered the recommendations of the Cope Committee on the Supply and Demand, Training and Qualifications of Physiotherapists in the National Health Service; and he played a leading part during the international congress in London which the Chartered Society organized for the World Confederation for Physical Therapy in 1953. Fortunately he was able to attend the annual congress of the Chartered Society in Harrogate last September, at the conclusion of which he retired from office.

In 1926 he married Miss Dorothy Margaret Lee, and he is survived by his widow and one son.

We are indebted to Professor W. R. SPURRELL for the following appreciation: At an early date in his medical training Whillis developed an interest in anatomy, and this led to his appointment as demonstrator of anatomy when he qualified in 1922. From that date onward the whole of his career lay within that subject, to the advancement and application of which he devoted so much time and energy. Brought up under the strong influence of Rutherford Morison and Grey Turner, his mind was always turned towards surgery, and he delighted to put his knowledge to use in that specialty.

He found himself in the period of the "changing face" of anatomy. An increasing revolt against the burden of topographical detail, a growing demand for a more dynamic outlook upon structural relationships, and the rapid development of new techniques for examining and recording were met by him in a sound and balanced fashion. In his hands there was no sudden upheaval but a steady change of emphasis. Into his department were introduced features of the anatomical "new look" with radiology, cinematography, electromyography, and modern cytology as its methods of expression. He was essentially a teacher and a great exponent of visual methods of presentation: for this reason he was put in charge of the department of medical illustration at Guy's, and this he brought to a very high pitch of perfection. In his teaching and writing the application of his subject to medicine was ever prominent: his clinical colleagues always received from him interested attention to their problems and sound constructive advice as to a solution.

He was scrupulously attentive to his administrative duties. At meetings he was sparing of speech but always constructive and to the point. He was the faithful champion of the man in a junior position, and all his subordinates worked happily under him. During the second world war he took a large share in the creation of the preclinical school at Tunbridge Wells; for this he faced all the detail, domestic and administrative, of housing, feeding, teaching, and training hundreds of students in quite unprepared surroundings. This work was very exacting, and it took its toll of his not unlimited strength.

For the last five years of his life he played a prominent part in many extra-university activities in which his anatomical and surgical knowledge was of value. Physiotherapy, speech therapy, and rehabilitation made great demands upon his time, and he was actively interested in many of the public bodies and institutions dealing with such problems. Here his balanced judgment and attention to practical detail were invaluable. He thoroughly enjoyed these outside duties, and to pay a visit with him to the rehabilitation unit of some big industrial concern was a very rewarding experience.

As a colleague Whillis was delightful, and if he had any enemies they must have been few in number. A variety of interests outside his work—golf, archaeology, and antiques—a well-informed mind, and a sense of humour made him very pleasant company. He brought to Guy's some of the robust forthrightness of his northern home, and Guy's accepted him as one of the family even as he accepted his adopted parent. He will be remembered by all, colleagues, students, and technical staff, as one who gave them a kindly ear, a helping hand, and an example of devotion to his task. Whatever he undertook he did well. Truly Guy's was fortunate in her adopted son.

F. W. J. COAKER, F.R.C.S.

Dr. F. W. J. Coaker, who died in retirement at his home at Dulverton, Somerset, on January 14, was well known in Worcestershire, having practised for many years in Bromsgrove. He was 83 years of age.

Francis William John Coaker was the son of a yeoman farmer at Kingsbridge, South Devon, and, after receiving his medical training at the London Hospital, qualified M.R.C.S., L.R.C.P. in 1893. After holding several resident appointments at the London Hospital, he obtained

the F.R.C.S. in 1896, and in the following year settled in practice at Bromsgrove, and there and in the surrounding district he was destined to perform his main life's work. In addition to conducting a large general practice he provided an outstanding example of that fast-disappearing type of doctor, the general-practitioner surgeon, who in the past dealt with the surgical needs of the people in the smaller towns and in the countryside. As surgeon to the Bromsgrove Cottage Hospital from almost the time he settled in the town he was largely responsible for the planning of the extensions to the building and the modernization of its equipment. As a result the hospital is now a most efficient unit. Dr. Coaker was able, by his skill as a surgeon and his character as a man, to inspire confidence and a real affection in his patients. These qualities were recognized by his fellow practitioners over a wide area, and they often sought and readily obtained his help and guidance.

Dr. Coaker held many public appointments. In addition to being medical officer of health for Bromsgrove Rural District Council from 1902 to 1946, he was medical officer to the guardians for many years, surgeon to the Worcestershire Mental Hospital, and a governor and later chairman of King Edward VII Sanatorium, Knightwick. In 1917 he was elected a member of the Worcestershire County Council and took an active part in the work of its committees, being one-time chairman of the health committee. Though not a fluent orator he had the gift of inspiring the confidence of his colleagues, besides possessing a wise understanding of persons and an ability to visualize the future when solutions of difficult problems had to be found. The medical profession owes him much for successfully advocating the adoption of the B.M.A. salary scale for public health medical officers in Worcestershire in the mid-twenties, before any national scale had been adopted. In an adjoining county a setback had occurred, but the wisdom and quiet patience of Dr. Coaker were largely responsible for the favourable outcome of a prolonged dispute. He was, when another councillor had failed, invited to act as arbitrator to resolve differences between two nursing associations over boundary lines. The matter was amicably settled by what is known as the "Coaker line." In the affairs of the British Medical Association Dr. Coaker also played a prominent part. He was chairman of the Bromsgrove Division in 1921-2 and of the Worcester and Bromsgrove Division in 1935-6, and president of the Worcestershire and Herefordshire Branch in 1937-8. During the second world war he was acting assistant secretary of the Worcester and Bromsgrove Division. For a number of years he served as a member of the Rural Practitioners Subcommittee of the old Insurance Acts Committee. He was a very active member of the local insurance committee over a long period, and secretary, later chairman, of the medical war emergency committee. Bromsgrove and Worcestershire will long remember the work of F. W. J. Coaker, and the fruits of his labour will always remind his successors of a great man who used his skill and wisdom to the full. —A. J. R.

D. C. M. writes: I first knew Dr. Coaker in 1925, when I went as a young general practitioner to the town of Bromsgrove. I was in an opposing practice, and I wondered what reception I should receive from the others practising there. From the first Dr. Coaker went out of his way to be generous and kind and helpful to me. He was one of the old school of general-practitioner surgeons, and his skill

and experience were of a high standard. He would always readily help me with advice in consultation and was willing to operate on my cases or to educate me in the realms of general-practitioner surgery. He was at the time the father of general practice in the town, and I shall always remember him with great affection and respect.

R. L. HORTON, M.S., F.R.C.S.

Mr. R. Lister Horton, formerly honorary surgeon to the Weymouth and District and Dorset County Hospitals, died at his home in Bournemouth on January 21, aged 65 years.

Robert Lister Horton was born at Torquay on October 22, 1889, the son of Dr. Thomas Horton. From Mill Hill School, where he was an entrance scholar, he went on to study medicine at University College, winning the Bucknill Scholarship. In later life he was elected a Fellow. After qualifying in 1912 and graduating M.B., B.S. in 1913, he held a number of resident posts at University College Hospital before taking the F.R.C.S. in 1914. During the first world war he served as a surgical specialist with the rank of major in the R.A.M.C. in France, being mentioned in dispatches for his services. Returning to University College Hospital after the war, he worked there as surgical registrar from 1919 to 1922. He was awarded the gold medal when taking the M.S. of London University in 1920. In 1922 Mr. Horton was appointed assistant surgeon to the Weymouth and District Hospital, and in a short time he had built up a flourishing surgical and general practice in and around Weymouth, where he was in partnership with Dr. H. L. Tasker and the late Dr. P. S. B. Wetherall. In due course he was appointed to the staff of the Dorset County, Bridport, Herrison, and Portwey Hospitals, and his reputation with the public and among his colleagues stood very high indeed. From 1934 to 1936 he was chairman of the West Dorset Division of the B.M.A., and for some years he was an examiner in surgery to the General Nursing Council. A man of strong character and high principles, he was a natural leader in a quiet and kindly way, and in any emergency his presence alone was enough to restore confidence. He retired from his post of consultant surgeon to the West Dorset group of hospitals only three months before his death. He married Elizabeth, daughter of John Macdonald, and he is survived by his widow and a son and a daughter, who followed her father into the medical profession.

Mr. THOMAS COLLEY writes: Mr. Horton came to Dorset in 1922, for, being married and feeling that the chance of an early staff appointment at University College Hospital was small, he had decided to join a surgical practice in the country. Thirty years ago it was not possible for a man to practise as a consultant surgeon in a semi-rural district. But Horton soon built up a reputation in general practice which was second only to that which quickly came to him as a surgeon. He had an ideal temperament, never hurried, and with a sure touch which spoke of his complete control and mastery of his subject. Additional appointments at the Dorset County Hospital, Dorchester, together with his work at the Bridport Cottage Hospital and Herrison Mental Hospital, demanded so much of his time that the second world war found him occupied almost solely in surgical work. Extra work from shortage of staff together with increasing numbers of military and civilian casualties took its toll, and finally, towards the end of the war, he was ordered a complete rest. His health never altogether recovered, and in 1945 he resigned his appointments at the Weymouth and District and the Dorset County Hospitals, though he continued to visit and work at Bridport

and at the Herrison Mental Hospital until his final retirement. He had always led a full life with outside activities, and in addition to other local appointments he was a county justice of the peace.

Horton was essentially a kindly man, and his many patients will probably remember him best for this quality. He was a genial companion, an excellent colleague, and a tower of strength in times of trouble; his memory will ever remain fresh in the thoughts of those who knew him. It is sad that he should have lived so short a time after his final retirement, but perhaps he might have wished it this way. To his widow, son, and daughter we extend our heartfelt sympathy.

His wide circle of friends in East Lancashire will have learned with deep regret of the death of Mr. A. J. McCREADIE at his home at Shipley, Yorkshire, on January 3. He was 65 years of age. Born at Alford, Aberdeenshire, on April 19, 1889, Anthony John McCreadie was educated at Aberdeen University, where he graduated M.B., Ch.B. in 1913. During the first world war he served as a captain in the R.A.M.C., attached to the Border Regiment, and was awarded the Military Cross in 1917. He held the appointments of medical officer at the military hospital for surgical cases at Alder Hey, Liverpool, where he interested himself particularly in orthopaedic work, and house-surgeon at Halifax Royal Infirmary, before settling at Nelson, Lancashire, where he took over the practice of the late Dr. Andrew Findlay, his father-in-law. He was elected F.R.C.S. in 1920. At Nelson he soon became associated with the local hospitals and served as a general and orthopaedic surgeon to the Burnley Victoria Hospital, the Reedyford Hospital, Nelson, and the Hartley Hospital, Colne, from 1927 until his retirement owing to failing health in 1950, when he was the recipient of a presentation from members of the medical, surgical, and nursing staffs of the Burnley Victoria Hospital. Although an accomplished general surgeon, his main interest lay in the field of traumatic and orthopaedic surgery, and it was fitting that in 1941 he was appointed to take charge of the newly formed fracture clinic at the Burnley Victoria Hospital. A member of the British Medical Association for thirty-five years, he was chairman of the Burnley Division in 1937-8. He was also a past president of the Nelson Rotary Club. His kindly nature, his great generosity, and his keen sense of humour will not soon be forgotten by those friends and colleagues who were privileged to know him. In spite of failing health and the loss of his wife two years ago he never lost those characteristics which endeared him to so many. To his daughter, who cared for him so faithfully during his brief retirement, and to his son, at present serving overseas as a captain in the Royal Signals, our sympathy is extended.—R. O. D.

Dr. SAMUEL EDGERLEY, for nearly 30 years medical superintendent of Menston Hospital, near Leeds, died at his home at Menston on November 16, 1954. He was 87 years of age. Samuel Edgerley was born at Old Calabar, West Africa, where both his father and his grandfather were pioneer missionaries and where both died at an early age. His father, in addition to his missionary work, was an explorer of note, and to his mother, a native of Shetland, he owed the soft intonation of voice which is a characteristic of the people of those isles. As a child Samuel Edgerley knew little of home life, for at an early age he was taken to Edinburgh and left there in the charge of a schoolmaster. After his father's death, when Samuel Edgerley was about 12 to 14 years of age, his mother settled at Portobello, near Edinburgh, and he was able to live with her. He was educated at George Watson's College and at Edinburgh University, where he graduated M.B., C.M. in 1891, having been awarded first-class honours in many subjects and honours in most of the others during his undergraduate career. He was a brilliant student with an excellent memory and with the mental approach of a mathematician to his work. He had been a member of the Watsonians Rugby

football team and never ceased to show a lively interest in the game. After graduation he went as an assistant to Dr. J. C. Balfour, a cousin of Robert Louis Stevenson, at Belford, Northumberland, and he loved to recall those early days. After holding the post of assistant medical officer at Roxburgh District Asylum, Melrose, he joined the staff of Menston Hospital as an assistant medical officer in 1897, remaining to become superintendent in 1906. He held this appointment for 27 years until he retired in 1933. A member of the Royal Medico-Psychological Association since 1895, he obtained its certificate (now diploma) in psychological medicine, and was chairman of the northern and midland division of the association from 1934 to 1936. While at Menston, in 1907, he married Dr. Catherine Mabel Blackwood, a descendant of the founder of the well-known publishing house. They had many interests in common, chief of which was membership of the Brontë Society. Catherine Edgerley was secretary of the society for 17 years and Samuel Edgerley a member of its council, and they did outstanding work in increasing its scope and interest at a time when it was becoming a society of national and even international appeal. While at Menston Dr. Samuel Edgerley's life was devoted to the welfare of his patients. One of his notable characteristics was a quiet sense of humour. He will be missed by many, but especially by those who had good cause to know his sterling qualities and who were privileged to be his friends for so many years. He had been a widower since 1946.

Dr. MARY BUCHANAN LEE, who died at her home at Sefton Park on January 6 at the age of 81, was almost the first woman to practise medicine in Liverpool, being preceded by only a few months by the late Dr. Lucy E. Cradock, who died in 1903. Dr. Lee was inspired by high ideals of voluntary service, and her life was one of devotion to her profession. She was born on May 23, 1873, and received her professional training at the Medical College for Women, Edinburgh, taking the Scottish triple qualification in 1895. She then went straight to Liverpool, where she worked first at the old Maternity Hospital in Brownlow Hill and later at the old Samaritan Hospital in Parliament Street, but only as a "postgraduate student," for at that time women were not eligible for appointment to the medical staff. Both these hospitals have since been demolished and replaced by modern buildings where men and women members of the medical staffs have equal status. Her patients came from all walks of life, but her sympathy was always for the underdog, and she did everything in her power to ease the distress of those who were ill and poor. When the National Health Service came into operation in 1948 she retired from practice, although she continued to attend to the medical needs of a few old and privileged patients.

Medical Notes in Parliament

Cleaner Air Proposals Accepted

The Government's acceptance in principle of the recommendations of the Beaver Committee on air pollution was announced by Mr. DUNCAN SANDYS, Minister of Housing and Local Government, on January 25, when Parliament reassembled after the recess.

The committee, he said, had estimated that the smoke, grit, dust, and noxious gases emitted into the air from domestic dwellings and industrial plant caused damage to property and other harmful effects to the tune of about £250m. a year. To this must be added the value of the heat wasted through excessive smoke, which was assessed by the committee at between £25m. and £50m. a year. These figures took no account of injury to health and loss of life, as, for example, the 4,000 deaths caused by smoke-laden fog in London two years ago.

The committee made a number of important proposals, the adoption of which would, in its opinion, reduce the

density of smoke in the atmosphere to an extent amounting perhaps to as much as 80% over the next 10 or 15 years.

After summarizing the main recommendations, Mr. Sandys said that these were far-reaching proposals. They involved a number of quite complex technical problems and entailed the expenditure of considerable sums of money. In addition, they raised important issues of policy, which directly affected local authorities, industry, and private individuals.

All these various questions were at present being examined by the Government in co-operation with outside interests concerned. He had already had preliminary discussions with representatives of local authorities and the Federation of British Industries. These first meetings indicated that industry would be ready to play its part in implementing this policy, and that the local authorities would be prepared to accept the additional responsibilities involved. The Secretary of State for Scotland was having similar consultations north of the border. At the same time the Minister of Fuel and Power was examining the question of increasing the availability of the smokeless fuels that would be needed.

These studies and consultations had not yet reached the stage at which he could make a detailed statement on the various aspects of this question, but the Government had decided in principle to adopt the policy recommended by the Beaver Committee.

Tuberculosis in Scotland

Mr. A. WOODBURN (Clackmannan and East Stirling, Lab.) asked the Secretary of State for Scotland whether he could report any conclusions as a result of the investigation, initiated in 1949-50, into the causes of the exceptional figures for tuberculosis in Scotland. Mr. J. STUART stated on January 25 that the expert committee which went into the question was unable to identify reasons for the exceptionally high incidence and death rates for respiratory tuberculosis in Scotland in the years immediately after the war. The Scottish position had come more into line with experience in England and elsewhere.

Training for Spastics

Mr. ERIC JOHNSON (Manchester, Blackley, Lab.) asked the Minister of Labour if he was aware of the need for a special approach to the matter of the training and subsequent placement in employment of spastics, whose need was habilitation rather than rehabilitation; and if he would set up, or co-operate with the voluntary organizations in setting up, an experimental unit for this purpose under the provisions of the Disabled Persons Employment Act, 1944. Mr. HAROLD WATKINSON, Parliamentary Secretary, replied on January 25 that he was aware that some spastics at school-leaving age or later might be able to profit from a special course of preliminary training designed to enable them to use their limbs more effectively, and he understood that the voluntary organizations concerned had in mind the establishment of centres where this kind of training could be given. One of the voluntary organizations had discussed this approach with his officers and was aware of the extent of the assistance which could be given at a later stage of training under the provisions of the Disabled Persons (Employment) Act. Mr. JOHNSON said that the existing centres catered chiefly for the very lightly handicapped spastics, and as a result of this the hard core of the problem of the employment and training of spastics was not really touched. Mr. WATKINSON answered that it was hoped, as a result of the initiative of the bodies interested, that there would be further centres. If so, they would do what they could to help.

Examination of Mrs. Christofi

Sir LESLIE PLUMMER (Deptford, Lab.) asked the Home Secretary how many of the doctors who examined Mrs. Christofi were psychiatrists, and what was the extent of their examination. Major G. LLOYD-GEORGE stated on January 27 that, of the three doctors appointed to conduct

a medical inquiry into Mrs. Christofi's mental condition, one held a diploma in psychological medicine, and the other two—a former medical superintendent of Broadmoor Institution and a former director of Prison Medical Services—had long and special experience of cases of this kind. The doctors had two prolonged interviews with the prisoner. They also interviewed the governor of the prison, the Church of England chaplain, the prison medical officers, the Greek Orthodox priest who ministered to Mrs. Christofi, and the prison officers who had charge of her.

Colonial Hospital Services

Mr. THOMAS REID (Swindon, Lab.) asked the Chancellor of the Exchequer if he would give an assurance that, in the Government's scheme of priorities, funds needed urgently for hospitals would take precedence over further gifts to dependencies, which had been allotted £530m. since the end of the first world war. Mr. R. A. BUTLER, replying on January 25, said "No," because the Government and Parliament, in deciding what funds should be allocated for the hospitals and for the Colonies, must be free to have regard to the merits of each individual case as well as to the general financial position. In the current financial year no less than £321m. had been provided for the expenses of the hospital, specialist, and ancillary services.

Preservatives in Food

Lord DOUGLAS of BARLOCH asked the Government on January 25 for what purposes mono-sodium glutamate was added to foodstuffs, and what research had been conducted relating to the effects on health of the ingestion of this chemical in small quantities for prolonged periods. Viscount WOOLTON, Chancellor of the Duchy of Lancaster, told him that the purpose was to enhance the flavour of certain kinds of food. It functioned as a condiment. It was used principally in canned soups and dry soup mixes. Glutamic acid, of which it was a salt, was a normal constituent of food proteins and had not been found to have any adverse effect on health. He was advised that there was no reason to believe that continued use of mono-sodium glutamate would have any such effect.

Lord DOUGLAS asked on January 26 in how many cases during 1954 action had been taken to prevent the sale of oranges and other citrus fruits treated with thiourea, and what had been done to prevent the importation of fruit so treated.

Earl St. ALDWYN, Parliamentary Secretary, Ministry of Agriculture, stated that court proceedings were taken in four cases and warnings were issued in a number of others. In addition, exporting countries, and food and drug authorities and the trade in this country, had been reminded that the sale of any article of food containing thiourea would be a contravention of the Public Health (Preservatives in Food) Regulations. So far as the Government was aware citrus fruit now imported was free of thiourea.

Lord DOUGLAS asked if the Government would make regulations which would ensure that purchasers of oranges and other citrus fruits would be warned when these fruits had been treated with paraffin wax.

Earl St. ALDWYN said the Government did not regard the imposition of such a requirement as desirable or necessary. They were advised that the minute amount of wax remaining on the peel after treatment was harmless. The waxing of citrus fruit was standard practice in U.S.A. and some other countries. Fruit was washed as it came from the groves to remove dirt and other extraneous matter. This washing removed much of the fruit's protective wax, and if this were not restored artificially the fruit would soften and the skin become hard and dry. He added that the quantity of mineral oil permitted in citrus fruit was limited to 0.1 of 1%. This was the same type of mineral oil as was used in the food industry for greasing baking-tins and other appliances with which food came into contact, and it was also used by most exporting countries for the surface treatment of dried fruits.

Proprietary Medicines

Mr. J. K. VAUGHAN-MORGAN (Reigate, Con.) asked the Minister of Health on January 31 what progress had been made in reducing the cost of certain proprietary medicines. Miss PAT HORNSBY-SMITH, Parliamentary Secretary, replied that discussions had been proceeding with the Association of British Pharmaceutical Industry, and the Minister was considering the position now reached. Meanwhile there had been some downward trend in the prices of preparations in those classes which were under investigation, and in addition special provisional reductions had recently been arranged with certain manufacturers in the prices of 19 of these preparations.

Doctors' Lists

The PARLIAMENTARY SECRETARY TO THE MINISTRY OF HEALTH stated on January 31 that on January 1, 1952, the average number of patients on the lists of doctors who were principals was 2,409. The corresponding figure for January, 1953, was 2,325; for July, 1953, 2,239; and for July, 1954, it was 2,210.

Disabled Inquiry.—The Committee of Inquiry on the Disabled is still engaged in hearing evidence from interested bodies, but is expected to furnish its report later in the year.

Islands Air Ambulance.—The D.H. Heron air ambulance will be able to land on the islands of North Ronaldsay, Sanday, and Stronsay, in addition to Orkney and Shetland.

Medico-Legal

DEATH FROM SALICYLATE IDIOSYNCRASY

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

At an inquest completed on January 10, 1955, Professor J. M. Webster gave evidence that the death was the result of personal idiosyncrasy to sodium salicylate.

Louis Jacobs, a corporation bus driver aged 52, was found by his physician, Dr. F. R. Gedye, on December 10, 1954, to be suffering from mild rheumatic fever with a temperature of 99° F. (37.2° C.) following a sore throat. Dr. Gedye put him on to the usual routine treatment of sodium salicylate, 20 gr. (1.3 g.), with sodium bicarbonate, 30 gr. (2 g.), to be taken every four hours. This was duly administered by Mrs. Jacobs. The patient improved and wanted to get up, but on December 20 he developed a sore throat and a temperature of 101° F. (38.3° C.). Oral penicillin tablets improved the throat, and the salicylate treatment was continued. A swab of his throat showed monilia. On the night of December 21 Dr. Gedye was sent for; he found him delirious and with a rash, and sent him into Little Bromwich Hospital.

Next morning his condition was improved, though there was still some confusion. He had an erythematous rash and was moderately dehydrated, but his temperature was 98° F. (36.7° C.) and his general condition good. A blood sample showed a salicylate content of 53 mg. per 100 ml., and he was given fluids with the object of eliminating the salicylate. He started to pass urine copiously, and as it contained 125 mg. salicylate per 100 ml. he was excreting salicylate fast and it was hoped that he would improve. Next day the salicylate in the blood had fallen to 34 mg. per 100 ml., but in the evening he suddenly collapsed and died.

Professor Webster, who carried out the post-mortem examination, found the cause of death to be acute cerebral and pulmonary oedema "due to respiratory cardiac failure." Analysis of the brain and liver showed the high content of 14 and 24 gr. (81 and 146 mg.) salicylic acid respectively. Professor Webster considered that the doses prescribed by Dr. Gedye were quite in keeping with normal medical dosage, and formed the view that this was a case of personal idiosyncrasy to sodium salicylate, causing death.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending January 15 (No. 2) and corresponding week 1954.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Vital Statistics

Influenza

In the week ending January 22 influenza deaths increased by only 2 compared with the preceding week, from 134 to 136, in the 160 great towns of England and Wales. Small increases occurred in London and the south-east, and the eastern, midland, and north-western regions; they were offset by decreases elsewhere. The infection remains clinically mild. The World Influenza Centre reports evidence of virus-B infection in Germany, Holland, Canada, and Malaya.

Smallpox in France

Up to January 18 there had been 59 cases of smallpox, including 8 deaths, in the Morbihan Department.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1945-53 are shown thus -----, the figures for 1954-5 thus ————. Except for the curves showing notifications in 1954-5, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The trend of infectious diseases in England and Wales during the week ending January 15 remained constant with the exceptions of a decrease of 1,585 for measles, from 9,385 to 7,800, and a rise of 56 for dysentery, from 346 to 402.

The largest falls in the incidence of measles were 809 in Lancashire, from 2,841 to 2,032, 213 in London, from 1,004 to 791, 179 in Yorkshire West Riding, from 972 to 793, 96 in Durham, from 503 to 407, 92 in Gloucestershire, from 253 to 161, and 80 in Essex, from 543 to 463, and the largest rises were 67 in Derbyshire, from 235 to 302, and 66 in Berkshire, from 60 to 126. The notifications of scarlet fever were 465, being 2 more than in the preceding week; variations in the local trends were only small. 1,769 cases of whooping-cough were notified, being 22 fewer than in the preceding week; the largest fluctuation was a rise of 36 in London, from 120 to 156. 14 cases of diphtheria, 1 more than in the preceding week, were notified.

22 cases of acute poliomyelitis were notified, and these were 7 fewer for paralytic and 4 more for non-paralytic cases than in the preceding week. The largest returns were 3 in London and in Worcestershire (Dudley C.B. 3).

The largest centres of dysentery were Lancashire 73 (Liverpool C.B. 15, Oldham C.B. 12), Yorkshire West Riding 47 (Sheffield C.B. 13), London 36, Glamorganshire 31 (Swansea C.B. 21), Norfolk 31 (Norwich C.B. 17), Yorkshire North Riding 21 (Middlesbrough C.B. 21), Durham 21, Staffordshire 19 (Stoke-on-Trent C.B. 15), Northumberland 17 (Newcastle-upon-Tyne C.B. 10), and Lincolnshire 16 (Scunthorpe M.B. 14).

Deaths from influenza in the great towns numbered 134, a rise of 32 on the total of the preceding week. The largest numbers of deaths registered were Birmingham C.B. 14, Manchester C.B. 6, London 6.

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in December was 120, compared with 103 in the previous month and 116 in December, 1953.

The numbers of cases of industrial diseases in the United Kingdom reported during December, 1954, were as follows: lead poisoning 8, chronic benzene poisoning 1, aniline poisoning 2, compressed air illness 2, anthrax 1, epitheliomatous ulceration 14, chrome ulceration 14; total 42. There were no deaths.—*Ministry of Labour Gazette*, January, 1955.

Week Ending January 22

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 650, whooping-cough 2,002, diphtheria 8, measles 7,038, acute pneumonia 929, acute poliomyelitis 24, dysentery 482, paratyphoid fever 2, and typhoid fever 1.

Medical News

President Eisenhower's Health Programme.—On January 31 President EISENHOWER again asked Congress to enact the health programme which he presented last year and which Congress rejected. According to a report in *The Times* he called for "an initial authorization of \$25m. for a federal reinsurance plan which would encourage private insurance companies to offer better protection, especially against expensive illness, and to extend coverage to millions more of the population." He also asked for \$20m. for public assistance cases, and for an increase of \$3m. in the Government's annual subscription to W.H.O.

Epsom's Centenary Appeal.—Lord WEBB-JOHNSON, president of the Royal Medical Foundation of Epsom College, in commending to the public, and especially the medical profession, Epsom's centenary appeal for not less than £150,000, writes: "I beg you to give sympathetic consideration to this appeal, and to subscribe as generously as you can." The money is urgently needed in order to provide improved living quarters for boys and domestic staff, and also better catering facilities. Epsom's close links with the medical profession are well known: about a third of those who go there become doctors, and there are many special awards to help the sons of doctors in difficult circumstances (see this *Journal*, November 27, 1954, p. 1280). The Queen heads the list of donors, and Lord Webb-Johnson himself has given £1,000; other large subscriptions have already been received from the Surrey Local Medical Committee (£650), the Medical Insurance Agency (£500), and the Nottingham Local Medical Committee (£105); and besides these there are gifts of amounts of up to £100 from individual doctors. So far about £12,000 has been raised. Donations should be sent to the Appeals Secretary, Epsom College, Epsom, Surrey. On the occasion of the centenary celebrations on May 13 the QUEEN and the DUKE OF EDINBURGH will visit the College.

World Health Organization.—In Geneva the W.H.O. Executive Board has been making plans for the Eighth World Assembly which opens in Mexico City on May 10. Among the current activities of W.H.O. is the establishment of a network of regional laboratories to identify locally occurring strains of poliomyelitis and related viruses. These laboratories will be extended, and it is expected that information from them will help those concerned with making vaccines and otherwise controlling poliomyelitis. At a meeting of the Board the representative of Japan initiated a discussion on the medical aspects of atomic energy. W.H.O. is participating in the United Nations' international conference on the subject this summer, and Dr. M. G. CANDAU, director-general of W.H.O., gave the Board his views on the most urgent medical problems. He advised further study of radiation-induced diseases, the disposal of radioactive waste and the dangers of industrial nuclear reactors, the health problems of uranium miners, the means of transporting active material, and the basic problems of measuring and standardizing the activity of radioactive isotopes. Another question before the Board is a proposal from Sweden for a study of the prevention of accidents in childhood.

Royal College of Physicians.—At the quarterly comitia on January 27 in London the following were appointed or reappointed as representatives of the College on various outside bodies: Professor A. A. MONCRIEFF, Central Midwives Board; Dr. N. G. HARRIS, National Association for Mental Health; Professor S. P. BEDSON, F.R.S., Conference on the Supply of Experimental Animals; Sir WELDON DALRYMPLE-CHAMPNEYS, Bt., Health Congress of the Royal Sanitary Institute; Dr. E. W. HART, Annual Conference of the National Association for Maternity and Child Welfare. Dr. G. E. S. WARD was reappointed external examiner in medicine for the Faculty of Radiologists.

College of General Practitioners.—Research Newsletter No. 5, which is printed in full in the current issue of the *Practitioner*, describes some of the steps the College is taking to ensure that the standard of research done under its auspices is of good quality. "It will not be in the interests of the College," says the Newsletter, "if work is done in its name which is not of the highest quality." Each regional faculty is to have a research committee, and these committees are asked to keep the College's central research committee informed of all proposed faculty investigations. The College also asks those who wish to publish research work in the name of the College to submit their papers to the council beforehand. To integrate research activities, the College is planning a yearly conference of representatives from all the faculty research committees.

Chair of Psychiatry at Edinburgh.—Professor ALEXANDER KENNEDY, professor of psychological medicine at Durham, has been appointed to the chair of psychiatry at Edinburgh in succession to Sir DAVID HENDERSON. Now aged 45, Professor Kennedy graduated from St. Thomas's Hospital in 1932. He subsequently studied at the Johns Hopkins University Medical School in Baltimore, being awarded a Rockefeller travelling fellowship in neuropsychiatry. During the second world war he was adviser in psychological medicine attached to Intelligence for the Balkan and Middle East Campaigns, and later scientific adviser to the Intelligence Branch of the Control Commission for Germany. After the war he was on the staff at the Maudsley Hospital and St. Thomas's. In 1947 he was appointed to the chair of psychological medicine at Durham University. In addition to books and scientific articles on psychiatric subjects, Professor Kennedy has written radio plays (under the name of Kenneth Alexander), and been a member of the Olympic Games medical executive and president of the medical commission of the Association Internationale de Boxe Amateur.

University College of the West Indies.—On January 20, as part of its Third Inter-American Congress, the American College of Surgeons, led by its President, Dr. A. BLALOCK, paid a one-day visit to Jamaica and to the University College Hospital of the West Indies. Two scientific sessions were held and some seventy Fellows of the College attended. The visitors were entertained to a luncheon given by the Government of Jamaica at the University College, at which PRINCESS ALICE, Chancellor of the College, presided. It is believed that this is the first occasion on which the American College of Surgeons has officially attended scientific sessions in a British Colony.

Classics of Pathology.—An exhibition of "Classics in the Literature of Pathology" opened at the Wellcome Historical Medical Library, Euston Road, London, N.W.1, on February 1, when it was visited by the Section of Pathology of the Royal Society of Medicine. The exhibition, which will remain open until further notice, contains the works of 26 authors, ranging from Celsus and Galen and the Hippocratic writings at one end of the scale to Virchow, Koch, and Metchnikoff at the other.

Princess Louise Children's Hospital.—The medical staff of the Princess Louise (Kensington) Hospital for Children have told both the Governors of St. Mary's Hospital and the Press that they oppose the conversion of the hospital to adult use. The situation was summarized in last week's *Journal* (p. 299).

Sir Charles Dodds, F.R.S., director of the Courtauld Institute of Biochemistry at the Middlesex Hospital, has been appointed a member of the Advisory Council for Scientific and Industrial Research.

Dr. W. F. J. Cuthbertson, who is head of Glaxo's biochemistry research unit at Greenford, has accepted an invitation to lecture to the medical students at University College, Ibadan, during the spring term. Dr. Cuthbertson will remain in Nigeria until the middle of April.

News in Brief.—The Ministry of Health, in a letter to local authorities, has stressed the need to continue public

propaganda against venereal diseases. In 1953 and the first half of 1954 there was a rise in the incidence of both non-specific urethritis and gonorrhoea.

The Comics Campaign Council, which was established in 1953 by the National Committee for the Defence of Children and the London Federation of Parent-Teacher Associations, has started publication of a 3d. bulletin. Its object is to inform people about the campaign against horror comics. Copies may be obtained from Mr. J. Benjamin, 44, Old Gloucester Street, London, W.C.1.

The American Tobacco Industry Research Committee has increased to one million dollars its fund for research on the effects of tobacco on health.

The golden jubilee of the *Nursing Times* falls on May 6 this year. A special number will be issued to celebrate the event.

COMING EVENTS

Finlayson Lecture.—Professor A. A. MILES will lecture on "The Role of Serum Proteins in the Vascular Phenomena of Inflammation" at the Royal Faculty of Physicians and Surgeons, Glasgow, on February 9 at 5 p.m.

Television.—Dr. GREY WALTER, from the Burden Neurological Institute, Bristol, will demonstrate electro-mechanical models illustrating theories about the working of the human brain. Friday, February 11, at 8.45 p.m.

Insect Pests.—Exhibition of insect pests causing damage to the nation's food and health at the Royal Sanitary Institute, 90, Buckingham Palace Road, London, S.W.1. Open February 14 to March 12.

International Symposium in Cardiovascular Surgery.—At the Henry Ford Hospital, Detroit, March 17 to 19. Subject: "Recent Studies in Physiology, Diagnosis, and Technique." Those wishing to attend should apply to the Secretary, International Symposium on Cardiovascular Surgery, Henry Ford Hospital, Detroit, 2, Michigan.

Refresher Course in Child and Family Psychiatry.—At the Department of Child Psychiatry, Ipswich Group Hospitals, March 28 to April 1. Open to all medical practitioners. No fee. Early application to Child Psychiatry Clinic, 11, Fore Street, Ipswich.

International College of Surgeons.—Twentieth anniversary congress in Geneva, May 23 to 26. Further information from the secretariat at 6-8, rue de la Confédération, Geneva.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, February 7

INSTITUTE OF PSYCHIATRY.—5.30 p.m., Dr. E. Stengel: lecture-demonstration.
OXFORD UNIVERSITY.—At Physiology Theatre, 12 noon, Professor G. L. Brown, F.R.S.: Sympathetic Nervous System.

Tuesday, February 8

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor J. R. Squire: Correlation Between Laboratory and Clinical Findings in Hypersensitivity.
CHELSEA CLINICAL SOCIETY.—At Rembrandt Hotel, 8.30 p.m., discussion to be opened by Right Hon. Lord Justice Denning, P.C., Q.C., and Dr. R. Forbes: Increase in Medical Litigation.
OXFORD UNIVERSITY MEDICAL SOCIETY.—At Radcliffe Infirmary, 8.15 p.m., Dr. B. E. D. Cooke: Mouths and Gift-Horses.
ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Milroy Lecture by Dr. J. A. Smiley: Personal Factors in Accident Proneness.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Imperial Cancer Research Fund Lecture by Dr. E. F. Scowen: Significance of the Endocrine in Breast Cancer.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Dr. H. A. Davidson: Infertility in the Male.

Wednesday, February 9

HARVEIAN SOCIETY OF LONDON.—At St. Mary's Hospital, Paddington, W., 5.30 p.m., clinical meeting.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Allergic Vasculitis.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. J. G. Sandrey: Vesical Neoplasms.
NOTTINGHAM MEDICO-CHIRURGICAL SOCIETY.—8.30 p.m., Mr. H. J. Seddon: Infantile Paralysis.
ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Finlayson Lecture by Professor A. A. Miles: Role of Serum Proteins in the Vascular Phenomena of Inflammation.
ST. MARYLEBONE HOSPITAL FOR PSYCHIATRY AND CHILD GUIDANCE.—5.30 p.m., Dr. M. S. M. Fordham: Psychological Treatment in Childhood.

Thursday, February 10

ALFRED ADLER MEDICAL SOCIETY.—At 11, Chandos Street, W., 8 p.m., Dr. James Moore: Concept of Unity in Psychosomatic Medicine.
BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor C. H. Gray: Chemistry of the Porphyrins.
GLASGOW UNIVERSITY MEDICO-CHIRURGICAL SOCIETY.—At Glasgow University Union, 7.30 p.m., Mr. Henry Wapshaw: Excursions in the Biliary Tract.
HUNTERIAN SOCIETY.—At Savoy Hotel, annual dinner.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. O. Oliver: Animal Parasites of the Skin.
LIVERPOOL MEDICAL INSTITUTION.—8 p.m., Dr. P. H. Whitaker and Dr. A. John Robertson: Tin Smelters' Pneumoconiosis (with colour film); Dr. E. Sherwood Jones: Scientific Investigation of Disease as Illustrated by Observations on Blood.
ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Milroy Lecture by Dr. J. A. Smiley: Personal Factors in Accident Proneness.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor P. H. Newman: Spondylolisthesis, its Cause and Effect.
ST. ANDREW'S UNIVERSITY.—At Physiology Department, Medical School, Small's Wynd, Dundee, 5 p.m., Professor W. I. C. Morris: Sudden Death in Pregnancy and Childbirth.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. D. J. Williams: neurology demonstration.

Friday, February 11

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. P. F. Borrie: Vascular Disorders.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., clinical demonstration by Dr. J. Smart: Miscellaneous Cases.
INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—3.30 p.m., Mr. C. Gill-Carey: Epistaxis.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—(1) 2 p.m., Mr. J. R. Armstrong: Differential Diagnosis of Sciatic Pain. (2) 4 p.m., Dr. J. W. Todd: Healthy Living.
ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Dr. Eric G. Oastler: Cushing's Syndrome and the Adreno-genital Syndrome.
ROYAL MEDICAL SOCIETY, Edinburgh.—8 p.m., dissertation by Mr. D. R. Millar: Epilepsy.

Saturday, February 12

KENT PAEDIATRIC AND CHILD HEALTH SOCIETY.—At Children's Clinic, Farnborough Hospital, 3 p.m., Dr. C. O. Carter: Eugenic Society's "Proposed Investigation into Promising Families."
SOUTH-EAST METROPOLITAN REGIONAL TUBERCULOSIS SOCIETY.—At London School of Hygiene and Tropical Medicine, 10.30 for 11 a.m., discussion, Dr. W. Hartston and Dr. J. F. Galloway: Preventive Measures in Pulmonary Tuberculosis.

APPOINTMENTS

McLAUGHLIN, G. P., M.B., Ch.B., D.P.H., D.C.H., Deputy Medical Officer of Health and School Medical Officer, Exeter.
MAYER-GROSS, W., M.D., F.R.C.P., Senior Fellow in the Department of Experimental Psychiatry, University of Birmingham, Part-time Consultant Psychiatrist, Winson Green and Uffculme Hospitals, Birmingham.
STEPHENS, L. SPENCER, M.B., Ch.B., D.P.H., D.Obst.R.C.O.G., Medical Officer of Health for Droitwich Municipal Borough, Droitwich Rural District, and Martley Rural District, and Assistant Medical Officer to Worcestershire County Council (combined appointment).

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Cummins.—On January 29, 1955, at St. Asaph Maternity Hospital, Flint, North Wales, to Eva (formerly Fisch), M.B., B.S., wife of Major George Cummins, a son.
McDougall.—On January 10, 1955, to Jean, M.B., Ch.B. (formerly Roberts), wife of Dr. Neil McDougall, 66, Egilsay Street, Glasgow, N., a sister for Sheena—Marion Cameron.
Powell.—On January 14, 1955, at the City General Hospital, Sheffield, Yorks, to Elizabeth Jean, wife of Dr. G. D. Powell, 56, Bents Drive, Sheffield, a daughter—Melinda Siân.

DEATHS

Bradbury.—On January 13, 1955, John Cecil Openshaw Bradbury, M.R.C.S., L.R.C.P., aged 81.
Coaker.—On January 14, 1955, Francis William John Coaker, F.R.C.S., of Hele House, Dulverton, Somerset, formerly of Bromsgrove, Worcestershire, aged 83.
Harris.—On January 12, 1955, at his home, Trees, Chislehurst, Kent, Herbert Harris, M.D., formerly of Rochdale, Lancs.
Jones.—On January 9, 1955, Cecil Meredith Jones, M.B., F.R.C.S., of 134, Addiscombe Road, Croydon, Surrey.
Leeming.—On January 9, 1955, at 2, The Quadrant, Bristol, Arnold Leeming, M.B., F.R.C.S.Ed.
Livingston.—On January 10, 1955, at his home, 85a, Ebury Street, London, S.W., Clement Livingston, L.M.S.S.A., aged 31.
Quin.—On December 23, 1955, at Addington Hospital, Durban, South Africa, Henry Christian Ernest Quin, L.R.C.P.&S.Ed., L.R.F.P.S., D.P.H., D.T.M.&H.
Trench.—On January 13, 1955, at San Remo Towers, Bournemouth, Hants, John Henry Trench, M.B., B.Ch., aged 76.
Walker.—On January 10, 1955, at "Highclose," St. Mary's Avenue, Carlton Grange, Bailey, Yorks, William Walter Walker, M.R.C.S., L.R.C.P., aged 80.
Westrup.—On January 13, 1955, at St. Edmund's Nursing Home, Ipswich, Suffolk, Joseph Percival Westrup, M.R.C.S., L.R.C.P., formerly of Salisbury, Wilts, aged 92.
White.—On January 6, 1955, at Sutton, Surrey, Robert George White, M.B.E., M.B., Ch.B., aged 79.
Wolters.—On January 5, 1955, the result of a car accident, Philip Benjamin Wolters, M.B., B.S., F.F.A.R.C.S.
Yule.—On January 6, 1955, at Adamson Hospital, Cupar, Fife, George Pratt Yule, M.D., F.R.C.P.Ed., of Gowan Park, Cupar.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Retrolental Fibroplasia

Q.—What is the fundamental lesion in retrolental fibroplasia, and what is the prognosis? What percentage of premature babies develop the condition if kept in an incubator?

A.—The fundamental lesion in retrolental fibroplasia is angioblastic in nature and is due to an excessive proliferation of the developing retinal vessels of the premature eye. The exuberant vasoformative tissue bursts through the internal limiting membrane of the retina and invades the vitreous. If the disease progresses, intravitreal organization results in total or partial retinal detachment; the organized tissue comes to form a fibrous membrane behind the lens, and, since the disease is bilateral, vision is lost or seriously impaired. Quite recently it has been shown by workers in Britain that high concentrations of oxygen have the peculiar property of obliterating developing retinal vessels, so that when the infant is transferred to air the retinal blood supply is grossly inadequate and an abnormal degree of vasoformation is thereby stimulated.

Prognosis depends upon whether retinal detachment develops or not, for while the early stages of the condition may regress it is generally agreed that once a marked degree of retinal detachment has occurred the disease is irreversible and no treatment is known which can modify the subsequent development.

Since it has not been the general practice in Britain to examine all premature babies ophthalmoscopically, it is not possible to give an estimate of the percentage of babies developing the condition in oxygen incubators, nor are figures yet available for the incidence of blindness from this cause. However, some idea of the extent of the problem may be obtained from American figures. Of infants weighing less than 3 lb. (1.36 kg.) at birth 50-60% treated with oxygen have early manifestations of the disease and 10-20% have permanent residual lesions. It has been estimated that approximately 650 cases of advanced retrolental fibroplasia are to be expected in the United States each year.

The importance of controlling the concentrations of oxygen in incubators can hardly be overstated, and all those responsible for the care of premature infants should be aware of the dangers of oxygen therapy. A recent report from the Johns Hopkins Hospital states that restriction of oxygen to not more than 40% led to a marked drop in incidence over a two-year period in both residual lesions and membranes, as compared with a previous period of unscrutinized high oxygen therapy. Survival rates were not adversely affected by restriction of oxygen.

Syphilis from Blood Transfusion

Q.—Is it held to be possible to contract syphilis by means of a blood transfusion? In an emergency, such as a ruptured ectopic, should a Kahn test always be done before the blood is used?

A.—The literature contains many reports of the transmission of syphilis by the transfusion of blood collected from infected donors at a stage of the disease when spirochaetes were present in the blood. The introduction of stored blood and the routine serological testing of all blood donors has undoubtedly diminished the number of these accidents. The spirochaete can survive for many hours in blood after its withdrawal from the body, but, as the work of Bloch,¹ Turner and Discker,² Kolmer,³ and Selbie⁴ showed, the spirochaete will not survive in citrated blood kept at 4°-6° C. for more than 72-96 hours. It is generally agreed that blood stored for five to six days or more at 4°-6° C.

is safe, and it is possible that blood stored for 24 hours at this temperature is safer than fresh blood in this respect.

Most would agree that, if only blood which has not been serologically tested is available for a transfusion which is deemed to be life-saving, and if the circumstances are such that the transfusion must not be delayed, it is justifiable to expose the patient to the risk of contracting syphilis from the blood transfused. In such circumstances certain precautions can be taken to protect the patient:

(a) The donor could subsequently be subjected to a clinical examination and tests for syphilis at monthly intervals for three months. Should the donor be found to be infected, vigorous anti-syphilitic treatment of the patient can then be instituted at once.

(b) Consideration might also be given to the addition to serologically untested blood of certain spirochaetocidal substances, such as penicillin, which were described in a previous answer.⁵ The literature appears to contain only reports of laboratory experiments, and the writer does not know whether these methods have been successfully used in clinical practice.

(c) Anti-syphilitic treatment of the patient could be instituted at once on the assumption that the donor was infected. Such a course of action has many obvious disadvantages, and in most instances it would have been followed unnecessarily. It is probably better to wait until the donor or the patient exhibits evidence of infection. There is one exception to this advice—the pregnant woman. In such an instance the patient should be told the circumstances which led to her exposure to the risk of contracting syphilis from the transfusion, and anti-syphilitic treatment should immediately be started.

Nephritis and Pregnancy

Q.—My patient is an unmarried girl aged 18 years. Four years ago she had acute nephritis. Although apparently well, she has a persistent albuminuria. The latest report on her urine is S.G. 1010, protein ++; centrifuge deposit contains numerous epithelial cells and a few red cells; blood urea, 28 mg.; B.P. 120/75. A number of previous tests have been similar to the above. She now wishes to marry. What advice should I give her on pregnancy?

A.—This girl undoubtedly has some form of nephritis (probably Type I), and the continued presence of red blood cells in the urine suggests that the disease is not yet quiescent. She should be advised to avoid pregnancy in the immediate future. From the standpoint of age she can well afford to wait some time, and it is not impossible that the urinary picture will change for the good. Later, if the albuminuria improves and the patient's desire for pregnancy becomes urgent, full investigation, including renal function tests and retinoscopy, should be carried out before an opinion is expressed.

As a rule, pregnancy and chronic nephritis form a dangerous combination. There are a considerable and possibly fatal risk to the mother and poor prospects for the foetus, which is often lost by way of abortion, placental infarction, or immaturity. The small chance of obtaining a live child should be stressed if the patient takes the view that she would be happier to risk her life rather than forgo pregnancy, and, ordinarily, the medical attendant should advise against pregnancy so long as any evidence of nephritis is present. It should be added, however, that when this advice is not heeded it is very occasionally found that a woman with heavy albuminuria (and even a raised blood urea) tolerates pregnancy surprisingly well and produces a healthy, well-developed baby. This exceptional outcome is most likely to be seen when the nephritis is unaccompanied by hypertension, as in this case, but it would be unwise to count on it.

Hormones and the Bust

Q.—I seem to recall some time ago you published an account of hormone therapy, giving the dosage which would produce breast development in women in whom this had failed. The patient is a constitutionally thin but healthy young woman whose menstrual function appears to be fairly normal.

A.—In a question and answer published in 1948¹ it was suggested that the development of the breasts might be improved by daily local inunction with an ointment containing 2 mg. oestradiol benzoate per gramme, the treatment being continued for several months. In addition, progesterone 10 mg. intramuscularly every two days, or ethisterone 10 mg. sublingually three times a day, could be given, but only during the 10 days preceding each menstruation.

In the present case there is no reason to believe that the hormone production by the body is deficient, and the trouble, if any, may lie in refractoriness of breast tissue. There may therefore be no response to hormone therapy. Moreover, any effect hormones may have is likely to be lost when treatment is suspended. The size of the breast is determined more by deposition of fat than by the amount of glandular tissue. This patient is constitutionally thin, and this is the more likely explanation for a small bust measurement. Perhaps the best treatment would be for the patient to try to increase her weight. The question does arise, however, of how far it is possible or desirable to attempt to alter the size and shape and other constitutional characteristics of healthy individuals.

Deviated Nasal Septum and Asthma

Q.—Clinically I have found that deviation of the nasal septum may be quite often associated with asthma and other pulmonary diseases. Is this relationship recognized, and, if so, what is the nature of the association?

A.—There is no special connexion between deviation of the nasal septum and asthma. Patients with asthma often have in addition allergic rhinitis, and if there is any structural abnormality of the nose they are commonly advised to have this put right. Usually this does not improve the asthma.

Precautions at Half-term

Q.—In a preparatory boarding school with an age range of 8–13 years it is customary to allow daily outings at the half-term week-end, but not travel by train and sleeping overnight at home. Will you please state how far this latter restriction is likely to be helpful in preventing infectious disease in the school?

A.—Of boys aged 13 leaving a preparatory school 75% have immunity against chickenpox and measles, even more against whooping-cough, as judged by the very few who get it later, and probably 60% against rubella and mumps. On entry at 8 years of age approximately 30% would have had chickenpox and measles, 50% whooping-cough, and 10% rubella and mumps. It is now assumed that an equal number have had subclinical rubella and mumps. Therefore in five years boys of this age group acquire two or three of these common complaints despite all reasonable precautions.

The restriction suggested is of greater theoretical value than practical, provided that sensible precautions are taken. Sleeping overnight at home, which for some reasons is frowned upon by headmasters, prevents unnecessary visits to hotels and tea-rooms, and the child's enjoyment of his home offsets any nostalgia. A medical officer of a famous public school which has long mid-term exeats once stated that in over 20 years' experience he had seen no medical harm from this. Preparatory boarding schools might well try the experiment with high hopes of success.

NOTES AND COMMENTS

Tincture of Belladonna.—Dr. G. F. B. PAGE (Exeter) writes: Your expert is undoubtedly correct in 99.9% or more cases ("Any Questions?" January 15, p. 178). But the odd case does occur where constipation, which belladonna may aggravate, may cause even small doses of the drug to become cumulative and toxic. Moreover, some people are more susceptible than others. The last case of belladonna poisoning seen by me (sent to hospital as scarlet fever) was of this nature, the symptoms being rash, dry mouth, dilated pupils, and mild confusion. The patient had been taking a mixture containing a trivial amount of the drug.

OUR EXPERT writes: Even if full allowance is made for individual variation in response and delay in absorption it is difficult to envisage toxic effects of this severity arising from small doses of belladonna. Mental confusion is the result of the central effects of atropine on the cerebral cortex and does not usually occur with doses of atropine below 5.0 mg. (1/12 gr.). This is equivalent to 16 ml. (240 minims) of tincture of belladonna or approximately a full 8-oz. bottle of medicine containing 15 minims of the tincture in each half-ounce dose.

Scarlet Fever and Nephritis.—Dr. R. E. O. WILLIAMS (London, N.W.9) writes: The recent observation that the streptococci causing throat infections complicated by acute nephritis are almost always of the serological type 12¹² throws considerable doubt on your expert's assertion ("Any Questions?" January 1, p. 55) that nephritis is in some way due to the "scarlatinal" toxin of the streptococcus, because several other types of streptococcus are found in scarlet fever cases—at least as often as type 12—and they are only very rarely associated with the development of nephritis. It is not known whether nephritis follows type 12 scarlet fever more commonly than it follows a type 12 sore throat without rash, but none of the patients reported by Wilmers *et al.*² had had scarlet fever.

OUR EXPERT writes: It was not categorically stated that nephritis never follows streptococcal tonsillitis (where no rash is present). The author's very extensive experience has never included a post-tonsillitis nephritis and it must be reasonable to assume that it is much less common in such circumstances. The fact that nephritis is far less common in those patients treated with antitoxic serum gives strong support to the assumption that early neutralization of the erythrogenic factor has an important bearing on prevention of nephritis. It may be possible that a "nephritogenic" factor is also neutralized. That type 12 streptococcus has been found to have a high "nephritogenic" factor seems indeed to be amply proved. It would be interesting to evaluate serum therapy in such cases in future, even when no obvious erythema was present.

Transfusion Problems in a Small Hospital.—In the description of the cross-matching technique recommended for the "occasional transfusionist" ("Any Questions?" January 29, p. 301), the method of reading the results should have read: "If the tubes marked 'test' show even a few clumps of cells, while those marked 'control' show none, then the blood should be regarded as incompatible."

Transvasin

brings the esters of NICOTINIC ACID
SALICYLIC ACID
p-AMINOBENZOIC ACID

to the focal point of
soft-tissue rheumatism

The esters in Transvasin, a new preparation developed by Hamol S.A., our Swiss associates, readily pass the skin barrier in therapeutic quantities and enable an effective concentration of the drugs to be built up where they are needed. Transvasin

not only induces vasodilation of the skin with a superficial erythema, but also brings about a deep hyperaemia of the underlying tissues. It is non-irritant, and can be safely used on delicate skins. It is now being widely prescribed, with successful clinical results. Since a very small quantity is sufficient for each application, the cost of treatment is extremely low.

Salicylic acid tetrahydrofurfuryl-ester	14%
Nicotinic acid ethyl-ester	2%
Nicotinic acid n-hexyl-ester	2%
p-Aminobenzoic acid ethyl-ester	2%
Water-miscible cream base ad	100%

Transvasin is available in 1 oz. tubes, basic price 2/6 plus 7½d. P.T., and is not advertised to the public. Samples and literature will be gladly sent on application.

LLOYD-HAMOL LTD., 11 WATERLOO PLACE, LONDON, S.W.1. WHITEHALL 8654/5/6
Transvasin is the registered trade mark of Lloyd-Hamol Ltd.

ERRORS OF DIAGNOSIS IN PAEDIATRICS*

BY

BERNARD SCHLESINGER, O.B.E., M.D., F.R.C.P.

Senior Physician to the Hospital for Sick Children, Great Ormond Street, and to the Children's Department, University College Hospital

One of the few benefits which a physician gains from advancing years is experience through his mistakes. The account that follows is not only a personal confession, but also a review of some of the errors encountered during the course of thirty years in practice.

The subject requires some tabulating under various headings, which can be incorporated under four main aspects, all based on misconceptions or false interpretations. References are also made to overpopular diagnoses and to mistakes that are made by giving too much or, alternatively, too little significance to certain clinical features.

Disease Patterns in Adults and Childhood

Errors are sometimes made by imposing, as a kind of miniature replica, the pattern of disease of adults on to childhood. As a rule, in fact, illness in children tends to be much more acute and overwhelming, but there are some infections which have an entirely different clinical picture. Tuberculosis is a good example. Children with a chronic cough, mild pyrexia, anorexia, loss of weight, a debilitated look, and a history of sweating at nights are often thought to be tuberculous. Phthisis, which these symptoms suggest, does not occur in childhood, except in the rarest circumstances, and the diagnosis generally turns out to be an intestinal disorder once described by Eustace Smith as "mucous disease." Children with this disorder have a coated tongue, halitosis, and mucus in the stools. Sometimes threadworms are also present. Night sweats have probably raised the greatest suspicion, but this symptom is so common in childhood as almost to be physiological, if it is not the result of too much clothing and bedding, with lack of sufficient ventilation.

Otitis media in infants may progress without the usual warnings, and the drum finally ruptures after a stormy illness; earache may never have been present, or may have been difficult to establish. Vomiting and diarrhoea may have been the predominant feature, confusing the issue, and no reliance can be placed on pyrexia and leucocytosis, which may well be absent.

At this early age, also, quite advanced meningitis may occur before the right diagnosis is established. Rapid increase of intracranial pressure is largely avoided by separation of the sutures, so that the classical features of the disease do not arise until late, and various wrong conjectures are made. Bulging of the fontanelle instead

of depression, to conform with the general state of dehydration and wasting, should finally throw true light on the condition.

Misconceptions

Perhaps the most dangerous diagnosis to make in an obviously sick infant is teething. Throughout the centuries it has been the refuge for doctors who are at a loss to know what is wrong. In this way I have known erysipelas, otitis, pyelitis, meningitis, and pneumonia go unrecognized. Although a physiological process, babies can be severely disturbed during the process, but all other sources of their trouble should be excluded before "teething" is blamed. The situation is not made any easier by the fact that during this episode the child's particular weakness may be set off, such as an attack of bronchitis or "croup," an intestinal upset, or even a fit.

Reactions of the blood to simple infections in children can be misinterpreted. Twice I have seen the lymphocytosis of pertussis labelled leukaemia. No diagnosis could be more serious, as the implications are so well known to most parents, and once made it is difficult to retract what has been said. With modern methods of bone-marrow puncture such a mistake could hardly occur.

Masked Clinical Picture

The course of pneumonia has been entirely altered by modern therapy, and it is rarely now a serious disease of some duration. Nevertheless, errors in its diagnosis and the oversight of other underlying conditions can occur. It can mask pertussis, which becomes obvious only as the pulmonary complication subsides. This may have troublesome consequences from spread of the infections to others in a ward before it is recognized.

In children, asthma is usually accompanied by so much catarrh and bronchial secretion that the clinical picture may be more like pneumonia. A history of repeated attacks of this nature of surprisingly short duration, and the association of an expiratory spasm with the general dyspnoea, should put the diagnosis straight and direct the correct treatment.

When an apparently straightforward case of pneumonia fails to react rapidly to penicillin or some other suitable antibiotic, and the clearing pulmonary skiagram reveals cyst-like cavities, the mystery of the protracted course seems to be explained. Still, it is unwise to jump to the conclusion immediately that cystic disease of the lung is present, as in some cases complete disappearance of the cavities eventually occurs. The "cysts" were

*Lecture delivered to the Plymouth Division of the British Medical Association on October 15, 1954.

abscesses which finally healed, and this can be demonstrated only by a series of x-ray films.

Turning to alimentary disorders, coeliac and fibrocystic disease (muco-viscidosis) in infants can be completely masked by diarrhoea. Gastro-enteritis which fails to improve with standard modern therapy after a reasonable period should raise a suspicion of one or other of these two disorders. Fibrocystic disease will be associated with very evil-smelling stools and possibly some pulmonary trouble as well.

One is never on safe ground in regard to appendicitis. To miss the condition in childhood is particularly serious, as peritonitis may so easily follow. An unusual position of the appendix behind the caecum or ascending colon is a well-known trap in the diagnosis, as then no tenderness and rigidity in the right iliac fossa need be present. I find that the good family doctor has an uncanny intuition in regard to this disease, and a specialist who disregards an opinion from that quarter is indeed a foolish man. When in doubt surely it is wiser to explore.

The situation has been further complicated by all too ready administration of antibiotics in doubtful cases. This can lead to an infected appendix being brought half under control; later it may rupture and produce a pelvic abscess. Diarrhoea may then be one of the main symptoms and, with the tense and tender abdomen, suggest some other abdominal disorder such as typhoid fever.

Misinterpreted Symptoms and Signs

Mothers often say they are able to tell the difference between their babies' crying from pain or from hunger; I wonder. The fact remains that the majority of infants who are brought to the doctor with supposed "colic" are suffering from underfeeding, and the trouble is easily remedied.

The aches and pains of muscular strain and spasm in genu valgum can be mistaken for those of subacute rheumatism, but rheumatic children seldom complain only of their legs. A much more serious error is to call osteomyelitis acute rheumatism. This has happened so often that a warning is given in most textbooks.

It should not be difficult to differentiate a tic from chorea, but they are continually being confused. When analysed, no choreic movement is entirely repetitive or can ever be said to have served a useful purpose. Children with tics, on the other hand, have insight into their ailment and can be encouraged to demonstrate their habit. The correct diagnosis is of more than academic importance, as the treatment of the two conditions is diametrically opposed.

A faint should be easy to distinguish from a fit if careful inquiry is made into the circumstances immediately preceding its occurrence, the aspect of the patient during the attack, and his behaviour afterwards. Emotional breath-holding in young children with resultant cerebral anoxia is easily recognized, although mistakes have been made and something more serious suspected. The real trouble arises in deciding whether a true fit is due to epilepsy or is merely an associated symptom of some febrile complaint. There are indeed some authorities who believe that "symptomatic" fits can occur only in potential epileptics. Certainly the E.E.G. gives some assistance, but one must always be quite convinced before labelling a child an epileptic.

Vomiting by its frequency in so many disorders of childhood inevitably leads to errors in diagnosis. Some newly born infants vomit all fluid for the first few days, and are soon thought to have a congenital abnormality of the alimentary tract. Abdominal distension and peristalsis are important signs in any form of intestinal obstruction, but are not always obvious and depend on the position of the lesion. Radiological evidence of pooling of air in the upper part of the gut and its absence at a lower level is sometimes

helpful in the diagnosis, but fluid levels can be misleading. If meconium has been freely expelled and there is no bile in the vomit it is safe to wait. Passage of a rubber catheter into the stomach will exclude an oesophageal malformation. An unusual amount of mucus is often found in the vomit; this seems to be the main source of the trouble and can be remedied by gastric lavage.

Age is important. Certain diagnoses can be discounted on this alone—hypertrophic congenital pyloric stenosis, for instance, when symptoms first appear after the age of 3 months.

Vomiting and headache together are such classical features of serious intracranial disease that I hesitate to mention them. Errors are still made by the unwary, and the possibility of a brain tumour, tuberculous meningitis, or some other serious complaint must at least be considered. Migraine and cyclical vomiting should never be diagnosed until renal and cerebral disease have been excluded. With this in view the fundi are an important part of the physical examination. Lead-poisoning is rare, but should be noted as likely to give rise to a similar mistake.

There are a number of physical signs which are open to misinterpretation. An apical systolic murmur is commonly attributed to an organic lesion with little justification. It is a decision that must not be lightly taken; rheumatic carditis is usually diagnosed and the child unnecessarily condemned to a semi-invalid life. An intense murmur immediately after the first sound, with a fairly wide area of conduction, becoming louder on exercise and better heard with the child recumbent, is more likely to be due to an organic lesion. Cardiac enlargement, the presence of a thrill, and possibly a rheumatic history would be confirmatory evidence.

Paroxysmal tachycardia in infants may masquerade as an acute abdomen. Cardiac failure can rapidly appear, and the enlarged tender liver may give rise to such abdominal rigidity that it cannot be easily palpated. Vomiting may be present and the child show speedy signs of distress. Concentration on the abdomen may result in the tachycardia being overlooked. I have seen a case like this saved from surgical intervention just in time.

Another condition which may appear to be a surgical emergency is acute enterocolitis of the dysentery group with melaena, which has to be distinguished from intussusception. On the other hand, melaena is not necessarily present in all cases of intussusception, particularly when the condition is incomplete or recurring.

In the past, scurvy has also been mistaken for osteomyelitis.

It is perhaps not generally known that a transient glycosuria may occur after severe vomiting or starvation, with resulting ketosis. Further urinary tests should therefore be made, especially after the child has been given some sugar, before the possibility of diabetes mellitus is entertained. I need hardly remind you that coli bacilluria commonly gives rise to signs suggesting an acute abdominal condition, and that this urinary infection, acute appendicitis, tuberculous peritonitis, and enteric fever have all to be considered in a differential diagnosis. The physical signs of appendicitis and tuberculous peritonitis are sometimes so indistinguishable that laparotomy is the safest procedure.

Urethral valves in boys usually lead to bilateral hydronephrosis and hydroureters, which easily become infected. Sometimes congenital aplastic kidneys are present. Uræmia is the main feature, with vomiting and an intestinal upset. The enlarged ureters may be mistaken for dilated gut, and the whole clinical picture looks more like some alimentary disorder. As the condition is rare, this is all the more likely to happen.

A more common complaint is incontinence of faeces, and the child suffers from continuous soiling of his pants. Some of these cases find their way quite wrongly to child guidance clinics; others are diagnosed as Hirschsprung's disease. The rectum is found to be loaded right down to the anus, and

faeces can often be felt on abdominal palpation. The condition is really a very severe dyschezia due to bad bowel habits, sometimes originating from defaecation fears due to pain of an anal abrasion or fissure. Absence of enuresis should exclude any psychological factor.

On the other hand, a true case of Hirschsprung's disease may be overlooked in infancy when it presents all the features of lower intestinal obstruction. The most likely disorder with which it is apt to be confused in the immediate neonatal period is meconium ileus, the infantile variety of fibrocystic disease.

The only common blood disease which may lead the doctor astray is leukaemia, since it may first appear in various obscure ways—as a case of serious anaemia, agranulocytosis, purpura, generalized adenitis—or give rise to bone pains from subperiosteal deposits and be mistaken for rheumatism.

Only two neurological difficulties will be discussed. Todd's paralysis after an epileptic fit may persist for quite an appreciable time and cause anxiety in respect of some organic lesion of the central nervous system. "Otitic" or "toxic" hydrocephalus is a mysterious complaint which has quite often been confused with a brain tumour. No one could be blamed for subjecting a child to ventriculography and even more drastic measures when headache and vomiting with papilloedema are so striking. It is true there may be no localizing signs, but these are not invariably present with a centrally placed neoplasm. There seems to be no way of avoiding this mistake.

Finally, Still's disease may be puzzling when it arises with little or no arthritis, and merely with an irregular undulating fever, a rash, and a neutrophil leucocytosis. The possible diagnoses will then be legion. Alternatively, pericarditis may be present at the onset and rheumatic fever would then seem to be the correct diagnosis. It is perhaps not generally known that rheumatoid arthritis in childhood may first attack one joint alone. The fever, leucocytosis, and toxic state of the child will naturally lead to fear of a pyogenic arthritis, and the doctor in charge feels impelled to explore the joint for pus. The subject of Still's disease should not be left without referring to polyarteritis nodosa, which runs a very similar course.

Overpopular Diagnoses

Bronchiectasis is certainly diagnosed too readily. If there is a persistent productive cough, steps should always be taken to exclude a chronic sinus infection or segmental pulmonary collapse. Glandular fever is the other popular diagnosis which is consistently made on insufficient evidence. If adenitis is confined to the cervical region, tonsillar sepsis is a much more likely cause. Recently we have also been told that a glandular-like fever with eosinophilia but a negative Paul-Bunnell reaction may in fact be toxoplasmosis, an infection which is apparently commoner than we thought.

Finally, I would like to issue two warnings. One is against calling a child hysterical until all other possible causes have been excluded. Serious diseases can begin in this way. Meningitis, for instance, in children may produce most curious temperamental changes. Once I was very nearly misled in a case of subacute bacterial endocarditis. It arose in an excitable rheumatic girl of 12 years who was suddenly struck dumb on seeing her mother after an interval of three weeks. Apart from an old mitral lesion there was nothing else to discover. I was sorely tempted to consider the whole affair an hysterical outburst, but somehow refrained from this. There soon followed a right-sided hemiplegia which proved fatal, and the loss of speech was due to a small embolus in Broca's area.

It is easy to place too little significance on clinical features, but one can err in the opposite direction. Children have been confined to bed for months on end for a continued mild pyrexia—a "ninety-niner" it could be called—with no symptoms, no signs, no leucocytosis, a normal sedimentation rate, and all investigations negative. Surely the

advice here is to throw the thermometer out of the window and allow the child to get up.

So ends what I have to say. My remarks have probably been of little value. Growing children rarely profit by the mistakes of others; they have to make their own experiences. I wonder if adults are any better, even those who belong to our profession.

Congreve was indeed wise when he wrote, "Error lives ere reason can be born."

A "FOLLOW-UP" CHEST X-RAY SURVEY IN THE RHONDDA FACH

I. PULMONARY TUBERCULOSIS

BY

A. L. COCHRANE, M.B., B.Ch., D.P.H.

Member of the Scientific Staff, Pneumoconiosis Research Unit of the Medical Research Council, Llandough Hospital, near Cardiff

IN COLLABORATION WITH

J. GLYN COX, M.R.C.S., L.R.C.P.

Consultant in Chest Diseases, Pontypridd and Rhondda District

AND

T. FRANCIS JARMAN, M.D.

Medical Director, Mass Radiography Service, Welsh Regional Hospital Board

Techniques for evaluating the effect of various therapies on groups of individuals have recently been much studied and most effectively applied both in the tuberculosis and in other fields. This report attempts the more difficult task of evaluating the effect of preventive medicine on a community.

In 1950-1, as the first step in a long-term investigation of the aetiology of progressive massive fibrosis (the more serious form of coal-workers' pneumoconiosis), 89.0% of the inhabitants of the Rhondda Fach over the age of 15 were x-rayed (Cochrane *et al.*, 1952). In addition, owing to the ready co-operation of the Welsh Regional Hospital Board, we were able to offer immediate admission to hospital to all "active" cases. In this way the inhabitants of the valley may be said to have received "radical" therapy for tuberculosis.

It will be argued by some that the technique would have been more radical if B.C.G. had been given to all those whom we found to be tuberculin-negative at the time of the first survey. This was not done for two reasons: (1) we did not think the evidence in favour of B.C.G. so convincing that it would be unethical not to vaccinate the tuberculin-negative, and (2) we were particularly anxious to measure the "conversion" and "reversion" rates. Tuberculin-negative children under 5 years of age were, however, given B.C.G. if they were "contacts," while older "contacts" were similarly vaccinated if their parents so wished.

In 1953, during the second stage of the investigation, the community was again x-rayed, and we are therefore in a position to measure the changes in the death rate and prevalence rate of tuberculosis and measure the attack rate of infection.

It is, however, impossible to cover all this in detail in one report. The epidemiology of pneumoconiosis,

including a discussion of the relationship between tuberculosis and progressive massive fibrosis—the main object of the scheme—has in general been reserved for a separate publication, and further papers will deal with such subjects as the results of tuberculin-testing and the factors influencing the attack rate of tuberculosis.

General Description and Plan of Work

(1) First Survey

We were conscious that there were some errors inherent in the techniques used at the time of the first survey, so advantage was taken of the second survey to reduce them. Fortunately, however, the errors discovered were small, but they necessitated some slight modifications of the results we published in 1952. In this report, the tables and diagrams incorporate these corrections.

(2) Between the Surveys

All those who were thought to be suffering from active tuberculosis were hospitalized, with two exceptions, at the time of the first survey. As expected, it was not found possible to keep all the infectious cases in hospital. After the first few months there were nearly always 40 known infectious cases in the valley, between the two surveys, who were carefully supervised by the health visitor.

Figs. 1 and 2 show the death rates from pulmonary tuberculosis amongst the men and women in the valley between 1949 and 1953. In Fig. 2 the female death rates are compared with those for the rest of the Rhondda Urban District (population 111,389), which is also predominantly a mining area.

The rates for women show (a) that the tuberculosis mortality in the Rhondda Fach was originally higher than in the rest of the R.U.D.; (b) that at the time of the first survey there was a slight rise (this was possibly due to more accurate notification of cause of death); and (c) that after the survey the death rate fell rapidly and was actually zero in 1953. The figures are small (Table I), but encouraging so far as they go. The rates for non-miners are very similar.

FIG. 1.—Crude tuberculosis death rates in the Rhondda Fach.

FIG. 2.—Comparison of tuberculosis death rates among females in the Rhondda Fach with those in the rest of the Rhondda Urban District.

Shortly after the survey started, another research project led to an ever-increasing proportion of miners and ex-miners in this area upon whom a post-mortem examination had been made. In 1953, more than 50% of such men who died had a post-mortem examination. This is very satisfactory from one point of view, but the increasing appearance of tuberculosis in the death certificates is al-

most certainly related to the increasing proportion of necropsies. It must be remembered that only 1% of cases of progressive massive fibrosis (P.M.F.) give a positive sputum in life (Cochrane *et al.*, 1952), while nearly 40% are positive bacteriologically at necropsy (James, 1954). It is not surprising, therefore, that the rates for miners and ex-miners have not shown the same fall as those for the females. However, it seems clear that mortality from tuberculosis among miners and ex-miners will remain a serious problem in South Wales long after it has virtually disappeared amongst the others.

(3) Second Survey

This second survey had three main objectives: (1) to reinforce the effect of the first survey in controlling tuberculous infection in the area; (2) to evaluate the effect of the first survey; and (3) to reduce the errors inherent in some of the techniques used in the first survey.

(4) General Method of Work

Our general approach was very similar to that used during the first survey, but the following changes were introduced: (a) We were, on this occasion, interested in two overlapping populations, the defined 1950-1 population (Population A), of which a nominal roll was made, and the 1953 population (Population B), which was defined by private census just before the survey started. This was found preferable to our previous use of corrected electoral rolls. (b) A records card (Fig. 3) was completed for everyone in the valley, in addition to the M.M.R. cards and P.R.U. industrial histories. They were also used for checking against the two populations, and were later coded and used as a basis for a punch-card analysis.

One point in connexion with the analysis must be stressed. The year of birth was punched in each case, but, as the time interval between the two surveys was 2 years 7 months (2.6 years), it was impossible to carry out an analysis by age at the time of each survey without either overestimating or underestimating the age at the time of the second survey in relation to that at the first survey. We have chosen, in effect, to overestimate the age (by 0.4 years) at the time of the second survey, and allowance for this must be made when interpreting some of the figures and tables.

Details of our methods of work are given in the Appendix.

Results

(1) The Defined Population

The two populations were in general defined as consisting of those of 5 years of age and over who were living in each town at the end of the survey there.

Some points, however, require greater definition. The survey did not take place at a single point in time; it lasted several months. It was therefore decided to consider the population as a composite one. The population of each town was defined as those inhabitants who were alive at the end of the survey in that particular town. The concept "inhabitant" also needed clearer definition. We were chiefly interested in these populations from the point of view of infection, so the time spent at home was the most important factor. We therefore excluded those who were in the armed Forces or who were "working away" unless they came home regularly at week-ends.

TABLE I.—Deaths from Pulmonary Tuberculosis in the Rhondda Fach, 1949-53

	Estimated Population	1949	1950	1951	1952	1953
		No. / 1,000	No. / 1,000	No. / 1,000	No. / 1,000	No. / 1,000
Females	13,464	8.5.9	11.8.2	6.4.5	2.1.5	0.0.0
Miners and ex-miners	6,513	7.10.7	5.7.7	7.10.7	9.13.8	8.12.3
Non-miners	6,207	3.4.8	4.6.4	2.3.2	0.0.0	1.1.6

FIG. 3.—The records card designed for use in the follow-up survey.

The Population B is analysed in Fig. 4. In Table II Population A is compared with Population B and also with our previous estimate. The differences between the two estimates of Population A are small (59 in the case of men and 31 in the case of women).

Lewis-Faning (1953) compared the age distribution of our survey population with that of Wales as indicated by the

FIG. 4.—Rhondda Fach. Defined population at time of 1953 survey.

preliminary figures of the 1951 Census, and suggested that either the population of the Rhondda Fach diverged markedly from that of Wales as a whole, or we had not completely enumerated its population.

However, on re-checking our population we were not able to discover any source of error, and, indeed, subsequent publication of the 1951 Census County Report of Glamorgan (Registrar-General, 1954) showed the age distribution of the Rhondda Urban District (of which the Rhondda Fach is a part) to be very similar to that which we published.

(2) Population X-rayed

The same criteria were used as in the previous survey—that is, the population x-rayed consisted of those who were over the age of 5 at the time of the survey, and of whom a technically acceptable radiograph had been obtained by one of the teams or by anyone else within six months of the survey, provided the film was either made available to us or had been read by some recognized authority. The remainder of the population were termed "lapses." All films were read in duplicate and sputum investigations were carried out on a large scale. The 35-mm. films were read independently by two observers (T. F. J. and Dr. W. E. Miall) and the 14 by 14-in. (35 by 35-cm.) films by two pairs of observers (A. L. C. and Dr. Idris Davies, and Drs. P. J. Chapman and S. Rae).

Tables II and III summarize the percentage x-rayed in the two surveys. The differences are chiefly in the younger age groups, and are probably due to the better definition of the population on the second occasion. All prevalence rates refer to these x-rayed populations.

TABLE II.—Defined and X-rayed Populations 1950-1 and 1953

Age	Population 1950-1 as Measured Then			Population 1950-1 Corrected 1953		Population, 1953			
	%	No. X-rayed	No. in Population	No. in Population	No. X-rayed	%	No. in Population	No. X-rayed	%
Females									
5				1,000	929	92.9	1,072	1,054	98.3
10				1,005	942	93.7	977	960	98.3
15	(95.6)	(758)	(793)	972	903	92.9	990	964	97.4
20	93.0	787	847	887	807	91.0	867	824	95.0
25	94.1	994	1,056	1,041	970	93.2	906	866	95.6

Fig. 5 shows the percentage of miners, ex-miners, non-miners, and women who were x-rayed during the second survey. Although age appears to be the most important factor influencing the lapse rate, occupation and sex also appear to be important.

FIG. 5.—Percentage x-rayed in the second Rhondda Fach survey.

(3) Prevalence of Tuberculosis

(a) Prevalence of Tuberculous Infection.

The schoolchildren were again "Mantoux"-tested by one of us (T.F.J.); and Fig. 6 summarizes the results. The change appears satisfactory, but the results will be discussed in greater detail in a subsequent paper.

FIG. 6.—Results of tuberculin testing in the Rhondda Fach in 1950-1 and 1953. (In this figure the ages have been adjusted to correct for the error of 0.4 year.)

(b) Prevalence of Tuberculous Disease

The same standards of diagnosis were made as on the previous occasion. Fig. 7 and Table IV show the prevalence of infectious tuberculosis amongst the women at the time of the two surveys. It is clear that there has been a satisfactory fall. So far as miners are concerned, however, a similar decrease is seen only amongst the younger miners

FIG. 7.—Prevalence of infectious pulmonary tuberculosis in Rhondda Fach females.

and ex-miners (Fig. 8); in the higher age groups there has been a definite increase. The results for the non-miners are somewhat difficult to interpret owing to their atypical age distribution (Fig. 9).

Those who had a positive sputum at the time of the first survey have been analysed in terms of their status at the time of the second survey (Table V). This assists us to understand some of the changes that have taken place in the prevalence of pulmonary tuberculosis. The lower mortality rate among females as shown in Fig. 1 would, of course, tend to increase rather than decrease the prevalence of infectious pulmonary tuberculosis. The cause of the fall must therefore be looked for elsewhere. The females have the highest rate of conversion from "positive" to negative sputum, and this may very well be an important factor contributing to the fall in prevalence. The highest sputum conversion rate is found among females in the younger age groups, and the lowest among cases of P.M.F., which corresponds with general clinical experience in the area. Although these overall conversion rates are relatively high, the number of cases that remained positive after treatment certainly suggests that there is still room for great clinical advances. Amongst the males with positive sputum at the time of the first survey there were 12 cases of P.M.F. It is of great interest that only one of them died during the

TABLE V.—Status in 1953 of the Infectious Cases at the Time of the 1950-1 Survey

	No. of Infectious Cases 1950-1	Status of the Same Cases in 1953			No. who Left the Area

Females	64	7 10.9	41 64.1	15 23.4	1

2.6 years between the surveys. This is very different from that found by Kilpatrick *et al.* (1954), who reported that 80% of such patients were dead in 2½ years. The difference may be partly due to the cases seen by Kilpatrick being

FIG. 8.—Prevalence of infectious pulmonary tuberculosis in Rhondda Fach miners and ex-miners.

FIG. 9.—Prevalence of infectious pulmonary tuberculosis in Rhondda Fach non-mining males (owing to small numbers in higher age groups these have been combined to give a smoother curve).

selected on the basis of severity or, more probably, to the effect of antibiotics which have been used in the treatment of our cases, and which appear to prolong life without, unfortunately, causing sputum conversion.

No marked changes could be expected in the total prevalence of all types of tuberculosis, as the main way of leaving the tuberculous population is the extremely slow one of progression from the group with "active" tuberculosis to that with "quiescent" disease, and finally to the group which has "arrested" disease. The small change in total prevalence that has occurred amongst females is shown in Fig. 10. It should, however, be stressed that, although the reduction in total prevalence of all types of pulmonary tuberculosis is small, the qualitative changes within this "tuberculous" population represent a very real improvement in the tuberculosis situation in the valley. A very important factor in causing changes in prevalence is, of course, the "attack rate" of new cases, which is considered below.

FIG. 10.—Prevalence of pulmonary tuberculosis in Rhondda Fach females.

(4) Attack Rate of Pulmonary Tuberculosis

This index measures the rate of appearance of shadows considered clinically to be tuberculous amongst those whose x-ray films were previously considered to be free of tuber-

culosis. Cases of definite simple pneumoconiosis (Categories 2 and 3) which developed early signs of progressive massive fibrosis are not included in this paper. They will be dealt with in a subsequent paper. The accuracy of such measurements depends mainly on the extent to which the original population has been followed up, and our results in this respect can conveniently be considered here.

Those who were x-rayed during the first survey fell into three groups at the time of the second survey: (1) those who had died in the interval, (2) those who had left the defined area, and (3) the survivors. The last-named could be further subdivided into those x-rayed again at the time of the second survey and those who refused.

The extent of the follow-up is shown in Table VI. It will be seen that 95% of the "surviving" men and women were x-rayed. This is shown diagrammatically in Fig. 11 for the women.

In order to calculate the attack rate on those whose x-ray films were considered normal as regards tuberculosis at the time of the first survey, those with active and quiescent

TABLE VI.—Summary Results of the "Follow-up" of Those X-rayed in 1950-1

	X-rayed 1950-1 (1)	No. Dead of (2)	No. Left of Area (3)	No. Remaining (4)	No. Re-X-rayed (5)
Females	10,618	168 1.6	650 6.1	9,800 92.3	9,315 95.1

FIG. 11.—Follow-up of females x-rayed in 1951.

lesions were excluded from the population of those x-rayed in 1950-1. When pulmonary tuberculosis was diagnosed during the second survey on 35-mm. film, and the records showed that the person concerned had been x-rayed and the x-ray considered normal on the previous survey, the two films were projected simultaneously and scrutinized by three readers. The technique was time-consuming but very satisfactory.

Fig. 12 shows the radiological attack rate of tuberculosis amongst women, non-miners, and miners and ex-miners whose films were read as "normal" for pneumoconiosis and tuberculosis at the first survey.

It is proposed to devote a later paper to a discussion of the attack rate of tuberculosis and the factors influencing it. We can, however, make the following points conveniently at this stage.

(1) We have clearly not succeeded in preventing the appearance of new tuberculous lesions, and owing to the

absence of any previous direct measurement of the attack rate in that area we cannot claim to have reduced it.

(2) Our figures in general confirm the pioneer measurements of attack rate made by Springett (1951), which are still the only ones available, as shown in Table VII. Superficially, too, it would appear that our attack rates are very

FIG. 12.—Annual radiological attack rate of tuberculosis in the Rhondda Fach.

diagnosed at clinics or hospitals (Springett, 1951), which would lead, as he points out, to his attack rates being underestimates. In addition, Springett (personal communication, 1954) did not include in his series cases of uncomplicated primary type tuberculosis or pleurisy. This again would make his figures a considerable underestimate in relation to ours, which include both types. In Table VII

TABLE VII.—Annual Radiological Attack Rates of Tuberculosis per Thousand

Source of Data	Females		Males without Pneumoconiosis	
	Age 15-24	Age 25-34	Age 15-24	Age 25-34
Rhondda Fach surveys 1950-1 and 1953	2.8	0.7	4.7	1.0
Springett (1951). London	3.5	2.0	3.0	2.0
The same Rhondda Fach data but excluding uncomplicated primary type tuberculosis, pleurisy, and those who were diagnosed between surveys on account of symptoms	0.6	0.7	0.4	1.0

a crude attempt has been made to allow for these differences by excluding from our series (a) cases of uncomplicated primary type tuberculosis and pleurisy, and (b) those who went to the clinic between the surveys on account of symptoms. Such an approach, it must be stressed, is very crude, as the factors influencing people to go to the clinic in the Rhondda Fach after the first survey were probably very different from those influencing Civil Servants in London. The comparison does, however, suggest that the attack rate in the Rhondda Fach between the surveys was less than that of Civil Servants in London in 1946-9.

(3) The way in which the appearance of new cases is confined to the younger age groups suggests the possibility of selective follow-up when a community has already been carefully surveyed. In a community where there is no progressive massive fibrosis it would be very reasonable to restrict the follow-up to those under the age of 35. The one female "new" case over this age was a diabetic. It would, of course, be necessary to have a careful follow-up of all male minimal quiescent lesions as well.

Discussion

From the point of view of epidemiology in general, our most important finding is a purely technical one. We have shown that it is technically possible to follow up a population of 25,000 people with a relatively low lapse rate. We believe this to be of considerable importance in the field of experimental preventive medicine.

As regards the epidemiology of tuberculosis, the most important finding is the confirmation of Springett's work that the radiological attack rate of tuberculosis in the two

sexes has a very similar age distribution in spite of the marked differences between the sexes in the relationship of tuberculosis mortality to age. This suggests, as Springett pointed out, that the higher tuberculosis mortality now being experienced by males in the higher age groups is mainly caused by the breakdown of lesions acquired in early adult life.

From the point of view of practical tuberculosis control, our results are less striking than we had hoped but less depressing than we had feared. There was a marked fall in tuberculosis mortality amongst women and non-miners; there was a considerable reduction in the prevalence of infectious cases, particularly among the younger people, and there was probably a reduction in the attack rate of tuberculosis.

The effects of such community surveys have recently been reviewed (Cochrane, 1954). There is no other survey with which a detailed comparison can be made. Olsen (1953) showed that the mortality rate was halved but that there was relatively little change in the notification rate after an extensive survey in Bornholm. The greater fall in mortality achieved in the Rhondda Fach is probably due to the availability of antibiotics after the first survey (the first Bornholm survey was completed in 1940). No details are given of changes in attack rate or prevalence rate, so no further comparison is possible with Bornholm. It is, however, of interest that there is nothing to suggest that a greater effect was achieved in Bornholm, where B.C.G. was given on a large scale in addition to hospital treatment. Davies (1946) and Davies *et al.* (1948) reported very much more striking results. In one instance no new cases were found during six years after x-raying a community of 367 and only one new case in the three years following a community survey of 6,000 people. The differences between their results and ours are possibly due to a very much lower initial prevalence in the communities they x-rayed, but unfortunately there is little evidence available on this point.

There are some points in relation to the results which deserve more detailed discussion:

(1) Of the 112 infectious cases known to us at the time of the first survey, all but two had had treatment and many had had surgical treatment. In 1953 14 were dead and 35 were still sputum-positive. This is a rude reminder that the therapeutic battle is only half won.

(2) If, as now seems probable, the tuberculous lesion in the male has a relatively long period of latency before cavitating and becoming infectious, the problem, as Springett pointed out, is a serious one, as the numbers are large and the period of observation long. Progressive massive fibrosis, probably pathologically and certainly administratively, presents this problem in its most serious form. These lesions are very slowly progressive over long periods of time, but may at any time become very infectious. Chemotherapy has undoubtedly improved their prognosis *qua vita*, but sputum conversion is only rarely achieved, and is even more rarely permanent. This group is undoubtedly the most serious obstacle to the elimination of tuberculosis from the valley.

(3) The speed at which the tuberculosis mortality rate fell in the valley, while the overall prevalence was scarcely altered, indicates that the mortality rate by itself is not an adequate index of prevalence. In addition, as mortality approaches zero it becomes less and less sensitive as an epidemiological index. This underlines the need for a new index. It is improbable that notification rates, however complete they are made by "intimation" or other means, and however much the inter- and intra-observer error is reduced among chest physicians, will ever be really satisfactory. In the discussion of new indices, too little attention has been paid to deciding which epidemiological index one wishes to estimate. If mortality indices are unsatisfactory, the only alternatives are attack rates, and no one would suggest it as a satisfactory routine measure.

Prevalence rates are not such a valuable measurement from the point of view of preventive medicine as attack rates, because changes in them are often rather difficult to interpret, since they vary directly with the attack rate and

inversely with the case fatality rate; but when the case fatality rate is low—as it soon will be in tuberculosis—they are much more satisfactory. They will, in any case, measure the administrative and social load on the community. Prevalence, unlike the attack rate, can, theoretically, be measured relatively accurately by x-raying a random sample of the community, and the way is thus open for obtaining a satisfactory index for various parts of the country. Whether this is a practical possibility can, of course, be decided only by actual experience.

(4) The relation between the effort put into the Rhondda Fach surveys and the results obtained should give other workers some idea of the effort required to eliminate tuberculosis from the country.

Summary

Part of the second stage of a field experiment in the Rhondda Fach to investigate the effect of reducing tuberculous infectivity upon the rate of appearance of progressive massive fibrosis in miners is described.

The valley was re-surveyed in the summer of 1953. On this occasion we succeeded in x-raying 91.3% of the new population over the age of 5, and 95% of those who had been previously x-rayed and who were still resident in the valley. The prevalence of infectious tuberculosis as compared with the figures at the time of the first survey (1950-1) shows a marked fall amongst the women and a lesser fall amongst the younger men. There has been a slight increase amongst the older miners and ex-miners.

The tuberculosis mortality for women and non-miners has fallen sharply between the two surveys. The same trend is not shown for miners and ex-miners.

In spite of ample hospital accommodation, 35 (amongst whom were 10 cases of progressive massive fibrosis) of the 112 cases which were infectious in 1951 were still infectious in 1953, and 46 new cases of tuberculosis developed in the valley between the two surveys.

APPENDIX

A. General Method of Work

As a result of our previous experience, we relied mainly on home-visiting as a means of persuading people to be x-rayed. Only one broadcast appeal was made, and there was little publicity in the Press. The actual x-raying was done between April 7 and July 31, 1953. In spite of the holidays which inevitably interfered with the survey, this was found preferable to the previous winter survey.

The staff was considerably enlarged in comparison with the previous survey. The Welsh Regional Hospital Board supplied two M.M.R. teams for most of the duration of the survey, and the Medical Research Council's P.R.U. team was assisted by two teams who were being trained for work with the National Coal Board. The x-raying was done at five main centres in the valley, at each of which there were (1) a mobile 35-mm. unit, x-raying the schoolchildren; (2) a "fixed" 35-mm. and a "fixed" 14 by 14 in. (35 by 35 cm.) unit in the centre of the town, x-raying women, non-miners, and ex-miners; and (3) a mobile 14 by 14 in. unit at the pithead x-raying miners. Slight modifications were introduced at each centre to suit local conditions. At the main centre, x-raying was continuous from 10 a.m. until 10 p.m. for women, children, ex-miners, and non-miners. On several occasions the mobile x-ray van (35-mm. film) was taken into the streets, but the results were less spectacular than expected.

We were, on this occasion, interested in two overlapping populations: (1) the "defined" population of 1950-1 (Population A), and (2) the new population of those living in the same geographical area in 1953 (Population B). For Population A, a typewritten nominal list was prepared from our previous records in street number order, including name, initials, address, and previous x-ray number for those x-rayed in the first survey. Population B was obtained by a

private census which antedated the survey by about two weeks. The technique proved highly satisfactory—much superior to our previous technique with electoral rolls.

A card was designed (Fig. 3) giving details of both surveys. These cards were completed at the three centres for everyone x-rayed, in addition to the usual M.M.R. cards and P.R.U. industrial histories. These cards were then sent from all four x-raying units to a central bureau, where they were sorted by streets and then checked first against Population B and then against Population A lists. Owing to the details available about each person, a very accurate check was possible. In the case of any doubt the person was visited. This served as a check on the accuracy of both Populations A and B. Those not marked as x-rayed on Population B were visited and, when possible, persuaded to be x-rayed. This proved a very much more difficult task than on the previous survey. This was possibly due to the lack of propaganda, but that was not our impression. Subsequently, Population A was checked against Population B, and the addresses of all those not marked as x-rayed or as refusals on the second survey were visited to discover whether the person was dead, had left the area, or whether there had been a mistake on one or other of the populations. Later, Population B was checked against Population A to discover, in the case of those members of Population B not x-rayed during the second survey, whether they were in Population A, and, if not, where they were living at the time of the previous survey. All this involved a great deal of home-visiting, but led to a great increase in accuracy in the definition of both populations.

The punching of the material on Hollerith cards and the subsequent analysis were carried out under the supervision of Mr. R. G. Carpenter, of the Pneumoconiosis Research Unit.

B. Radiographic Technique

The P.R.U. work was done under the supervision of Mr. W. G. Clarke. The P.R.U. mobile van was re-equipped with a Siemens four-valve unit with an output of 125 kV and 500 mA. The tube-cassette stand was specially designed for use in a van and ensured that the tube was always correctly centred to the film. Exposures were controlled by the "ionomat," the new automatic exposure control which incorporates an ionization chamber to measure the x-radiation reaching the film. The processing of the films in the van was done using the N.R.D. automatic processing unit. Electrical power was supplied by a mobile diesel generator of large capacity, 32 kVA. This also supplied power for the heating of the tents and a second mobile van which was used for film reading. This unit operated at the pithead.

A second unit, a Victor KX8, which had been installed in the van for the first survey, was assembled in the various halls and chapels and was used for the examination of ex-miners. Large film retakes, requested by the M.M.R. unit, were also taken on this unit. Power was supplied for this unit by a generator with the same output as that supplying the van.

M.M.R. units were installed in the same halls and staffed by the mass radiography service of the Welsh Regional Hospital Board, under the administrative direction of Mr. John H. Phillips. These units were responsible for the examination of women, children, and non-miners. The M.M.R. technique was exactly similar to that described for the first survey.

The proximity of the two units introduced the possibility of excessive scatter radiation affecting the staff. This was overcome by the use of lead screens. That this was effective was shown by checks made on dental film worn by the staff and measured by the N.P.L.

Acknowledgments.—The difficulties of making adequate acknowledgment in work which involves the active assistance of so many people increase as time passes and the personnel changes. But we wish to record our gratitude to the many members of the staff of the Welsh Regional Hospital Board and their Mass Radiography Service, the Pneumoconiosis Research Unit, the Public Health Laboratory Service, Tyntyla Hospital, Pontypridd

Chest Clinic, the National Coal Board, and the National Union of Mineworkers; and especially to the members of the two teams who gave such devoted service, and to the men, women, and children of the Rhondda Fach, without whose co-operation the scheme would have been impossible.

We express our thanks for the assistance given by the members of the Local Advisory Committee of the Rhondda Fach Scheme, and in particular to the members of its executive subcommittee. The views expressed in the paper are, however, our own and not necessarily those of the members of the Committee.

AORTIC ANEURYSM DUE TO TUBERCULOUS LYMPHADENITIS

BY

C. G. ROB, M.C., M.Chir., F.R.C.S.

AND

H. H. G. EASTCOTT, M.S., F.R.C.S.

From the Surgical Unit, St. Mary's Hospital, London

The term "mycotic aneurysm" was first used by Osler in 1885 when he described a patient with multiple aneurysms of the aorta secondary to what he termed "malignant mycotic endocarditis." Since then a group of diseases have been named the mycoses, and so the word "mycotic" has been given another meaning in addition to its original one. To-day the accepted definition of a mycotic aneurysm is one due to septic infection in the wall of an artery; it is usually associated with bacterial endocarditis. The mode of formation of a mycotic aneurysm depends upon whether it is of the embolic or of the erosive type. If embolic, an infected embolus lodges in the vessel or in one of its vasa vasorum, and the inflammation, by weakening the arterial wall, causes it to give way with the formation of an aneurysm. If erosive, the inflammation spreads from the aortic valve or from a coarctation to the adjoining aorta, or, much less frequently, it comes from an extravascular source and weakens the vessel wall by spreading from the adventitia inwards.

In this paper we describe a case in which a mycotic aneurysm of the abdominal aorta developed owing to erosion of the aortic wall by tuberculosis of the pre-aortic lymph nodes.

Case Report

The patient was aged 59. Two months before admission to St. Mary's Hospital he noticed a pain in his back; this was a constant ache, worse at night, and was gradually getting more severe. He also suffered from pain in his calves and feet; this was worse when he stood up and relieved by rest in bed. He had occasional attacks of vomiting. Two weeks before admission he noticed a pulsatile swelling in his abdomen which was rapidly enlarging. He consulted Mr. A. Emlyn Williams at the Hampstead General Hospital, who considered that he had an aneurysm of the abdominal aorta and referred him to us for treatment.

He gave a past history of two bouts of pulmonary tuberculosis occurring respectively nine years and two years previously. Nine months before admission he had a cold abscess of the chest wall treated surgically at the Brompton

Hospital. One of his brothers had died of pulmonary tuberculosis and one of his daughters also suffered from this disease.

On admission the scar of the operation on the chest wall was soundly healed and x-ray examination showed no evidence of an active pulmonary lesion. He was seen by Dr. W. D. W. Brooks, who considered that the pulmonary disease was quiescent. Examination of the abdomen revealed a slightly tender mass in the epigastrium situated just above and to the left of the umbilicus; this pulsated in an expansile manner and was considered to be an aneurysm of the aorta. Apart from a mild urinary infection, no other abnormality was detectable on clinical examination. Aortography (performed by Dr. David Sutton) demonstrated an aneurysm of the abdominal aorta between the renal arteries and the aortic bifurcation (Fig. 1).

FIG. 1.—Pre-operative aortogram showing an aneurysm of the abdominal aorta.

At this stage the patient exhibited two unusual features as compared with the usual case of abdominal aortic aneurysm which we treat with a blood-vessel graft. He had an evening temperature of 100° F. (37.8° C.) and the aneurysm was unusually large clinically when compared with the size shown on the aortogram. The pyrexia was at first thought to be due to the urinary infection, but although this infection cleared with treatment the pyrexia persisted. In view of these findings and his previous medical history it was considered possible that he suffered from tuberculosis of the abdominal lymph nodes as well as an aneurysm of the aorta.

At operation a large mass of caseating tuberculous lymph nodes was found to be adherent to the anterior and lateral walls of an aortic aneurysm. At one point the aneurysm was very thin walled and about to rupture. The whole mass and the aneurysm were resected, the inferior mesenteric artery was tied, and continuity was restored by means of a prosthesis of "orlon" cloth. Orlon cloth was used in preference to an arterial homograft because the graft bed consisted in part of tuberculous tissue, and it was felt that this might spread and involve a graft.

The patient made a satisfactory recovery from the operation, and was discharged from hospital to a convalescent home one month later. There he completed a twelve-weeks course of streptomycin and P.A.S.

On examination of the specimen the resected portion of aorta was seen to have a moderate degree of atheroma; many enlarged caseating lymph nodes surrounded a saccular aneurysm. Microscopical examination demonstrated tuberculous granulation tissue with much central caseation abutting on the outer surface of the aorta, replacing the adventitia

and media in places, so that there was only thickened intima between the tuberculous tissue and the lumen of the aorta. In view of these findings we consider that this patient had a mycotic aneurysm of the abdominal aorta of the extravascular erosive type, the tuberculous disease in the lymph nodes having destroyed the adventitia and media of the aorta so that an aneurysm resulted.

Aortography performed one month after operation showed that there was good filling of the aorta, the orlon prosthesis, and the iliac arteries (Fig. 2). The patient has returned to work in his city office.

FIG. 2.—Post-operative aortogram showing the orlon cloth prosthesis in position.

Previous Reported Cases

In 1913 Haythorn reviewed the literature on tuberculosis of arteries and reported finding only one record of an aneurysm of the abdominal aorta due to erosion of the arterial wall by tuberculous granulation tissue. Since then occasional cases have been reported, and by 1933 Gellerstedt and Säfwenberg were able to collect 21 cases of aneurysm of the abdominal aorta due to erosion by tuberculous granulation tissue. The literature since 1933 contains reports of two more cases (Owens and Bass, 1944; Scott, Maxwell, and Grimes 1949), so it appears that, including our patient, only 24 cases of tuberculous mycotic aneurysm of the abdominal aorta have been recorded. Also, as the other reports were based upon material obtained at necropsy, ours is the first record of the diagnosis of this lesion with the subsequent recovery of the patient.

Summary

A case is reported of an aneurysm of the abdominal aorta due to erosion of the aortic wall by tuberculous granulation tissue from caseating abdominal lymph nodes. Treatment, which included resection of the aneurysm followed by reconstruction of the aorta with a prosthesis of orlon cloth, has enabled the patient to return to work.

Of 23 such cases previously reported in the literature, all were fatal.

THE NUCLEIC ACID CONTENT OF BONE-MARROW CELLS IN PERNICIOUS ANAEMIA

BY

HUGH BREBNER, M.D., M.R.C.P.

Senior Registrar, Manchester Royal Infirmary

AND

JOHN F. WILKINSON, M.D., M.Sc., Ph.D.
F.R.C.P., F.R.I.C.Physician and Director, Department of Haematology,
Manchester Royal Infirmary

The understanding of disordered processes of cell development has in the past depended mainly on the observation of morphological differences between cells at various stages of their life-cycle. By modern chemical and histochemical methods it is possible to analyse, in certain of the chemical constituents of cells, changes that are probably the underlying cause of alterations in morphology. The disordered cell development that occurs in pernicious anaemia is particularly worthy of study, for the cells are easily accessible, and, furthermore, the disease process is one that can be corrected by appropriate treatment. Of the therapeutic agents that restore the bone-marrow picture to normal, the most potent is vitamin B₁₂, which appears to be closely connected with the synthesis of nucleic acids that accompanies growth (Wright *et al.*, 1948; Rose and Schweigert, 1952). In spite of the fact that, from bacterial and animal experiments, much has been learned about the biological activity of vitamin B₁₂, very little is known of its mode of action in pernicious anaemia. There is as yet no real understanding of the nature of the cellular defect that is apparently remedied by vitamin B₁₂, but it seems possible that it may be a defect in nucleic acid metabolism.

It has been demonstrated that the deep basophilia of the cytoplasm of early megaloblasts is due to the presence of ribonucleic acid (Thorell, 1947; White, 1947); it has also been shown by chemical analysis that the mean amount of ribonucleic acid phosphorus (R.N.A.P.) per cell is much greater in megaloblastic marrows than in normal marrows (Davidson *et al.*, 1951). Accumulation of ribonucleic acid in the cell cytoplasm appears, therefore, to be a specific feature of megaloblastic haemopoiesis. That abnormalities may also occur in the cellular content of deoxyribonucleic acid (D.N.A.) was suggested by La Cour (1944), who, by histological methods, demonstrated chromosomal abnormalities in both the red-cell and the white-cell series in pernicious anaemia. The mean deoxyribonucleic acid phosphorus (D.N.A.P.) per cell is, in fact, greater in megaloblastic marrows than in normal marrows (Davidson *et al.*, 1951, 1953). On the other hand, it has been shown by microspectrophotometric techniques that the D.N.A. content of individual megaloblasts is no greater than that of normoblasts of comparable nuclear size (Reisner and Korson, 1951; Marinone, 1951).

In this paper we present the results of chemical estimations of the nucleic acid content of bone-marrow cells in pernicious anaemia, and make an attempt to assess the significance of the findings, particularly with regard to the cellular content of D.N.A.P. Quantitative changes in nucleic acids during *in vitro* culture will be described elsewhere.

Experimental Work

Estimations of nucleic acids were carried out on suspensions of blood or bone marrow containing a known number of nucleated cells per cubic millimetre, thus enabling the mean amount of nucleic acid per cell to be calculated. Sternal marrow samples were taken from 18 patients suffering from classical pernicious anaemia, and the series of observations has been compared, not with normal marrows, but with observations on nine bone marrows showing normoblastic hyperplasia. Cases in the latter group were selected because the clinical and bone-marrow findings suggested that the erythroid elements of the marrow might be functioning near their maximum capacity, which would cause the marrow aspirates to contain a high proportion of "active" cells. The use of such cases was thought to afford a better comparison between megaloblastic and normoblastic haemopoiesis than the use of normal subjects, from whom marrow aspirates contain a high proportion of mature leucocytes. In addition, seven samples of normal blood were examined.

Technique

Blood samples of approximately 3 ml., obtained by venepuncture, were collected in bijou bottles containing as an anticoagulant the standard mixture of ammonium and potassium oxalate. Sternal marrow puncture was performed by the standard technique, employing a Salah sternal puncture needle and an all-glass syringe, both siliconed. When approximately 1 ml. of the blood-and-marrow mixture had been aspirated, the syringe was quickly detached from the needle and its contents were ejected into 20 ml. of normal saline in a universal container. Although anticoagulants were not used, it was found that if the mixture of marrow and saline was shaken for 20 minutes clotting did not occur. After centrifugation for five minutes, the fatty debris was taken from the top of the liquid and the supernatant fluid removed by Pasteur pipette until about 2 ml. remained. Agitation then produced an even cellular suspension, on which three independent nucleated cell counts were made.

Nucleic acids were estimated as nucleic acid phosphorus (N.A.P.) by the technique described by Davidson *et al.* (1949), in which the D.N.A.P. and R.N.A.P. fractions are separated by the method of Schmidt and Thannhauser (1945). The amount of inorganic phosphorus present in the two fractions was measured by the colorimetric method of Berenblum and Chain (1938). Readings were taken on a calibrated Unicam spectrophotometer, and by this technique satisfactory measurement was obtained of quantities of phosphorus between 0.5 and 4 μg .

Results

In Table I, II, and III are recorded the mean values of nucleic acid phosphorus per cell found in normal leucocytes, in cells from bone marrows undergoing active normoblastic hyperplasia, and in cells from the bone marrow of patients suffering from pernicious anaemia. No figures are recorded for the mean amount of R.N.A.P. per leucocyte, because difficulty was experienced in extracting all the acid-soluble phosphorus compounds from whole blood, thus making the R.N.A.P. figures unreliable.

The mean value for the cellular content of R.N.A.P. is higher in the pernicious anaemia series than in the normoblastic ($t=2.548$; $n=19$; $P<0.02$); this finding is consistent with the observations that the early megaloblasts pre-

sented in the marrow of pernicious anaemia are unusually rich in R.N.A. (White, 1947; Thorell, 1947). The distribution of the individual D.N.A.P. results in each series is depicted in the Chart, and the grand means are compared in Table IV. The lack of a significant difference between the marrow cells

				(6.9, 7.1, 6.8)	(21.5, 19.2, 22.0)

Figures in parentheses are individual results in cases in which estimations were carried out on more than one marrow suspension from the same patient. Clearly, the wide range of nucleic acids in pernicious anaemia is due, not entirely to experimental error, but mainly to a real case-to-case difference. Grand mean D.N.A.P. per cell = 8.85×10^{-7} μg . Grand mean R.N.A.P. per cell = 18.53×10^{-7} μg .

TABLE IV.—Comparison of the Mean Nucleic Acid Phosphorus Per Cell in Blood and Bone-marrow Cells (Numbers of Cases in Parentheses)

	A	B	C
	Blood Leucocytes	Active Normoblastic Marrow	Pernicious Anaemia Marrow
D.N.A.P. as $\mu\text{g.} \times 10^{-7}$ /cell	5.89 (7)	8.51 (9)	8.85 (18)
R.N.A.P. as $\mu\text{g.} \times 10^{-7}$ /cell	—	10.69 (7)	18.53 (14)

The difference between the D.N.A.P. means in A and B is not significant ($t=2.116$, $n=14$, $P=0.053$); that between the means in A and C is of borderline significance ($t=2.258$, $n=23$, $P=0.05$). The R.N.A.P. mean of C is greater than that of B ($t=2.548$, $n=19$, $P<0.02$).

Mean = 5.89×10^{-7} μg .

as compared with leucocytes is due to the relatively small numbers in two of the three series, but the present object is not to demonstrate such a difference but rather to compare the bone marrow of pernicious anaemia with that of active normoblastic hyperplasia. The results indicate that the cellular content of D.N.A.P. is quantitatively similar in these two types of bone marrow.

Chart showing the mean cellular content of D.N.A.P.

Discussion

Appreciation of the significance of the results depends on a knowledge of the role of D.N.A. in the life of the cell, in which it forms an essential part of nuclear chromatin (Brachet, 1933). A considerable amount of evidence points towards the idea that, in any given genus, the mean content of D.N.A. per mature diploid cell is constant, being twice that of the haploid sperm (Boivin *et al.*, 1948; Vendrely and Vendrely, 1948, 1949; Mandel *et al.*, 1950; Davidson *et al.*, 1951).

During cell proliferation, changes must of course occur, and these have, in recent years, been studied intensively by a number of workers using quantitative spectrophotometric techniques that enable the D.N.A. content of individual cells to be estimated. It has been shown that D.N.A. increases during interphase until at prophase twice as much is present as in the non-dividing cell; hence daughter nuclei have the normal complement of D.N.A. (Swift, 1950; Pasteels and Lison, 1950; Walker and Yates, 1952). Thus if the mean amount of D.N.A. per cell in a population is high it may be presumed that a high proportion of cells are of actively dividing type, or that mitotic abnormalities have occurred, resulting in polyploid cells, or that some fundamental abnormality exists in the chromosomal content of D.N.A.

The blood leucocyte is a good example of a mature non-dividing diploid cell, and the results recorded in Table I indicate that in normal subjects the mean amount of D.N.A.P. per leucocyte is remarkably constant. Moreover, as the results are in agreement with published figures for the D.N.A.P. content of other mammalian cells (Table V), they lend support to the theory of constant D.N.A. per cell.

Tables II and III demonstrate the wide variability that occurs between different bone marrows as regards the mean

TABLE V.—Mean D.N.A.P. Content of Various Mammalian Cells. D.N.A.P. as $\mu\text{g.} \times 10^{-7}$ Per Cell. (Figures Published as D.N.A. Have Been Multiplied by 0.099.)

* Cells from liver, kidney, etc. (may include some dividing cells).

content of D.N.A.P. per cell, a finding that has also been observed by Davidson *et al.* (1951) and by Menten and Willms (1952). In a series of 31 cases showing a preponderance of erythroblasts in bone-marrow smears, the latter authors found values of D.N.A.P. per cell ranging from 4.0 to 26.3×10^{-7} μg . Included in their series were six cases of pernicious anaemia, the mean value for those being 16.0×10^{-7} μg . Values higher than the present figure of 8.81 were also found by Davidson *et al.*, who in 17 cases of megaloblastic marrows reported a mean value of 12.7×10^{-7} μg . D.N.A.P. per cell. However, the latter figure represents approximately 180% of their mean value of D.N.A.P. per leucocyte (7.04), whereas the mean of the present series represents 150% of the present leucocyte value, so that differences between the present results and those of Davidson *et al.* probably depend on technique and may not be of great significance. Other important findings of Davidson *et al.* were that the mean content of D.N.A.P. per cell in megaloblastic marrows was higher than in normal marrows, marrows from cases of leukaemia, or marrows of iron-deficiency anaemia. Those authors considered that the high values in their megaloblastic series indicated the presence of nuclear abnormality, either polyploidy or polyteny. Such a theory is in agreement with the frequent finding of abnormal mitotic figures in megaloblastic marrow smears and with the suggestion, made by La Cour (1944), that tetraploid cells are common in the bone marrow of pernicious anaemia.

The present results, although they do not in any way invalidate the theory of nuclear abnormalities, are more in favour of the alternative hypothesis that the high cellular D.N.A.P. of the pernicious anaemia marrow is due to the presence of proliferating cells. In the hyperplastic normoblastic marrows a considerable amount of cellular multiplication was going on, and the figures for the mean cellular D.N.A.P. must depend on the fact that there was a mixed population of cells, some containing the diploid quantity, others containing an excess of D.N.A.P. in preparation for mitosis. The mean content of D.N.A.P. per cell for the whole series of pernicious-anaemia marrows is similar to that of the normoblastic series, which suggests that the same factors may have operated in each case.

Thus it would appear that the high cellular content of D.N.A.P. encountered in the bone marrow in pernicious anaemia may be due, not to some specific abnormality of mitosis, but to the prevalence in the marrow of cells of proliferative type.

Summary

Chemical estimations of nucleic acids have been carried out on suspensions of blood and bone-marrow cells.

The cellular content of R.N.A.P. is higher in pernicious-anaemia marrows than in hyperactive normoblastic marrows: accumulation of R.N.A. in the cell is therefore a specific feature of megaloblastic haemopoiesis.

The cells of pernicious-anaemia marrows and those of hyperactive normoblastic marrows contain approximately the same amount of D.N.A.P., the figures in each

case being about 150% of values for blood leucocytes. This finding suggests that many of the cells of the perniciosa-anaemia marrow are of proliferative type and are engaged in building up D.N.A. in preparation for mitosis.

CEREBROVASCULAR ACCIDENTS IN HOSPITALS FOR ACUTE CASES

BY

P. E. BROWN, M.B., M.R.C.P.Ed., D.P.H.

(From the Department of Public Health and Social Medicine, University of Edinburgh)

Patients with intracranial vascular lesions, especially those over 70, are a serious problem to the general practitioner called upon to arrange suitable care and accommodation. Hospitals are unwilling to admit cases likely to remain as chronic hemiplegics occupying acute medical beds for long periods. Those who do get admitted are often accepted with reluctance after tedious negotiations which are irritating to both house officers and practitioners. The attitude of hospital staffs would be easier to defend if it were not based as much on traditional prejudice as on an appreciation of what actually happens to these cases after admission.

This paper reports an analysis of 239 cases admitted after cerebrovascular accidents in which the length of stay in hospital and the eventual disposal have been investigated.

Material and Methods

The in-patient records of two hospitals were examined for the two-year period 1948-9. Extracts of age, sex, length of stay, and disposal were made of all cases admitted with the diagnoses of cerebral haemorrhage, thrombosis and embolism, subarachnoid haemorrhage, hemiplegia, and coma of unknown cause. The 239 cases collected were analysed with respect to length of stay in hospital by age and sex. The duration of symptoms before admission was not studied in detail, but only three of the cases were admitted as long-standing hemiplegics and the majority were victims of recent cerebrovascular accidents.

The two hospitals selected are situated in a large industrial county town in the midlands of England. Hospital A is an ex-voluntary hospital of over 600 beds with a casualty department. Hospital B is an ex-municipal hospital of 400 beds with no casualty department. Between them the two hospitals accommodate most of the acute medical admissions from a population of 600,000.

Results

Table I summarizes the patients with intracranial vascular lesions admitted to the two hospitals. Of the 239 patients 165 (69%) died in hospital and 74 (31%) were discharged. Of the discharges 61 (25.5% of admissions) were sent home, and 13 (5.4% of admissions) were transferred to other hospitals.

TABLE I.—Summary of 239 Cases with Intracranial Vascular Lesions Admitted to Hospital in 1948-9

	Hospital A			Hospital B			Total

Cumulative frequency diagram showing the percentage of patients remaining in hospital, discharged, or dead after a given period of time.

The length of stay in hospital is shown in the form of a cumulative frequency diagram. Over 30% of admissions died in the first two days. By the end of 10 days 54.2% had died and 5% had been discharged, leaving 40.8% still in hospital. After six weeks 67.6% had died, 21.8% had been discharged, and 10.6% remained. Only 3.8% stayed in hospital more than 12 weeks.

Table II gives the length of stay in hospital according to age. Of those over 60 years old 10 out of 141 (7.1%) stayed in more than six weeks, compared with 14 out of 98 (14.3%) of those under 60. The difference between these percentages is not significant. The number of deaths in the higher

hospital more than a given time, is also indicated. From this table can also be estimated the proportion of beds saved by transfer of cases after, say, three or four weeks to a special hemiplegic unit.

Discussion

It is surprising to find that less than 5% of patients with intracranial vascular lesions became chronic hospital patients, and these occupied only a small proportion of the total medical beds. Patients over 60, because of the high mortality in this group, were not especially liable to become chronic cases. In fact, it was the younger groups which provided the largest number of long-term cases, probably owing to their greater ability to survive grossly disabling lesions.

The most striking feature of this series was the extremely high death rate in the first few days after admission. The expectation of survival increased rapidly with the age of the lesion. Hospitals which accept early cases, particularly those with casualty departments where patients with sudden apoplexy are taken from the street, can expect a large intake, a high mortality, and a rapid turnover, with relatively few chronic survivors. Those which accept late cases will have a smaller intake, a low mortality, and a long average stay in hospital. For this reason the experience of some hospitals may differ considerably from the two which have been studied in this investigation. What the present series does show is that a generous acceptance of early cases is not necessarily followed by an accumulation of chronic hemiplegics.

There are good reasons why cerebrovascular accidents should be admitted to hospital as soon as they occur, irrespective of the age of the patient or other social factor. Rehabilitation must be started early if it is to prevent permanent disability from contractures (Rusk and Taylor, 1952). Old people must be forced to help themselves before they become reconciled to a life of bed-fast dependence. Such treatment is more effectively carried out in hospital than in the patient's own home. Denial of hospital facilities in these circumstances is likely to add to the number of helpless cases at large in the community, and in the long run actually increase the demand for their accommodation in beds for acute cases.

Summary

The hospital records of 239 cases admitted to hospital following cerebrovascular accidents have been examined.

Less than 5% remained in hospital more than three months. Patients over 70 were not especially liable to become chronic hemiplegics.

VALUE OF SERUM IRON LEVELS IN ASSESSING EFFECT OF HAEMATINICS IN THE MACROCYTIC ANAEMIAS

BY

C. F. HAWKINS, M.D., M.R.C.P.

Consulting Physician to the United Birmingham Hospitals;
Lecturer in Clinical Medicine to the University of Birmingham

The serum iron shows specific variations in different types of anaemia (Riecker, 1930; Powell, 1944; Laurell, 1947; Cartwright and Wintrobe, 1952). It is low when the cause is iron deficiency, infection, or malignancy. Higher values than normal usually occur in the macrocytic anaemias and in those due to haemolysis or hypoplasia of the bone marrow. Moore and Doan (1937) reported two cases of pernicious anaemia in which the initial high figures of serum iron fell to a low level during a remission. The following is a study of the variations of serum iron before and after treatment in the macrocytic anaemias. It was thought that a definite correlation between an early fall in serum iron and effective therapy might provide a quick and simple method of assessing the effect of a haematinic in the macrocytic anaemias.

Material and Methods

Macrocytic anaemias of all types, such as pernicious anaemia, the sprue syndrome, liver disease, and pregnancy, were studied. The patients were treated by an injection of a haematinic, usually vitamin B₁₂ or folic acid, in hospital. The response in the blood was measured by the rise in erythrocytes after 15 days (Ungley, 1949) and by the reticulocyte count.

The blood for serum iron estimation was always taken at about 10 a.m. to avoid errors due to the diurnal variation (Vahlquist, 1941; Hoyer, 1944; Hamilton *et al.*, 1950). Modern methods for serum iron determination (Laurell, 1947; Vannotti and Delachaux, 1949) are simple and accurate. A fastidious cleanliness is needed, as iron is a common contaminant; so that all-glass syringes and specimen tubes, dry sterilized and specifically cleaned, are used for taking samples of blood. The following technique, adapted by P. W. Perryman (1948, personal communication), has been used.

In a centrifuge tube is placed 4 ml. of serum, to which 1 ml. of 6 N HCl is added, mixed well, and left to stand for ten minutes. Then 3 ml. of 20% trichloroacetic acid is added, stirred with a glass rod, left for 5 minutes, and centrifuged at high speed for approximately 20 minutes. (A longer period may be necessary if particles are still present when the supernatant fluid is drawn off.) Then 4 ml. of supernatant fluid is placed in a glass-stoppered tube and approximately 50 mg. of ascorbic acid added and the solution left for 10 minutes, with occasional shaking to encourage the ascorbic acid to dissolve. Finally, 0.5 ml. of α -dipyridyl in 0.1 N HCl, or 1 ml. of 0.1% orthophenanthroline, and 0.5 ml. of concentrated ammonia solution, are added. The tubes must be agitated well immediately on adding these last two solutions. 1 ml. of doubly distilled water is added to bring the final solution to 6 ml. for the cell of the spectrophotometer (Unicam, S.P.500). The blank consists of 3 ml. of doubly distilled water, 0.5 ml. of 6 N HCl, 1.5 ml. of 20% trichloroacetic acid, then ascorbic acid, reagent, and ammonia solution as above.

Calibration curves were prepared by making known solutions of ferrous ammonium sulphate, through the range of 50 to 500 μ g. per 100 ml., and putting them through the same process as for serum. If, for other reasons, it is desirable to avoid using strong ammonia in the laboratory,

0.5 ml. of saturated sodium acetate can be used as a buffer instead; for this, the serum is incubated at 37° C. for one hour with 2 ml. of 0.3 N HCl, then 2 ml. of 20% trichloroacetic acid is added, and the solution left for one hour. Otherwise there is no change in the technique. All the glassware is washed, left in cleaning fluid (potassium dichromate 100 g., sulphuric acid conc. 800 ml., water 1,200 ml.), washed thoroughly again in running tap-water, then rinsed in distilled water. All the reagents must be chemically pure, and made in doubly distilled water.

The standard deviation of a single determination from the mean, calculated from 42 duplicate analyses, was $\pm 3.05 \mu\text{g. per 100 ml. of serum}$. Seventy-four samples were analysed from 48 normal males and 26 normal females. The mean serum iron concentration was $126.8 \mu\text{g. per 100 ml. (S.D. 30)}$, and the values ranged from 71 to 205 $\mu\text{g. per 100 ml.}$ The mean serum iron for males was $130.8 \mu\text{g. per 100 ml. (S.D. 30.8)}$; for females, $119.4 \mu\text{g. per 100 ml. (S.D. 27)}$.

Results

The serum iron was studied before and after therapy on 100 occasions. In 60 the treatment was effective, and in every case the serum iron fell to a low figure during the remission. In 40 the haematinic was ineffective and the serum iron remained within similar limits. The fall in serum iron after successful treatment is striking and abrupt (Fig. 1). It was next determined how soon this took place,

FIG. 1.—The fall in serum iron after effective treatment by folic acid in a case of megaloblastic anaemia of unknown origin.

and the earliest reliable time to estimate this change. To six patients with pernicious anaemia an injection of 100 $\mu\text{g. of vitamin B}_{12}$ was given, and readings were taken at two-hourly intervals for eight hours; a significant fall occurred in one only. However, at 24 hours a significant change was obvious in 21 out of 23 cases; in the two with little or no change a further figure at 48 hours showed the characteristic fall. It was thereafter decided to rely upon the 48-hour reading of the serum iron.

The 48-hour reading of the serum iron has been studied on 33 occasions, and the change correlated with the result of therapy in every instance except one, a case of steatorrhoea in which a submaximal reticulocyte response occurred after vitamin B₁₂ without any rise in the red blood cells. Here the fall was transient and returned to normal within the week. The maximum change was $228 \mu\text{g. per 100 ml. (from 278 to 50 } \mu\text{g. per 100 ml.)}$, and the minimum significant fall was $20 \mu\text{g. per 100 ml. (from 46 to 26 } \mu\text{g. per 100 ml.)}$; the mean was $105 \mu\text{g. per 100 ml.}$ Whatever the initial height of serum iron, the values tended to fall to about the same level (Fig. 2); they then remained at about 50–60 $\mu\text{g. per 100 ml.}$ —unaffected by the reticulocyte response—until the blood count returned to normal. Insufficient dosage of the

haematinic was shown by the serum iron rising to the previous levels. Impending iron deficiency was indicated by a fall to a lower level; values below 40 $\mu\text{g. per 100 ml.}$ were suggestive, and below 30 $\mu\text{g. per 100 ml.}$ diagnostic of this. The mean of nine cases at one week that later developed iron deficiency was $27.3 \mu\text{g. per 100 ml. (range from 11 to 39 } \mu\text{g. per 100 ml.)}$. This often preceded the signs of iron deficiency in the blood count by several weeks.

The total iron-binding capacity (Cartwright and Wintrobe, 1949) was measured on five occasions before and after successful therapy. There is no significant change unless iron deficiency develops, when the typical high figures are seen. Twelve normal controls were given injections of vitamin B₁₂ or folic acid, and no change took place in the serum iron or total iron-binding capacity.

Discussion

The 48-hours serum iron test is a reliable method of assessing the effect of haematins in the macrocytic anaemias. A fall in the serum iron is probably the earliest sign of a haematological response, for the bone-marrow reversion is not complete until 32 to 72 hours (Davidson *et al.*, 1942), and the reticulocyte response does not appear for several days. The test is useful if the level of the initial red-cell count is such (3,000,000 cells per c.mm. or more) that the reticulocyte change is slight or inconclusive, and in out-patient trials where the patient cannot attend daily for reticulocyte counts. It is helpful in severely ill patients, in whom the earliest indication of effective therapy is needed as waiting may be dangerous. It is probably unaffected by a blood transfusion being given at the same time as the haematinic. It is the first sign of impending iron deficiency. It is not necessarily suggested that this test should be used for routine clinical work, as the reticulocyte response and the rise in red cells are already sufficient. However, the study of the macrocytic anaemias and their response to various haematins is becoming a complex problem, and it may be that a simple test, with a precise and sharp end point, will be of value.

The explanation of the fall to a low level is perhaps that the rate of release of iron from the stores, possibly by enzymic action, cannot keep pace with the increased demand. It is interesting that, irrespective of the initial height, the level after successful therapy is similar in all. This figure may represent a state of physiological balance between the stores and the bone marrow. The test is an index of an increased turnover of iron in the body, and the low serum iron a measure of erythropoietic activity.

Summary

A test for assessing the effect of haematins in the macrocytic anaemias is described.

The fall in the serum iron is the first sign of effective therapy.

The level of the serum iron gives the earliest indication of impending iron deficiency.

I am grateful to our deputy biochemist, Mrs. R. M. Lainbury, for doing the serum iron estimations, and to my colleagues

FIG. 2.—A composite graph showing the fall in serum iron following effective therapy in cases of macrocytic anaemia.

on the staff of the United Birmingham Hospitals for allowing me access to their cases. Dr. J. A. H. Waterhouse, of the department of medical statistics, also gave me helpful advice.

IRON DEFICIENCY IN PREGNANCY

BY

MARY FISHER, B.Sc., M.R.C.S., D.C.H.

Health Department, City of Oxford

AND

ROSEMARY BIGGS, M.D.

Department of Haematology, Radcliffe Infirmary, Oxford

Some fall in the level of haemoglobin during pregnancy is usual. This relative anaemia is often attributed to the rise in blood volume of 18–23% (Dieckmann and Wegner, 1934; Roscoe and Donaldson, 1946; Berlin *et al.*, 1953) which occurs towards the end of pregnancy. Since the haemoglobin levels of most non-pregnant women range from 80 to 95%, levels of haemoglobin of 70–85% at the end of pregnancy have come to be accepted as normal.

The fact that throws doubt on the "physiological" nature of the anaemia of pregnancy is that the anaemia can in most cases be prevented by the administration of iron (Corrigan and Strauss, 1936; Fullerton, 1936; Wills *et al.*, 1947; Klopfer and Ventura, 1951; Scott and Govan, 1949; Benstead and Theobald, 1952; Davis and Jennison, 1954).

The present investigation does little more than confirm this finding, but it was thought that our evidence should be added to that already available both because low haemoglobin levels in pregnancy are undesirable and because there is a continuing failure to recognize that they are unnecessary.

Plan of the Present Investigation

The investigation was carried out on patients booked for domiciliary delivery and attending two local health authority antenatal clinics between January, 1951, and April, 1953. All patients presenting themselves before the end of the fourth month of pregnancy were included. The haemoglobin levels were measured by the M.R.C. neutral grey photometer, taking 100% haemoglobin to be equivalent to 14.8 g.% of haemoglobin. Haemoglobin estimations were made at the first attendance, at 28 weeks, at 38 weeks, and six weeks after delivery. These dates are approximate, and occasionally the post-natal reading was at a rather later date.

Every patient was given an iron preparation by mouth from the time of first attendance until delivery. This was given in the form of one "fersolate" tablet (containing 3 gr. (0.2 g.) of ferrous sulphate) three times a day. The preparation was changed to "ferro-redoxon" (containing 2.04 gr. (132 mg.) ferrous sulphate and 50 mg. of ascorbic acid) if the patient complained of digestive disturbances or if the haemoglobin level had not risen. This change was made in about

half the cases, and it appeared that the preparation containing ascorbic acid was better tolerated. The main difficulty in satisfactory iron therapy during pregnancy is that patients who feel well cannot be relied on to take it regularly, partly because any minor discomfort is attributed to it and partly because they see no necessity for it. We explained that taking iron regularly would make them feel "fighting fit" for their labour and also for their return to household duties after the lying-in period. In general this produced ready co-operation. At every attendance the patient was given the exact number of tablets to cover the period till she was due to come again and was asked to bring back the box with any that were left. These were counted and the number was recorded. It is clearly impossible to be certain that all the tablets not returned were consumed, but we felt that the record was as accurate as it could be, short of seeing the tablets swallowed.

The investigation included 138 patients. Of these, five could not be persuaded to persevere with iron and were excluded. In 26 instances the complete set of haemoglobin estimations was not obtained, either because the baby arrived before the calculated date, so that the 38-week reading was not made, or because the patient removed from the district or was transferred to the care of a hospital or general practitioner. Three further patients were excluded because they were given blood transfusions after post-partum haemorrhage. The 104 remaining cases are listed according to age and parity in Table I. There were no complications of pregnancy or labour in these patients apart from three forceps deliveries.

TABLE I.—Age and Parity of 104 Women who Took Iron Regularly During Pregnancy

Age	Parity					
	0	1	2	3	4	5
Under 20	3	—	—	—	—	—
20–29	14	18	11	6	1	—
30–39	1	9	12	17	6	1
40 or over	—	—	3	1	1	—
Totals	18	27	26	24	8	1

Results

A difficulty in the analysis of the results of this survey is that a few patients failed to respond to iron therapy. We have isolated as a separate group all those in whom the haemoglobin level was still below 85% at 38 weeks and have termed them "non-responders." Table II shows the distribution of haemoglobin levels before the end of the fourth

TABLE II.—Haemoglobin Levels Before the End of the Fourth Month of Pregnancy in 104 Patients who Took Iron Regularly

	Hb Levels				Total
	80% or Less	81–89%	90–99%	100% +	
Responders	15	33	33	11	92
Non-responders	4	3	5	0	12

Note.—Statistical examination of the age and parity of the responders does not show any significant difference between the four groups.

month of pregnancy in both "responders" and "non-responders" and indicates that there is no systematic difference in this respect between the two groups.

The effect of iron on the haemoglobin level is illustrated in the chart, where the "responders" have been subdivided according to their initial haemoglobin. This shows that when the initial haemoglobin is below 90% the administration of iron leads to a marked rise during pregnancy. When the initial haemoglobin is above 90% there is little systematic change in the level. In all the "responding" groups the haemoglobin level is around 98% at 38 weeks and remains at much the same level for six or more weeks after delivery. The "non-responders," who show a general downward trend

in haemoglobin levels from 16 to 38 weeks, show a sharp post-partum rise to the same level as all the "responding" groups.

It is to be noted that very little effect on the form of the curves would be produced if the "non-responding" cases were included in the appropriate subclasses of "responders." In general the curves would be not more than 2% lower at 28 weeks, not more than 4% lower at 38 weeks, and unaltered post partum.

Change in mean haemoglobin level in pregnant women receiving iron. The line marked 75 gives mean values for 15 patients whose haemoglobins were initially 80% or under. That marked 85 refers to 33 patients starting between 81 and 89%. Similarly, 95 denotes the range 90-99% (33 patients) and 105 denotes initial levels from 100% upwards (11 patients). The interrupted line refers to the 12 patients classified as "non-responders."

Discussion

The results of this investigation suggest that patients whose haemoglobin levels are below 90% at the beginning of pregnancy are iron-deficient, since the level rises steeply when they are treated with iron. The patients whose haemoglobin level is over 90% at the beginning of pregnancy maintain their high level at 38 weeks when treated with iron. Thus the steady fall in haemoglobin repeatedly reported to be characteristic of pregnancy—for example, M.R.C. (1945)—does not occur if iron is administered, except in the small group of "non-responders." Moreover, the level of haemoglobin at 38 weeks is almost the same as that observed six weeks or more after delivery—again with the exception of the few "non-responders." This finding appears to dispose of the idea that a fall in haemoglobin as pregnancy proceeds is due to haemodilution and is therefore "physiological." It is possible that this process may occur in the "non-responders," in view of the sharp rise that they show in their haemoglobin level after delivery; alternatively, they may have been unable to utilize iron during pregnancy but able to do so after delivery. These 12 patients were clinically well at all stages. Full haematological investigations were carried out in six of them, but no cause for their failure to respond was found.

It has been suggested that even if the fall in haemoglobin which occurs in pregnancy is not prevented by iron therapy the patients are none the worse clinically (Samuel, 1952). It

is probable that this belief is widely held. In spite of repeated demonstrations that iron raises the haemoglobin in pregnancy, it is not administered routinely to pregnant women. It is, of course, difficult to prove that patients with haemoglobin levels above 90% are in better health than those with levels between 70 and 80%. One gains the impression that at the higher level they are more energetic and tire less easily; and there can be no doubt that they are in a better position to withstand haemorrhage or infection. Apart from the benefit to the patients, the confidence of both doctor and midwife, particularly in domiciliary practice, is greatly increased by the knowledge that the haemoglobin level is high at term.

Throughout this communication the figures quoted are averages, and averages are in some ways misleading. In this small series, 15 of the "responding" patients had initial haemoglobin levels of 80% or less. Some of these, if untreated, might have had terminal levels of 60% or less and would have been in a dangerous condition if not transfused during pregnancy. Considered on a national scale, it is probable that these dangerously low levels (sometimes but not always detected and treated by transfusion) could be avoided in the vast majority of cases by iron therapy.

It is customary to give iron to pregnant women who are "really" anaemic, the critical level at which treatment is considered necessary varying from one centre to another. When facilities for haemoglobin estimations are not readily available the presence or absence of "anaemia" is sometimes judged clinically. This is highly fallacious, as one of us (M.F.) proved some years ago by comparing the haemoglobin levels in pregnant women as judged clinically and estimated in the laboratory. Comparisons were made on 173 occasions and an error of 10% or more was observed on 87 of them. The limits of error were a clinical overestimation of 34% and an underestimation of 46%. In view of the findings in our series of patients, it would seem advisable to prescribe iron for all pregnant women and to see that it is really taken. If this is done it is doubtful whether routine haemoglobin estimations are necessary, though any patient with symptoms indicating anaemia should be fully investigated in case she is suffering from the rare macrocytic anaemia of pregnancy.

Conclusions

The administration of iron in pregnancy ensures a high level of haemoglobin at term in about 90% of cases.

It is suggested that giving iron as a routine to all pregnant women is a valuable and inexpensive preventive measure worthy of general application. The safety of domiciliary midwifery—which is questioned at times—would undoubtedly be increased by this means.

We are indebted to Dr. R. G. Macfarlane for helpful criticism to Dr. Sheila Callender for the haematological investigation of "non-responders," to Dr. R. B. Fisher for statistical advice, and to Glaxo Laboratories and Roche Products Limited for generously supplying fersolate and ferro-redoxon respectively for this trial.

RECURRING MENTAL CONFUSION AFTER PORTO-CAVAL ANASTOMOSIS

BY

L. J. HURWITZ, M.D., B.Sc.

AND

R. S. ALLISON, M.D., F.R.C.P., D.P.M.

(From the Department of Neurology, the Royal Victoria Hospital, Belfast)

Alterations in the level of consciousness varying from light clouding to stupor and coma have been described after the operation of porto-caval anastomosis by McDermott and Adams (1954). Their patient had been so treated because of suspected carcinoma of the head of the pancreas, and "episodic stupor" could be induced readily by feeding with various nitrogenous substances. Earlier, Gabuzda *et al.* (1952) and Philips *et al.* (1952) noted that diets rich in nitrogen reduced many of their patients with cirrhosis of the liver to a state bordering on hepatic coma, and their findings are linked with the experimental work of Baló and Korpásky (1932), who produced "meat intoxication" in dogs with Eck fistulae. The mechanism is believed by Walshe (1951) and Riddell and McDermott (1954) to involve ammonia metabolism and the utilization of glutamic acid by the brain cells.

The electroencephalographic changes in developing hepatic coma have been reviewed by Adams and Foley (1953), who believe that constant although non-specific changes occur at first. These are paroxysmal, bilateral, and synchronous theta waves at 1½-3 c/s on a background of normal frequencies; gradually, with increasing mental confusion, the slow activity becomes dominant.

The following case is reported for its clinical interest and because the confusional episodes occurred spontaneously. They could also be induced by high-protein feeding and relieved by the reverse procedure.

Case Report

A Merchant Navy officer aged 52 was first seen on March 13, 1954. There had been excessive indulgence in spirits since 1923, but, apart from intermittent epigastric pain, no illnesses occurred until 1943, when he had jaundice. He recovered after some weeks, but in 1944 contracted syphilis, for which he was treated energetically with neoarsphenamine, the blood Wassermann reaction becoming negative. In 1952 there was a small haematemesis, and in February, 1953, a more severe one with melaena.

He was admitted to the Royal Victoria Hospital, Belfast, under the care of Dr. Robert Marshall, the chief physical findings being a firm palpable enlargement of the liver and spleen. On March 27, 1953, Professor H. Rodgers did a laparotomy. A cirrhotic liver was found, and a portal phlebogram showed gross intrahepatic distortion. A porto-caval shunt operation was performed. The post-operative period was marked by a low-grade pyrexia and slight jaundice, but on discharge on April 29 he was feeling fairly fit and had no symptoms or signs apart from the firm palpable liver, two fingerbreadths below the costal margin.

From that date until his readmission a year later, he had at least five attacks of "confusion," of which he had a hazy recollection. He readily admitted that most of the details had been furnished by his wife. The attacks described had a similar pattern, but varied a little in their effects. The first symptoms included "shakiness in the hands," noted especially when eating, writing, or dressing himself, and blurring of vision. He would feel "stupid" and unable to concentrate, and was difficult to waken in the morning. The

most striking episode occurred in November, 1953. Late one evening, just before retiring, he wanted to pass water but could not find the lavatory. He wandered all over the house, and then eventually went to bed unrelieved. Some hours later he got up and renewed his search. This time his wife noticed his peculiar behaviour and showed him the way; but after relieving himself he found he did not know how to unlock the door. His wife eventually had to go outside and climb in through the window to let him out. The following morning he was awakened with difficulty and then proceeded to dress himself, but, in his own words: "I could not get my clothes on properly. They were either inside-out or upside-down." His wife watched, amazed at his performance and his persistence in trying to dress, but when she went to help him he resented interference, and nearly one and a half hours elapsed before he had his trousers on properly. In the other episodes he was noted to be querulous and unreasonable at times, and on one occasion he micturated on the floor of the sitting-room. The patient himself did not relate his attacks in any way to increased ingestion of food.

He was readmitted in March, 1954, to the neurological department, having been referred to us by Professor Rodgers. He was fully orientated and co-operative, and displayed no definite signs of impaired mental function on formal testing. The tendon reflexes were symmetrically increased, but the plantars were flexor. There was a fine rapid tremor of the outstretched hands. No other abnormal signs in the central nervous system were elicited. The blood pressure was 170/100 mm. Hg, and there was a precordial systolic murmur, but no diastolic murmur was heard. The breath at times had a peculiar odour, difficult to describe—like fresh meat or concentrated liquid extract of vitamin B. The liver was firmly enlarged to two fingerbreadths below the costal margin and was slightly tender. There was no evidence of ascites.

The results of recent chemical and radiological tests are compared in the Table with those of a year previously.

Investigations

	February and March, 1953 (Pre-operative)	May, 1954
Blood W.R.	Negative	Negative
Bromsulphthalein excretion	3% retention	17% retention
Plasma proteins	6.8 g./100 ml. A/G ratio 1.8	5.8 g./100 ml. A/G ratio 3
Thymol turbidity	4 units	1.0 unit
Serum bilirubin	0.6 mg. per 100 ml.	0.8 mg. per 100 ml.
Alkaline phosphatase	8 units K.A.	12 units K.A.
Urinary chromatogram	Slight excess in amino-aciduria of a general pattern	Slight excess in amino-aciduria of a general pattern
Blood group	AB, Rh-positive	94
Haemoglobin	56%	1.0
Colour index	1.0	6,500 cmm.
White-cell count	7,200 cmm. (normal differential)	No significant lesion
X-ray chest	Suggestion of oesophageal varices	No evidence of varices
Barium swallow	Normal	Normal
Barium meal	Normal	228 mg. per 100 ml. (normal 99-111 mg.)
Serum copper	Normal	0.230 mg. in 24 hours.
Urinary	Pressure, 90 mm. C.S.F.; cells, 1; protein, 20 mg. per 100 ml.; W.R. negative	Lag storage curve
Lumbar puncture	Some resistance to insulin	
Glucose-tolerance test		
Insulin-sensitivity test		

Methods of Investigation.—The patient was given a basic diet containing 70 g. of protein daily. Additional protein was given by mouth in the form of "casilan." Electroencephalograms were taken at regular intervals and the mental state was assessed by observing the behaviour and applying simple tests for his ability to concentrate (counting forwards and backwards), to register and recall (name and address), to calculate, and to grasp simple problems (Kohs blocks) (see Fig. 1).

On a diet containing 170 g. of protein, the E.E.G. showed excess slow activity, he was unable to concentrate well, and his performance with the Kohs blocks was impaired. Within

24 hours of giving 270 g. of protein daily, both the E.E.G. and the mental state became grossly abnormal, the behaviour corresponding to that of his condition previous to admission. Thus on one occasion he wandered around the ward looking for the bathroom, and was quite indignant when told that another patient's cubicle was not the lavatory. He was observed to have considerable difficulty in dressing himself, and he complained of blurring of vision and "shaking." The fetor of the breath was striking. The tremor of the hands became more coarse with flexion and extension movements at the wrist, giving the "flapping" appearance emphasized in most reports, and recently by Sherlock *et al.* (1954). It is of interest that it was more pronounced in the right hand. He was disorientated in place and time, and was unable to draw the points of the compass, in doing which at other times he was accurate.

Examination of the cerebrospinal fluid at this stage gave normal results, the blood-sugar values being also in the normal range. The injection intravenously of 50 ml. of 50% glucose had no effect. However, as the daily protein intake was reduced so both the mental state and the E.E.G. returned to normal. Two values of the blood ammonia were taken, using the technique described by Conway (1935), and were found to be significantly raised.

Discussion

Other possible explanations for the symptoms considered in this case were neurosyphilis and hypoglycaemia, but the blood and cerebrospinal fluid were quite normal and there was no alteration in the state of the reflexes or in the pupils. Insulin sensitivity was investigated and the effect on the blood sugar of physical exertion noted, but the results were against any association with hypoglycaemia. Further, there was the convincing manner in which the symptoms and abnormal electroencephalographic findings could be reproduced by a high-protein diet. If this is the explanation, it is somewhat surprising that such quantities of protein were necessary to produce them. The patient's wife had no doubt that he did not eat comparable amounts at home, where the same symptoms were first noted. However, when the protein intake was reduced the symptoms were reversible

within 24 to 48 hours. It is possible that at home some added factor, such as alcohol or an intercurrent infection, combined to produce symptoms with a lower intake of protein, but we could not obtain any confirmation of this suggestion.

The normal pressure and the cellular and protein content of the cerebrospinal fluid at the time when confusion was maximal are in agreement with other workers (Adams and Foley, 1953). In spite of the clinical evidence of cirrhosis, except for the bromsulphthalein excretion liver-function tests were normal, so that it is likely that the presence of the shunt itself is significant in producing the disordered metabolism as suggested by Singh *et al.* (1954). The E.E.G. abnormality also proved reversible, the slow bilaterally synchronous waves giving way to a normal alpha rhythm (Fig. 2).

We would like to emphasize that we found the E.E.G. an extremely reliable and sensitive guide in predicting mental changes. Thus the most abnormal record preceded by 12 hours the development of severe confusion. The dressing dyspraxia was interesting. Experience with this case suggests that the symptom, although often a feature of parietal lobe disease (Critchley, 1953), is without localizing value and depends to some extent on a general lowering of the level of consciousness.

Summary

The case of a man aged 52 with cirrhosis of the liver is described. Following porto-caval anastomosis for portal hypertension, several episodes of mental confusion occurred which could be reproduced by high-protein feeding. Reversible E.E.G. changes were also seen giving way to a normal alpha rhythm. A high-protein diet is contraindicated in such patients.

Acknowledgments are due to Professor H. Rodgers for giving us the opportunity of investigating this patient. We thank Dr. J. H. D. Millar for the E.E.G. reports and Miss A. Coey, senior electroencephalographer, for technical assistance. We are also grateful for the advice Mr. D. Neill, of the biochemical department, gave us in planning tests and for the copper and ammonia estimations.

FIG. 1.

FIG. 1.—Results of investigation. Normal electroencephalographic record before increased feeding: grade 3, 3 c/s waves, main activity; grade 2, moderate excess; grade 1, slight excess, slow activity; grade 0, normal. Mental state: grade 3, disorientated, dressing dyspraxia, etc.; grade 2, tremor, blurring of vision, drowsy; grade 1, impaired concentration; grade 0, normal.

FIG. 2.—E.E.G. recordings taken, from top to bottom, on May 27, 29, and 31, and June 2, 4, 11, and 17, 1954.

FIG. 2.

ADDENDUM

We have seen another case through the courtesy of Professor G. M. Bull in which dressing dyspraxia was a prominent feature.

Case Report.—A man aged 59 was first seen in September, 1953, with oedema of the legs, ascites, and hypertension (210/120). A continuous venous hum was heard in the epigastrium (Cruveilhier-Baumgarten syndrome). A biopsy of the liver showed multiple nodular hyperplasia. He was treated with a high-protein diet and kept well until August, 1954, when his doctor reported: "Yesterday the patient became rather confused, and attempts to dress himself were unsuccessful." He was also reported to have melaena. On admission there was jaundice, and he was apathetic and disorientated. On examination there was enlargement of the liver and spleen, and ascites, and the venous hum was very marked. With treatment by low-protein diet he made a good recovery.

An annotation in the *British Medical Journal* (1954) refers to the dual role of liver damage and the effects of a porto-caval shunt in producing mental symptoms. It seems to us, however, that a third factor, not mentioned by the annotator, is important. In the first case described, alcohol and intercurrent infection, and in the second, gastrointestinal bleeding, may have played a part in precipitating the confusional episodes. One of us (Allison, 1952) has emphasized how often anoxia, dehydration, alkalaemia, the injudicious use of drugs, and electrolytic imbalance lead to psychiatric disturbances in later life. In both our cases the possible ancillary action of some such factor cannot be excluded.

MUSCULAR DYSTROPHY OCCURRING IN IDENTICAL TWINS

BY

A. G. BECKETT, B.M., M.R.C.P.

Senior Medical Registrar, Royal Free Hospital, London;
Late Medical Registrar, Addenbrooke's Hospital,
Cambridge

Since the second half of the nineteenth century muscular dystrophy has been recognized as a hereditary disorder (Gowers, 1879; Erb, 1891) although there has been disagreement about the way it is inherited. Much difficulty was experienced in the classification and genetics of the many varieties described. Recently further attempts were made to introduce simpler classifications, but, owing to the variability of expression of the defective gene and the similarity of the genetic types, difficulties remain.

After studying 1,228 cases from the literature and 113 case records from the National Hospital, Queen Square, Bell (1943) divided the dystrophies into three clinical groups: group A, the pseudo-hypertrophic form characterized by the enlargement of certain muscles, wasting of others, and progressive weakness in all affected muscles;

group B, cases with wasting and weakness of the affected muscles, no history of enlargement, and no affection of the facial muscles; group C, all cases in which the facial muscles were affected. She considered that there were three genetic groups—recessive, dominant, and sex-linked—and that the same gene could produce any of the three clinical types. This theory was supported by Boyes *et al.* (1950), who studied the history of an English and Canadian family in which both group A and group C occurred, the family distribution indicating a simple dominant type of inheritance.

More recently Tyler and Stephens (1950, 1951) suggested making only two groups: the childhood and the facio-scapulo-humeral groups. For the first type they preferred the term "progressive muscular dystrophy of childhood" to the more usual one of "pseudo-hypertrophic muscular dystrophy," as pseudo-hypertrophy may sometimes be absent in this group and present in the second one. This illness runs a steadily progressive downhill course, terminating fatally in adolescence or young adult life. It occurs only in males and is transmitted by females, the gene being a sex-linked recessive. The facio-scapulo-humeral type is inherited as a simple dominant affecting both sexes and half the offspring with a wide variability of expression and penetration. It starts usually in young adult life and runs a very variable course. Tyler and Stephens studied a large family in Utah founded by an affected emigrant born in 1775. In six generations there have been 1,249 descendants, of whom 159 have been affected with dystrophy of the second type. A similar classification was favoured by Ramsey and McCarroll (1952).

After studying 71 cases at Massachusetts General Hospital, Brown (1951) was unable to make a rigid classification but considered that the cases fell into three main groups: group 1, cases with pseudo-hypertrophy; group 2, cases with generalized muscular atrophy starting in the thighs; and group 3, cases with generalized muscular atrophy starting in the scapulo-humeral muscles.

Stevenson (1953) studied all the known cases of muscular dystrophy in Northern Ireland together with their families. There were 72 cases in 51 families. He concluded that there are only two groups: (a) the pseudo-hypertrophic variety occurring in boys and transmitted as a sex-linked recessive disease. For this he suggested the clumsy but more accurate title, "Duchenne type rapidly progressive muscular dystrophy of young boys"; (b) the second group consists of all the other types which he believed to be variants of the same condition determined by single autosomal recessive gene inheritance. For this group he suggested the term "autosomal limb-girdle muscular dystrophy."

The occurrence of a disease in twins is helpful in studying its heredity. Few twins, however, have been affected with muscular dystrophy, and so far there has been no report of the variety without hypertrophy occurring in identical twins. Stephens and Tyler (1951) described male identical twins who had the pseudo-hypertrophic form. The disease ran an identical course in each, being first recognized at the age of 6 years, causing complete incapacity at 11 years, and death, within a few months of each other, at the age of 25. No other member of this family was affected. The occurrence of progressive muscular dystrophy (without hypertrophy) in a male twin but not in the corresponding female has been reported by Milhorat and Wolff (1943) and Karnosh and LaTona (1947).

The cases reported here occurred in identical twin males who had muscular dystrophy of the autosomal limb-girdle type; one was severely affected, but the other only mildly so.

Case 1

An unmarried man aged 45 was sent to hospital to obtain an invalid chair. At the age of 18 he had noticed weakness of the legs, which was worse proximally. The weakness increased gradually during the next 13 years until after an attack of influenza at the age of 31 it became much worse and affected the shoulder muscles. Progressive weakness made him retire at the age of 38 from his work as a farm labourer with some blacksmith's duties. Deterioration continued slowly until a second attack of influenza at the age of 48, when again the weakness and atrophy increased rapidly, particularly in the legs. He has had no other illnesses.

Case 1.

On examination there was postural oedema of the feet but no other abnormality outside the muscular system. The gait was waddling, with marked lumbar lordosis. The buccinator muscles were weak but the other facial muscles were normal. The sterno-mastoid muscles were severely affected, being very weak and wasted. There was marked wasting of the shoulder-girdle muscles with winging of the scapulae. The deltoids were moderately weak and atrophied, as were the biceps and triceps, but the muscles of the fore-arms and hands were not so severely affected. The inter-costal and spinal muscles were weakened and wasted. There was severe weakness of all the muscles acting on the hip-joint, so that he was unable to raise his legs against gravity. The severe weakness and wasting of the legs was more marked proximally. No fasciculation was visible. Tendon jerks were diminished, commensurate with the muscular weakness. Plantar responses were flexor. There was no sensory loss. He was confined to the house, being unable to walk

more than a few yards, and this only with the aid of sticks. He could not get up from a sitting position without help, and once up could stand unsupported for only a few minutes.

Case 2

The twin brother, married but without children, was not aware that he was affected. He was able to do general farm duties without difficulty.

On examination no abnormality outside the muscular system was found. There was slight hypertrophy of the right deltoid. The legs were wasted, particularly the quadriceps, sartorius, and calf muscles. No demonstrable weak-

Case 1.

Case 2.

ness was seen. No fasciculation was visible. Knee- and ankle-jerks were slightly diminished. There was no sensory loss.

The twins were not weighed at birth, but were not full-term. The younger twin (Case 1) was born ten minutes after the other, there being one afterbirth, which came after the second twin. The parents observed that the younger twin was always a little slower than the elder, but there was no other difference between them as children. They were identical physically and were mistaken for each other even until recently. No other member of the family is known to be or to have been affected.

Discussion

In the younger, more seriously affected, twin the disorder started first in the proximal muscles of the legs. It has affected the facial muscles and has not produced any

hypertrophy. Thus the case falls into Bell's group C. In the elder twin the right deltoid is larger than the left, but this may well be work hypertrophy. His legs are the parts most affected, the facial muscles not at all. Thus his disorder falls into Bell's group B. Both cases fall into Brown's group 2, Tyler and Stephens's group 2, and Stevenson's "autosomal" limb-girdle muscular dystrophy group.

The physical characteristics of the twins were carefully examined in an attempt to establish that they were identical. There was a striking physical resemblance in spite of the marked wasting of the younger twin. The colours of their hair and eyes were the same; their height differed by only $\frac{1}{2}$ in. (1.3 cm.), whilst their biparietal, fronto-occipital, and bizygomatic diameters differed by no more than $\frac{1}{4}$ in. (6 mm.).

Their main blood groups were the same: ABO: A₁; Rh: CDe/cde; MN: M. The subgroups, done by the Blood Group Reference Laboratory, were the same:

	S	P	Lu ^a	Kell	Lea	Leb	Fy ^a
Case 1	+	+	-	-	-	+	+
Case 2	+	+	-	-	-	+	+

Although the fingerprints of identical twins are not the same, the fingerprints of these twins are of interest. All the impressions of the younger twin were of the type known as "ulnar loop" with the exception of the right forefinger, which was a radial loop, whereas the impressions of the elder twin were all ulnar loops except that of the left forefinger, which was the same pattern as that of the right forefinger of the younger twin—that is, radial.

These findings, although not conclusive, support the opinion of the family that the twins are identical.

It is noteworthy that the younger twin is severely incapacitated, whereas the elder is so mildly affected that he does not realize that he has the disorder. This raises the question of whether there is some environmental factor which determines the severity of the disease.

Boyes *et al.* (1950) found that in several of their cases the onset of the disease was associated with a specific environmental stress, and that a period of unusual physical strain precipitated the onset of the disease in the muscles under stress. Thus in one case the disease started in the shoulder of a woman after working long hours as a waitress carrying trays, and later affected her legs in pregnancy.

In the present cases no such explanation could be found. Both were brought up on the same farm and have lived in the same area since, the younger twin remaining at home and the elder at the age of 17 moving to the farm of an uncle only ten miles away. Their modes of life, nutrition, and work on the two farms were similar.

The two illnesses described by the younger twin as influenza caused marked deterioration on each occasion. It is possible that these illnesses were caused by a particular strain of influenza virus or some unusual type of virus which did not affect the other twin. It is more probable, however, that they were ordinary influenzal attacks, that the other twin has had similar attacks, and that some other unidentified factor has been responsible for the marked difference between the two.

Summary

Muscular dystrophy is reported as occurring in identical male twins now aged 45; in one the disease is severe and incapacitating, but in the other it is so mild that he is unaware that he is affected. No explanation can be given for this difference.

I wish to thank Dr. A. P. Dick for permission to publish these cases and for his help in the preparation of the report; Dr. Helen Dimsdale for her criticisms; Dr. C. B. V. Walker, of the Blood Transfusion Service, Cambridge, and Dr. D. M. Parkin, of the Blood Reference Laboratory, for their opinions in the blood grouping; Mr. P. Graham for the photographs; and the superintendent of the Huntingdonshire County Constabulary for the fingerprints.

ESSENTIAL PENTOSURIA*

BY

F. V. FLYNN, M.D.

(From the Department of Clinical Pathology, University College Hospital, London)

Essential, or idiopathic, pentosuria is a rare condition which has been included by Garrod (1923) among the inborn errors of metabolism. Its occurrence was first described by Salkowski and Jastrowitz in 1892, but since then only about 200 cases have been recorded in the literature, and only one clinical report dealing with the condition has been published in this country—namely, that of Cammidge and Howard, which appeared in 1920 and described seven cases. The early case reports have been reviewed by Garrod (1923) and Margolis (1929a), and, more recently, Bock (1944) has summarized the features of the condition in a review of the benign meliturias. Since 1944 case reports have been added by Bloomberg *et al.* (1946), Caven (1947), and Barnes and Bloomberg (1953).

The clinical importance of pentosuria depends on the fact that it may be confused with diabetes mellitus. Nowadays, however, when chemical confirmation of a diagnosis of mild diabetes is almost a universal practice, it is more likely to be misdiagnosed as renal glycosuria.

The identification of urinary reducing substances has been greatly facilitated by the introduction of paper chromatography. In the department of clinical pathology at University College Hospital we have been applying this method to identify the reducing substance excreted in cases which appear to have a low renal threshold for glucose. In the course of 4½ years two cases of essential pentosuria have been encountered. These two cases are described here and existing knowledge of the condition is reviewed.

The following methods were used: (1) Qualitative Benedict tests (Flynn *et al.*, 1953). (2) Bial's test (Lasker, 1950). (3) Osazones (Enklewitz and Lasker, 1935a). (4) Blood sugar (Hagedorn and Jensen, 1923). (5) Urine nitrogen (micro-Kjeldahl). (6) Urine xylulose (Lasker and Enklewitz, 1933), using the factor of Greenwald (1930a) for the calculation. (7) Chromatography (Horrocks and Manning, 1949), using a 3:2:1.5 *n*-butanol-pyridine-water solvent (Hough *et al.*, 1950) as well as the 4:5:1 *n*-butanol-acetic-acid-water mixture of Partridge and Westall (1948). The paraphenylenediamine reagent of Flynn *et al.* (1953) was used for showing up the sugar spots on the paper chromatograms.

*Based on a communication read at a meeting of the British Diabetic Association on July 17, 1954.

Case 1

A married Hungarian Jewess aged 34 was admitted to University College Hospital under the care of Dr. J. F. Stokes in May, 1950, suffering from infective hepatitis. During her stay in hospital it was noted that her urine gave a yellowish-green reduction of Benedict's reagent.

History of "Glycosuria."—Sugar was first discovered in the urine in October, 1947, when the patient was in University College Hospital under Dr. F. M. R. Walshe, with poliomyelitis. So far as she was aware this was the first time her urine had been tested. She was referred to the diabetic clinic, but failed to attend. She had no symptoms suggestive of diabetes at any time apart from two boils in October, 1949. She had gained 2-3 st. (12.7-19 kg.) in weight in the last three years. Glycosuria had been noted more than once by the several doctors she had consulted in the previous year, but she was told that her blood sugar was normal and that she had renal glycosuria.

There was no family history of diabetes, though the patient recalled that one of her three siblings had once been thought to have sugar in the urine.

FIG. 1.—Blood-sugar curve in Case 1 after 50 g. oral glucose. G_2 =yellowish-green reduction.

Investigation of "Glycosuria"

The urine was tested repeatedly over a six-day period. Reduction of Benedict's reagent was found to occur with all specimens, regardless of the time of day; most gave a yellowish-green reduction. Rothera's test was consistently negative.

A glucose-tolerance test was performed, the result being shown in Fig. 1. This shows a normal blood-sugar curve, but sugar is present in all three specimens of urine, the concentration being the same in each.

Paper chromatography of the urine disclosed the presence of a small amount of glucose and glucuronate and a large amount of another substance which we had not previously encountered. This unknown substance moved relatively fast on the chromatogram and was recognized, by the reddish colour produced on spraying with paraphenylenediamine, as being a pentose. The R_f value of this sugar was greater than that of xylose or arabinose, however, and was nearest to that of rhamnose. Subsequently we realized that the sugar must be xylulose (also known as xyloketose), and were able to confirm this by showing that it gave the typical chemical reactions, and had an identical R_f value to that of a synthetic xylulose solution prepared from xylose according to the method of Schmidt and Treiber (1933).

Chemical studies showed that the urine gave a positive Lasker-Enklewitz test (see below), and a positive Bial test. The reducing property of the urine was destroyed by treatment with dilute hydrogen peroxide solution (Enklewitz, 1936), and by heating with strong acid (Enklewitz and Lasker, 1933), but treatment with bromide did not affect the results of reduction tests (Greenwald, 1930a). An osazone was prepared which showed the typical properties of L-xylulose (Greenwald, 1930a, 1930b; Barnes and Bloomberg, 1953). Direct examination of the urine in the polarimeter did not disclose any optical activity.

The concentration of xylulose was estimated in a random afternoon specimen of urine and was shown to be 0.5 g. per 100 ml. The concentration of other reducing substances present was 0.2 g. per 100 ml. (when expressed as xylulose).

Case 2

A German Jewess aged 55 first attended Professor M. L. Rosenheim's out-patient clinic at University College Hospital in February, 1951, having been referred by her doctor on account of hypertension. Diabetes was said to have been present for 30 years. On examination the only abnormal findings were a blood pressure of 225/130 and a bluish-green reduction of Benedict's reagent on testing the urine. No ketones were present. A diagnosis of benign essential hypertension was made.

History of "Glycosuria."—In 1919, when the patient was aged 24, her urine was tested for the first time. She had been feeling unwell immediately following her father's death, and while in Austria consulted a chemist, who found sugar and acetone in her urine. She had lost much weight, and her cousin, a doctor, diagnosed diabetes. She was put on a strict diet in a clinic at Wiesbaden, and subsequently attended there each year for 12 years. In 1920 she was said to have had a coma. In 1923 she was given two injections of insulin, with severe reactions. In 1933 she gave up going to Wiesbaden and ceased to worry about her diet, as she found she kept well without it. She returned to it, however, before visits to her doctor. In 1936 insulin was tried again and was followed by fairly typical hypoglycaemic attacks. In 1941 she was in hospital in this country on account of pyrexia of unknown origin. Routine testing of the urine revealed sugar, and she was again advised to take insulin, but refused to do so.

It is also noteworthy that she underwent appendicectomy in 1924, left radical mastectomy in 1933, hysterectomy in 1943, and a further gynaecological operation in 1946, all without complications.

FIG. 2.—Blood-sugar curve in Case 2 after 50 g. oral glucose. G_2 =yellowish-green reduction.

The family history revealed that her father and her maternal grandfather had been known to have small amounts of sugar in the urine, but none of her five sisters was known to be so affected.

Investigation of "Glycosuria"

A glucose-tolerance test was performed, and the result is shown in Fig. 2. This shows a blood-sugar curve which is just within normal limits, but sugar is present in all three specimens of urine, the concentration being the same in all and unrelated, therefore, to the height of the blood sugar.

The urine-reducing substance was shown by paper chromatography to be a pentose and was subsequently identified.

FIG. 3.—Paper chromatogram of urine sugar from Case 2 with appropriate markers.

as in Case 1, as xylulose. A chromatogram of a later specimen of this patient's urine, with appropriate markers, is reproduced in Fig. 3, and shows the presence of glucuronic acid and xylulose. The large quantity of glucuronic acid in this specimen was due to prior administration of glucurone.

Further tests, carried out in June, 1951, when the patient was admitted to the wards, showed that the condition was in every way typical of essential pentosuria. The results (Figs. 4 and 5) show: (a) that the daily excretion of xylulose is constant at about 3.5 g. a day when no drug is being given, regardless of minor changes in the diet; (b) that xylulose excretion is not affected by feeding fructose; (c) that xylulose excretion is increased by administration of glucurone and amidopyrine; (d) that xylulose excretion is not related to nitrogen output; (e) that xylulose excretion is not related to urine volume; (f) that the rate of xylulose excretion rises more rapidly after glucurone than amidopyrine; and (g) that there is a direct relationship between glucuronate and xylulose excretion.

We were also able to demonstrate xylulose in the plasma by heavily loading protein-free filtrate on to paper chroma-

FIG. 4.—Urine findings during metabolic investigations in Case 2.

FIG. 5.—Correlation between urinary excretion of xylulose and glucuronate in Case 2. (Glucuronate excretion assessed from size and intensity of spot on chromatogram.)

tograms. It was just detectable in the fasting state, but the concentration was increased following administration of glucurone.

Urine specimens were obtained from the one relative resident in this country—a sister—and the first specimen reduced Benedict's reagent and showed xylose on chromatography. This startling finding must be attributed to fruit-eating, for subsequent specimens were sugar-free.

Discussion

Types of Pentosuria

These two cases are typical of essential pentosuria, which is characterized by the constant excretion of small amounts of L-xylulose. Other forms of pentosuria from which this condition has to be distinguished are alimentary pentosuria, in which arabinose or xylose is found in the urine after ingestion of a large amount of fruit or fruit product, and possibly also ribosuria, which has recently been claimed to accompany some cases of muscular dystrophy (Minot *et al.*, 1949; Orr and Minot, 1952).

Features of Essential Pentosuria

The incidence of essential pentosuria has been estimated from insurance records to be 1 in 50,000 (Larson *et al.*, 1937). It is found almost exclusively in people of Jewish lineage, but proved cases have been recorded in non-Jews (Barnes and Bloomberg, 1953). There is a distinct familial tendency, and the studies of Lasker *et al.* (1936) indicate that the disorder is inherited as a simple recessive. The condition has been found more often in males, but, as pointed out by Bock (1944), this may merely reflect the fact that more males than females apply for life assurance. It has been discovered at all ages, and persists throughout life. As yet no case has been proved to be present from birth.

The condition appears to be harmless to health. Margolis (1929a) noted that a high proportion of these patients suffered from headaches and were psychoneurotic; such symptoms, however, may have resulted from the patients worrying unduly about their so-called diabetes. In all cases reported by Cammidge and Howard (1920) excess urobilin and amino-acid nitrogen were found in the urine. This finding has not been confirmed by others and there was no amino-aciduria in either of the cases reported here. Excess urobilin was not found in the urine of Case 2 at any time.

The salient feature of essential pentosuria is the continuous excretion in the urine of small amounts of

L-xylulose. Usually 2-5 g. is excreted per day, the amount apparently varying with body weight (Enklewitz and Lasker, 1933); the concentration is always less than 1%. In the early literature arabinose was reported to be the sugar excreted, but later workers have agreed with Levene and La Forge (1914) that L-xylulose is the sugar present. Many cases reported as arabinosuria were in all probability cases of xylulosuria; indeed, two such cases have been proved to be so (Lasker, 1950). Wolfson *et al.* (1949) and Barnes and Bloomberg (1953) have shown by paper chromatography that pentosurics may excrete traces of xylose and other sugars in addition to xylulose.

For a given patient the amount of xylulose excreted is constant from day to day regardless of diet (Enklewitz and Lasker, 1935a). Feeding hexoses or pentoses is without effect (Cohen, 1910; Cammidge and Howard, 1920; Engle-witz and Lasker, 1933; Bloomberg *et al.*, 1946), but fasting for 24 hours has been shown to halve the excretion (Enkle-witz and Lasker, 1933). It has been claimed that the xylulose excreted paralleled the purine and protein content of the diet (Janeway, 1906; Cammidge and Howard, 1920), but Margolis (1929b) was unable to confirm this, and our results in Case 2 do not show an obvious relationship between nitrogen and xylulose excretion. Exercise and admin-istration of thyroid and insulin are without effect on xylulose excretion (Rabinowitch, 1925; Enklewitz and Lasker, 1933), but feeding glucuronic acid or drugs which are excreted as glucuronates—such as amidopyrine and codeine—results in increased excretion (Margolis, 1929a, 1929b; Lasker and Enklewitz, 1933; Enklewitz and Lasker, 1935a), as demon-strated in Case 2.

Metabolic Defect in Essential Pentosuria

Enklewitz and Lasker (1935a) seem to have established that glucuronic acid is the precursor of L-xylulose in pen-tosurics. Thus feeding them glucuronic acid or drugs excreted as glucuronates leads to increased excretion of xylulose, but feeding conjugated glucuronate is without effect. Moreover, there appears to be a direct relation between the amount of glucuronic acid administered or produced in the body and the extra amount of xylulose excreted. Our results in Case 2 seem to bear this out. It is odd that feeding drugs which are excreted as glucuronates should lead to increased xylulose excretion; presumably they stimulate the formation of more glucuronic acid than is required for their conjuga-tion.

As feeding glucuronic acid to normals does not lead to pentose excretion, the suggestion has been made that pen-tosuric patients have an abnormal enzyme system which decarboxylates glucuronic acid to yield xylulose (Everett, 1946). There is evidence, however, that L-xylulose may be a normal intermediary metabolite rather than an abnormal one. Thus L-xylulose appears to be metabolized by dogs (Greenwald, 1931; Larson *et al.*, 1939), and in a normal man, after oral administration of 5 g., none could be recovered in the urine in 24 hours (Enklewitz and Lasker, 1933). If L-xylulose is a normal metabolite in man then essential pentosuria could result from a block in the further metabolism of xylulose, for when 5 g. of L-xylulose was fed to a pentosuric an extra 0.5 g. was recoverable in the urine in the next 24 hours (Enklewitz and Lasker, 1933).

The nature of the error in essential pentosuria would appear, then, to be a partial or complete block in the meta-bolism of xylulose—one of the normal derivatives of glucuronic acid metabolism. A possible alternative explana-tion is that there is an abnormally large production of xylulose which overwhelms the mechanism that normally disposes of this sugar.

Diagnosis of Essential Pentosuria

Diagnosis depends on (a) discovering a constant meli-turia; (b) excluding diabetes by demonstration of normal glucose tolerance; and (c) identifying xylulose in the urine. Usually diagnosis is straightforward, but cases have been recorded with a coexistent diabetes (Edelman and Reiner,

1943), with diabetic symptoms (Enklewitz and Lasker, 1935b; Peterman, 1945), and where a reduction by the urine was not found in all specimens (Derivaux, 1943). In the case reported by Peterman the urine sugar was not proved to be xylulose.

Regarding tests for xylulose in the urine, that of Lasker and Enklewitz (1933) is an ideal screening test, as it can be readily performed by the clinician. It is carried out by adding 1 ml. of urine to 5 ml. of Benedict's qualitative reagent, mixing, and placing the test-tube in a water-bath at 55° C. for 10 minutes; if a water-bath is not available the mixture is left at room temperature for 3 or, preferably, 24 hours. The appearance of a yellow precipitate under these conditions is very suggestive of xylulose. Fructose, ascorbic acid, and glucose in high concentration may cause false positives, so confirmation is essential (Lasker and Enklewitz, 1933; Enklewitz, 1936; Barnes and Bloomberg, 1953).

For final identification of xylulose in the urine, paper chromatography provides the most satisfactory test, and is simpler than preparation and purification of osazones for melting-point and nitrogen determinations. With the use

FIG. 6.—Separation of sugars by one-dimensional paper chromato-graphy using 3:2:1.5 n-butanol-pyridine-water solvent.

of a butanol-pyridine-water solvent, and a spray reagent which distinguishes pentoses from hexoses, it is possible to identify all the urinary sugars on a one-dimensional chromatogram as shown in Fig. 6. It is likely that with the help of paper chromatography many more cases of essential pentosuria will be discovered.

Summary

Two unrelated cases of essential pentosuria are de-scribed; one masqueraded as diabetes mellitus, the other as renal glycosuria.

Results of metabolic investigations in one case are presented.

The features of the condition are reviewed and the nature of the metabolic defect is discussed.

The simple Lasker-Enklewitz test for detecting xylulose in the urine is described, and attention is drawn to the value of paper chromatography for final identi-fication of the sugar.

I wish to thank Professor M. L. Rosenheim and Dr. J. I. Stokes for permission to publish these cases and for helpful criticism; Mr. A. J. Cummings for valuable technical assistance; Mr. V. K. Asta for the diagrams; Mr. A. Bligh for the photo-graphs; and Dr. Ann Warrick for help with the manuscript.

TRUE HERMAPHRODITISM

BY

A. F. BROMWICH, M.B., F.R.C.S.
Surgical Registrar, Charing Cross Hospital

An individual who has both ovarian and testicular tissue is a true hermaphrodite. Proof of the presence of both types of gonad in the same individual is histological, as the secondary sex characters may be affected by other factors, such as overactivity of the adrenal cortex.

Adopting these criteria, an examination of the litera-ture has disclosed 59 unequivocal cases of true hermaphroditism, to which two further cases are added below. The further progress of the case originally recorded by Broster *et al.* (1938) is also noted.

Case 1

J. O., the third child of healthy parents of English extrac-tion, was first seen at the age of 16 months, having been brought for determination of the sex. No family history of any endocrine disease or congenital abnormality was forthcoming, except for talipes in the second child. The mother had suffered no illness during the pregnancy.

On examination the child appeared healthy and apparently normal except for the genitalia, which showed the following abnormalities. The phallus, about 3 cm. long, curved down-wards and had a hooded prepuce. About 3 cm. behind the phallus lay an orifice into which opened the urethra and a short recess. This recess admitted a probe for 2.5 cm. and presumably represented the lower part of the vagina. The labio-scrotal folds were rugose and contained no testes or hernial sacs.

Investigations.—Urinary 17-ketosteroids, 0.3 mg. a day (this is at the lower limit of assay, and indicates only that the 17-ketosteroid excretion was not increased). X-ray examination of the pituitary fossa showed no abnormality. The epiphysal bone age was 2-3 years—that is, about one year more than the actual age.

Operation.—Mr. L. R. Broster performed a laparotomy on July 17, 1953. A small (4 cm.) uterus was observed, from which ran two Fallopian tubes, terminating in fimbriated ends. In the usual position of the right ovary lay a structure about 2 cm. long, resembling a testis, a portion of which was removed for microscopical examination. No epididymis or other Wolffian elements could be found on either side. The adrenal glands felt normal in size and consistency. Samples of skin were taken from both sides of the abdomen for examination of the somatic nuclei by the method de-scribed by Moore *et al.* (1953). Dr. W. E. Evans reported

that the whole of the piece of tissue (8 by 3 mm.) from the right gonad consisted of immature testicular tissue, with seminiferous tubules separated by a loose, clear-celled stroma. Interstitial cells were not identified. A narrow fibrous capsule lay along one edge of the biopsy. The specimen, about 3 by 3 mm., from the left gonad consisted of a strip of young ovarian tissue beneath which was loose fibrous tissue. No ovarian "germinal" epithelium was found on the surface. Several ova were present, each sur-rounded by rather flattened cells with deeply stained nuclei, apparently derived from the ovarian stroma.

Skin Biopsies.—Professor M. L. Barr reported that a chromatin mass was present in less than 10% of epidermal nuclei. It has been observed (Moore *et al.*, 1953) that, in sections of tissue taken from a normal female, more than 80% of the nuclei seen contain a speck of chromatin on the periphery of the nucleus. In normal males such a mass is seen in less than 10% of nuclei in tissue sections. This observation is in accordance with the difference between the female sex chromosome pattern (XX) and the male pattern (XY). The nuclear picture in this case therefore conforms to the male type.

Case 2

P. F. was first seen in July, 1940, at the age of 20 months. The child had been brought up as a girl, but was already rougher and more masculine in behaviour than the elder sister, who was a normal girl. The patient was a muscular child with a deep voice and of normal intelligence. The phallus was about the normal size for a male of that age, but the urethra terminated at its base. No gonads could be felt in the scrotum, which was split, and a small uterus was palpated rectally.

Investigations.—Urinary 17-ketosteroid excretion, 0.3 mg. a day. Perineal insufflation gave no evidence of adrenal enlargement.

Operation.—Laparotomy was performed on September 1, 1940, by Mr. L. R. Broster. A small infantile uterus with fimbriated Fallopian tubes was found. Two gonads lay in the position of the ovaries. The left gonad was the size of a pea and the right gonad was slightly larger. No epididymis or vas deferens was seen on either side. Both gonads were removed for microscopical examination.

Professor H. W. C. Vines reported that the left gonad con-sisted of ovarian tissue and the right gonad of fibrotic testi-cular tissue.

The child was clearly more male than female in its behaviour, and was therefore brought up as a boy. From the age of 4 years a series of operations were performed to correct the hypospadias. Injections and local injection of testosterone from the age of 6 years have produced some increase in the size of the penis, which was, however, still smaller than normal when he was last seen in 1951 at the age of 13. He was then psychologically male, but rather shy, tending to cling to his mother.

Unfortunately, it has not proved possible to get in touch with the patient in order to obtain a sample of skin for nuclear examination.

Case 3

B. T. (Broster *et al.*, 1938) was regarded as a female at birth. At the age of 3 years, however, the child's social and legal sex was changed to male. Two years later hair began to grow on the face, legs, and pubis, and the voice cracked. When seen at the age of 9 years the child had a small penis with complete hypospadias and a split scrotum containing no testes. He was psychologically male. At laparotomy on November 30, 1936, at the age of 9, an infantile uterus with tubes was present. The gonads, which were in the position normally occupied by the ovaries, were shown by biopsy to be both ovotestes.

The patient's hypospadias was successfully repaired at the age of 14, and since then injections and implants of testo-sterone have been given to encourage penile growth.

When last seen, in January, 1954, he had the appearance of a normal adult male except for a small penis and no

testes in the scrotum. The nipples and areolae have a brown pigmentation, but there is no gynecomastia. Psychologically, he is a normal male and has been married for over a year. Intercourse has been achieved with some difficulty owing to the small size of the penis. Professor Barr has, however, reported that the nuclear picture in skin samples from both sides of the body is that of a normal female. The chromosomal determination is therefore at variance with the psychological sex.

Discussion

Diagnosis.—In many of the reported cases of true hermaphroditism the diagnosis was made incidentally during operation for other conditions such as hernia, or at post-mortem examination. The question of clinical diagnosis only arises in those patients brought for opinion because of genital malformation and consequent doubt about the sex. Such patients may be female or male pseudo-hermaphrodites or, much more rarely, true hermaphrodites. The female (adrenal) pseudo-hermaphrodite presents clinically with an enlarged clitoris and a uterus palpable on pelvic examination. There may be a history suggesting Addisonian crisis. The diagnosis is suggested by a raised urinary 17-ketosteroid level and confirmed by demonstration of enlarged adrenal glands, usually at laparotomy. The male pseudo-hermaphrodite or intersex with hypospadias and cryptorchidism will have no uterus and a normal urinary 17-ketosteroid level for his age. These two conditions may also be differentiated by examination of the epidermal nuclei, as outlined above. Most cases of true hermaphroditism have a uterus, and a phallus intermediate in size between penis and clitoris. The 17-ketosteroid level is, however, not raised. The diagnosis is made finally by laparotomy and biopsy of the gonads.

Classification.—From the published cases it appears that in true hermaphroditism either gonad may be a testis, an ovary, or ovotestis, independently of the condition found in the other gonad. The various possible combinations have been classified by Hinman (1935) as follows:

Type	One Side	Other Side	Reported Cases
Lateral	Testis	Ovary	22
Unilateral	Ovotestis	Ovary or testis	17
Bilateral	Ovotestis	Ovotestis	14
(Indeterminate)	"	Not sectioned	8

It will be seen that Cases 1 and 2 reported here are lateral hermaphrodites and Case 3 is a bilateral hermaphrodite. In the majority of lateral cases reported the adnexae on each side corresponded to the gonad on that side. In the case of Brachetto-Brian *et al.* (1943) the asymmetry involved the whole body, one half being male and the other half female. In Cases 1 and 2 above, and that reported by Davis and Scheffey (1946), however, the abnormality was restricted to the gonads, the adnexae being female on both sides.

Aetiology.—The case mentioned above in which one-half of the body was male and the other female is analogous to the condition of gynandromorphism found in lower animals, such as insects and birds. Crew (1927) has shown that gynandromorphism in insects is due to loss of sex chromatin at the time of the first division of the fertilized ovum. It is well known that anomalies are not uncommon at this stage of development, such as the complete or partial separation of the primary cells which is thought to give rise to identical or conjoined twins. Since genetic maleness appears to depend on the absence of a second X chromosome rather than on the presence of the Y chromosome, the loss of one sex chromosome during the first division of the female zygote would result in one male and one female cell. It is possible that some such mechanism may operate in man. In the higher animals, however, sex may not be absolutely predetermined by the sex chromosomes, and the genetic direction of development may be overridden by other factors, of which hormones appear to be the most important. The relative significance of genetic, hormonal, and environmental factors in producing the many different varieties of human hermaphroditism is as yet unknown.

Management.—The major problem in the management of these cases is to decide on the predominant sex. In patients first diagnosed in adult life it is usually found that the emotions are appropriate to the sex of upbringing (the "social" sex) and that removal of the inappropriate gonad and suitable hormone therapy to reinforce the remaining gonadal tissue is satisfactory. In children, however, it is difficult to predict the direction the emotions will take at puberty. This is well shown in the case reported by Lattimer *et al.* (1943) and Engle *et al.* (1946). This patient had been brought up as a girl, but was masculine in behaviour. At the age of 11 an ovotestis and an ovary were removed, leaving a third gonad, which was thought to be a testis. The patient was then regarded as a boy, but at puberty three years later a strong female trend became apparent. The remaining gonad was removed (and proved to be an ovotestis) and the social sex changed back to female.

In Case 1 above, the parents were advised to bring up the child as a boy in view of the testis being much the larger gonad and the large size of the phallus, and in spite of the presence of female adnexae. This advice was reinforced by Professor Barr's opinion on the somatic nuclei. In consequence of this decision the hypospadias will be corrected at a later date.

The third patient mentioned above is psychically a normal male, although the epidermal nuclear picture is that of a female. It must be remembered that the patient has been treated with testosterone and also emotionally conditioned to some extent by his environment. Nevertheless it would appear that considerable caution is required when assessing the results of skin biopsy in true hermaphrodites. It is of interest in this connexion that 16 cases of true hermaphroditism have been social females and 41 social males (plus 2 neonatal cases), whereas skin biopsy on five true hermaphrodites has shown four with a female nuclear picture and only one with a male picture—Case 1 described above (M. L. Barr, 1954, personal communication).

Cases in the Literature

True hermaphroditism is probably less rare than the number of case reports might suggest. Several cases—for example, Photakis (1916) and Moriarty (1944)—were discovered by chance at post-mortem examination. Young (1937) collected 20 cases from the literature, to which McIver *et al.* (1944) added 11 others and two of their own. Greene *et al.* (1952) collected 48 cases and added one, and Fischer *et al.* (1952) collected 49 cases and added one. Two cases in the latter's list were, however, rejected by Greene (Stirling (1946)—"microscopy of testis unconvincing"; and Malgras and Gricouroff (1939) as ovarian tissue was deduced indirectly and not demonstrated histologically). Excluding these two cases, we are left with a net total of 53 cases. To these must be added six further cases: Broster *et al.* (1938), Berardinelli (1952), Brewer *et al.* (1952), Baker *et al.* (1953), Delore *et al.* (1953), and Laycock and Davies (1953). With the new cases reported here, the total number of acceptable cases is therefore 61.

Summary

Two cases of true lateral hermaphroditism are reported and the further progress of a third (bilateral) case is noted.

The first case presents the clinical problem of predicting the predominant psychological sex in adult life when true hermaphroditism is diagnosed in infancy. In this case the chromosomal sex, as determined by the method of Moore *et al.* (1953), was male, which agreed with the preponderance of male gonadal tissue. On the other hand, the third case cited has grown up a psychologically normal male, but the chromosomal sex is female. This suggests that the chromosomal determination of sex is of limited value in these cases and must

be considered in conjunction with all the available clinical evidence in deciding on the sex of upbringing.

The diagnosis of true hermaphroditism rests finally on the histology of the gonads, but a tentative diagnosis may be made on clinical grounds.

Fifty-nine previous cases of true hermaphroditism have been found in the literature. This small number is probably not a true indication of the real incidence of the condition.

I am indebted to Mr. L. R. Broster for permission to publish these cases under his care, and for his encouragement and help in the preparation of this paper. I have also to thank Dr. W. E. Evans and Professor M. L. Barr for reports on the sections.

Medical Memoranda

Hair-grips as Foreign Bodies

The accidental swallowing of metallic foreign bodies by children is of everyday occurrence. The great majority pass through the gastro-intestinal tract without incident, being voided per anum in a few days, and, considering their size and shape, it is indeed remarkable how some manage to get through in tiny children without causing harm.

I would here like to draw attention to one variety of metallic foreign body commonly swallowed by young children—the familiar hair-grip. Hair-grips do not always pass through the gastro-intestinal tract with the same ease as the many other types of foreign body; sometimes they remain in the stomach or become impacted in the second part of the duodenum. This is particularly the case in very young children.

During the past ten years I have treated seven children with swallowed hair-grips and have had to resort to operation for the removal of the grip on four occasions. The four cases which came to operation comprised two girls and one boy, all under the age of 4 years, and one girl aged 7 years. The other three, all girls, were aged 4½, 6½, and 13 years, and in these the grip was passed normally in a short space of time. Fig. 1 is a photograph of the four sizes of grip in common use, and it is the third largest size which is usually swallowed.

In children, particularly those under the age of 4 years, the grip tends to remain in the stomach, or, if it passes the

pylorus, may become impacted vertically across the second part of the duodenum. Fig. 2 is an x-ray film showing the grip in such a position.

In two of the four cases which came to operation the grip was impacted across the duodenum, one child having swallowed the grip 17 days and the other 14 days before admission. The other two failed to pass the pylorus, one having been in the stomach five days and the other ten days before operation.

It is a simple matter to remove grips from the stomach, but nothing like so easy from the second part of the duodenum. In one of my two cases the grip was coaxed back into the stomach, and in the other it was coaxed onwards into the jejunum before removal, both being difficult manoeuvres. However, I feel it is better to coax the grip

FIG. 1.—Photograph (actual size) of the four hair-grips in common use. The third largest is the one usually swallowed.

FIG. 2.—X-ray photograph of a grip impacted vertically in the second part of the duodenum in a girl aged 7 years. The gas-filled shadows of the stomach and colon can be clearly seen.

into an accessible region for removal than to open up or attempt to mobilize the second part of the duodenum in a young infant.

Prevention is better than cure, and mothers should be warned not to use grips for dressing young children's hair, but instead to employ the old-fashioned hair-slide with a large ornamental ring attached. It is the practice of the nursing staff of the children's surgical ward at the Royal Bucks Hospital, Aylesbury, to remove all hair-grips from young children on admission.

In those who have swallowed a hair-grip, treatment with a bulky diet and "normacol" is at once started, and x-ray films are taken of the whole abdomen at forty-eight-hour intervals to check progress. All stools are examined for the passage of the foreign body. In many cases emetics have been administered prior to admission to hospital in the

hope that the foreign body would be vomited, a dangerous practice when pointed or sharp objects have been swallowed. Furthermore, children who have swallowed foreign bodies should be admitted to hospital without delay so that skilled surgical treatment is at once available should the necessity arise.

The danger of delayed perforation by a hair-grip from pressure necrosis of the bowel wall will be only too apparent, especially if the grip has been impacted for any length of time.

Surgeon, Aylesbury.

Effect of "Venostasin" on Serum Cholesterol Levels

In recent years attention has been drawn to the correlation in some instances between the serum cholesterol level and the occurrence of atheroma. The subject has been reviewed in the *Annals of Internal Medicine* (1950) and more recently by Gutman (1953). In 1953 Schimert and Schwarz reported that an extract of the horse chestnut, "venostasin," caused a significant reduction in the serum cholesterol level, which fell in 25 subjects from a mean level of 204 mg. per 100 ml. to 154 mg. after five daily intravenous injections of 5 ml. They found the extract inactive when given by mouth, but no toxic effects were noted after as many as 50 daily intravenous injections of 5 ml. each. The mode of action of venostasin is unknown, but if this effect is confirmed the material might prove of value in studying factors which influence the serum cholesterol level and in treating or preventing atheroma.

METHOD

Six patients were studied by a "double-blind" technique using venostasin and an inert solution of burnt sugar indistinguishable in appearance from the venostasin. Neither the analyst nor the person giving the material knew whether the patient was receiving the horse chestnut extract or the inert solution. After a control period of three days the patients were given a daily injection of 5 ml. of one substance for five or ten days, followed by the other substance for a similar period of time. Blood was collected in the fasting state at approximately the same time each morning, and the cholesterol level estimated by a modification (MacIntyre and Ralston, 1954) of the method of Zlatkis *et al.* (1953). Throughout the period of study the patients received an ordinary ward diet.

RESULTS

The results are shown in the Table and two illustrative examples in the Figure. In all six patients venostasin had no

Failure of venostasin or a solution of burnt sugar ("inert substance") to influence the serum cholesterol level in two patients.

detectable influence on the serum cholesterol level, whether this was in the high or in the low normal range.

Effect of Venostasin and an Inert Substance on the Serum Cholesterol Level

Case No.	Diagnosis	Average Cholesterol (mg. 100 ml.)		
		Control Period	Venostasin Period	Inert Substance Period
1	Essential hypertension	193	191	193
2	Peptic ulcer	188	197	198
3	Coronary sclerosis	339	327	340
4	Essential hypertension	312	297	326
5	Coronary sclerosis	228	198	191
6	Mitral stenosis	183	201	218

We are indebted to Dr. R. I. S. Bayliss, at whose suggestion and on whose patients this investigation was carried out.

Nitric Oxide Haemoglobin in Urine Due to Contamination

Nitric oxide haemoglobinaemia is probably incompatible with life. Banham, Haldane, and Savage (1925) described the finding of nitric oxide haemoglobin in the blood of a patient who died of pneumonia; they postulated a nitrifying organism in the blood as the agent producing the nitrification, though they did not confirm the identity of the abnormal pigment by spectroscopic examination. Barton (1954) described a fatal case of nitric oxide haemoglobinaemia due to sodium nitrite poisoning.

Nitric oxide haemoglobinuria has not been described. Below we report the identification of the pigment in urine, although the pigment was an artifact and not present in the patient.

A dark urine, which had been collected from a female patient in an open container eight hours previously, was examined in the laboratory. Nitric oxide haemoglobin was identified by spectroscopic and chemical tests (Harrison, 1947). As the patient was not desperately ill, but was suffering from stone in the urinary tract, the urine specimen was re-examined. It was found to be heavily infected with a mixed growth—one organism was a member of the *Bacillus* group. A catheter-specimen of urine was sterile. The mixed bacterial growth was cultivated in normal urine to which a little fresh blood had been added. The nitrifying action of the bacteria produced nitric oxide haemoglobin within 24 hours. The contaminated mixture was examined by a bacteriologist, but he was able to give no more detailed identification than the one here presented.

The conclusion reached was that the patient's urine originally contained blood: the haemoglobin was converted to nitric oxide haemoglobin as a result of bacterial contamination from the faeces, the container, or the air.

We wish to thank Professor Sir Charles Dodds for his interest in this case.

Reviews

OPERATIVE GYNAECOLOGY

Textbook of Operative Gynaecology. By Wilfred Shaw, M.A., M.D., F.R.C.S., F.R.C.O.G. (Pp. 444; 382 figures. £5.) London and Edinburgh: E. and S. Livingstone, 1954.

"Si monumentum requiris, circumspice"—these words, famed in other settings, could well be found on the title-page of this book. The author, whose contributions to gynaecological pathology and practice have made him famous, was in the front rank of modern teachers of obstetrics and gynaecology. His ambition to publish a *magnum opus* on gynaecology was half realized when he was stricken by a mortal illness. His active practice ceased, but, realizing that it was now a race with time, he laboured successfully with characteristic courage to complete the text of his book. Unfortunately, he did not live to see it published, or to correlate the manuscripts and illustrations—a task which was well completed by his junior colleague, Mr. John Howkins. This posthumous publication of a first edition is a great tribute to a distinguished and courageous man.

The early influence on the author of the Viennese school of Amreich and Werner is apparent throughout the book, and the debt owed to these masters is generously acknowledged. Mr. Shaw believed that in a textbook on operative technique the illustrations must be of the highest order. New blocks were made from some of the original pictures of Karl Hajek, and others were prepared from drawings by Erich Lepier; but most of the drawings with which the book is lavishly illustrated are the work of Mr. Leslie Caswell. These illustrations are of the highest standard and are an outstanding feature of the book. The captions are not always worthy of the drawings above them; for example, on page 181 the description of Fig. 126 refers to a left-sided hydrosalpinx when bilateral disease is portrayed, with no evidence of the adhesions referred to. On page 254, Fig. 190 illustrates a large enterocele which is described as a prolapse of the posterior vaginal wall. The drawings are, however, really superb, and their reproduction leaves nothing to be desired. They form a clear and permanent record of the technique Mr. Shaw adopted and taught.

A book so magnificently produced is necessarily expensive, and the prospective buyer must ask himself if it is worth the price. The answer will depend on what contribution he expects the book to make. If he wants a permanent visual record of how various gynaecological operations can be performed the money will be well spent; but surgery consists of much more than operative technique, and in the broadest sense this book is not a surgical guide. It reminds one of the student, harassed in a viva-voce examination, who when asked what treatment he would advise for menorrhagia due to fibroids seeks doubtful refuge in the evasive statement that "you can perform a subtotal hysterectomy, or perhaps a total hysterectomy, or possibly a myomectomy," and ends with the afterthought that "radiation might be used."

This book may not have a great appeal to those who have not had the good fortune to come under the personal influence of Mr. Shaw and who believe that surgery must be learned the hard way by apprenticeship to masters of experience and skill. For those who have been his students it should be in great demand as a beautiful record of the views and practice of an outstanding teacher.

JOHN STALLWORTHY.

PHYSIOLOGY AND BIOCHEMISTRY OF THE SKIN

Physiology and Biochemistry of the Skin. By Stephen Rothman, M.D. (Pp. 741+xiii; illustrated. £7 6s. 6d.) Chicago: The University Press. London: Cambridge University Press, 1954.

To review this book adequately would require the space allotted by the *Edinburgh Review* to Macaulay; for different

reasons both editor and reviewer must plead *non possumus*. Suffice it to say that for dermatologists, and for many physiologists and biochemists, this book is of exceptional interest; nothing similar has previously been published in English. Unlike many promising ventures, there are no large gaps in the subject-matter and no amateurishness in the presentation. It is, in fact, the mature work of a senior man aided by seven collaborators, and most readers will appreciate that the subjects considered not only have been thought over in the study, the library, and the laboratory, but are presented with the assuredness and dexterity of the expert who has had frequently to lecture about and teach his subject.

A look at the table of contents is enough to reassure most prospective purchasers; a rapid glance through the pages reveals a sufficiency of diagrams, tables, and illustrations, and an adequacy of references.

Rothman has written 21 chapters; they vary in subject-matter from the mechanical properties and electrical behaviour of skin to epidermal proteins and lipid constituents. As was to be expected, he has contributed several chapters concerning sweat and a few on sebum. G. C. Wells writes about connective-tissue ground substance; Z. Felsner about collagen, reticulin, and elastin; A. L. Lorincz on pigmentation and nutrition; A. B. Lerner on enzymes; H. Pinkus on the biology of epidermal cells; and P. Flesch on the growth of hair.

If one requires facts they are here in plenty; their presentation is often brightened with interesting and valuable speculations and comments on the clinical application of the work under consideration. Further, the information is culled from international sources and is not merely an epitome of American work. In greeting this book one can be certain that it is but the first edition of a textbook which is certain to run to many editions.

R. M. B. MACKENNA.

COLLECTED PAPERS OF OTTO FENICHEL

The Collected Papers of Otto Fenichel. First Series. Collected and edited by Hanna Fenichel and David Rapaport. (Pp. 408+xiv. 35s.) London: Routledge and Kegan Paul Ltd. 1954.

Fenichel was from first to last the classical exponent of classical psycho-analysis in both its theoretical and its clinical aspects. His earlier published work, it is true, was perhaps governed a little too much by a respect for correct tradition, and, being also extremely compendious, suffered from lack of perspective and discrimination—a common failing among psycho-analysts. But these faults in presentation Fenichel gradually corrected; and he thoroughly deserved the international reputation he ultimately gained as a good clinician, a cautious theoretician, and a sound teacher.

This first volume of collected papers is arranged in chronological order and covers the years 1922-35 inclusive. It therefore gives the background of his earlier approach to psycho-analysis and its many theoretical and clinical problems. (Fenichel died in 1946.) Although the volume covers a wide range, the most important contributions to it are those dealing with the concepts of introjection and identification; infantile sexual theories and the aetiology of some perversions; the Oedipus complex and its pregenital antecedents, in particular the early sexual development of the girl; and the concept of defence against anxiety through libidization. There is also an interesting paper on Freud's theory of the "death instinct," which Fenichel did not regard as of much heuristic value.

Fenichel was not a particularly original thinker or writer, and his boldest speculations concerned the concept of "respiratory introjection": though even here the credit for the concept of "respiratory erotism" belongs to the late David Forsyth. Nevertheless he is a persuasive writer, and this collection of papers should be obligatory reading for the psycho-analytical student. Although caviare to the general psychiatrist, it could also be perused with profit by his analytically minded confreres.

EDWARD GLOVER.

HORMONE RESEARCH

Recent Progress in Hormone Research: The Proceedings of the Laurentian Hormone Conference. Edited by Gregory Pincus. Volume X. (Pp. 511; illustrated. \$9.80.) New York: Academic Press Inc. London: Academic Books Ltd. 1954.

This book records the proceedings of the tenth Laurentian Hormone Conference, which took place in September, 1953, in Quebec. The subjects discussed included hormone relationships and the nervous system, the physiology of thyroid hormones, comparative endocrinology, the chemistry of protein hormones, the relation of hormones to blood formation and destruction, and three aspects of clinical endocrinology. The discussions were, as usual, brisk, expert, and fully reported. Dr. Jack Gross and Mrs. Pitt-Rivers stated that thyroglobulin contains monoiodotyrosine and diiodotyrosine, thyroxine, and triiodothyronine. Thyroxine and triiodothyronine escape into the circulation, and then thyroxine is strongly bound to a specified protein, which is deiodinated at the target sites to enter the cells as triiodothyronine. Bernhard Zondek maintained that oestrogenic hormone is the regulator of the ovarian cycle, small continued doses initiating pituitary activity and large doses inhibiting it. By inserting a pellet of 20 mg. of oestradiol benzoate sub-mucosally into the vagina, full function culminating in pregnancy was achieved in five patients with primary amenorrhoea and in thirteen with secondary amenorrhoea. Luft talked on electrolyte and fluid metabolism and discussed the results of hypophysectomy in the treatment of cancer of the breast and prostate and in diabetic retinopathy. It is too early to assess the therapeutic results of this operation; now, one year later, Luft finds the results of hypophysectomy in prostatic cancer more hopeful than in any other neoplasm.

The interesting physiological observation has emerged that it is possible to maintain for three or four weeks, without any substitution therapy whatever, patients who have undergone complete hypophysectomy: de Bodo compared this observation with the results in hypophysectomized dogs, which, despite consequent severe adrenocortical atrophy, were still able to conserve a sodium load normally.

Amidst much work that is of primary interest to biochemists this book contains a great deal which concerns the clinician.

D. V. HUBBLE.

CLINICAL NEUROLOGY

Textbook of the Nervous System—A Foundation for Clinical Neurology. By H. Chandler Elliott, M.A., Ph.D. Second edition. Introduction by Wilder Penfield, M.D. (Pp. 437+xx; 158 illustrations, and atlas of 50 plates. 72s.) London, Philadelphia, and Montreal: J. B. Lippincott Company. 1954.

This book has as its subtitle "A Foundation for Clinical Neurology," and it is essentially a textbook of the anatomy of the central and autonomic nervous systems as treated by the author, who is associate professor of anatomy at the University of Nebraska, in his lectures to medical students.

The arrangement of the book is unusual. The first section gives an outline account of the nervous system, and this is followed by a considerably longer section in which much fuller detail is included. This method naturally leads to a certain amount of repetition. The subject-matter is well handled and there is reference to function as well as to structure, which should make the book more interesting reading for a student. There are a large number of diagrams in the two sections, but some of them are rather difficult to understand. An unusual feature is an appendix of Latin and Greek words from which neuro-anatomical terms have been derived, and this should be useful, for, as the author says, "many students enter medicine without having been subjected to any Latin, much less Greek"—a state of affairs becoming more common in this country also.

The best feature of the book is the atlas of sections of the brain; this has been considerably enlarged since the first edition. Opposite each photograph is a line diagram on which are indicated the various structures potentially visible in the section, although it is by no means easy to recognize some of the structures so labelled.

J. W. ALDREN TURNER.

CARDIAC ENERGY

Myokardstoffwechsel und Herztherapie. By Dr. Med. Fritz Pendl. (Pp. 248+xii; 52 illustrations. D.M. 29.70.) Stuttgart: Georg Thieme. 1954.

The title of this book, which may be translated "Myocardial Metabolism and Cardiac Therapy," gives a very fair idea of its aims and scope. Though the subject is a difficult one, it is likely to become more and more important. After discussing the capacity of the human heart for work and describing the structure of the muscle cell, the author gives an interesting account of the origin of the cardiac energy. The part played by adenosine triphosphoric acid is fully dealt with.

In the next section is considered the influence of potassium, calcium, and sodium on the cardiac energy. Oedema and its treatment follow. Particular attention is given to the protection of the liver from damage so far as this is possible. There is a chapter on sugar metabolism, and the action of certain vitamins is considered.

Then finally the hormones are discussed. Each chapter has a full list of references and is provided with a practical summary. The matter is difficult and the expression is not always as clear as could be wished, but the author has made a very good attempt to present this most important subject in a way useful to the clinician. The emphasis on diet is greater than is usual in this country. Throughout the object has been to base therapy on a scientific foundation so far as present knowledge allows; the author points out how the study of these matters is still in a very early stage.

TERENCE EAST.

PERIMETRY

Perimetry. By Joshua Zuckerman, B.Sc., M.D., C.M., F.A.C.S. (Pp. 391+xxiv; 156 illustrations. 80s.) London, Philadelphia, Montreal: J. B. Lippincott Company. 1954.

A new volume on perimetry inevitably invites comparison with Traquair's book, and in the present instance a greater contrast in style could hardly be imagined. The economy and simplicity of Traquair are diametrically opposed to the reiteration and elaboration of this book.

Part I opens with a brief description of the usual apparatus employed in perimetry and continues with a dictionary of all the terms in common use, including brief notes on the pathological conditions which may produce field defects and the basic anatomy of the visual fibres. In Part II the instruments and technique are described in detail and the anatomy and physiology expanded. Normal and abnormal fields are then dealt with likewise. Part III is a summary at length of Part II and is followed by a tabular review of the whole book. Almost all the material is therefore presented some three times in varying arrangements and detail. For the duller student such a scheme may be useful, but it makes irritating reading for a practising ophthalmologist.

Disentangled from the reiteration, the substance of the book constitutes a good description of methods of examining the visual fields, of the anatomy and physiology of the visual paths, and of the field defects likely to be encountered in practice. There is little new matter, and a chapter on pitfalls in perimetry, containing some ninety items, fails to emphasize that the whole test is highly subjective and that elaborate perimetry is of no avail unless the patient is reasonably intelligent and co-operative.

E. S. PERKINS.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY FEBRUARY 12 1955

PREVALENCE OF DYSENTERY

Since it became notifiable thirty-five years ago dysentery has shown great changes in both incidence and severity. Notification was introduced because soldiers returning to Britain brought with them this classical companion of the martial camp, but in time the number of cases reported declined, until in 1925 (345 cases) the nadir was reached. Thereafter a slow irregular rise brought the number of cases to roughly four times that figure by 1936. An explosive rise occurred in the autumn of 1937, when there was a threefold increase, and this level was continued in the following year but fell sharply in 1939. This proved to be the first of five great waves—1937 (4,167), 1941 (6,670), 1944 (13,025), 1950 (17,286), rising steeply to 28,590 in 1951. The uncorrected notifications for 1954 total 33,976. Three of these waves are separated by deep troughs, but the years of comparatively low incidence now show many more notifications than in any year preceding the first wave. Accompanying this vast increase in the number of cases reported each year is an equally remarkable diminution in virulence. In 1925, when notifications were fewest, the case fatality rate was nearly 40%; in the last two years for which complete figures are available it was 0.2%; and in the last five years, when the apparent spread has been so great, there has been an absolute fall in the number of deaths from dysentery. Although *Shigella sonnei* undoubtedly caused human infection earlier, it was first recognized in Britain in 1926; and this is perhaps of significance because in the recent epidemic years almost all of the confirmed cases have been due to this organism. In the years when prevalence is less the proportion of Sonne infections is lower. The changes in reported incidence and case mortality of dysentery can be explained by assuming that in the early years there was a fall in the incidence of the more severe Flexner dysentery and that the increase since 1925 represents the spread of the much milder Sonne infection, superimposed on a small, fairly static number of other infections.

Sonne dysentery is essentially a disease of temperate climates. Although *Shigella sonnei* has often been

demonstrated in the Tropics, it is responsible there for only a small proportion of bacillary dysentery, and that this is not due to the milder infections being overlooked is shown by its relative infrequency in carrier surveys. That Sonne dysentery is also an infection which can spread rapidly where the standard of hygiene is relatively high we know to our cost in this country, and it differs from the majority of intestinal infections in being most common in the early months of the year. The frequency and extent of the spread of bacteriological infection in families, nurseries, and other institutions suggest that the infecting dose of *Shigella sonnei* is small. Compared with typhoid fever, in which the infecting dose is also small, the spread among contacts is much wider. Food-borne outbreaks of Sonne dysentery occur from time to time, but they are uncommon and do not account for more than a small proportion of the total cases. During an outbreak it is uncommon to discover a single common article of food, and *Shigella sonnei* has been isolated from foods much less frequently than the salmonella group of organisms, although the total Sonne infections greatly exceed the total salmonella infections. It seems preferable not to look on Sonne dysentery as a food-borne infection but to regard it as a "contagion," spreading directly from case to case with symptomless excretors and convalescent carriers playing some part. It is possible that the infection may also be passed on indirectly through infected fomites.

Most of the notified cases are in children, both of school age and under. Many outbreaks have been reported in schools, particularly in the infant classes, nursery schools, and day nurseries. Day nurseries in particular have been singled out as a possible source of infection of the general public, but there seems to be little to justify this view, since the decrease in the number of day nurseries since 1945 has not led to any fall in the reported incidence of the disease.

There seem to be real differences in the incidence of the disease both in time and in place. They are not fully accounted for by differences in diagnosis, notification policy, or laboratory facilities. In the large centres of population dysentery is probably always present. At some times it is confined to relatively small areas, not necessarily characterized by poor housing and overcrowding; at other times it spreads widely from these centres through the suburbs and into the surrounding countryside, but may miss completely many small and some large centres of population. The factors that determine whether the infection will spread widely or not are not well understood;

immunity of the population, housing conditions, social behaviour, even the weather may all play a part.

Almost all of the commoner bacteriological causes of human infectious disease have been split up in the laboratory into "types" by virtue of their different reactions to biochemical or serological tests or to different bacteriophages, and much of our precise knowledge of the way in which infections spread has been derived from a study of how the individual types spread. It has been possible to type strains of *Shigella sonnei* by a bacteriophage technique; but it has proved laborious to apply, the resulting types have not always proved stable epidemiologically, and the information gained has shown that the majority of all strains tested belong to a single type, so that we have not gained from this technique much additional insight into the way in which the organism spreads. Recent work on the distribution of sulphonamide-sensitive and resistant strains suggests that certain areas may well have their own individual infecting strains.

Sonne dysentery is not a very serious infection in man, yet it causes much discomfort and loss of working time and an appreciable number of severe and some fatal infections. The fatalities are mostly among the very young and the very old, debilitated by other conditions. It is a council of despair to recommend taking no action to prevent its spread, but we still lack sufficient knowledge to approach the problem in a practical way. To exclude all infected persons from school or work or from the society of their friends and neighbours entails more dislocation than the severity of the infection warrants. If we could recognize, as is possible to some extent in streptococcal infections, the dangerous carrier, a logical and practicable solution might perhaps be attainable, but at present all infected persons, young and old, with and without diarrhoea, have to be regarded as equally dangerous.

The widespread distribution in certain areas of strains resistant to sulphonamides suggests that chemoprophylaxis with these drugs can have but limited application, and the indiscriminate use of antibiotics cannot be recommended. Reports of outbreaks in schools provide some evidence that it is possible to control the spread of infection by excluding clinical cases and their home contacts from school, leaving the numerous symptomless excretors to continue to attend the school. Such action has the merit of being practicable. But much more experimental work is needed in schools, day nurseries, and other institutions before we learn how to control outbreaks effectively.

THE NATIONAL FORMULARY

A formulary provides a convenient collection of medical preparations for use in a community, and a national formulary reflects the prescribing habits of its country of origin. The existence of such formularies makes it unnecessary to prescribe a multiplicity of preparations with essentially the same composition and therapeutic value. The task of both prescriber and pharmacist is thereby eased and therapy is often made more efficient. The third edition of the *National Formulary—The National Formulary 1955*—is now being distributed and will be welcomed by all who have used its predecessors and have looked forward to an up-to-date version. Inevitably, however, its appearance in its present form will occasion criticism, for any volume so widely used by such a diversity of medical men is unlikely to meet with universal approbation.

Most ordinary prescribing demands can be met by the use of preparations included in the *Formulary*, which is admirably comprehensive and includes the more important effective modern therapeutic remedies. The new edition contains useful lists of those preparations which have been added to, and deleted from, the *National Formulary 1952*, and the substantial list of changes is a reflection of modern therapeutic advance with its recognition of the limited efficacy of many time-honoured remedies. It is therefore all the more surprising to find added to the formulary a number of preparations, especially mixtures, for which there is little therapeutic or pharmacological justification. They represent a concession to the extravagant lay and medical passion for a "bottle of medicine" and a reversion to the principles of Victorian and Edwardian polypharmacy. It is obligatory to prescribe only a strictly limited number of drugs—such as chloral hydrate or potassium citrate—in the form of mixtures, which are expensive compared with tablets and are a much less accurate way of prescribing medicines. It is therefore regrettable that an ammonia and senega mixture and a strychnine and iron mixture are added. The latter contains a negligible quantity of iron, but by its title may give the delusion of therapeutic efficacy. The inclusion of these formulae must represent the declared policy of the Joint Committee in the preface to include "a preparation, even if its justification on pharmacological grounds is disputed, if it is still being frequently prescribed." The committee has not always subscribed to this view; as, to quote the 1949 preface with regard to the exclusion of bismuth carbonate from antacid mixtures and powders, "The committee

realizes that these preparations are likely to be prescribed for some time to come, but it finds no evidence to show that bismuth carbonate has any advantage over, and should therefore replace, the analogous preparations which have been widely used in recent years and which are included in this formulary." This statement could be equally applied to several of the new formulae included in the 1955 edition. The new policy implies that the volume may be years behind contemporary advances in medical and therapeutic knowledge. The *National Formulary* is a potentially powerful and effective medium for the promulgation of good, sensible, and economic prescribing, and it should certainly have a more constructive function than that of slavishly following customs which may be ill-informed.

Major changes in the *British Pharmacopoeia 1953* were the substitution of English for Latin titles for monographs and drugs, and the use of the metric system for doses, imperial equivalents being quoted in brackets only where previously and traditionally used. The *National Formulary 1952* introduced English for the headings of subsections, despite the fact that in each section Latin titles were used for individual drugs. The arrangement of the sections was according to the alphabetical order of the English subsection headings, and this illogical compromise not unnaturally led to considerable confusion and irritation among users of the *Formulary*. The 1955 committee has taken what they realize will be regarded by a minority as a retrograde step, by deciding to revert to Latin for the titles of each group of preparations, and abbreviated Latin for the main title of individual preparations. This step will undoubtedly occasion some controversy. The committee has not seen fit to follow the lead of the *British Pharmacopoeia 1953*, and the *British Pharmaceutical Codex 1954*, and its refusal to follow such an authoritative lead may be a less reactionary step than some will undoubtedly think it is. The World Health Organization published in 1951 its *Pharmacopoea Internationalis*, and gave Latin names to the drugs listed in it, presumably on the highly sensible understanding that they would thus be readily recognized by users in the civilized world, and on the probable assumption that pharmacopoeias, at least in Europe, are in Latin. There is of course a practical side to this. Any national travelling or staying in a country not his own may need to have medicines prescribed by his home doctor dispensed by a foreign pharmacist: such a pharmacist should not have to cope with a vernacular prescription, or, for that matter, with a local system of weights and measures instead of the

metric system. In the *Formulary* not only are metric equivalents quoted for the older galenicals which have been traditionally prescribed in imperial measures, but imperial doses are given, quite unnecessarily, for modern preparations such as isoniazid, digoxin, and methyl thiouracil which never have been and never will be either prescribed or dispensed in such a form.

The monographs at the beginning of the book are of a high standard and have been thoroughly revised. Those on antibiotics, sulphonamides, analgesics, and hypnotics are particularly good, but it is unfortunate that phenadoxone, an ineffective analgesic not included in the *Formulary* itself, will still retain the cachet derived from its mention in the monograph. A useful new section on anthelmintics has been added, and that on expectorants deleted, an omission which reflects the contemporary opinion that they are unnecessary and ineffectual, and which was forecast by the terms of the monograph in 1952. The index is of first importance, and great improvements have been incorporated. It is now most comprehensive, with many useful cross-references, and greatly increases the value of the volume.

The *National Formulary 1955* has manifest imperfections which can be regarded as inevitable in a work with such a heterogeneous parentage, there being no fewer than eleven bodies represented among the thirty-seven members of the Joint Committee. Nevertheless it will be found to be of great value and assistance in practice and in hospital. It is a pity, however, especially from the viewpoint of the education of the younger generation of doctors and medical students, that it contains features which will undoubtedly retard the development of sensible, honest, logical, and economical prescribing habits.

ERADICATION OF TUBERCULOSIS

Until recently the steady decline of tuberculous mortality remained unexplained except as a reflection of rising standards of living or as the declining phase of a long-term epidemic which was started by the industrial revolution. During the past ten years, however, miniature mass radiography (M.M.R.) has provided a means of finding unsuspected sources of infection and the antibacterial drugs have enormously strengthened the clinician's therapeutic powers—a subject on which we have recently commented.¹ The results upon tuberculosis mortality have been dramatic. During the last six years the annual decline in mortality from

respiratory tuberculosis has averaged 15%, while the average decline for the previous ten years was a mere 1.5%. But a falling mortality from a chronic disease may be accompanied by a rising prevalence, and of this we have no satisfactory index. The annual rate of notification of new cases rose after the war, perhaps owing to mass miniature radiography, but in 1953 there was for the first time a decline in the figures despite increasing use of M.M.R. and increasing investigation of contacts,² so that it may be that morbidity as well as mortality is beginning to decline.

It is against this epidemiological background that the results (see p. 371) should be viewed of the first full deployment of medical resources against tuberculosis ever made in this country. The plan³ was simple—to x-ray the lungs of the school and adult population of a coal-mining community in the Little Rhondda Valley (The Rhondda Fach). Every case of tuberculosis was thus to be discovered, all those with a positive sputum were to be treated—the Welsh Regional Hospital Board providing special wards for this purpose. If sputum conversion could not be achieved these patients were to be kept under rigorous supervision by a health visitor to deter them from spreading their infection. The effects upon morbidity and mortality from tuberculosis were to be assessed by periodic x-ray and Mantoux surveys. The paper by Drs. A. L. Cochrane, J. Glyn Cox,⁴ and T. Francis Jarman which we publish to-day gives some preliminary results from the first of these follow-up surveys. They show first that the plan succeeded technically, since 90% of the population were examined at each survey, and 95% of those x-rayed the first time were x-rayed again two and a half years later. This is an almost unique achievement.⁴

Four indices of the effects of the surveys are reported. First, there was a steep fall in the crude mortality rate from tuberculosis among the women and non-miners, a fall that was proportionately much greater than that experienced by the neighbouring part of the Rhondda or by the rest of England and Wales. There was at the same time a rise in tuberculosis mortality among miners, but this can reasonably be attributed to changes in the accuracy of death certification, and by the fact that tuberculosis in association with advanced pneumoconiosis is resistant to treatment. Secondly, the crude results of Mantoux-testings of schoolchildren suggest that the conversion rate must have been very low between the surveys, but a detailed report on this is to follow. Thirdly, the

changes in the prevalence of tuberculosis are described. Large changes in such a chronic disease could not be expected, but, as a result of the treatment given, there was a notable decline in the prevalence of cases with a positive sputum, especially among the younger women; the decline was smaller among the men, and there was even an increase in the older men. After two and a half years 23.1% of the women and 41.7% of the men retained a positive sputum, the high rate of failure among the men being attributable largely to one quarter of the cases having advanced pneumoconiosis. These figures show that even to-day therapy cannot of itself be relied upon to control tuberculous infectivity.

The fourth and most important index was the attack rate of tuberculosis among those with normal radiographs in the first survey. At ages 15-24, it was 2.8% per annum for women and 4.7% for men, while at ages 25-34 it was 0.7% and 1.0% respectively. There was a negligible attack rate at later ages. This is the first time the attack rate of tuberculosis has ever been measured in a complete community in this country, so that it is impossible to say whether these are high or low figures; but a comparison with Springett's figures⁵ for Civil Servants in London suggests that the Rhondda rates are low. A full analysis of the factors affecting the attack rate is to be published later. Meanwhile a hint has been given⁶ that nearly all the new cases could be traced to contact with infectious cases before the latter were detected by the first survey and brought under control. If this is so, repeated surveys should undoubtedly achieve their object of reducing the attack rate to negligible levels and thus ultimately of abolishing tuberculosis from the community. One or two more surveys may be necessary, perhaps restricted to the younger age groups; and all known cases of tuberculosis (including massive fibrosis among the miners) will have to be followed to ensure that they do not become infectious.

The Rhondda Fach scheme is an example of epidemiology at its best, for the public benefits as research continues—research which is not confined only to tuberculosis and pneumoconiosis. Such diverse conditions as asthma, bronchitis, bronchiectasis, diabetes, hypertension, coronary artery disease, and rheumatism are also being investigated. Clinical research has been confined within the four walls of hospitals for too long. Pioneers such as the late Sir James Spence have led the way, and it is to be hoped that academic departments of medicine and surgery will increasingly undertake these field investigations as an essential activity. So far as tuberculosis is concerned the Rhondda survey has shown sufficient promise as a measure of preventive medicine to justify

any regional hospital board spending the necessary time and money to carry out pilot schemes of a similar nature. A clearer picture of the results which may be achieved will emerge when surveys have been carried out in areas where pneumoconiosis is not a complication.

FABRIC ARTERIAL IMPLANTS

Since 1912, when Carrel was awarded the Nobel Prize for his study of vascular transplants, there has been a steadily increasing literature on the subject which has appeared at a greatly increasing rate since the last war. Arterial replacement by means of autogenous vein grafts and arterial homografts was discussed in a recent leading article in this *Journal*.¹ The subject is again to the fore, for elsewhere in this issue Professor C. G. Rob and Mr. H. H. G. Eastcott describe the resection of an aortic aneurysm caused by tuberculous arteritis—a rare condition—with restoration of aortic continuity by an "orlon" prosthesis. It is certainly remarkable that a woven fabric identical with that used for clothing should be suitable for such a purpose. Blackemore and Voorhees² have already reported on the implantation of "vinyon N" cloth prostheses in eighteen patients, and Hufnagel³ has also recently mentioned that he is using plastic cloths of various types to bridge arterial defects.

Many attempts have been made in the past to bridge arterial gaps with inert tubes, but they have all proved unsatisfactory, usually because of thrombosis or anastomotic leakage. With a porous fabric, however, fibroblasts from the surrounding tissues migrate between the interstices of the material to form a tough fibrous tube of living tissue. The fabric thus bears the entire burden of arterial pressure in the first few weeks only. At operation blood leaks through the pores in the cloth for a few seconds. The inner surface is covered with fibrin and polymorphs within a few hours, and acquires islands of endothelial cells which coalesce within three months. Blackemore and Voorhees, before using this method clinically, found that cloth implants in dogs remained satisfactory for periods of up to three years: thrombosis or leakage occurred in only seven of the thirty animals of the series. Encouraged by this success, they have used "vinyon N" tubes in seventeen patients with aortic aneurysms and in one with a popliteal aneurysm. There was a high operative mortality (40%) due to the technical difficulties of clamping and suturing the diseased aorta adjacent to the aneurysm. These hazards are present also when homografts are used. Ten of the seventeen patients survived the operation and all have remained well: the longest period of follow-up in any patient so far is ten months.

It is too soon to assess the final results of arterial reconstruction with grafts or fabric tubes. Homologous grafts often calcify and have been known to rupture. The only justification for introducing homologous tissue or foreign material into large blood vessels is when the life of the patient or a limb is in jeopardy. At the

present time it is possible only to theorize on the relative merits of homografts and fabric tubes. Both are associated with the risk of rupture and thrombosis. As a rule the body ultimately rejects foreign material however inert it may be; the greatest use for it is as a scaffold on which living tissue can form, as in the repair of hernias with tantalum mesh. Such a process is claimed to take place around fabric tubes, so that it is immaterial if the fabric ultimately disintegrates by a process akin to metal fatigue. A word of caution is needed here, however, since collagen alone without elastic tissue can stretch. Collagenous tissue, artificially induced, not infrequently calcifies. Theoretically, then, fresh aneurysm formation and sudden rupture are still possibilities. The answer to this surgical problem should be available in ten years' time. In the meantime most surgeons will probably continue to use homografts, except when there is a special indication for a fabric implant. In the case reported by Rob and Eastcott there was a danger that an arterial homograft might become infected by the tuberculous tissue in the graft bed. In war surgery particularly fabric tubes would have the great advantage of availability and compactness: even if not a permanent solution to the problem of replacing wounded segments of major arteries they would be of great temporary value. If further laboratory and clinical experience eventually confirms that the results achieved by this method are permanently reliable, then, in the words of Brown and Hufnagel,⁴ "most of the problems relating to procurement, processing, storage, and transportation of arterial grafts will be solved."

IRON DEFICIENCY IN PREGNANCY

Blood is thicker than water, but less so in pregnancy. Varying figures are quoted, but W. L. Caton and his colleagues,¹ using radioactive isotopes, calculated that the total blood volume increased progressively in pregnancy by 45%, the peak being reached about the thirty-second week. The total number of red blood cells increased by about 40%, and the total amount of haemoglobin also rose. But a disproportionate increase of 55% in plasma volume caused haemodilution, so that the amount of haemoglobin per 100 ml. of plasma fell, producing the hydraemia or so-called physiological anaemia of pregnancy. A. S. Simpson² has recently pointed out that these factors make it difficult to interpret haemoglobin readings in pregnancy. He therefore also estimates the packed cell volume and thereby calculates the mean cell haemoglobin concentration. He contends that this concentration, which usually varies little through pregnancy, is the only reliable index of iron sufficiency, the critical level being 30.7%. Nevertheless, many clinical reports have been published over the last twenty years supporting the administration of iron to counter the usual fall

in haemoglobin concentration in pregnancy. Among the more recent workers, for instance, N. Benstead and G. W. Theobald* and L. R. Davis and R. F. Jennison⁷ have concluded that the so-called physiological anaemia of pregnancy is an indication of iron deficiency, and that an adequate intake of iron enables the concentration of haemoglobin normally found in non-pregnant women to be maintained throughout pregnancy. For maximum effect the oral iron must be taken from at least the twenty-fourth week.

On p. 385 of this issue of the *Journal* Drs. Mary Fisher and Rosemary Biggs offer further confirmation of this view. They carried out haemoglobin estimations on 104 pregnant women at the first antenatal attendance, at the twenty-eighth and thirty-eighth weeks, and also at the sixth week after delivery. They found that when the initial haemoglobin level was below 90% the administration of oral iron caused it to rise, while where the initial reading was over 90% this treatment maintained it at a high level. Twelve women did not respond to oral iron; in such cases the addition of ascorbic acid or dilute hydrochloric acid may be effective⁸; but it is doubtful whether the addition of molybdenum oxide is helpful. If there is no response to these preparations, and the patient is not suffering from the uncommon macrocytic anaemia of pregnancy, saccharated oxide of iron may be given intravenously or intramuscularly.

Drs. Fisher and Biggs remark that the clinical assessment of anaemia is highly fallacious, and they advise that, unless haemoglobin estimations can be done as a routine, oral iron should be prescribed for all pregnant women. They appreciate the difficulty of being sure that what is prescribed is really taken, but they claim that this treatment will probably avert dangerously low levels of haemoglobin. The attainment and maintenance of a high haemoglobin level during and after pregnancy not only increases the margin of safety for mother and foetus, but it also ensures the woman a quicker recovery from childbirth and gives her more energy to resume her household duties and to enjoy her motherhood.

ADMITTING TO HOSPITAL

Many general practitioners have had the frustrating experience of trying to persuade their local hospital to admit patients with certain disorders which do not, it seems, engage the hospital's interest. Typical of these are the victims of cerebral vascular accidents, about whom Dr. P. E. Brown writes at p. 382 of this week's *Journal*. He asserts that "those who do get admitted are often accepted with reluctance after tedious negotiations which are irritating to both house officers and practitioners." It is a familiar enough story, and some family doctors might admit that they have been driven to embellish the facts slightly in order to obtain an admission which they believed to be necessary: they may remember, too, the other side of the picture when they were residents in hospitals. Teaching hospitals naturally have to select patients in the interests of research and of teaching, and this gives the "interesting

case" an advantage when it comes to admission, though cases can be interesting for other than purely academic reasons, and not least because they are the sort that make up much of general practice. But it is not only irremediable cases about which general hospitals are apt to raise difficulties. There are, too, the unfortunate bronchitics suffering winter exacerbations, the man with recurrent retention of urine, the obese old lady who unaccountably develops urinary incontinence, and the sick man from the common lodging-house, regarded with disfavour because he might be dirty and verminous. All may have a fair and urgent claim to a bed in hospital. Even old age itself is held to tell against a patient's need for admission. While discrimination is necessary in an imperfect world, the criteria that govern it deserve examination every so often lest the convenience of the hospital and its staff come to overbear the medical and social needs of the individual patients.

Some management committees, backed by medical opinion, may take the view that their first duty is to get the younger patient, the productive element in society, back to work, and that the elderly and the unemployable must take second place for hospital beds and other facilities. Economically, this is a reasonable view; by other standards it is surely hard-hearted. Anyhow, the need to care for an elderly relative in a sudden illness may keep an able-bodied man or woman away from work. Hospital staffs fear also that such patients will block the beds for a long time; if this happens, admitting house officers do not always find their seniors sympathetic. Dr. Brown's figures may not apply to all areas and in all circumstances, but they are enough to show that, for cases of cerebral vascular accident, this fear has no foundation. Energetic and early treatment of patients who have survived the first impact of a cerebral thrombosis, or of elderly people who have lately taken to their beds for one reason or another, often makes them fit to return to an independent existence. Yet if they are neglected for even a short while a serious long-stay problem may be created. But family doctors can help to ease the strain on hospital beds by careful selection of cases whose admission they seek. Brown's figures suggest the advisability, for instance, of not asking for admission of patients with cerebral vascular accidents until after the third day, if home conditions allow, when 30%—those with a hopeless prognosis—will have died whatever is done. Again, simple arteriosclerotic gangrene, a traditional reason for prompt admission, should perhaps not be regarded as so urgent a matter, for the disease in many cases progresses slowly.

Part of the solution to these problems is to set up properly constituted geriatric units with adequate medical and nursing staff, led by consultants, having their own admission wards, rehabilitation departments, and long-stay annexes, with access to the facilities of a general hospital. Such units, relieved of duties towards younger patients and patients with short illnesses, need not discriminate against the rest. General practitioners in the areas where they have been set up are relieved of many worries. The units sometimes have the additional satisfaction of counting among their successes just those cases which others have rejected.

EMERGENCIES IN GENERAL PRACTICE

SUDDEN OCCLUSION OF A MAJOR PERIPHERAL ARTERY

BY

C. G. ROB, M.C., M.Chir., F.R.C.S.

Professor of Surgery, St. Mary's Hospital, London

Sudden occlusion of an artery may be due to an injury, either open or closed, an arterial embolus, or an arterial thrombosis. Any artery in the body may be involved, but in this article only sudden occlusion of the major arteries supplying blood to the limbs is discussed.

This catastrophe does not necessarily imperil the life of the limb; in many patients the collateral circulation proves to be adequate. The popliteal artery has a particularly bad reputation and the incidence of amputation following sudden occlusion of the iliac, femoral, and axillary arteries is also high. But in the case of occlusion of other peripheral arteries gangrene is a rarity and the clinical effects often transitory, whilst slow occlusion of a vessel as large as the bifurcation of the abdominal aorta may produce surprisingly little disturbance. Eleven out of 26 of my patients with thrombosis of the aorta at this level are able to work on a medical regime of treatment, admittedly at only sedentary occupations.

Clinical Picture

A patient with sudden occlusion of a major peripheral artery calls in his doctor because the limb has become cold, pale, and perhaps numb, because agonizing pain has developed at rest, or because of the sudden onset of severe exercise pain (intermittent claudication). The severity of the symptoms varies with the rate of occlusion of the vessel, which means that they are usually more pronounced when the vessel has been blocked by an embolus than when it thromboses. There may be a previous history of intermittent claudication, a stroke, or angina pectoris, pointing to an arterial thrombosis as the reason for the new symptoms; or the patient may be suffering from auricular fibrillation or bacterial endocarditis, indicating that an embolus is the likely cause.

Pain is said to be a marked feature of an arterial embolus and usually absent when the blood flow has been interrupted by a thrombosis or an injury. This is on the whole true, but some patients develop no pain after an undoubted arterial embolus and others suffer agonizing pain from a thrombosis. Later the limb becomes numb, and, if gangrene is likely, the muscles can no longer contract and ischaemia of the nerve fibres leads to complete sensory and motor paralysis; in other patients gangrene is averted but severe rest pain develops.

The limb at first is pale and cold; in a severe case the skin looks and feels dead. Later the skin becomes cyanosed and, if gangrene is certain, a dark purple colour; usually areas of pallor are adjacent to areas of cyanosis, giving the skin a blotchy appearance. The temperature of the environment is of great importance both to the rate of onset of the various clinical signs and to the chances of recovery. If the part is kept cool, skin can withstand severe anoxia for 48 hours or more, muscle for 10 hours or so; nerve conduction ceases after about 30 minutes. Recovery from complete anoxia is much more likely after restoration of the blood flow if the part has been cooled. On the other hand, if the part has been warmed, blisters may form on the skin within 12 hours and muscle becomes gangrenous within a few hours.

The pulses are absent distal to the lesion and increased proximally. Thus a patient with a popliteal embolus will have no palpable pulsation in either the dorsalis pedis or posterior tibial arteries, but the popliteal artery will be

unduly prominent because the embolus usually rests on the bifurcation of an artery and the main vessel above appears to pulsate more forcibly than on the normal side.

Treatment

There can be few emergencies which are influenced to a greater extent by good initial medical care than sudden occlusion of the main artery to a limb. Whilst admission to hospital should be obtained if possible, the first few hours are of great importance. Incurable changes can occur during this time. Simple measures taken in the patient's own home serve to minimize the effects of such a lesion. Unfortunately there can be no doubt that many patients with sudden arterial occlusion do not receive the best treatment. In particular, heating the limb by blankets or hot-water bottles does much harm. It can be stated that a patient who receives no treatment at all is better off than one whose limb has been either heated or elevated.

Treatment is discussed under the following headings: the reduction of the metabolic needs of the part; development of the collateral circulation; anticoagulants; maintenance of the patient's general health, and the prevention of infection and deformity; and surgical operations.

Reduction of the Metabolic Needs

This is best achieved by keeping the limb cool. It should not be frozen but exposed to the air at room temperature in temperate or cool climates or cooled by a fan in the Tropics. Cooling reduces cell metabolism and less oxygen is required, so that the part has a better chance of surviving until the blood flow is restored. Rest further reduces the metabolic needs: therefore active movements of the affected limb should be avoided and if necessary a light and well-padded splint applied. Rest may also be encouraged by the relief of pain, for which purpose pethidine, 100 to 150 mg., is usually more effective than morphine, $\frac{1}{4}$ gr. (16 mg.). For those patients with minimal pain a hypnotic such as amyl-barbitone, 3 gr. (0.2 g.), is of value. A good drug for this purpose is alcohol; this often relieves the pain of sudden vascular occlusion, probably because it is an antispasmodic, and at the same time it helps the patient to sleep. One to 2 oz. (28-57 ml.) of whisky or brandy four-hourly is a satisfactory dose for these patients. It is important not to elevate the limb; the position of maximum comfort which most patients adopt in bed with the head and shoulders raised on two or three pillows and the trunk and limbs flat is also the best position for an ischaemic lower limb. Some patients obtain considerable relief when the limb is dependent; in acute vascular occlusion this may be allowed, but not for long periods.

Collateral Circulation

The development of the collateral circulation may be encouraged in a number of ways. The most efficient and at the same time the simplest measure is to establish reflex vasodilatation. To obtain this the affected part should be cooled and the rest of the body heated. With the patient in bed the method we use is to arrange the bedclothes in such a way that the affected limb is exposed to the air. The patient's other lower limb should be covered with a thick woollen sock, and both it and the trunk covered with blankets; a long-sleeved sweater and vest should be worn over the pyjama jacket and the hands in particular should be warmed; this is most easily achieved by asking the patient to wear a pair of woollen gloves, although electrically heated gloves are better if available. In the case

of sudden occlusion of a main artery to the upper limb, this limb should be cooled, and the feet, trunk, and other hand warmed.

Evidence produced by Sir Thomas Lewis and others has established that the vasodilatation produced in this way equals and possibly exceeds that of either a sympathectomy or a sympathetic nerve block. In some patients reflex vasodilatation worsens pain, but this often coincides with recovery of the circulation and is therefore a worth-while price to pay. This pain can be reduced by pethidine, 100 to 200 mg., or, if less severe, by tablets of codeine or aspirin.

It is important that splints, dressings, or the patient's posture should not constrict the region of vascular occlusion around which the collateral vessels must develop. Vasodilator drugs are of value, but in my opinion no proprietary preparation is superior to alcohol as a vasodilator in patients with sudden peripheral arterial occlusion; as already stated, this should be prescribed in liberal doses. Papaverine hydrochloride, $\frac{1}{2}$ to 1 gr. (32-65 mg.), given intra-arterially, proximal to the lesion, may help to promote vasodilatation. Tobacco, on the other hand, causes peripheral vasoconstriction, and a wise patient stops smoking after sudden occlusion of a peripheral artery.

Sympathetic block with procaine hydrochloride or phenol is no better than reflex vasodilatation in promoting the development of the collateral circulation, but if performed with phenol it does enable some patients who would otherwise be bedridden to resume a sedentary occupation. It has no place in the treatment of an acutely ischaemic limb, but a real place in the treatment of elderly and poor-risk patients and of those who need prolonged sympathetic denervation but do not want a surgical operation. The technique consists in placing the patient on his side with the vertebral column straight, the third lumbar vertebra is located and a long (12-cm.) needle inserted at this level, and at a distance of 7 cm. (2 $\frac{1}{2}$ in.) from the midline; the needle should be directed inwards and advanced until it reaches the side of the body of the vertebra, it should then be manipulated until it slides forward to lie just in front of the convex antero-lateral surface of this bone. Aspiration serves to exclude the presence of blood or cerebro-spinal fluid, and then 4 ml. of 4% procaine should be injected; if this produces a sympathetic block 10 ml. of 10% phenol in water is injected and the patient told to lie still for half an hour. This type of block produces a long-lasting sympathetic denervation.

Anticoagulants

Anticoagulants have an important place in the management of patients with sudden vascular occlusion. They help to limit the extension of the thrombus, particularly into the vessel distal to the block where the blood flow is sluggish. They should be used as a routine during the acute stage in all patients with sudden occlusion of the main artery to a limb, and for long periods afterwards in certain patients with arterial thromboses. Heparin, 15,000 units, should be given at once, preferably by intravenous injection, alternatively intramuscularly, and repeated six-hourly for 18 hours. At the same time phenylindanedione, 200 mg., by mouth, should be given and repeated twice daily in doses of 100 mg. Phenylindanedione takes about 18 hours to become effective, and so this combination of drugs produces a rapid effect which can be maintained for an indefinite period by the oral route. Control is by the prothrombin time; this should be reduced to give a prothrombin level of approximately 20% of normal in the acute phase and to about 30% or slightly more when long-term out-patient treatment is used. Most patients reach this level on a dose of 75 mg. twice daily, but some require only 50 mg., and others as much as 150 mg.

Phenylindanedione, once the dose has been stabilized, does not cause wide alterations in the prothrombin level and is therefore a relatively safe drug; once the level has become stabilized, weekly prothrombin estimations are sufficient for control. Should an overdose of heparin be given

the antidote is an intravenous injection of 10 ml. of 1% protamine sulphate, and the antidote for phenylindanedione is 20 mg. of vitamin K₁ given orally. The above dosages for heparin and phenylindanedione refer to patients without a recent surgical or other wound. Both drugs are very difficult to control in patients with a recent wound, and should only be prescribed by those with considerable experience.

General Management

The general health of the patient must be maintained by ensuring an adequate intake of food and adequate sleep. Infection, an ever-present danger in ischaemic tissues, is best prevented by dressing all breaches in the skin with a careful aseptic technique and prescribing penicillin, 1,000,000 units twice daily, at the slightest sign that an infection is becoming established. Deformities may occur, particularly if a Volkmann type of contracture develops in the ischaemic muscle; these may be minimized by putting all joints through a full range of passive movement once a day. In some patients the ischaemic muscles are too painful to permit this. In these cases a light splint helps to prevent the development of gross deformities, particularly that of foot-drop.

Operative Treatment

Surgical operations, such as embolectomy, endarterectomy, arterial repair, or an arterial graft may succeed in restoring a normal blood flow. Others—for example, sympathectomy, incisions in the deep fascia, or arterectomy—may be used to assist the development of a collateral circulation. Alternatively, operation may be resorted to because conservative treatment has failed, when an amputation is necessary either for gangrene or for intolerable rest pain.

Embolectomy is rarely needed in the upper limb; the collateral circulation here is so efficient that the pulse usually returns to the wrist within 48 hours of a brachial embolus. On the other hand, embolic obstruction of the bifurcation of the abdominal aorta is best treated by immediate operation, as are many embolic obstructions of the popliteal or common femoral arteries. A great deal depends upon the appearance of the limb; in many patients the blood flow is returning by the time the patient reaches hospital, and conservative treatment with anticoagulants and reflex vasodilatation alone is effective; however, where there are good facilities popliteal or common femoral embolectomy usually pays, for by this means a normal blood flow can be restored. Arterial repair and arterial grafting have their most important indication in those patients with sudden arterial occlusion due to an injury; of obvious importance in war, these injuries when they occur in peacetime require adequate surgical treatment. For example, I have seen in the last two years three butchers who had accidentally divided their femoral arteries with their own knives; in one an end-to-end suture was possible, and in the other two an arterial graft was necessary; all now have patent vessels with a good blood flow and palpable pulses distal to the lesion.

Sympathectomy is of great value after the acute phase has passed; before this it has a place in those patients who cannot tolerate reflex vasodilatation. The object of the operation is to increase the collateral circulation around the occluded artery; therefore, those ganglia which control the appropriate area of the patient's vascular tree should be removed. For example, removal of the second and third lumbar ganglia denervates the patient from the knee downwards, and when the first lumbar ganglion has been removed the denervated area includes the upper thigh. In addition, sympathectomy makes the skin warm and dry—a valuable contribution to the welfare of a patient with an ischaemic limb. The other two operations designed to assist the development of the collateral circulation—arterectomy and incisions in the deep fascia—have in my view little real value.

Amputation, whilst being a last resort, should not be unduly delayed in patients with rest pain. The level varies

with the level of occlusion in the arterial tree and the efficiency of the collateral circulation. With experience, many patients can receive the added benefit of a conservative operation, but in others a major above-knee amputation is required. The important thing is to obtain primary healing of the skin flaps and a stump which is useful.

Conclusion

Sudden occlusion of a major peripheral artery is an emergency the outcome of which depends to a large extent upon the initial care which the patient receives. The importance of local cooling, reflex vasodilatation, and anticoagulants has been stressed. The ideal to aim at is restoration of the blood flow to normal, but this is not often possible. The alternative is to encourage the development of an efficient collateral circulation.

Refresher Course Books.—Copies of the first two volumes of collected articles from the Refresher Course for General Practitioners published in the *Journal* are still available at 25s. (postage 1s.) each. The first volume contains 55 articles and the second 60. Each article has been revised and brought up to date by its author.

These books may be obtained from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or through any bookseller.

LEGAL LIABILITY OF DOCTORS

In the fourth of his series of lectures* at the City of London College on February 2, Mr. J. P. EDDY, Q.C., discussed the liability of doctors, hospitals, and dentists to actions for negligence. In recent years, he said, there had been a considerable increase in the number of actions brought against doctors and hospitals. Figures provided by the Ministry of Health showed that payments by hospital authorities in England and Wales by way of compensation of all kinds amounted in 1948-9 to £7,500, in 1950 to £23,000, in 1951 to £38,000, in 1952 to £106,000, and in 1953 to £153,000. The causes of this increase of litigation were: (1) the changed status of the hospital; (2) the payment of hospital staffs; (3) the availability of free legal aid; and (4) the decision of the Court of Appeal under which hospital authorities were responsible for the negligence of their staffs.

*Changed Status of the Hospital

Formerly many members of the community devoted much time, thought, and energy to the welfare of the hospital, which was regarded as “our” hospital. Nowadays they were not taking the same personal interest and the hospitals were regarded as State hospitals. Consultants and other members of the hospital staff were formerly not paid or were paid such a modest sum that it might be described as an honorarium. Nowadays consultants, registrars, and house officers were paid a salary; they were appointees, or indeed employees of hospital management committees or regional hospital boards or boards of governors.

Again, the legal-aid scheme had made it possible for members of the public to institute actions against doctors or hospital authorities or both. The committees charged with the duty of issuing legal-aid certificates had been doing their work well, taking reasonable care to satisfy themselves that a prima-facie case existed before issuing a certificate. Where there was an allegation of negligence against a doctor or hospital a medical report was called for. In Scotland the prospective litigant had an opportunity of being heard before a certificate was granted. Mr. Eddy did not think that that

*The first lecture was reported in the *Journal* of January 22, p. 221.

was desirable; there should be nothing in the nature of a preliminary trial, it was enough that there was a prima-facie case.

Finally, the decision of the Court of Appeal in *Cassidy v. Ministry of Health* (1951, 2 K.B. 343) had transformed the legal position in regard to liability of hospitals for negligence on the part of their medical staffs.

Duty of the Doctor

The duty owed by a doctor to his patient was laid down in 1838 in the case of *Lanphier v. Phipps*. A doctor undertook to bring to the exercise of his profession a reasonable degree of care and skill, but before the duty arose there must exist the relationship of doctor and patient. If a doctor saw a person lying injured in the street and passed him by he was not guilty of negligence, because there was no such relationship and consequently he owed no duty; but if he played the part of a good Samaritan the professional relationship was created, even though the doctor had no hope of reward. Moreover, he was liable only when he undertook the treatment of a person, not when he merely examined him at the request of someone else. A doctor incurred liability when he set out to treat a patient, but not when he expressed an opinion at the request of another person (1920, 3 K.B. 163).

In the *British Encyclopaedia of Medical Practice*, Dr. Walter Levitt, pointing out that the doctor must exercise a reasonable degree of care and skill, added:

“What is a competent degree of skill will depend on the circumstances in which the practitioner finds himself. If he practises in a remote village, away from modern sources of inspiration and knowledge, very much less will be expected of him than if he practises in a large town attached to a hospital with every possible convenience and inducement for keeping his knowledge up to date.”

The duty of warning the patient of possible danger in the treatment to be undertaken was pointed out in the judgment in *Clarke v. Adams* (1950, 94 Sol. Jo., 599). In an earlier action in 1934, in which the patient complained that a hypodermic needle had broken and been left in her tissues, the defendant claimed that the breaking was due to muscular spasm on the part of the patient, and the judge, while finding that there was no negligence, came to the conclusion that the doctor should have told the patient of the accident. The patient was awarded five guineas damages. Mr. Eddy cited other cases which turned upon the adequacy of the warning given to the patient.

Hospital Liability

In 1906, in the case of *Evans v. Liverpool Corporation* (1 K.B. 160) the plaintiff claimed damages on the ground that his son had been discharged from an infectious diseases hospital while still in an infectious condition and had communicated scarlet fever to his other children. It was held that the plaintiff was not entitled to recover, for the legal obligation of the defendants extended only to the provision of reasonably skilled and competent medical attendance. To-day beyond any question the hospital would have been held liable.

Mr. Eddy mentioned the cases of *Lindsey C.C. v. Marshall* (1937, A.C. 97) and of *Gold v. Essex C.C.* (1942, 2 K.B. 293). The latter did much to clarify the legal position. It turned upon the failure of a radiographer adequately to protect a child's face when Grenz rays were being given. Mr. Justice Tucker held that the defendants were not liable for negligence, but an appeal succeeded, and it was held that a whole-time servant of the hospital, in failing to provide adequate screening material, rendered the hospital liable.

But it was the decision of the Court of Appeal in the *Cassidy* case, already cited, which was one of the reasons for the increased litigation to-day. This was a case originally tried by Mr. Justice Streatfeild at Liverpool Assizes. The patient, suffering from a contracture, had been treated in a Liverpool hospital, and in the treatment his arm had

been kept rigid in a splint for several days. When it was released it was found that the hand was to all intents and purposes useless. The case went to the Court of Appeal, and there Lord Justice Singleton said that it was clear that there was negligence in the post-operative treatment. He also pointed out that it was not possible for the patient to say that the negligence was that of any particular individual; it might be that a number of people were at fault or that lack of system was the cause. The responsibility lay upon the hospital. Lord Justice Denning said:

"If a man goes to a doctor because he is ill no one doubts that the doctor must exercise reasonable care and skill in his treatment of him, and that is so whether the doctor is paid for his services or not. But if the doctor is unable to treat the man himself and sends him to hospital, are not the hospital authorities then under a duty of care for their treatment of him? I think they are. . . . Why should it make any difference if he does not pay them (the hospital) directly, but only indirectly through the rates which he pays to the local authority or through insurance contributions which he makes in order to get the treatment?"

Lord Justice Denning also pointed out that, since the hospitals had no ears to listen through the stethoscope and no hands to hold the surgeon's knife, they must do it by the staff which they employed, and if the staff was negligent in giving the treatment the hospitals were as liable for that negligence as was anyone else who employed others to do his duties for him. This seemed all so clear that one wondered why there should have been any doubt about it, yet for over thirty years it was the general opinion of the profession that hospital authorities were not liable for the negligence of their staff in the course of their professional duties. When a doctor or surgeon, whether consultant or not, was employed and paid not by the patient but by the hospital authorities, he was of opinion that the hospital authorities were liable for his negligence in treating the patient. It did not depend on whether the contract under which he was employed was a contract of service or a contract for services.

Mr. Eddy went on to mention the case of *Jones v. Manchester Corporation* (1952 2 Q.B. 852) in which Mr. Justice Oliver found the doctor guilty of negligence in the administration of thiopentone to a patient who had been already anaesthetized. In this case the responsibility was apportioned as to 20% on the doctor and 80% on the hospital board. In the Court of Appeal Lord Justice Denning said in this case that the hospital board had no right to indemnity or contribution from any member of its staff except in so far as the court thought it just and equitable having regard to the extent of the person's responsibility for the damage.

After reviewing some other recent cases Mr. Eddy concluded this part of his lecture by again quoting Lord Justice Denning to the effect that the term "consultant" did not denote a particular relation between a doctor and hospital; it was merely a title denoting a place in the hierarchy of the hospital staff. The consultant was a senior member of the staff, but just as much a member of the staff as a house-surgeon.

Reports of Societies

STRIPPING OPERATION FOR VARICOSE VEINS

On February 2 the Surgical Section of the Royal Society of Medicine met to hear three papers, one of them by Professor J. B. KINMONTH on his experience of the stripping operation for varicose veins.

Professor Kinmonth explained that the operation of stripping varicose veins was not new. In the second century Galen avulsed them with a hook. At the beginning of this century the procedure was rediscovered by Keller, Mayo, Babcock, and others. After the first world war the injection

of sclerosing solutions came into vogue and stripping went out of fashion, and it was not until 1947 that the operation again became popular with the work of Myers. The design of the stripper had varied. Keller in 1905 used a length of wire which turned the vein inside out, and Mayo in the following year invented an extraluminal instrument similar to a tendon stripper. Babcock in 1907 used a rigid wire with an olive head, and Myers modified this by making the wire flexible. This was the instrument in use to-day.

Professor Kinmonth said that he preferred to strip the saphenous vein from below upwards, having first carried out a standard Trendelenburg operation at the groin. He made a transverse incision at the ankle and at the knee, and the vein was removed in two lengths, using a small stripper below the knee, since it was less traumatic and less likely to damage the saphenous nerve. When necessary both legs were treated at one operation. The commonest complication was haematoma formation, and various precautions were taken to prevent this: the operation was carried out in the Trendelenburg position, and a sterile Esmarch's bandage was applied as the vein was stripped and left *in situ* until the wounds were sutured. After the operation, wool and crêpe were applied and the Trendelenburg position was maintained for some hours.

Complications

The feared complications of stripping varicose veins were thrombosis and pulmonary embolism. Accordingly Professor Kinmonth made his patients walk the day after operation, and crêpe bandages remained in place for a month. In fact the danger of pulmonary embolism was no greater than in general surgical operations as a whole, and occurred in about 0.5% of cases. In a series of 204 stripping operations at St. Thomas's Hospital there had been one case. At St. Bartholomew's Hospital there was one case in 157 operations, and at University College Hospital one case in 237 operations. None of these were fatal. Similar figures have been reported from the Mayo Clinic. In 1950 Murley had reported that in a series of general surgical operations performed at St. Bartholomew's Hospital, where special precautions were taken, there were 6 cases of pulmonary embolism in 1,289 patients, an incidence of 0.5%, and at the Mayo Clinic the figures were similar. Professor Kinmonth felt that the results of the stripping operation for varicose veins was very satisfactory, and, although statistical evidence was almost impossible to obtain because of the nature of the condition, recurrences were fewer than with other forms of treatment.

In the ensuing discussion Mr. F. B. COCKETT stated that at the vein clinic at St. Thomas's Hospital stripping had become a routine operation in the moderate and severe cases, since it gave better results than other methods and reduced the operating time. He pointed out that ablating the saphenous vein did not necessarily interfere with all the perforating veins, especially near the ankle.

Mr. J. B. OLDHAM stressed the importance of conservative treatment for varicose veins and the division of all tributaries at the sapheno-femoral junction when doing the Trendelenburg operation. He felt that, although there was no one single operation which cured varicose veins, the stripping operation was the most promising so far. Concerning the technique, he advised a vertical incision at the ankle and application of strips of adhesive felt along the course of the vein as it was removed. Mr. H. DODD stated that he operated on one leg at a time because of the danger of venous thrombosis. He noted that the operation was singularly free from discomfort. The results were good, and in consequence post-operative injections of sclerosants were rarely necessary.

Professor KINMONTH, in replying to a question from Professor C. G. ROB, said that he occasionally stripped the short saphenous vein, but that it was not often worth while. He concluded by saying that the operation of stripping varicose veins did not cure the condition, and he told the patients so.

LOCAL MEDICAL SOCIETIES MANCHESTER MEDICAL SOCIETY

At a joint meeting of the Sections of Medicine and Pathology on January 12 Professor C. H. GRAY gave an account of "Some Clinical Studies of Urinary Adrenal Steroids."

He said that although there was evidence that the physiologically important hormones secreted by the adrenal gland were hydrocortisone, corticosterone, aldosterone, and two androgens, a very much larger number of substances chemically related to these were excreted in the urine. Some might perhaps be intermediates in the synthesis of the important steroids in the adrenal gland which had leaked out in small quantities. Others, however, were metabolites of the active hormones. It was small wonder, therefore, that the earlier methods of determining adrenocortical steroid hormones in urine had been unsatisfactory, either because of lack of specificity or because they estimate some functional group common to a number of metabolites. Separation and estimation of all the adrenal metabolites in urine was necessary for a complete picture but would tax the time and energy of a mammoth institute.

Hormone Assays in Endocrine Disorders

The estimation of cortisone, hydrocortisone, and tetrahydrocortisone by paper chromatography seemed to be of value in the diagnosis of hypoadrenalism, continued Professor Gray, although these three metabolites accounted for only an extremely small fraction of endogenous or exogenously administered adrenal hormones. In both Addison's and Simmonds's diseases the excretion of these three compounds was greatly reduced, and might not be measurable in many patients with the former disease. In Simmonds's disease administration of A.C.T.H. restored the excretion to normal limits. The appearance of hydrocortisone in the urine after administration of cortisone, and of cortisone after administration of hydrocortisone, to patients with Addison's disease or after adrenalectomy showed that hydrocortisone and cortisone were freely interconvertible in the body even in the absence of the adrenals. The proportions of cortisone, hydrocortisone, and tetrahydrocortisone in the urine were approximately the same whichever hormone was administered. There was no doubt that cortisone and hydrocortisone were therapeutically equivalent, except possibly when some local action was required, as with some ophthalmological and joint conditions.

Some, but not all, cases of Cushing's disease showed an increased excretion of hydrocortisone, cortisone, and tetrahydrocortisone. When the total excretion of these three compounds was within normal limits, the excretion of either cortisone or hydrocortisone might be increased, suggesting that delayed inactivation of the active hormones might sometimes be an important factor in Cushing's disease. In other cases, however, none of these metabolites was increased, and, while it was possible that in these the adrenocortical hormones might be metabolized to a greater extent via other pathways, it was not impossible that in this disease phases of normal activity and of overactivity of the adrenal gland might alternate. Perhaps hypersensitivity of the tissues also played some part.

The excretion of cortisone, hydrocortisone, and tetrahydrocortisone was not increased during salicylate therapy, so that unless there was an alteration of the metabolism of the adrenocortical hormone from normal it seemed unlikely that salicylates produced their therapeutic effect by stimulating the pituitary-adrenal axis.

North of England Obstetrical and Gynaecological Society

At the annual general meeting in Manchester on January 21 the following officers were elected for 1955: *President*, Mr. H. J. MALKIN (Nottingham); *hon. treasurer*, Mr. C. H. WALSH (Liverpool); *hon. general secretary*, Mr. J. B. COCHRANE (Nottingham); *hon. reporting secretary*, Miss U. M. LISTER (Leeds).

Nova et Vetera

THE ILLNESS OF EDWARD THE BLACK PRINCE

Edward the Black Prince seems to have enjoyed good health up to 1366 (including his successful campaigns in France), and led an active, vigorous, and warlike life. His ill-health dates from his unfortunate expedition to Spain, undertaken to restore Don Pedro the Cruel to the throne of Castile. In 1366, when the Prince was at Valladolid waiting in vain for the promised money from King Pedro, "his army suffered so terribly from dysentery and other diseases that it is said that scarcely one Englishman out of five ever saw England again." "The army also were half-starved, and the free companions in the prince's pay ravaged the country."

The Prince contracted a severe and debilitating illness, which lasted for ten years. It was probably amoebic dysentery which merged into the chronic form, for there are contemporary references to his dysentery subsequently. Sir George McRobert informs me that amoebic dysentery still occurs in Spain as well as the bacillary forms. In 1369, when the Prince was at war with Charles V of France, Froissart states that his health was so feeble that he could not take an active part: he was swollen with dropsy and could not ride. Oedema of the legs and ascites have been noted in dysentery due to anaemia caused by intestinal haemorrhage. Alternatively, the Prince's dropsy may have been due to chronic nephritis, which sometimes complicates dysentery. A third suggestion is that it was a "hunger oedema," due to semi-starvation in Spain. The first explanation seems the most probable one.

In 1370 Charles V of France raised armies for the invasion of Aquitaine. Though ill, the Prince left his sick bed in Angoulême, gathered an army at Cognac, and sacked Limoges. A sick man, he was carried in a litter.

In January, 1371, on the advice of his physicians, he returned to England and went to his manor of Berkhamstead "ruined in health and fortune." His health improved, presumably with rest and dieting. In August, 1372, he sailed on an expedition with King Edward III, his father, to relieve Thouars, but the fleet, exposed to contrary winds for nine weeks, eventually returned without landing on the French coast.

Later, "the Prince's sickness became very heavy." He knew he was dying, was much in prayer, and did many good and charitable works. "His dysentery became very violent, and he often fainted from weakness, so that his household believed he was actually dead."

This was the result of the severe dysenteric haemorrhages and associated weakness and anaemia.

The Prince eventually died from dysentery and exhaustion in 1376, aged 46. His body was brought from the Palace of Westminster to Canterbury and buried with great state in the Cathedral.

In her Annual Report for the year 1953 Dr. Catherine B. Crane, medical officer of health of the city of York, reports that attendances at the antenatal clinics, apart from midwives' clinics, were negligible, because the major part of the antenatal work in York is carried out by the patient's own doctor in domiciliary cases and by the hospital staff in cases booked for hospital confinement. "This we welcome," Dr. Crane writes, "provided adequate antenatal teaching can be given."

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Agranulocytosis

SIR,—In an annotation¹ you recommended that A.C.T.H. or cortisone should form a routine addition to the standard treatment of drug-induced agranulocytosis, though with a warning that not all cases might respond. This view was based on the reports of two cases of agranulocytosis in Canada² and U.S.A.³ respectively which, caused by sulphonamides, were successfully treated with A.C.T.H., and a case reported in the *Journal*⁴ caused by "novalgin" and treated with A.C.T.H. with recovery. Further cases of drug-induced agranulocytosis have been since reported in your *Journal*⁵ and elsewhere,⁶⁻⁹ in which A.C.T.H. was considered to have aided recovery. The use of A.C.T.H. in the treatment of agranulocytosis caused by drugs has also been referred to in a standard textbook.¹⁰

The potential danger of amidopyrine as a cause of agranulocytosis is well known, and certain related proprietary preparations—for example, novalgin—carry the same risk; for this reason the latter has been placed on Schedule 4. The case reported in the *Journal* (January 22, p. 207) by Drs. H. E. Hutchison and Hugh Conway died of an embolus five days after admission after improvement had occurred on antibiotics alone. As corticotropin and cortisone were not mentioned in their note we felt that attention should be directed to a form of therapy which is occasionally of great assistance in drug-induced agranulocytosis.—We are, etc.,

D. G. WRAITH.
F. DUDLEY HART.

Disk Lesions and Low Backache

SIR,—The paper by Dr. James Cyriax (*Journal*, January 15, p. 140) and the letter from Mr. John Charnley (p. 163) illustrate the difference of opinion—not to say confusion of thought—about these conditions, granted that there is a larger field for the use of manipulation. Dr. Cyriax is altogether too facile in regarding the great majority of patients suffering from lumbago and sciatica as subjects in some degree of disk lesion. The diagnosis of disk lesion is not as easy as all that. What does it rest on? (a) A history of injury or sudden onset (but many a case gives neither); (b) pain which on strict analysis is truly acute, with confirming clinical signs of local spasm and sciatica; (c) some element of confirmation by x-ray. With many others, I have had the misfortune to perform laminectomy at several levels in the "certain" case, only to find no evidence of disk protrusion. X-ray films often show no evidence of diminution of the intervertebral space, and, conversely, gross diminution may appear in films taken for some other condition—for example, the flat film of a barium series—with no complaint from the patient of lumbago or sciatica. It should be remembered that the intervertebral articulation comprises three elements—the disk, the spinal ligaments, and the apophyseal joints—and that any pathological condition which affects one affects all.

The late Dr. H. A. Cookson examined 22 patients at necropsy, none of whom in life gave any history of backache or sciatica;

of these, eight showed obvious disk protrusions, apparently symptomless. In operating for disk lesions, the apophyseal joints when examined consistently show pathological evidence of osteoarthritis, degeneration of hyaline cartilage, capsular thickening, and resultant narrowing of the channels through which the nerve roots emerge, especially that of the 4th lumbar. My personal view is that this condition is more frequently the source of lumbago-sciatica than minor disk protrusions.

Dr. Cyriax stresses fairly the value of manipulation and traction; Mr. Charnley recognizes the value of psychological concord with the patient, but rightly dreads the prospect of a multiplication of the physiotherapy services. May I suggest a method of treatment which effects the first and obviates the second? It is not original; it was put forward in a clinical lecture on scoliosis by that shrewd observer the late Professor Alexis Thompson, in 1909. The patient hangs from a ladder, arms fully extended, head retracted, knees bent up; in this position he hyperextends the pelvis on the lumbar spine, then swings from side to side. In the home a ladder is not normally available, but the top of a door is, and makes a good substitute. Having reached the limit of tolerance, he now lowers himself carefully to the four-foot position, and crawls round the room half a dozen times. If sciatica is present, he crawls away from the affected limb, as in Klapp's exercise, the hand and knee being approximated on the contralateral side. A firm pillow, 12 in. (30 cm.) square, is strapped to the lumbar area, and the patient instructed to repeat the routine, at least once daily. Thick gloves should be worn, and the knees protected by cotton-wool pads.

This procedure is effective in the great majority of patients, and not infrequently dramatic; it has the advantage of simplicity, it can be repeated *ad lib.* by the patient, and throws little strain on the physiotherapist or the overwrought orthopaedic surgeon. Most important, it emphasizes the principle that what the patient does for himself is worth a ton of what someone else, lay or medical, does for him. I use injections very little—when I do, I give 5 ml. of lactic acid, without procaine, paravertebrally on either side, trying to reach the root of the lumbar-transverse process at the appropriate joint. Most procaine preparations, being hydrochlorides, have a pH on the acid side.—I am, etc.,

Sunderland.

W. GRANT WAUGH.

SIR,—For many years now I have been carrying out Dr. James Cyriax's methods of diagnosing and treating low backache. This I have done in general practice. I would therefore like to give my figures for a twelve months' period, in reply to the request of Mr. W. D. Coltart and Mr. H. Osmond-Clarke in their letter (*Journal*, January 29, p. 288). I would like to add that these patients could not easily hide their recurrent backaches from me, as I was their N.H.S. doctor and they could not therefore seek advice elsewhere, as suggested by Dr. D. M. Freeman (p. 289), and very few complain that the treatment was painful.

	No.	%
Cases treated	185	
Considered suitable for manipulative reduction	133	
Relieved in one session		57
" " two sessions		194
" " three "		1
" " four "		6
" " traction		9
Referred to St. Thomas's Hospital		7
Recurrences		20
Cases considered suitable for traction	52	
Relieved in 1-5 treatments		43
" " 6-10 "		23
" " more than 10, or referred		35

I consider that these results substantiate the claims made by Dr. Cyriax. I should add that many of the treatments were given by my physiotherapist. I think it is a pity that so many of our noble profession criticize his methods, without having a working knowledge of them. Those who do watch the diagnosis being worked out, and the treatment being carried out, are usually enthusiastic.—I am, etc.,

London, W.1.

R. BARBOR.

SIR,—Mr. John Charnley (*Journal*, January 15, p. 163) defends the orthopaedic surgeon's approach towards the problem of chronic low backache. Unfortunately only a small percentage of genuine derangements of the musculo-ligamentary-skeletal structure of the lower back can be demonstrated by x-ray or any other scientific investigation. Nevertheless, they are the undoubted cause of a great deal of chronic invalidism and most of them can be cured by simple manipulation. The Cyriax traction is an aid—but I prefer to use my hands. I must confess that I sympathize with the patient who, having been sent from one specialist to another and from one x-ray department to another, says that nothing has been done for him, for nothing has in fact been done to relieve him of his backache, which is after all what he has asked for.

Simple manipulation does not require an anaesthetic, takes only a few minutes of the manipulator's time, and the question of expense does not arise, since the only equipment necessary is a couch and a pair of trained and confident hands. I still hope that we are approaching the day when the profession will at last realize the value of this type of manipulation and will accept it wholeheartedly.—I am, etc.,

London, S.W.16.

HARRIS AVERY.

SIR,—In his article on spinal disk lesions (*Journal*, January 15, p. 140) Dr. James Cyriax states that manipulation of the spine should not be in the hands of "lay manipulators." Yet that is the very thing he does by relegating this work to physiotherapists. The American osteopaths have a far superior training to the physiotherapists, and, in fact, the training of those recognized by the British Osteopathic Association compares very favourably with that given by many of the medical schools in every way. These osteopaths are recognized by the United States Government, and in many cases have to pass the same State Board Examination as the medical graduates before they can practise.

Manipulation of the spine is an extremely skilled work. It is true that anyone can be taught the necessary movements, but the application of the manipulation is the important thing, and this cannot be taught nor can it be relegated to those who have not had the thorough training that an American osteopath has had. There must be definite reasoning, ingenuity, the requisite skill, and, above all, the ability to apply the manipulation. It cannot be left to those who have not had considerable experience. There are some osteopaths who are just "joint crackers," and they are the ones who throw discredit on the true osteopaths. There are many physiotherapists who are just "skin rubbers," but that does not mean that there are not many who fill a very necessary need. American osteopaths, however, are taught manipulation from every angle, and in so many cases each manipulation must be reasoned out. There can never be any stereotyped method of manipulating a spine. The variations of restricted movement of the spinal joints are so numerous that unless the treatment is correctly applied there can be no certainty of the outcome and, what is more, the patient may be worse. This work cannot be accomplished unless one knows how and why.

What is a disk lesion in its early stage? Is not this the osteopathic lesion? Apart from this definite and simple cause, there is no other reason for what are styled disk lesions. Are they disk lesions? Has the medical profession ever improved upon the manipulations of the osteopath? It has copied them and imitated them, and claimed them as original, but there the comparison ends.—I am, etc.,

Newcastle-upon-Tyne, 2.

R. W. R. WATSON.

SIR,—I have read the correspondence on the treatment of low back pain with very great interest. From my own experience I can state that a modification of Dr. James Cyriax's method does work. The patient who is brought to an out-patient department by ambulance, in such severe pain that he cannot stand or walk, can be relieved so rapidly that he can walk to hospital next day, and return to work within a week.

This very fact raises doubts in my mind as to the diagnosis. From the consideration of the anatomy of a lumbar intervertebral disk, it is hard to believe that a herniation of the nucleus pulposus or a tear of the ligamentum annulare can be "replaced" so that they remain in position. Is it not more likely that these acute cases are really lesions of the interlaminar joints, possibly a subluxation? Weight is given to this view by the fact that the majority of these acute cases are caused by a flexion and a rotation strain. Might it not be well to reserve the diagnosis of a disk lesion for those cases with sciatic pain and/or neurological signs?—I am, etc.,

London, W.1.

A. C. ELKIN.

Tonsillectomy

SIR,—Following the article by Dr. Christine M. Rendell on the premedication of children for tonsillectomy (*Journal*, December 11, 1954, p. 1397) there has been varied and interesting correspondence. I do not propose to comment on this, but rather on a fact which has been mentioned *en passant*, and which may be of interest to posterity: the fact that guillotine tonsillectomies were still being performed in large numbers in the second half of the twentieth century—*circa* 1955.

In May, 1909, there appeared in the *Lancet* an article of extreme clarity and simplicity by George Waugh,¹ then senior surgeon to out-patients at the Hospital for Sick Children, Great Ormond Street. This paper, which dealt with "A simple operation for the complete removal of tonsils, with notes on 900 cases," was destined to revolutionize the surgical treatment of chronic tonsillitis. Of the 900 cases mentioned 143 had already had their tonsils guillotined, some of them as often as two or three times. I quote verbatim: "It is probably a common experience of all large out-patient departments—and certainly of my own at Great Ormond Street—to find a large number of patients upon whom tonsillotomy has been performed and to whom no relief either of the local or general condition for which the operation was done has resulted. From the frequency with which the operation has been repeated, sometimes as often as three times, and from the fact that the operation has been performed by many operators at other hospitals in these 143 cases, it seems right to conclude that the cause of failure lies not with the operator but with the type of operation. Even in highly skilled and experienced hands the complete removal of a tonsil by means of the guillotine is a task of such mechanical difficulty as to be, except in a few rare cases, quite impossible."

Waugh was accustomed to seeing many patients who had been subject to inadequate, inaccurate surgery. To-day, 46 years later, the same type of patient continues to attend the clinics, with huge masses of infected tonsillar remnant, and in some cases a deficiency of uvula, faucial pillars, or soft palate suggesting that these innocent anatomical structures must have been indicted and sentenced to mutilation along with the tonsils and adenoids. Guillotine apologists advance the following arguments: long waiting-lists preclude the performance of the dissection operation in every case, but this more lengthy, deliberate, and precise operation may be reserved for cases in which pre-operative findings are suggestive of adherent tonsils. In some centres the post-operative haemorrhage rate is higher in dissected than in guillotined cases: a longer anaesthetic is necessary for the dissection operation: but perhaps the most dangerous and frequently repeated platitude of all is that in the hands of experts the guillotine operation gives satisfactory results. I hasten to agree, but expert guillotinists are few.

Not one of these reasons is valid. A lengthy waiting-list cannot be said to justify any technique other than the best. Which method would the surgeon wish in the case of his own child? Of course the post-operative haemorrhage rate is higher following the removal of abnormally adherent tonsils, and if dissection is reserved for these cases any comparison of the haemorrhage rates following the two methods is bound to give rise to fallacious conclusions. As regards the length of anaesthetic, I think most of us would agree that anaesthetists have not been the least progressive of our colleagues, and the era when operation-time was reduced to a minimum, in order to curtail their activities has long since passed.

I anticipate much opposition to the view that the guillotine operation should be relegated to the historical section of every textbook, but let me make it quite clear that I am in no way critical of those revered colleagues who for many years have employed the method with diligence and success. But rather, in the words of Waugh, "The cause of failure lies not with the operator but with the type of operation."—I am, etc.,

London, W.1.

Carcinogens in Cigarette Smoke

SIR,—The interesting point made by Professor R. D. Passey (*Journal*, December 18, 1954, p. 1485) referring to the prolonged exposure of the skin of the fingers of cigarette smokers to the products of the combustion of tobacco has often puzzled me. It has occurred to me that one possible explanation might be related to the relative absence of sebaceous follicles in the skin of the finger-tips (of course, this does not apply in the case of the lip or the eyebrows). The skin of young mice devoid of sebaceous follicles was shown to be resistant to the carcinogenic action of methylcholanthrene by Lacassagne and Latarjet,¹ and I have failed over a period of many years to induce any epithelial tumours in the skin of fowls with a variety of chemical carcinogens that are potent for the skin of mice. One of the peculiarities of the skin of the domestic fowl is an absence of sebaceous follicles except in the preening glands. Another and simpler explanation would be that the products of combustion of cigarette smoke are not carcinogenic for human skin.

I make these comments without prejudice in regard to the possible carcinogenic action of cigarette smoke on the epithelium of the bronchus and lung.—I am, etc.,

Obstruction from Orange Pith

SIR,—One of the disadvantages of being in a distant part of the Commonwealth is that the *Journal* takes so long to reach us. I have only recently received the numbers in which your correspondents discuss the dangers of orange pith (*Journal*, November 27, 1954, p. 1301, and December 18, p. 1484). I, too, have had an experience with the fruit which I think merits recording.

On March 20, 1951, I was urgently requested to see a coloured male child aged 4 years at the Coronation Hospital, Johannesburg. This child had been treated recumbent in a Jones's frame for four months for a tuberculous lesion of the 8th thoracic vertebra. He had been perfectly well until 7.30 p.m. that day, when a nurse had noticed the child was struggling for breath. The houseman was called and diagnosed acute tracheal obstruction, and, as I happened to be in the building, asked me to see the child. When seen at 7.45 p.m., the patient was semi-conscious and deeply cyanosed. Rib recession was marked and the accessory respiratory muscles were contracting forcefully. Air entry into both lungs was scarcely audible. It was presumed that a foreign body had been inhaled and an immediate bronchoscopy was performed in the ward without anaesthesia. No difficulty was experienced in introducing the instrument, but intense bronchial spasm was produced which lasted only a short while and was followed by total flaccidity, unconsciousness, and an impalpable pulse. A rapid cursory inspection of the main bronchi failed to reveal the presence of a foreign body. The bronchoscope was withdrawn into the trachea and the lungs inflated with oxygen. While we were debating whether the heart had stopped the houseman jubilantly reported the return of feeble radial pulsations. Within a few minutes the child was pink and the heart beats forceful. Trichlorethylene was then administered to the now struggling child and a more leisurely inspection of the bronchi failed to produce the expected foreign body. The bronchoscope was then slowly withdrawn, and it was noticed that the upper tracheal lumen was reduced to a slit by an extra-tracheal mass projecting from behind. As soon as the instrument was withdrawn into the larynx the obstruction recurred. Nothing had been noticed during the hasty introduction of the instrument; no bar to its advancement had been met. The bronchoscope

was again pushed beyond the obstruction and with a laryngoscope the interarytenoid fold was lifted forwards. A mass of white cotton-like material was seen to be impacted in the lower pharynx and on withdrawal was found to be a mass of orange pith. A considerable quantity was removed, which must have extended for some distance down the oesophagus. This completely relieved the tracheal obstruction. I subsequently learned that the child had eaten an orange about an hour before the tracheal obstruction was first noticed.

One wonders whether the bolus lodged in the pharynx and oesophagus had slowly increased in size by absorption of saliva and other fluids until eventually the soft trachea was sufficiently compressed to impede breathing, or whether actual difficulty had been experienced for an hour before it was eventually noted. I was assured that the child had shown no signs of restlessness after his evening meal and had certainly made no complaint.—I am, etc.,

Johannesburg.

PAUL MARCHAND.

Silver Stool Sign

SIR,—Sir Heneage Ogilvie's description (*Journal*, January 22, p. 208) of this condition in cancer of the ampulla of Vater is very important. It may be of interest to report that we have occasionally received silver stools from young children convalescing from diarrhoea. We have assumed, but without proof, that sulphonamide or other medicaments were responsible for this odd appearance.—I am, etc.,

London, N.9.

M. E. M. THOMAS.

SIR,—It was with considerable interest that I read Sir Heneage Ogilvie's medical memorandum on "Thomas's Sign, or the Silver Stool in Cancer of the Ampulla of Vater" (*Journal*, January 22, p. 208).

A 65-year-old patient was admitted to hospital in the early hours of December 25, 1954, with abdominal pain and vomiting of over 24 hours' duration. He was found to have a paralytic ileus and peripheral circulatory failure due to peritonitis. Although there was much discussion about the cause of the peritonitis, the most likely one was considered to be a perforated peptic ulcer. He was treated conservatively and never really became fit enough for laparotomy. During the course of his illness he passed quite a definite "silver stool." My wife, who happened to be the ward sister at the time, stated that she had been taught that "silver stools" were characteristic of pancreatic disease. I consulted several surgical and medical colleagues, as well as the professor of pathology, and none had met the use of the term "silver stools" in pancreatic disease, or in any other condition. On being referred to a textbook of nursing¹ I found the statement that "in some diseases of the pancreas the stools have a silvery appearance." The patient referred to above died on December 30, 1954, and necropsy revealed gross haemorrhagic pancreatitis.

In view of this case I respectfully suggest that this is not the first description of "silver stools." Also, "silver stools" are not really diagnostic of carcinoma of the ampulla of Vater and can evidently occur in other diseases of the pancreas.—I am, etc.,

Manchester, 13.

W. J. METCALFE.

REFERENCE

¹ Riddell, M. S. (1938). *Lectures to Nurses*, 7th ed. Faber and Faber, London.

SIR,—Sir Heneage Ogilvie's memorandum entitled "Thomas's Sign, or the Silver Stool in Cancer of the Ampulla of Vater" (*Journal*, January 22, p. 208) immediately attracted my attention, as I have once observed the phenomenon which he describes, but was not aware of the significance which he attributes to it.

The patient was a diabetic man aged 68 years who had been jaundiced for five weeks as a result of obstruction of his common bile duct by a large stone. He was passing clay-coloured motions at the time when he was first seen. At operation the stone was removed from the grossly dilated common duct, which was then drained with a rubber catheter. The patient's condition was very poor and he developed a profuse biliary fistula around the tube

and died of bronchopneumonia a few days after the operation. On the morning of his death the sister of the ward called my attention to a stool which the patient had just passed and which had been saved because neither she nor the staff-nurse had ever seen anything resembling it. It was a bulky well-formed stool which resembled exactly, in colour and appearance, the aluminium paint which is commonly sprayed on pipes and radiators. It was not merely grey in colour but had a definite metallic lustre. I was at a loss to explain the phenomenon but had a colour photograph of the specimen taken, and, as it was not repeated, was unable to investigate it further.

If, as Sir Heneage says, the phenomenon is due to the presence of altered blood in the pale stool of obstructive jaundice, then the origin of the bleeding in my case was no doubt the operative trauma to the common bile duct. Sir Heneage suggests the passing of silver stools may be an important sign in the diagnosis of carcinoma of the ampulla of Vater: one wonders whether it will be of much practical value. In the first place I suspect that the phenomenon must be very rare, as I cannot imagine the passage of stools, the colour of the one that I have described, escaping notice and comment by the nurses and the ward sisters. In the second place, surely the existence of unexplained obstructive jaundice is in itself an adequate reason for surgical exploration, and, as Sir Heneage has mentioned, the source of the haemorrhage which may be responsible for the silver stools is not necessarily from the obstructive lesion itself. It would be interesting to know whether others have observed the phenomenon of silver stools, and if they have I hope that they will write making their observations available.—I am, etc.,

Cardiff.

ARNOLD S. ALDIS.

Alcohol as a Diuretic

SIR,—I was shocked to detect my revered ex-teacher of clinical medicine in an error both of fact and implication. In Professor L. J. Witts's review of the third series of "Any Questions?" (*Journal*, January 29, p. 271) he invokes Shakespeare to his support in his contention that alcohol is a diuretic. He quotes a reference which I cannot verify, as my copy of *Macbeth* shows Act II to have but two scenes. If he refers to the conversation between Macduff and the porter in Scene I, then what does Shakespeare say?

Porter.—Faith, Sir, we were carousing till the second cock: and drink, Sir, is a great provoker of three things.

Macduff.—What three things does drink especially provoke?

Porter.—Marry, Sir, nose-painting, sleep, and urine.

Will he quote an authority who supports the outworn theory that excessive drinking causes a red nose? What, I wonder, did the porter at Inverness castle drink? Unless he can be shown to have ingested pure alcohol, then Professor Witts's contention is vain, for most drinks contain other ingredients—for example, oil, juniperi—which may well be specific diuretics.

All the good Will Shakespeare says is that if you drink much you pass much urine, and that can hardly be denied.—I am, etc.,

Wellesbourne, Warwick.

LAWRENCE MACKIE.

Hypodermic Injection Technique

SIR,—When, as a student at St. Thomas's, I had my first lesson in the use of the hypodermic syringe it was impressed on me that never under any circumstances should the plunger be depressed without a previous withdrawal to ensure that the needle had not entered the lumen of a dilated venule. I have withdrawn the plunger in every injection I have ever given since then, and in the course of thirty years I have withdrawn blood on at least five or six occasions. Depending on the drug or serum used, each of these half-dozen cases might have been a fatality.

I am astonished to find that no nurses I come across have been taught this elementary safety-first precaution. Surely so simple a thing should be drilled into everybody who handles this ubiquitous, but nevertheless potentially lethal, weapon.—I am, etc.,

St. Ives, Cornwall.

L. P. LOCKHART.

Dyspareunia

SIR,—Mr. G. W. Theobald (*Journal*, January 22, p. 228) suggests that Mr. R. Christie-Brown (*Journal*, January 8, p. 106) might find his new dyspareunia clinic unnecessary (for the relief of infertility) if he would try cauterizing the internal os uteri with a stick of silver nitrate, which he believes "would cure most cases of dyspareunia provoked by deep penetration of the penis." But if the infertile patient's cervical anatomy and physiology happen to be normal, what then? Might not the stick of nitrate change all this?

I would rather see the dyspareunia clinic abandoned for other reasons. I agree wholeheartedly with Mr. Oswald Lloyd (*Journal*, January 22, p. 228) that "these cases are a challenge to the patience and ingenuity of the non-surgical aspect of our specialty" and, like him, I regard as unfortunate the present tendency to hive off into component clinics various groups of gynaecological disorders. The groups selected are usually those less spectacular conditions which require time-consuming histories, investigations and/or treatments; they are, in fact, the very cases which need mature clinical judgment in their handling to bring maximum benefit to the patient. Unfortunately, such cases interfere with the tempo of the conveyor-belt system of out-patient departments, so dear to the heart of the lay administrator these days.

The herding together of similar cases into clinics may be an administrative expediency and may be justified for the purposes of research and the collecting of data, but it is good neither for the patients themselves nor those who staff them (and how often is this work delegated to juniors?). Both are apt to develop distorted ideas. In short, unless the patient derives maximum benefit from her visit to the hospital, what appears to be administrative efficiency is, in fact, the reverse.—I am, etc.,

South Shields.

TERENCE ROBINSON.

What is Health?

SIR,—I read with great interest Dr. A. H. Macklin's letter (*Journal*, January 22, p. 229) in which he set out certain constructive criticisms of the Kent Paediatric Society's report¹ and gave a few details of the 10-year survey at present being carried out in the University of Aberdeen.

In undertaking a mathematical assessment of health, the Society was well aware of the difficulties and dangers of such an approach and appreciates that the method set out in the study represents but a first step in the evolution of a generally acceptable standard. Indeed, it is hoped that not only the marking form but all the other measurements will be studied and improved upon by other workers in this field. As one reviewer has put it,² "The modern locomotive engineer may laugh at some of the original crudities of the first productions of Watts and Boulton, but without their work there could have been no Flying Scotsman." Although we are, yet, by no means convinced that health can be measured, we hope that this analogy may prove to be a sound one.

It may be that surveys based on the correlation of factors applied to individuals in special groups by methods of observation and record may yield satisfactory results; but the fact that such surveys take ten or more years reduces considerably their usefulness in field trials, where a more rapid assessment is desirable. Besides, the subjective element in such surveys is very strong and it is not always those whose "all-round qualities" appear to be outstanding who deserve to be placed in the highest category of health: the dark horse has always to be reckoned with. Neither do such methods lend themselves to standardization, which alone would permit of their universal application.

The assessment of personality or character is, perhaps, the most important (and certainly the most fallible) aspect of health assessment, for on character may depend the power of the individual to rise above physical or even intellectual disability. Health, in the absolute sense of "wholeness," can rarely, if ever, be a human attribute, and the most that we can aim at is the highest degree of well-being which can result from the individual's

endowment of physique, intelligence, and character. Any method of assessment must take into account this compensatory mechanism. How would a Franklin D. Roosevelt or a Helen Keller be placed in the Aberdeen survey, or the Kent survey for that matter? Certainly the latter could and should be modified to ensure that these would not be rejected from the category of health.

Even the "intelligent, highly reactive personality" must, somehow, come to terms with his environment by a process of mutual interaction, failing which the result can only be withdrawal, which may well be an element in psychopathology. This may be the reason why genius is so often associated with disease and must therefore be regarded as abnormal. It is, of course, not necessarily the "healthy" who contribute most to human advancement, and, indeed, the reverse may be the case; but health must not, on this account, be thought of as a state of dull, uninspired mediocrity. The stability of society may well depend on "normal," "healthy" people, and it is the aim of the infant science of "hygiology" to be able to recognize health, if possible to measure it and to discover its causes. For has not health its specific causes no less than disease? The results of the Aberdeen survey may shed much light on some of these problems.—I am, etc.,

Cortisone, A.C.T.H., and Asthma

SIR,—Your annotation on this subject (*Journal*, January 22, p. 216) deserves comment. During the last few years I have treated 28 asthmatic patients with A.C.T.H. or cortisone with a high percentage of pronounced improvements. This result does not differ from those of Dr. J. E. G. Pearson (p. 189) nor from those of the numerous authors who have reported the results of controlled and uncontrolled trials in many countries during the last five years. A few relevant details may be worth recording.

Fifteen patients were put on maintenance doses. They are still so maintained, some of them for longer than two years. There were no serious side-effects like diabetes, hypertension, or bleeding ulcer. Mooning and ankle oedema were frequent, but subsided after one or two weeks, as has been observed by others. In only two cases was it necessary to increase the maintenance dose permanently. Both were complicated by severe emphysema, and this disorder and the accompanying chronic bronchitis took their natural progressive course. In the other patients on maintenance doses (which varied from 25–150 mg./day) it was often necessary to increase the dose temporarily when the asthma became more severe after an intercurrent respiratory infection or after exposure to an allergen. In all such cases the daily dose was stepped up briskly to 150 or 200 mg. of cortisone and reduced gradually within the next 10 days until the previous maintenance dose was reached again. In all of them the asthma returned to its previous well-controlled degree of severity. Thirteen patients, who received the drug only temporarily in order to tide them over severe seasonal bouts of the disease, also returned to their previous moderate degree of chronic asthma after cortisone or A.C.T.H. had been gradually withdrawn.

In view of my own observations and those of many others, I must express disagreement with the somewhat gloomy view of your annotator, which is likely to discourage practitioners from the use of these most beneficial substances. We all know that cortisone and A.C.T.H. are only effective as long as they are given, and that they may have dangerous side-effects; so have many other drugs, including adrenaline, insulin, and chloramphenicol. We must try to avoid these dangers, but not by not using the drugs. Your annotator bases his view partly on the conclusions of Savidge and Brockbank,¹ who reported two deaths among their patients and collected nine other deaths from the literature. Their report makes it very likely that these two patients died not because they had too much but because they

had too little cortisone. It was not continued or not suitably stepped up when the asthma temporarily increased in violence. Such violent bouts frequently occur in severe chronic asthma, and we must remember that, at present, cortisone is mostly used for severe cases in whom the risk of a fatal outcome is always present. The conclusion of Savidge and Brockbank "that the cortisone cannot be exonerated" (a conclusion echoed by your annotator) therefore seems unjustified. The authors contradict their conclusion themselves, for they suggest that in future higher doses should be given in such cases of deterioration.

Your further remark that trials with such a drug "must be blind" is not a happy one either. It may be interesting to stage a blind trial of cortisone against a placebo in order to determine statistically the percentage of placebo improvements. Such a trial would not be necessary to confirm the efficiency of cortisone, because its beneficial effect has already been generally confirmed and accepted—I shall not encroach on your space by quoting the 50 or so papers which have appeared on the subject since 1950. In view of this I wonder what is meant by the phrase, "So far as this country is concerned [my italics] the therapeutic value of cortisone and corticotrophin in asthma is still *sub judice*." I feel it is going a little too far to disregard the experience of reliable authors all over the world. The therapeutic value of cortisone has been established beyond doubt. We have still to learn many things about it, but this is no reason to discourage its use.

May I add a plea that leading articles and annotations be signed in the future? Their authors ought to shoulder their responsibility in public.—I am, etc.,

London, W.C.1.

H. HERXHEIMER.

Human Nutrition and the Sophistication of Foods and Feeding Habits

SIR,—It is the duty of every commercial organization concerned with nutrition to ensure that their products not only conform to the relative applicable standards, but also to keep abreast of research in such a way that improvements may be introduced in any processing involved. Following Professor B. S. Platt's paper (*Journal*, January 22, p. 179), and since this department is concerned most particularly with the use of unsweetened evaporated milk in the field of infant feeding, we feel some reference to its protein value could be usefully made.

Hodson and Kreuger,¹ referring to evaporated milk samples obtained from six different areas, found a small and nutritionally insignificant loss of lysine in the heat processing of evaporated milk. They state: "When the variability of the assays is considered this is the only measurable indication of a loss of an essential amino-acid during the processing of evaporated or dried milk." More recently Hodson² reported the amino-acid content of evaporated milk on prolonged storage. In his summary of this work he stated: "Of the seventeen amino-acids studied, significant losses were found for only lysine (17%), histidine (17%), and arginine (11%) during five years' storage. During fifteen to seventeen months' storage, which is longer than the customary storage period, losses of these three amino-acids were not greater than 4% in any case."

We feel that perhaps even greater significance can be attached to the fact that the work of Hodson¹ in relation to yet further heating of the already heat-processed evaporated milk, utilizing the terminal heating method technique of preparing feeds, showed no further destruction of lysine. He stated: "Evaporated milk formulas, which were heat treated, either by low pressure method (100° C. for 15 minutes) or high pressure method (autoclaved at 110° C. for 10 minutes), showed no loss of the essential amino-acid, lysine." Further observations by Hodson refer to the darkening in colour when evaporated milk is stored for several years. He felt that because amino-acids contribute to the development of brown colour in food products, through their role in the Maillard browning reaction, a study of amino-acid loss during storage would be of interest. The study, therefore, embraced both essential and non-essential amino-acids, for which microbiological procedures had been devised. Having found the resultant loss of the seventeen amino-acids quoted above, Hodson² says: "If the amino-acids produce the brown colour in stored evaporated milk, through participation in the

Maillard reaction, then small amounts of lysine, histidine, and arginine must be very effective in producing the brown colour, inasmuch as only 2% of the total protein amino-acids would take part in the reaction during five years' storage."

In relation to curd and nitrogen storage, the investigation conducted at the Pennsylvania State College School of Agriculture by Professor Dizikes and F. J. Doan³ shows that raw and pasteurized milk have unsatisfactory curd characteristics, since after three hours of digestion more than 50% of the nitrogen was found in curds failing to pass a 4-mesh screen. At this same stage—that is, three hours and 4-mesh—breast milk gave 0.0%, unsweetened evaporated milk 0.26%, and boiled milk 10.60%.

We trust this information will show our anxiety not to rest content with our product, and that we take into account as many factors as are currently known in relation to the use of a substitute food for infants when breast feeding is not possible.—I am, etc.,

Myxoedema After Thyrotoxicosis

SIR.—The case report by Drs. Russell Fraser and B. E. C. Nordin (*Journal*, January 29, p. 255) is interesting, but, although they mention Hashimoto's thyroiditis in the preamble, they do not describe the clinical state of the thyroid gland in their patient's myxoedema phase. There is some evidence that thyrotoxicosis may be present, and not uncommonly, early in Hashimoto's disease; is their case one of "struma lymphomatosa" in a male, which would be a rarity?—I am, etc.,

West Hartlepool.

R. T. COOKE.

Prophylactic Thyroid Treatment in Cancer

SIR,—We disagree with the conclusion drawn by Dr. A. A. Loeser from the results given in the first paragraph of that part of his paper subheaded "Clinical Observations" (*Journal*, December 11, 1954, p. 1381). In the following paragraph the author states: "This fact shows that a lack of thyroid hormone in the body favours tumour development."

It is not stated whether or not the seven patients with cancer development had received thyroid hormone after thyroidectomy. Therefore, considering for the moment only the remaining 93 patients, we calculate that if 100 similar samples of thyroidectomized patients were examined, 18 would be expected to show differences of the observed amount (or greater), and in the observed direction, on the basis of random sampling. The chances against such an occurrence are 4.4 to 1. Therefore the observed difference of tumour development between the group which had received thyroid hormone and that which had not has very low statistical significance. If the seven patients with cancer development are supposed not to have received thyroid hormone (which would be favourable to the conclusion drawn in the paper), and are included in the analysis, the chances are 9 to 1 against the observation being the result of chance. This result is one-half the chance which is considered by many to indicate "satisfactory significance" in a biological experiment, and falls far short of that which would permit an almost certain conclusion to be drawn.

If Dr. Loeser's conclusion is correct, it might be shown to be so statistically with greater certainty if a larger number of patients were included in the group having received thyroid hormone. We note, also, that reference is made on two occasions to cancer incidence in the "average population" for purposes of comparison, but we can find no mention of the magnitude of this incidence.—We are, etc.,

Medical Aspects of Amateur Boxing

SIR,—We would like to answer some of the points raised by Dr. J. C. Laurie in his letter (*Journal*, January 22, p. 227) concerning medical aspects of amateur boxing. We cannot accept the pathological concept that concussion invariably produces oedema of the brain, and, while admitting that full recovery from a knock-out may not be instantaneous, we believe that lasting brain damage is unlikely to occur in amateur boxers if adequate medical supervision is enforced. In London a boy who is knocked out has to stay off boxing for at least a month, and all boys are examined before all contests. A bout is stopped immediately a contestant receives a cut, whereas in professional boxing the bout may be allowed to continue. A solar plexus blow does not cause unconsciousness, but a transient muscular weakness of the legs is produced and the boxer rapidly recovers, with no after-effects. We made no reference to it in our article (*Journal*, December 25, 1954, p. 1524), because it has never been a serious medical aspect of amateur boxing and is not related to the problem of head injury.

We are amazed at the conditions described by Dr. Laurie under which amateur boxing is alleged to be conducted in Scotland. If these facts are true, the sport must be in a very primitive state. We are also surprised that Dr. Laurie, who is shocked by the lack of medical control, continues to act as medical officer, thus condoning a state of affairs of which he justifiably disapproves. We can only suggest that the Scottish Amateur Boxing Association should be given the opportunity to refute these allegations.—We are, etc.,

EDWIN CLARKE.

Trichomonal Vaginitis

SIR,—We are grateful to Mr. Aleck Bourne for his letter (*Journal*, January 22, p. 226) drawing attention once again to the difficulties of treating and curing trichomonal vaginitis. We agree with many of his observations, but were particularly interested in his remarks about placing pessaries in the vaginal fornices under direct vision through a speculum. We have treated a few cases of trichomonal vaginitis by filling the vagina with a liquid preparation of amido-nitrothiazole. The patient was placed in the lithotomy position and the vaginal walls were stretched with a bivalved Cusco speculum. The fluid was injected with a Ritchie's bladder syringe and was retained in the vagina for twenty minutes. The fluid was then removed and a paste containing amido-nitrothiazole liberally applied to the vaginal walls, care being taken to see that the fornices were well filled. A plug of cotton wool was then inserted into the vagina and the patient was sent home and reported the following day for examination. It was hoped that such treatment would be effective without the necessity of relying upon the patient to insert pessaries herself. Unfortunately all five patients so treated relapsed, or were perhaps reinfected, shortly afterwards. Details of this work will be published soon in a forthcoming number of the *British Journal of Venereal Diseases*.

Our primary object in describing our work (*Journal*, January 8, p. 78) with amido-nitrothiazole was not merely to add yet another trichomonocidal drug to the large list already available, but to introduce a substance which was found to be almost as effective as acetarsol, but which was a non-arsenical and did not carry the risk of arsenical sensitization. We have found that in the long-term treatment of resistant cases or chronic relapsing cases it is useful to have an alternative drug available. Perhaps the most important conclusion to be drawn from our results and Mr. Bourne's comments upon them, as well as from most other recent work, is that the problem has been much neglected and requires more investigation if this widespread and distressing condition is to be controlled.—We are, etc.,

R. D. CATTERALL.

MARY WILLIAMSON.

London, E.1.

Tuberculous Patients in General Hospitals

SIR,—Any prospective entrant to the nursing profession who has read or heard of the recent correspondence in the *Journal* on the vexed question of tuberculous patients in general hospitals would, in my opinion, be stout-hearted indeed if her prospective entry became fact. Against this, might I submit that an intelligent girl presented with a factual and up-to-date account of tuberculosis nursing might not forgo a nursing career simply because a part of her training period was to be spent in a tuberculosis hospital, and later—who knows—she might even voluntarily join the staff of a chest hospital.

It has been well said that one of the places where one is least likely to contract tuberculosis is in a chest hospital—and this was said at a time when the incidence of "human wrecks" in tuberculosis wards was far higher than to-day. Evidence from Papworth Settlement substantiates this. The "overall infectivity" of a tuberculosis unit in a chemotherapeutic age is surely well-nigh negligible, when compared with bygone days. Even Dr. J. F. Brailsford's "unbiased layman" (*Journal*, January 15, p. 164) would probably agree with this—if he knew the facts.

The dread of tuberculosis was once well founded. But can it be that an almost superstitious fear is still infiltrating professional and lay ranks alike? Constant contemplation of the fearful in many instances promotes a *laissez faire* attitude. One is reminded of the dog on the thistle, in considerable pain but too lazy to get off. Let us have a forceful, up-to-date, and factual propaganda with regard to tuberculosis nursing, and even the fondest parent—so often the chief barrier to the prospective student nurse—would see things far less through a glass darkly. There would then perhaps be no need even to consider Dr. Brailsford's possible solution of more and more domiciliary treatment of tuberculosis, which bristles with pitfalls and difficulties, some of which, in many instances, can be quite insuperable.—I am, etc.,

Stornoway.

EWEN A. CAMERON.

SIR,—The case for and against the use of wards in general hospitals for the treatment of patients with pulmonary tuberculosis has been argued for some weeks now since you published Dr. A. B. Cowan's letter (*Journal*, November 20, 1954, p. 1227). Such a scheme may be an innovation for Glasgow; it is certainly not so for London.

But is this controversy wholly necessary? The Royal National Hospital for Diseases of the Chest, founded, equipped, and staffed for the treatment of tuberculosis by all methods, ancient and modern, medical and surgical, has been unable to find patients to fill all its beds since June, 1954; and for several weeks now has had no fewer than 70 beds unoccupied—more than a quarter of its total. (This is in no way due to shortage of staff. Only once in our history has part of one ward been closed for lack of nurses; and, *pace* Dr. J. F. Brailsford (*Journal*, January 15, p. 164), there has more than once since the war been a waiting-list for our nursing staff.) Such a situation is certainly frustrating for the staff and presumably uneconomic for the service. No doubt it will be remedied when the necessary committees have had time to give it the necessary consideration, and one may hope that one step will be the liberation of some of the wards in general hospitals in London, which are so badly needed for other purposes. I do not refer to the wards of which Dr. P. Stradling (*Journal*, December 18, 1954, p. 1483) writes—one cannot but agree with him that continuity of treatment is an overriding advantage—but there are others where the chest physician does not attend his patients; indeed, until recently it was no uncommon thing for a patient to have been in three, and even four, different London hospitals before reaching here.

Meanwhile the Regional Board has, happily, permitted the hospital to accept patients from all parts of the country, as it always had the honour of doing before July, 1948. It is very much hoped that use will be made of this opportunity. One realizes that many would not wish to come from, say, the north or

the midlands to the far south. But there will always be some who are glad to do so; others who may actually benefit by being at a distance from their daily troubles; and yet others who will gladly submit to the inconveniences in order to save delay. It would be a great pity if administrative difficulties were put in the way of patients (or their physicians) willing to go to a distance for their treatment. Transport is truly expensive; but less so than the undebited cost of needless prolongation of treatment.

It is not suggested that these 70 beds are the answer by themselves to our problems. But they can help and surely should be allowed to do so. One solution to present difficulties is to see that we have a national and not a regional health service.—I am, etc.,

Ventnor, J. of W.

E. F. LAIDLAW.

Treatment Abroad of Tuberculous Children

SIR,—A recent news item in a national daily paper¹ draws attention to treatment in Denmark of children "from industrial towns in all parts of Britain where the hospitals are overcrowded." It would be interesting to know which of our towns are concerned and why in any event treatment has to be sought outside the country. My own hospital treats tuberculous children from all over London and the home counties. We have no waiting-list and no overcrowding. On the contrary, at the present time there are many empty staffed beds waiting for patients.—I am, etc.,

Brentwood, Essex.

Fluoridation of Water Supplies

SIR,—Much has been written on the value of fluorine in the prevention of dental caries. A certain amount has also been written on the role of fluorine in the causation of dental caries. In *Hygiene*,¹ under "Dental Fluorosis": "This dystrophy of the teeth of children begins with a dark mottling of the enamel which may go on to permanent blackening or even disintegration of the dental substance... the active agent of the mischief is fluorine... one part per million of the element enables a water to start the process of destruction, which, it should be noted, is almost exclusively limited to the permanent teeth." Dr. Eugene Payne, in "Islands of Immunity,"² writes: "In some countries a number of communities are artificially fluorinating their water supplies to prevent tooth decay. In Brazil, in areas where fluorine in the water is absent, I found communities with sensationally good teeth. The incidence was lower than any reported in the fluorine-using towns. We need to investigate the reason why."

In small amounts fluorine appears to cause calcium fixation and in larger amounts calcium deprivation. Chronic fluorism may thus present as osteosclerosis, osteomalacia, and calcification of ligamentous attachments, whilst acute excess may be manifested by persistent cough, dyspnoea, sickness, constipation or obstipation, effects reminiscent of the other 'flu'. In its affinity for calcium its action recalls that of lead, and it is of interest that both substances are again associated in the production of high octane aviation fuel as hydrogen fluoride and lead tetra-ethyl. In addition to its violent chemical affinities, fluorine is highly reactive to electro-magnetic radiations, a property employed, for example, in x-radiography, television, and atomic physics. One is fascinated by the prospect of "selected" communities subsequently exhibiting fluorescence under the influence of atomic radiation. Seriously, however, it does seem a matter calling for further trials on a more limited scale, and in the meantime those of us who exhibit dental caries may find consolation in the knowledge that dental excellence is pre-eminently the attribute of the negro and the American.—I am, etc.,

Uffculme, Devon.

Differential Diagnosis of Coma

SIR,—It is with regret that I must point out an omission in the otherwise excellent article by Dr. M. J. Parsonage (*Journal*, January 22, p. 217). In discussing the differential diagnosis of coma no reference is made to the possibility of this being caused by cerebral malaria. The omission emphasizes the fact that this form of malaria is commonly overlooked, and this probably in part results from defects in the teaching of medical students. In many schools students are not made sufficiently aware of the emergencies which, even in this country, may result from tropical illness.

In these days of increasing air travel it is possible for many varieties of exogenous disease to be contracted abroad but not to become manifest until the patient has returned to a temperate region and, in spite of being advised to do so, patients or their relatives when reporting illness to a doctor commonly do not tell him when they have recently been abroad. The previous movements of the patient should be ascertained by the doctor as a routine in every case in which they are not known, and when the patient has been to the Tropics the possibility of tropical illness should be considered whenever the diagnosis is in doubt.—I am, etc.,

London, N.W.1.

A. W. WOODRUFF.

SIR,—In the refresher course on the differential diagnosis of coma (*Journal*, January 22, p. 217) I was horrified to see that there was no mention of malaria.

In malarious countries, where many thousands of your readers reside, this omission will only have the effect of lowering the prestige of your excellent *Journal*, since nearly all the readers will know that the first thing one thinks about when a comatose child (especially) is brought into the dispensary is malaria, and that when this has been satisfactorily excluded it will be time to embark on Dr. Parsonage's "orderly approach."

However, in Great Britain the effect of this omission may be much more serious. In these days of easy and rapid air travel it is by no means uncommon for the first clinical evidence of malaria to appear in this country. For example, schoolchildren often spend part of their holidays with their parents in the Tropics. Not all are given prophylactic antimalarials, and, even if they were, there are certain strains of *Plasmodium falciparum* that are resistant to some of the newer antimalarials; one of these children might well develop an attack of cerebral malaria at school. In his "orderly approach" Dr. Parsonage would be well advised to include an inquiry as to the recent movements of the patient, since there is no medical emergency in which treatment is so dramatically rewarding as it may be in cerebral malaria.—I am, etc.,

London, W.1.

L. EVERARD NAPIER.

The Princess Louise Children's Hospital

SIR,—The Goodenough Committee recommended¹ that a teaching hospital should provide for paediatric teaching not more than 10% of its beds; because in the St. Mary's Hospital group the children's beds amount to 19.2%, its board of governors are considering achieving a reduction to 10% by converting to adult use the Princess Louise Children's Hospital, a small hospital which has served the children of the Royal Borough of Kensington and its neighbours since 1840.

There are at present 9,690 beds for undergraduate teaching in London, of which 9.3% (909) are beds for children. If the St. Mary's group has 19.2% of its beds devoted to children, then it is clear that some other teaching groups have much less than the 10% recommended by the Goodenough Committee: so that although the conversion of this small hospital to adult use will benefit St. Mary's to the extent of relieving its board of governors of an arithmetical problem, it will benefit no one else, and the recommendations of the Goodenough Committee in this matter as they

relate to the London teaching hospitals as a whole will be further from attainment than ever before.

The "Co-ordinating Committee" responsible for making this recommendation seeks to show that the waiting-lists of the children's department of St. Mary's Hospital reflect a fall in demand for children's beds throughout the country, and it presents figures—not fully quoted in your note (*Journal*, January 29, p. 299)—to support this view. If we examine these figures, we find that they do not in fact do so. The Committee says that the children's waiting-list has fallen from 539 in 1952 to 235 at the present time, of which 159 are ear, nose, and throat cases. What it does not disclose is that in 1952 the proportion of ear, nose, and throat cases was 435, so that the fall in the numbers on the general medical and surgical waiting-lists has been from 104 to 76, a reduction which few will regard as being significant of the trend it is sought to demonstrate. In fact, the reduction of the numbers on the children's waiting-lists reflects not a reduction in demand for the services of the hospital, but the results of a drive on the part of the staff of the ear, nose, and throat departments to reduce the tonsil and adenoid lists.

It is right that the governors of St. Mary's Hospital should show due concern over the training of their students, but it is a little unfortunate that this should seem to overshadow their concern for the welfare of their patients in this thickly populated and rather inaccessible part of London. In the statement they have issued this latter aspect of the question receives no practical consideration at all.—I am, etc.,

London, W.10.

JOHN BATE.

Unwrapping the "Journal"

SIR,—A year ago you published a discussion on the wrapping of the *Journal*. May I, as the initiator of the correspondence (*Journal*, December 12, 1953, p. 1326) and after controlled observation and experiment, pay a tribute to the efficacy of the method advocated by Dr. G. M. Grant, of Dundee (*Journal*, December 26, 1953, p. 1432)? That is, gripping the wrapped *Journal* in the supinated left hand, so creating a trough; inserting a finger of the right hand into the trough and pushing it along. Your part in ensuring the success of this simple procedure is to see that the journal is loosely and *not tightly* rolled before postage.—I am, etc.,

Cross-in-Hand, Sussex.

H. LYNDBURST DUKE.

POINTS FROM LETTERS

Crying in Infants and Children

Dr. E. BARNES (Manchester) writes: I once was called to a perfectly good baby of 3 months. The mother complained that when she laid him down he cried; on picking him up, he cried happily. After four or five of these trials, she sent for me. I asked her to strip him, and I found in his singlet a short bristle of a tooth-brush perpendicular to the material. Removal put matters right.

Disk Lesions and Low Backache

Dr. A. LASK (London, W.13) writes: Mr. John Charnley's stimulating letter (*Journal*, January 15, p. 163) should provoke much comment. . . . I refer, of course, to his therapy of reassurance. The emotionally charged tone of his letter, obviously sincere, suggests that Mr. Charnley just does not see these patients as sick human beings (psychoneurotics) at all, but only as sound non-pathological spinal columns with bodies attached. He does not seem to recognize that there is a real problem here. What is the process by which an individual with no organic lesion comes to suffer so much discomfort or dis-ease that he continues to appeal for help in relief of his pain? What is the best method of helping these neurotics? The psychotherapist should offer the soundest opinion here. The orthopaedic surgeon has no special authority, and no justification for acting as the "final court of appeal." Let him refer these patients to the right quarter.

Obituary

J. HARDIE NEIL, C.B.E., D.S.O., F.R.A.C.S., F.A.C.S.

Mr. J. Hardie Neil, consulting aural surgeon to Auckland Hospital, New Zealand, died at Auckland on January 28 at the age of 79.

James Hardie Neil was born at Dunedin, New Zealand, on February 27, 1875. From Otago Boys High School he entered Otago University as a medical student, and, after graduating M.B., Ch.B. in 1898, held the appointment of resident surgeon at Auckland Hospital. Soon afterwards he went as a surgeon captain with the 4th New Zealand Mounted Rifles to serve in the South African War in 1900-1, being awarded the Queen's medal with four clasps. After the war he came to England and took the London Conjoint Diploma in 1902.

Returning to New Zealand, Hardie Neil was appointed ear, nose, and throat surgeon to Auckland Hospital in 1903, and he held the post for the long period of 45 years until 1948, when he was appointed consulting surgeon. For many years he was also aural surgeon to the Mater Hospital at Auckland. During the first world war he served as a lieutenant-colonel in the New Zealand Medical Corps, and was in command of No. 3 Field Ambulance with the New Zealand Rifle Brigade from 1915 to 1918. For his services he was awarded the D.S.O. and the Belgian Croix de Guerre in 1918, and was three times mentioned in dispatches. From 1924 to 1929 he was A.D.M.S. of the New Zealand Northern Command. During the last war he was deputy director of Auckland medical boards from 1940 to 1946. In 1947 he was appointed C.B.E.

A member of the British Medical Association since 1899, he was chairman of the Auckland Division in 1923-4. In 1921 he was elected the first president of the newly formed Auckland Clinical Society. He was also president of the otolaryngological section of the New Zealand Medical Conference in 1924 and of the Pan-Pacific Surgical Association in 1939. His presidency of the New Zealand League for the Hard of Hearing was no titular office, for he conducted an energetic campaign against unscrupulous salesmen and misleading advertisements of commercial hearing-aids, always with the aim of alleviating the distress of the afflicted. In recent years he had devoted much time and thought to the nomenclature of the anatomy of the bronchial tree, a subject neglected until just before the second world war. With Drs. W. Gilmour and F. J. Gwynne, Hardie Neil was the author of an authoritative article printed in this *Journal* in 1939. This paper, the result of long and painstaking work, was followed by another presenting in greater detail the results of their study. The second communication was read before the Auckland Clinical Society in 1945 and was printed in the *New Zealand Medical Journal* in the following year. He also wrote, jointly with Dr. Gilmour, an article on broncho-pulmonary segments of the lung and their terminology, which was published in the *British Medical Journal* in 1949. Other writings from his pen included a small book on *Field Ambulance Organization and Administration*, published in 1918, and *Ear, Nose, and Throat Nursing*, which ran to several editions.

Hardie Neil was elected a Foundation Fellow of the Royal Australasian College of Surgeons in 1927. He

was also a Fellow of the American College of Surgeons. He married Miss Mary E. Coates in 1904 and had two sons and four daughters.

Sir FRANCIS TREHERNE, K.C.M.G., F.R.C.S.Ed.

Major-General Sir Francis Treherne, one of the oldest members of the Army Medical Service, died at his home at Woodbridge, Suffolk, on January 30.

Francis Harper Treherne was born in 1858, the son of an audit clerk at Somerset House. He was educated at Godolphin School and received his medical training at St. Bartholomew's Hospital, qualifying in medicine in 1881. Three years later he took the F.R.C.S.Ed. and in 1887 the D.P.H. of Cambridge. He immediately adopted the Army as a career. In 1884 he was serving with the Egyptian Expeditionary Force and in the following year in the Sudan Expedition. In each case his services were recognized by mention in dispatches and by decorations. The year 1893 saw him in India, now a major in what, a few years later, became the R.A.M.C., and for five years he was surgeon to the Commander-in-Chief.

Then came the South African War, during the whole of which he served with the British forces and won campaign medals and further mention in dispatches. Later on, in 1908, he saw service on the North-west Frontier of India. In 1912 he was honorary surgeon to the Viceroy (Lord Hardinge of Penshurst), and for three years Assistant Director of Medical Services in India. When the first world war broke out in 1914 he was Deputy Director of Medical Services of the Indian Corps which formed part of the British Expeditionary Force, and during the later years of the war he served as Director of Medical Services of the Third Army. His services in France in 1914-16 received mention three times in dispatches, and afterwards he was sent to Mesopotamia and was in the actions at Kut and Djalal and at the capture of Bagdad. Later he was Deputy Director of Medical Services in the London District and inspector of hospitals in the Southern Command. His last period of service was as Inspector of Medical Services, stationed at the War Office. Appointed C.M.G. in 1915 and K.C.M.G. in 1917, he retired in 1919 with the rank of major-general and went to live at Woodbridge, in Suffolk. He married twice. One of his sons by his first marriage, Captain Claude Treherne, R.A.M.C., died of wounds in the first world war.

G. PRATT YULE, M.D., F.R.C.P.Ed.

Dr. G. Pratt Yule, formerly medical officer of health for Fife County, died in the Adamson Cottage Hospital, Cupar, on January 6. He was 81 years of age.

George Pratt Yule was born on July 30, 1873, and was educated at George Watson's College and at Edinburgh University, where he graduated M.B., C.M. in 1894. Two years later he obtained the B.Sc. in public health and in 1899 proceeded to the M.D. He became a Member of the Royal College of Physicians of Edinburgh in 1900 and was elected a Fellow in 1905.

After graduation he worked in the pathological laboratories at Larbert Institution and later at the Crichton Royal Institution, Dumfries. He was then appointed assistant to Dr. (later Sir) Leslie Mackenzie, medical officer of health, Leith. Subsequently he became resident medical officer at the Edinburgh City Fever Hospital and still later went to the Corporation Fever Hospital, Manchester. In 1900 he volunteered for service in

the South African War and was appointed second in command of the Edinburgh and East of Scotland Hospital, stationed at Norval's Point, on the Orange River. He was given this post because of his specialized knowledge of fevers, particularly typhoid fever, since typhoid fever was at that time rife among the troops. Dr. Pratt Yule remained in Africa to work in a military hospital at Bloemfontein until he was appointed health officer for the area. After a brief return to this country he was recalled by Lord Milner to serve as principal medical officer for the Orange River Colony, a post which he held until he left South Africa in 1912. The position he held was a responsible one and he carried out his duties with vigour and foresight. He assisted in the introduction of legislation covering a wide field of public health practice and medical service and thereby established for the first time in the State an organized medical service.

In 1912, soon after his return to Britain, he was appointed medical officer of health for Fife, a position he held until his retirement in 1938. He became an examiner in public health in Edinburgh University, and in Fife played a big part in the intensive work of reorganization which followed the introduction of the Local Government (Scotland) Act, 1929. He was successful in bringing into being a unified maternal, child health, and school health service. The first health visitor was appointed in Fife in 1909, and Dr. Pratt Yule, throughout his whole period of office, fostered and expanded this form of domiciliary service. He was instrumental in securing the erection of Glenlomond Sanatorium. The foresight and determination with which he utilized the increased powers devolving upon local authorities for the promotion of the public health resulted in his laying the solid foundation on which the health services of Fife stand to-day.

Dr. Pratt Yule is survived by a widow, a son, Dr. Alastair Pratt Yule, who is in practice in Cumberland, and two daughters, one of whom, Mrs. Lawrence, was appointed professor of psychology in the University of Natal in 1953.

ROBERT GRIEVE, M.D., F.R.C.S.Ed.

Mr. Robert Grieve, honorary consultant surgeon to the Hull Royal Infirmary and the Victoria Hospital for Sick Children, Hull, died suddenly at his home at Hull on December 30, 1954. He was 83 years of age and had been in active practice over a period of sixty years.

Born in London on November 22, 1871, the son of Dr. Robert Grieve, who at one time was Surgeon-General of British Guiana, Robert Grieve, junior, came of a family of Scottish lowlanders with a long medical tradition. He received his early education at Bedford, later studying medicine at Edinburgh University and graduating M.B., C.M. in 1894. Three years later he proceeded to the M.D., with commendation, and in 1900 he was elected F.R.C.S.Ed. In the same year, after having held several appointments, he became honorary assistant surgeon to the Hull Royal Infirmary. In 1918 he was elected full surgeon, a post which he held until reaching the age of retirement in 1932. During his years on the full staff he became senior surgeon, chairman of the medical committee, and a member of the board of management. On retiring from the infirmary staff he continued to serve as honorary surgeon at the Victoria Hospital for Sick Children until the inception of the National Health Service in 1948. During the second world war, although then well on in years, he never

failed to respond to the many calls on his services for the treatment of air-raid casualties and other emergencies.

Throughout a busy surgical life Robert Grieve remained in general practice, the last of a generation of general-practitioner surgeons who rendered such outstanding service to voluntary hospitals in the locality. On relinquishing surgical work he continued in his general practice and was visiting patients on the day he died. A member of the British Medical Association for 57 years, he was chairman of the East Yorkshire Division in 1928-9. He was also a member and a past-president of the Hull Medical Society, and only recently he had been elected an honorary member of the society as a mark of the affection and esteem in which he was held by his colleagues. Robert Grieve was a man of quiet and kindly disposition, which endeared him to all. He had a pawky sense of humour and a fund of medical anecdotes. A skilful and versatile surgeon, he devoted his whole life to his profession, earning the gratitude of his colleagues and countless patients. As befitted his character, he enjoyed the quieter pursuits, reading, his garden, and the company of his friends. He was a bachelor, and is survived by a brother and two sisters, to whom our sympathy is extended.—J. N. Y.

Sir EDWARD MELLANBY, G.B.E., K.C.B. M.D., F.R.C.P., F.R.S.

The obituary notice of Sir Edward Mellanby was published in last week's *Journal*. We have since received the following appreciations.

Sir ARTHUR MACNALLY writes: Edward Mellanby and I were friends for many years. When I became Chief Medical Officer of the Ministry of Health in 1935, one of my chief aims was to bring the work of the Medical Research Council into closer relation with that of the Ministry. Mellanby supported me in this endeavour. He became a member of the Minister's Medical Advisory Committee, and he and I met at least once a week to discuss problems of medical research and their practical application. He and Sir John Ledingham helped me to get diphtheria immunization more generally applied; this work has reaped a golden harvest in combating a disease so fatal to child life and especially to the schoolchild.

In the early years of the second world war we planned the Emergency Public Health Laboratory Service together, for which the Medical Research Council took practical responsibility. Its value in aiding national health during the war and subsequently cannot be overestimated. When I left Whitehall to become editor-in-chief of the official medical history of the war, Mellanby joined our editorial board, and by his nomination of Dr. F. H. K. Green and Sir Gordon Covell enabled the war work of the Medical Research Council to be adequately recorded in a volume of the *History*.

These were our official relations, but they were facilitated and made pleasant by our friendship. Sometimes we disagreed on a particular policy, but we always agreed to differ. He was ever young in mind and body. Through his endeavours in peace and war he lived to see the work of the Medical Research Council greatly extended on the foundations so ably laid by Sir Walter Fletcher. Mellanby's own work on rickets has blessed mankind. He was fortunate in his life and work, and not least in the collaboration of his distinguished wife, Lady Mellanby, to whom our sympathy goes out to-day.

Professor A. E. BARNES writes: When Mellanby became the first professor of pharmacology at Sheffield an attempt had been made to arrange facilities for him for clinical work in his own beds as a physician at the Royal Infirmary as well as laboratory work in the pharmacological department at the University. In a few months he had succeeded

in adding the field laboratory at Lodge Moor, where very careful nutritional work was done on dogs. It was a tremendous job, but he and his wife worked for all they were worth and did their famous researches on rickets, including May Mellanby's work on the nutritional problems of dentition. Although it was not until many years afterwards, I think it is true that it was there that they first met with the toxic results of agene. The final incrimination of agene as the active factor in the causation of canine hysteria was a masterpiece of criminal detection aided by their scrupulous experimental methods. His conclusions were attacked with zeal by able and well-equipped workers, only to elicit confirmation just as had been the case years before when he announced the presence of an anti-calcification factor in oatmeal.

As a teacher Mellanby was superb. He aroused the enthusiasm of his students and of his colleagues. The general practitioners of Sheffield were enlisted in the enthusiasm, and the panel committee gave a donation (from a voluntary levy) of about £2,000 to the department. He was interested in the metabolism of alcohol, especially in diabetics, at a time when the Allen pre-insulin methods were our only resort and every calorie counted. One patient who submitted himself to venepuncture in these experiments was also many months later his first insulin patient. Rarely has a physiologist had such an opportunity of repaying one of his human "guinea-pigs," for he won only by a very short head. As a member of the staff at the Royal Infirmary he was a general favourite with all ranks. He was most stimulating, not to say provoking, and one member a year or two after his departure to London said at lunch one day, "Are we not a dull crowd since Mellanby left?"

Some time ago he and Lady Mellanby went to a dinner at Sheffield held by the newly formed Medical Students' Association, and they had a great reception. In a letter he summed it up, "It was a jolly evening except for my speech." Of his work as secretary of the Medical Research Council others have written. After his retirement he again found more time for research and was very busy indeed. Tissue culture (in collaboration with Honor Fell) occupied a lot of his attention. In a recent letter he states: "Lately we have been using radioactive isotopes and making autoradiographs in the tissue culture experiments, and it has been most enlightening. These new techniques, including chromatography, have transformed the study of biological problems, and I am only sorry that I was born too soon to get my teeth into them." These were, however only a part of his activities during his "retirement." As he would have wished, he died at work, though not actually in the laboratory. On holiday he was a delightful big boy, always good company. His death ends not only a happy marriage but a long and useful partnership in the service of medical science. The heartfelt sympathy of innumerable friends will go out to Lady Mellanby.

Dr. M. N. GHOSH writes: I find no reference in your obituary notice of Sir Edward Mellanby to the significant part he played in establishing the Central Drug Research Institute at Lucknow—one of the 11 national laboratories that have been started in India since her independence. This Drug Research Institute, the primary function of which is to investigate the potentialities of the indigenous drugs of India, was formally opened in 1951 by Mr. Nehru, the prime minister, and Sir Edward Mellanby was its first director, from November, 1950, to February, 1951. During his stay in India at that time Sir Edward also presided over the eleventh session of the All-India Pharmaceutical Conference, which was held at Bangalore along with the Indian Science Congress.

C. H. HAMPSHIRE, C.M.G., M.B., Ph.C.

Dr. F. H. K. GREEN, Principal Medical Officer of the Medical Research Council, writes: I do not think that any of the obituary notices of Dr. Hampshire so far published have mentioned the important work he did during the second world war as secretary of the Medical Research Council's

Therapeutic Requirements Committee. This committee was appointed at the request of the Ministry of Health, and by arrangement with the Ministry of Agriculture and other Government departments, to advise the wartime controllers of the importation and manufacture of drugs as to which drugs were vitally necessary and must be supplied at all costs, and which were less important; it informed the medical and veterinary professions and those responsible for the formularies, indents, and quotas, as to which medicaments were scarce and must be used economically; and it dealt with the manifold and difficult problems which inevitably arise when restriction has to be practised and indicated where exceptions should be made to avoid hardship. For all these functions Dr. Hampshire's unique experience made him the ideal secretary of the committee, and he discharged the duties with tact and skill.

I personally shall always be grateful to Dr. Hampshire for the help he gave to me and to my colleague, Dr. F. Hawking, when we were editing the two editions of the Medical Research Council War Memorandum No. 10, *The Medical Use of Sulphonamides*. We frequently went to him for advice on points within his wide field of expert knowledge, and never in vain.

R. J. WILLAN, C.B.E., M.V.O., M.S., F.R.C.S.

R. A. writes: The passing of R. J. Willan is indeed a sad blow to the profession and a great sorrow to his friends and colleagues. I had the privilege of serving under him in the first world war and of knowing him more intimately since the last war. One remembers with affection and gratitude the care and the time he devoted to the guidance and the instruction of surgeon probationers. Professor Willan was a man admired alike for his great personal charm and for his distinguished professional career. He was at all times courteous and modest, yet ready and willing to advise from his superior and expert knowledge. Of upright principles, he was kindness itself, understanding and sympathetic, and would do all in his power—even when physically unfit—to help the sick. As a patient he was co-operative and courageous in his painful malady, and always grateful for anything one could do for him. Professor Willan will be sadly missed by all who knew him.

H. A. C. writes: I should like to pay my small tribute to the memory of Surgeon Rear-Admiral Willan. I first met him in 1945 when he used to visit the R.N. Hospital, Port Edgar, in his capacity as consulting surgeon to the Navy in Scotland. It was his custom to leave after lunch in his car to travel back to Newcastle; but one day he altered his routine and spent the night in the medical mess. I shall always remember that evening after dinner, how he entertained us all with his stories and kept us up to a late hour thoroughly enjoying ourselves. Although I have never seen him again since that night, I have always had a soft spot in my heart for him. He must indeed have been a very good messmate in his younger days while serving at sea in the R.N.V.R. during the first world war. I am sure that all R.N. medical officers who met him held him in high esteem and liked him, for he was indeed a very likeable man.

HENRI GOUGEROT, M.D.

Dr. Henri Gougerot, the eminent French dermatologist, died in Paris on January 15, aged 73. He was born at St. Ouen-sur-Seine on July 2, 1881, and after a medical education in Paris he qualified in 1908. Two years later he became professeur agrégé in the faculty of medicine and a hospital physician. He served in the French Army during the war of 1914-18, being awarded the Croix de Guerre. In 1928 he was appointed to the chair of clinical dermatology and syphilology at Paris University and became chief physician at the Hôpital St. Louis, posts which he held at the time of his death.

Gougerot made a number of important contributions to the literature of his subject; in 1909 he first described

hemisporosis and, with de Beurmann, gave the first complete account of sporotrichosis (de Beurmann-Gougerot disease) in 1912. He wrote also on sarcoidosis, lupus, cutaneous papillomatosis, and the prevention of venereal diseases, edited the *Archives dermato-syphigraphiques de la clinique de l'Hôpital Saint-Louis*, and was a co-editor with Darier, Sabouraud, and others of the *Nouvelle Pratique Dermatologique* (published in eight volumes in 1936). He was president of the Société de Dermatologie et Syphiligraphie in 1934, and an honorary president of the ninth international congress of dermatology and syphilology, Budapest, 1935. He also presided over a number of national organizations concerned with social hygiene.

JAMES WHILLIS, M.D., M.S., F.R.C.S.

T. P. K. writes: I crave space for a small tribute to Professor James Whillis (whose obituary was published in last week's *Journal*) from that group of consultants, registrars, and visitors who meet at Stoke Mandeville Hospital every Monday to discuss their problems of construction, reconstruction, and repair. James Whillis visited us once a month, and only illness or the pressing call of one of his other "extramural" activities was allowed to cause us the disappointment produced by a cancellation of the visit. Not everyone will know that Stoke Mandeville Hospital, Aylesbury, is roughly 40 miles north-west of London, and that Whillis lived at Seal, near Sevenoaks, some 30 miles south of the Metropolis. It was a measure of the value he placed on these visits that he was prepared to arrive at the hospital mid-morning and not leave to travel home by train via London until night, with the expectation of reaching home about midnight. These visits were to us a means of keeping us on the right lines anatomically and functionally, and to him a link with the clinical applications of his specialty, and, indeed, with clinical matters in general. Our apologies to his wife for this imposition were always considered unnecessary, because she knew how much her husband enjoyed these visits. He would watch operations until lunch and spend the whole afternoon in the clinic, where out-patients and in-patients were freely and fully discussed. To these discussions he always contributed much sage advice, and his presence was as invigorating as a breath of fresh air. If time allowed he would round off the session with a "lecturette" on some anatomical subject of our choice before we carried him off to dine with us in Aylesbury, hear one of those yarns he told so well, and reluctantly see him to his train.

Everyone who met Whillis was fascinated by his boyish (almost puckish) outlook; all who knew him developed for him a deeply affectionate regard. He had many friends and surely no enemies. We shall remember him as the man with the articulated finger bones in his pocket—always ready to demonstrate the disturbances of function so commonly seen in the burnt finger—and as that rare teacher who could make anatomy live and embryology understandable. We shall keep on remembering (and missing) him in a thousand and one ways, but most of all for his warm and loyal friendship.

The winter number of the *Army Medical Services Magazine*, published last month, includes a reproduction of a photograph of the funeral procession of the late Major (temporary Lieutenant-Colonel) W. R. W. WEST-WATSON, R.A.M.C., who lost his life in an aeroplane disaster in Alaska on February 5 last year, and was buried in the Kermit-Roosevelt cemetery in Alaska. His father was the late Dr. W. N. West-Watson, who died in 1949, and who was a tower of strength to the Bradford Division of the British Medical Association as its secretary for many years and later its chairman; he was also local general secretary of the Bradford Annual Meeting of the Association in 1924. William Ronald West West-Watson was born on April 6,

1914, and was educated at Aldenham School and at Leeds University, taking the London degrees of M.B., B.S. in 1938. After graduation he held the appointments of junior casualty officer at the General Infirmary at Leeds and house-surgeon at Bradford Royal Infirmary. In April, 1939, he received a commission as a lieutenant in the R.A.M.C. Reserve of Officers and was mobilized on the outbreak of the second world war a few months later. Promotion to captain followed in 1940, and four years later he became a Regular. During his career in the R.A.M.C. he served in Madagascar and with Paiforce, the Middle East Land Forces, the Central Mediterranean Force, and with the Army Medical Directorate as deputy assistant director-general. In 1944 he was appointed M.B.E. for gallant and distinguished services in Italy, and in the following year he was mentioned in dispatches. When he met his tragic death he was on his way to attend a United States Army exercise as medical liaison officer of the British Joint Service Liaison (Army Staff) at Washington. West-Watson was an efficient, experienced, and popular officer, and his early death is a great loss to the R.A.M.C. A memorial service was held in the chapel of Queen Alexandra Military Hospital on July 27, 1954. He is survived by a widow and two children.

Dr. G. E. TILSLEY, who died on November 11, 1954, at Sheffield, where he had been in practice since 1934, was for some years before that a medical missionary in the Belgian Congo. He was 59 years of age. George Edwin Tilsley, whose parents were Plymouth Brethren, was born on July 10, 1895, the eldest of the seven children. He began the study of medicine at Bristol University with little material support but with the firm conviction that God would provide for his needs. After the first year he supported himself and paid his way by coaching fellow students, dispensing for general practitioners, and demonstrating anatomy. He played hockey for his university and was in the team that beat Oxford before the first world war cut short his sporting career. After qualifying M.R.C.S., L.R.C.P. in 1918 he remained as casualty officer at Bristol Royal Infirmary until called up, when he was sent to Salonika. He became staff officer in hygiene to the Army of the Black Sea and so remained until demobilization, when he returned to Bristol University for a short time as lecturer in pathology. His mind, however, was already turning to the mission field, and he went to Luanza on Lake Mweru in the Belgian Congo, where he built a hospital and also one of the first leper colonies in the Congo. His nearest colleagues were at the Government Hospital at Elizabethville, some 350 miles away. At first the people were somewhat suspicious of "the new medicine," but later on, as the news of successful treatment spread, they came in increasing numbers, and it was no unusual thing for patients to travel for six weeks in order to have a consultation. To feed the patients he established a farm and employed fishermen and hunters. In the early days Dr. Tilsley suffered much from malaria. During his second furlough he obtained the D.T.M.&H. in 1930, but in 1933 he retired from the mission field and in the following year acquired a small practice at Sheffield. He steadily enlarged the practice—his aim being ever to treat the whole man and not just the immediate disease. The advice his patients sought on matters other than medicine was willingly given. His interests were many, and he contributed much to problems concerning the well-being of the people generally, particularly in regard to road safety. Both his two sons are now doctors and to them and to his widow and daughter the sympathy of his colleagues is extended.

The sudden death of Dr. D. C. DEVITT in a bathing accident at Hermanus, Natal, South Africa, on December 26, 1954, came as a shock to all who knew him. He was 48 years of age. Denys Christian de Wet (he changed his name to Devitt in 1933) was born at Cradock, Cape Province, the son of a well-known local medical practitioner, and came to England to enrol as a medical student at

St. Thomas's Hospital Medical School in 1927. After qualifying M.R.C.S., L.R.C.P. in 1932 he was in general practice at Eastcote, Middlesex, for some years, becoming also a medical officer to the Ruislip-Northwood Hospital, before deciding to specialize in anaesthesia. Later he became anaesthetist to Mount Vernon Hospital, an appointment he held for 10 years. He obtained the D.A. in 1942 and only last year he was elected a fellow of the Faculty of Anaesthetists. He served in the last war as a member of the R.A.F.V.R., attaining the rank of squadron leader, resigning his commission in 1948, the year after he returned to South Africa. In 1933 he married Christine Margaret, elder daughter of the late Dr. Charles Sampson.

We are indebted to Dr. J. C. NICHOLSON for the following appreciation: In South Africa, as senior full-time anaesthetist to the largest teaching hospital in the country—the Johannesburg Hospital—Denys Devitt played a prominent part in the development of modern anaesthesia. It was his work in that field which gained him the respect of all his colleagues; and his solid, practical approach to the most difficult problem was generally admired by all who were privileged to work with him. With his enthusiasm for progress he also displayed a shrewd conservatism, based on sound physiological principles, which was a sheet anchor to his pupils and enabled them, amid a maze of innovations, to sift the wheat from the chaff. His loss is irreplaceable, for he belonged to that rapidly disappearing group of men who are able to combine the breadth of vision and human understanding of a first-class general practitioner with the skill and judgment of the specialist. Those who were privileged to know him more intimately knew him as a kind and generous friend and as a devoted husband and father.

Dr. H. J. S. MORTON, who for the last few years had been living in retirement at Brinkley, near Newmarket, died in London on January 3 after a long illness. He was in his 70th year. Harold James Storrs Morton was born at Sheffield on January 31, 1886, the second son of the Rev. C. J. F. Morton, and was educated at Uppingham, Pembroke College, Cambridge, and the London Hospital. After gaining a second class in the Natural Sciences Tripos, he qualified by taking the conjoint diploma in 1912, graduated M.B., B.Chir. in 1916, and proceeded to his M.D. in 1919. After qualification he held a series of house appointments at the London Hospital until the outbreak of the first world war in 1914, when he took a commission in the R.A.M.C.(S.R.) and served in France till 1918. After a period as assistant medical officer at King Edward VII Sanatorium, Midhurst, he joined a practice at Bridlington, and remained there till 1935, when he moved to the St. John's Wood area of London. He retired from practice in 1947 and went to live in Brinkley, but continued to sit on medical boards till ill-health finally forced him to give up work altogether. Morton was an old international Rugby forward, having played for England in 1909 and 1910 and for Cambridge in 1908.

C. J. G. T. writes: I had the privilege of knowing Harold Morton intimately, as a fellow houseman at the London and later as a partner in practice for twelve years. Morton was a big man in every way, a typical Rucker forward in appearance, but in manner no one could have been more gentle. Quiet of voice, showing the utmost consideration for the feelings of others, self-effacing in company, the whole man rather belied his great and well-earned reputation on the football field, and this probably helped to give him the name "Tiny," by which he was known among his student friends. He possessed a droll sense of humour which delighted his associates. Morton was a very able and most conscientious doctor, who never spared himself when the interests of his patients demanded his services. He was a first-rate physician and a very capable anaesthetist. It is no exaggeration to say that he was universally beloved by his patients, and he had a perfectly wonderful way with old ladies, who simply adored him. He had no use whatever for the National Health Service Act, and gave up practice

rather than have anything to do with it. He was a man of very high ideals, who was incapable of anything underhand, and he won the respect of all with whom he came in contact. Morton had to suffer grievous misfortune and disappointments, but never allowed these to sour him. He lost his first wife with tragic suddenness while she was bathing, and he was called to the beach not knowing that she was the victim. To a man of his temperament this was even a bigger blow than it would have been to many others, especially at a time when his three sons were at the difficult age when a mother can do so much for them. It was a comfort to his friends to know that his second marriage was such a happy one. We offer our profound sympathy to his widow and three sons.

The distress caused to his family and friends by the death on January 4 at St. Andrews of Dr. J. A. MACDONALD-SMITH was deepened 18 days later by the death of his widow, Dr. Elizabeth G. Macdonald-Smith, on January 22. Born on May 21, 1872, at Belfast, the son of John Smith, plumber, of Aberdeen, and Jane Smith, of Carrickfergus, John Alfred Smith was the eldest of a family of 13 and left school at the age of 14 to work in the Post Office, where he eventually became an expert telegraphist. His heart was set on becoming a medical missionary, and at first he attended night classes and later worked at night in the telegraph office so that he could attend lectures in the morning at Queen's University, where he began his medical education. In 1896 he went to Edinburgh to continue his training, helped by the Edinburgh Medical Missionary Society, and graduated M.B., Ch.B. in 1900. In the same year he went to India to establish a medical mission station at Rajshahi, Eastern Bengal, for the Presbyterian Church of England, and, overcoming many difficulties, financial and climatic he built a hospital and a mission bungalow at Naogaon. In 1901 he married Elizabeth Greer, the youngest daughter of the Rev. K. S. Macdonald, of Duff College, Calcutta. She had been a fellow student at Edinburgh University and graduated M.B., Ch.B. with distinction a year before him. During his first furlough, while doing deputation work for the Church's foreign missions, he found time to continue his postgraduate studies and took the F.R.C.S.Ed. in 1909 before returning to India. There was an interlude in his missionary service from 1914 to 1921, when he was in general practice at Nottingham. During part of this time he was also attached to one of the military hospitals in the district. When the educational future of his family was secure, Dr. Macdonald-Smith sailed for India again, this time to serve the Church of Scotland at Kalimpong, North Bengal where he had to learn a new language and cope with new problems. He also found a new cause to fight for—the treatment and control of leprosy. In addition to his work at the Charteris Hospital he established, not without early opposition, a leper hospital and supervised its building on the hillside overlooking the Teesta valley with a magnificent view on all sides. Its reputation was quickly made and patients came, sometimes long distances, from the surrounding states of Nepal, Bhutan, and Tibet. A church was also built at the tip of the spur and is a landmark for miles on either side, a lasting memorial to his perseverance and devoted service. On his retirement in 1939 he could not immediately return to this country on account of the war, so his offer of help in South India was gratefully received to enable other missionaries to take overdue holidays. He continued working, first in Chingleput and then in Sholinghur (for the Australian Presbyterian Church) until 1944, when, with his wife, he travelled home for the last time. Their retirement was spent in the home his father had made in Bangor, Co. Down, but towards the end they had been staying with their daughter at St. Andrews. Dr. Macdonald-Smith's long life was one of dedication to the overseas work of the Church in the field of medicine. Difficulties and disappointments were many, but he met and overcame them with courage, determination, and prayer. He was a man of high principles and inflexible purpose.

softened by a saving sense of humour. His wise counsels and his example will be sadly missed by many friends all over the world. His son, Dr. K. S. Macdonald-Smith, is in practice at Nottingham.

Dr. ELIZABETH G. MACDONALD-SMITH, who had been in failing health for a long time, did not long survive her husband, Dr. J. A. Macdonald-Smith, whose obituary is printed above, for she died on January 22 in her 79th year. Born at Calcutta on June 17, 1876, the youngest daughter of the Rev. and Mrs. K. S. Macdonald, Free Church of Scotland missionaries, Elizabeth Greer Macdonald had a distinguished career at Edinburgh University and graduated M.B., Ch.B. in 1899, soon after the degree in medicine had become available to women students. She preceded her husband to the mission field, and after their marriage in 1901 she was his constant helpmate in all his medical missionary work throughout their long life together. She will be remembered also in Nottingham, where, after her husband's return to India in 1921, she remained with her children for five years and was an assistant school medical officer in the city. Those who mourn the passing of Dr. and Mrs. Macdonald-Smith will remember with gratitude their useful life of service together, and will be glad that in their death they were not divided.

Dr. WILLIAM ARNOLD, who was in practice for many years at Waltham-on-the-Wolds, near Melton Mowbray, died on January 3 in his 92nd year. William Arnold was born on May 13, 1863, and was educated at Trent College and Owens College, Manchester, qualifying in 1885 by taking both the M.R.C.S. and L.S.A. diplomas. He then held the appointment of junior house-surgeon at Ancoats Hospital, Manchester, before entering general practice at Blisworth, Northamptonshire, where he also performed the duties of medical officer to the Blisworth district of the Towcester Union. From Blisworth he moved first to Great Milton, in Oxfordshire, where he became medical officer to the Great and Little Milton districts of the Thame Union, and then to Crawley, in Sussex. About 1897 he settled in practice at Waltham-on-the-Wolds, becoming medical officer and public vaccinator for the district and medical officer to the Melton Mowbray Medical Club. In a very short time all who knew him in the hunting districts of Leicestershire came to revere and love him. He retired in 1933 at the age of 70, and, after a visit to his only son in Kenya, settled at Stratford-on-Avon to be near his married daughters. He found retirement very tedious, however, and in a few months' time was acting as locum tenens for friends, later buying another practice at Four Marks, in Hampshire, where he worked until the death of his wife in 1942. He then returned to Stratford-on-Avon to live with his youngest daughter.

Mr. ARNOLD LEEMING, who died at Bristol on January 9, was well known as a general surgeon both at Sudbury, Suffolk, and at Cheltenham. Born at Halifax, Yorkshire, in 1881, the son of an architect, Arnold Leeming was educated at the City of London School and at University College, London, before becoming a medical student at Guy's Hospital. There he was fellow dresser, under Mr. W. H. A. Jacobson, with the late Mr. E. C. Hughes, and he was house-surgeon to Mr. C. H. Golding-Bird just before the latter's retirement, Hughes being house-surgeon to Mr. (later Sir) Arbuthnot Lane at the same time. Leeming and Hughes remained warm friends for many years. After graduating M.B., B.S., with honours, in 1904, and holding a house-surgeoncy, he went to Sudbury as a locum tenens, but decided to stay there, and was for some years in partnership with Dr. H. D. King. He also became honorary medical officer to St. Leonard's Hospital, Sudbury, acquiring a high reputation for the emergency surgery he had to undertake. During the first world war he served in the R.A.M.C. as a surgical specialist at the 67th and 63rd General Hospitals in France and Salonika, attaining the rank of major. In 1922 he retired from private practice for a time, and then settled at Cheltenham with Mr. Thomas

Holmes, another Guy's man, as a general-practitioner surgeon. Obtaining the F.R.C.S.Ed. in 1924, he was elected to the honorary surgical staff of Cheltenham General Hospital and for many years was medical officer to the Cheltenham Colleges. Particularly interested in the radium treatment of cancer, he did much good work as a surgeon, and his opinion was greatly valued by his colleagues and by practitioners in the surrounding district. He had a kindly nature and was extremely conscientious in his work. In his younger days he was a good cricketer and footballer; he played cricket for Guy's and later for the Suffolk County Club. He finally retired from practice in 1945 and went to live at Tankerton, in Kent, where he became keenly interested in gardening. He married Miss Anne Lamprey, and they had three daughters and one son, who is Dr. John A. L. Leeming, a dermatologist at Durban, Natal. His brother is Dr. A. Norman Leeming, and Dr. Donald N. Leeming and Dr. Roy A. Leeming are his nephews. All are Guy's men.

Dr. CECIL MERIDYTH JONES, a well-known Croydon general practitioner and for many years a surgeon at Croydon General Hospital, died on January 9 at the age of 64. From University College, Cardiff, he went on to the Westminster Hospital, and graduated M.B., B.S., with honours in medicine, in 1912. After working as house-surgeon at the Westminster Hospital and later at the Taunton General Hospital, he joined the R.A.M.C. at the outbreak of the first world war, being wounded in 1916. In 1921 he took the F.R.C.S., and in the following year settled in practice at Croydon in partnership with Dr. C. Poulett Harris and Dr. J. H. Thompson. Soon he was elected to the surgical staff of the Croydon General Hospital, where he continued his operative work until 1948. Although in failing health for the past two years, Dr. Jones was at work in his busy practice until about six weeks before his death. He leaves a widow and one daughter.

Dr. W. F. MUNRO, the senior medical practitioner in Burnley, died suddenly at his home there on January 18, aged 74. Born on March 20, 1880, William Fraser Munro was educated at Aberdeen University, graduating M.B., Ch.B. in 1903 and proceeding M.D. in 1929. Settling in Burnley in 1906, he was in active practice there until the day of his death, a span of almost 50 years. A member of the British Medical Association for 48 years, he was honorary secretary of the Burnley Division from 1921 to 1932 and chairman in 1932-3. He was a member of the Burnley Insurance Committee from 1929, and from 1947 a member of the Burnley Executive Council, being vice-chairman of the latter body since 1952. For 30 years he was a member of the local medical committee and had been chairman for the past 10 years. In spite of his busy professional life he found time for much public service. For 15 years he was a member of the town council, being chairman of many of its committees concerned with health matters. He was also a borough magistrate for many years. During the first world war he served with great distinction in the R.A.M.C., attaining the rank of lieutenant-colonel and being awarded the Military Cross in 1917. He received the Territorial Decoration in 1923. Keenly interested in the welfare of ex-Service men, he was president of the Burnley branch of the Old Contemptibles' Association for 25 years.

C. E. B. L. writes: At a crowded memorial service held in Burnley parish church Dr. Munro was described as "one of the most outstanding characters that Burnley had known this century." As one who has known him for many years as a colleague, I should like to add my humble tribute. Above all, William Fraser Munro was a man of good will; he loved his fellow men, understood their troubles, and in his own kindly way helped to lighten their burdens. In short he was, what so few of us manage to become, an outstanding example of the family doctor. As chairman of the medical committee he acted as a cushion, not to be sat

on, but to soften the verbal blows of conflicting views. Until his death he was most active both physically and mentally, and had no difficulty in fitting into the rapidly changing face of medicine. Through it all, his kindly smile, his courteous manner, and his quiet humour remained unaltered. He was most truly a gentle man. To his widow, son, and daughter we extend our deepest sympathy.

The death took place on January 30, at the age of 81, of Brevet-Colonel A. E. HAMERTON, who had spent 28 years of his life in the medical services of the Army, and afterwards served for 18 years as pathologist to the Zoological Society of London. Albert Ernest Hamerton took his medical training at the Leeds Medical School, qualifying in 1899. After a period as resident medical officer at Leeds Public Dispensary he joined the Army in 1900. In 1904, by which time he had attained the rank of captain, he saw active service in Somaliland, in the operations against the "Mad" Mullah, and he was in the battle at Jidballa when 1,000 of the enemy were killed and the British loss in killed and wounded was 58. For his services in that action he was mentioned in dispatches and received the D.S.O. From 1908 to 1910 he was a member of the Sleeping Sickness Commission in Uganda, and no sooner had he completed that task than he was sent on a similar commission to Nyasaland, which lasted until 1913. He joined the British Expeditionary Force in France at the outbreak of the first world war, and served until 1919; here again he was mentioned in dispatches and also received the C.M.G. From 1920 to 1922 he was director of the Central Laboratory and Pasteur Institute at Bagdad. Returning to this country in 1923, he became assistant director of pathology at the War Office. He retired from the Army in 1928 and took charge of the prosectorium at the London Zoological Gardens, where he performed innumerable post-mortem examinations on many species of animals. He had always taken an interest in comparative medicine and had written various papers on such subjects as rabies in Iraq and its treatment by carbolized vaccine, and on trypanosomiasis in man and beast in Africa. He was vice-president of the Section of Comparative Medicine at the Centenary Meeting of the British Medical Association in 1932. Colonel Hamerton served on the Council of the B.M.A. and on the Naval and Military Committee from 1929 to 1932, and did some very useful work on subcommittees concerned with conditions in the R.A.M.C. He was a Fellow of the Royal Society of Medicine, the Royal Society of Tropical Medicine and Hygiene, and the Zoological Society of London, and a member of the Pathological Society of Great Britain and Ireland.

Dr. J. H. MURDOCH, principal medical officer at Wandsworth Prison, died in St. James's Hospital, Balham, on January 22 at the age of 54. He had been in poor health for some years, but carried on with his work until a few days before his death. James Hunter Murdoch, a direct descendant of William Murdoch, the inventor of gas lighting, was born at Glasgow on May 27, 1900. He received his early education at Whitehill School and then volunteered, at the age of 17, for service in the Army during the first world war. On return to civilian life he entered Glasgow University as a medical student and graduated M.B., Ch.B. in 1924. In 1925 he was appointed resident medical officer at the Glasgow District Mental Hospital, where he was one of the first to become interested in the malaria therapy of general paralysis of the insane, later publishing his observations. He joined the prison medical service in 1928 and held appointments in various prisons throughout the country, gaining an increasingly high reputation as time went on. At Broadmoor he made a special study of crime in schizophrenia, publishing a paper on the subject in the *Journal of Mental Science* in 1933. In 1949 he and three other prison medical officers submitted a memorandum to the Royal Commission on Capital Punishment. Most of his work, however, must remain unknown to the general public, but while at Wandsworth he gave valuable expert advice in many well-known

criminal cases. James Murdoch, before his illness, was a keen all-round games player. He was an enthusiastic amateur footballer and a good cricketer, golfer, and tennis player, and will be remembered by many senior prison officers for his stamina in these games. He spent many of his holidays camping and boating in Scotland. His ability extended beyond his own specialty, and he was ever ready to lend a helping hand to a local practitioner at short notice. He was an excellent companion and a sincere and reliable friend. His early death came as a great shock to all who knew him, and he is mourned not only by the prison staff but by a much wider circle of friends in Wandsworth. He is survived by a widow and daughter, who is a science graduate of St. Andrews University, and to them we offer our sincere sympathy.—T. J. L.

A memorial service for the late Dr. HAROLD K. WALLER will be held in the chapel of the British Hospital for Mothers and Babies, Samuel Street, Woolwich, S.E.18, on Thursday, February 17, at 3 p.m.

Medico-Legal

SURGEON PHYSICALLY FIT

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On February 3 the Court of Appeal Dismissed the appeal of Mrs. Winifred Nickolls against the Ministry of Health as successors under the National Health Service Act to the liabilities of the Royal Free Hospital. Mrs. Nickolls's case was that she was operated upon for the removal of a goitre on December 1, 1944, by the late Mr. Cecil Joll, who was then suffering from carcinoma of the lung, that he and the hospital authorities knew or ought to have known that his state of health was such that he was unfit to perform the operation, and that by reason of his unfitness the result of the operation was that she now suffered from permanent bilateral laryngeal paralysis because of damage to the recurrent laryngeal nerves.

Mr. Justice Gorman had dismissed the action on July 2, 1954, because he came to the conclusion that Mr. Joll had in fact been quite fit to perform the operation.

In his judgment dismissing the appeal Lord Justice Denning¹ said that Mr. Joll was at that time the greatest surgeon in England for that type of quite simple operation, during which in some way or other both Mrs. Nickolls's laryngeal nerves had been damaged, which was a very rare thing to have happened. Mrs. Nickolls said that the cause was Mr. Joll's state of health. In June, 1944, he was diagnosed as suffering from cancer of the lung. By September he was also suffering from diabetes and was having deep x-ray therapy and insulin. In November, 1944, the cancer was found to be spreading through his body, but he went on operating until January 9, 1945, and died 16 days later. He was a brave man who carried on with his work to the last possible moment. Mrs. Nickolls said that that would have been wholly admirable but for the fact that other people's lives were in his hands.

Lord Justice Denning felt that something must have gone wrong with the operation owing to Mr. Joll's illness, resulting in the damage to Mrs. Nickolls's laryngeal nerves, but that was not negligence unless it could be said that there was negligence every time a surgeon was taken ill in the theatre. There was no question of want of skill or care by Mr. Joll. The real question was whether he was fit to undertake the operation at all, for obviously surgeons should not undertake operations unless they were fit to carry them out. The judge had found that Mr. Joll was fit to perform this operation and the Court of Appeal could not differ from him on that point.

Lord Justice Hodson delivered a concurring judgment, and Lord Justice Parker agreed.

¹ *The Times*, February 4, 1955.

OBSCENE PUBLICATIONS

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

A committee appointed on the initiative of the Society of Authors to inquire into and report on the law relating to obscenity in literature has now submitted its principal recommendations to the Home Secretary in the form of a draft Bill. This is designed to remedy what the committee considers to be anomalies and defects in the existing law relating to the common-law misdemeanour of publishing obscene libels, the powers of justices to order the destruction of obscene matter under the Obscene Publications Act, 1857, and the powers of the Commissioners of Customs and Excise to destroy indecent matter seized on import.

The committee's objection to the present common law relating to obscenity is that the test to be applied in deciding whether the matter is obscene is purely objective: in the view of the jury is the matter calculated to deprave and corrupt those whose minds are open to its influence and into whose hands it may fall? The committee observes that the intention and purpose of author and publisher are ignored, that it is no defence that the matter is of literary, artistic, or scientific merit, that expert evidence of literary, artistic, or scientific value is not admitted, that it is not clear whether a work objectionable only in isolated passages rather than in its "dominant effect" can be obscene, that they think that horror, murder, violence, and sadism are not caught by the present law, and that maximum penalties are not defined.

While the force of the committee's objections from the point of view of authors, printers, publishers, and booksellers is plain enough, others may think that an objective test is perhaps not only right but the only one susceptible of practical application if there is to be any legal restriction on obscene publications at all.

The remedies proposed by the Bill are that the intention and general character of author and publisher are to affect the matter, and the court is required to consider the "dominant effect" of the publication, whether it has in fact corrupted anyone, its literary, artistic, or scientific merit, on which expert evidence is to be admissible, and the class of persons among whom it is likely to circulate. The word "obscene" is to cover matter which, whether or not concerned with sex, "unduly exploits" horror, cruelty, or violence. The maximum penalty for an offence is to be £100 or six months' imprisonment.

The chief objections to the procedure under the Obscene Publications Act, 1857, are in addition that author, publisher, and printer have no *locus standi* to defend their work: that neither the prosecutor in attacking the work nor the magistrates in condemning it are obliged to indicate what in it they consider to be obscene, and prosecutions can be instituted, as indeed they can for the common-law misdemeanour, without the blessing of the Director of Public Prosecutions. The committee's objections to the Customs and Excise powers are that they are exercisable by the commissioners without any judicial determination by magistrates and without reference to the Director of Public Prosecutions.

The proposed remedies are that magistrates, in making destruction orders, shall take into consideration the same matters which the court is to consider in trying a case of obscene libel, that the author, publisher, printer, and distributor shall all have the right to give and call evidence, that the Customs authorities shall act only on the issue of a destruction order by a magistrate, and that all prosecutions shall be subject to the consent of the Director of Public Prosecutions.

As to medical textbooks, even in the present state of the law, magistrates and jurors are not likely to confuse them with pornography.

SLIPPERY FLOOR

Because cleaners in a ward at St. John's Hospital, London, S.W., failed to warn Mrs. Rose Hannah Slade, aged 67, of the presence of polish on the floor, Mrs. Slade, who slipped on the polish and broke her right thigh, was awarded £781

damages with costs by Mr. Justice Finnmere in the Queen's Bench Division on February 3. His lordship held that the Battersea and Putney Group Hospital Management Committee were liable because of the negligence of their servants.

On October 27, 1953, Mrs. Slade was visiting her husband, who was seriously ill in the hospital and has since died. When she was leaving the ward she saw two women standing with mops but not working. She slipped on a patch of polish that had not been rubbed in and fell. Evidence was given that, according to the hospital's accident book, 16 persons had slipped or fallen on the polished floors of wards and corridors in 14 months.

In his judgment, Mr. Justice Finnmere said he was satisfied that Mrs. Slade slipped on a part of the floor where polish had been spread and not properly finished off. Someone should have warned her of the danger, but they did not. The patch of polish, of which Mrs. Slade was not aware, was a concealed danger, he said, especially in the absence of any warning. It was more slippery than after the floor had been polished. He was satisfied there was no negligence on Mrs. Slade's part in failing to notice the small difference in the appearance of the floor. She did not know there was an unusual danger there. Was it negligent to leave that polish on the floor without giving a person warning? He thought the hospital committee were negligent through their servants, who did not act with reasonable care or give the warning required.

Awarding £750 general damages, in addition to the £31 special damages agreed, his lordship said Mrs. Slade had permanent limitation of movement of her right hip, and was incapable of doing any work that involved kneeling or stooping.

CRITERIA OF LIABILITY

The First Division of the Scottish Court of Session on February 4 ordered a new trial in an action which arose out of the breaking of a hypodermic needle. In the course of his judgment the Lord President (Lord Clyde) made some observations¹ on the establishing of negligence, and remarked that the standard seemed to be the same in England as in Scotland. He said that, to establish liability by a doctor where deviation from normal practice was alleged, three facts required to be established. First of all it must be proved that there was a usual and normal practice. Secondly, it must be proved that the defender had not adopted that practice. Thirdly (and this was of crucial importance), it must be established that the course the doctor adopted was one which no professional man of ordinary skill would have taken if he had been acting with ordinary care.

Medical Notes in Parliament

CLEARING THE AIR

Clean air legislation has attained a place in the forefront of the political picture with the undertaking given on February 4 that a Government Bill, Beaver Report "in principle," would be introduced this session. So the campaign, which began with the outcry after the deaths and damage to health caused by the great fog in December, 1952, given formal shape by the investigations conducted by Sir Hugh Beaver and his committee, and political impetus from the Bill presented by Mr. Gerald Nabarro, the Conservative M.P. for Kidderminster, has achieved its first objective.

Mr. NABARRO, moving the second reading of his Clean Air Bill, traced the ineffective efforts made to deal with smoke pollution back as far as 1257, when Queen Eleanor was reported to have moved from Nottingham because of the fumes caused by the burning of sea coal. In bringing the record up to date with an examination of the economic

¹ *Scotsman*, February 5, 1955.

losses caused by smoke pollution—estimated by the Beaver Committee at £250m. a year—he went on to quote Mr. Edward MacLellan, a surgeon, who had advised him and made the following statement: "It has been established beyond reasonable doubt that the alarming increase in the incidence of cancer of the lung is associated with the fouling of the atmosphere by smoke, exhaust fumes, and the offensive and deadly eruptions of gas works, power stations, and so on. There are more than twice as many victims of cancer of the lung in the towns as in the country, and the mortality from lung cancer among workers in the gas industry is double that of the general population."

Mr. Nabarro quoted also the Beaver Report on the medical aspects of smoke pollution. He declared that he and his supporters wanted an assurance from the Government that they would introduce a comprehensive and effective measure during the present session of Parliament.

Mr. ALFRED ROBENS (Blyth, Lab.) gave the Opposition's blessing in advance to such legislation.

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) moved the rejection of Mr. Nabarro's Bill, but only because, as a private Member's Bill, it could not go far enough and lacked the essential financial provisions. Even to assume that in ten years an 80% reduction of atmospheric pollution could be achieved meant that there was no time for delay and that no half-measures could be tolerated. Most authorities would agree that the worst pollution was sulphur dioxide, either by its own action as an isolated gas or through its synergic effects when it combined with sulphuric acid mist. He wondered whether the substitution of oil for coke in central heating plants would not inevitably mean a greater concentration of sulphur dioxide in the hearts of cities, since the 4% sulphur in oil compared with the 1½% in coke would mean more sulphur fumes in the air, unless costly preventive action was taken.

Mr. SOMERVILLE HASTINGS (Barking, Lab.) expressed his belief that the results of polluted air on health were almost entirely due to sulphur oxides and his doubt whether these would be appreciably decreased by the Bill.

Mr. DUNCAN SANDYS, Minister of Housing and Local Government, stated the Government's views, and gave the promise of their own Bill. Consultations with industry and local authorities were going ahead satisfactorily, but were not yet complete. Mr. Nabarro's text differed in many ways from the Beaver proposals, would present many difficulties, and could not of necessity contain the financial teeth to make it effective. But there was general agreement on the policy, and when its consultations were concluded the Government would frame and introduce a comprehensive measure on the general lines of the Beaver Report, which he hoped would be completed this session.

Mr. NABARRO exclaimed, "That is all we wanted," Dr. STROSS withdrew his motion for rejection, and Mr. NABARRO withdrew his Bill.

Colouring Matter in Food

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) asked the Minister of Food on January 31 what type of dye was used for the purpose of colouring some types of sugar purple, yellow, and green; and whether he would make a statement on the possible dangers to health that are involved. Dr. CHARLES HILL, Parliamentary Secretary, Ministry of Food, said that the Public Health (Preservatives in Food) Regulations forbade the use of five named coal-tar colours, but he had no reason to suppose that any one of these was being used in the coloured sugars in question. If Dr. Stross had any information to the contrary he would be glad to have it.

Mr. JOHN RANKIN (Glasgow, Tradeston, Lab.) asked the Minister of Food what steps he was taking to control the colouring materials put into foodstuffs so as to ensure that no substances deleterious to human health would be added. Dr. CHARLES HILL replied that the use of certain colouring matters including certain coal-tar colours was already prohibited. A report of the Food Standards Committee on the addition to foods of colouring matters, including coal-tar

colours, had recently been published. As was customary, it was proposed to await representations from interested parties before reaching a decision on the committee's recommendations.

Fluoridation Tests

Mr. S. P. VIAN (Willesden, West, Lab.) asked the Minister of Health whether the Anglesey water authority had yet investigated for fluorine content the urine of the area in which fluoridation was to be introduced, and the urine of the control area; how many persons participated in this investigation, and what were their ages; how far the condition of teeth of infants and older children in the areas had been ascertained; and if he would ensure that accurate and consecutive records of fluorine content of urine, and condition of teeth, were kept in the two areas. Mr. IAIN MACLEOD stated on February 3 that a pilot study of urinary excretion of fluoride in children in this country confirmed the result of work done in the United States and New Zealand, and made it clear that more exclusive studies need not be undertaken before fluoridation in Anglesey was begun. Arrangements were being made to examine the teeth of samples of children in each age group up to and including 15 years (and to some extent of adults), and consecutive records would be kept of all the most relevant facts.

Hospital Administration Report

Mr. J. K. VAUGHAN-MORGAN (Reigate, Con.) asked the Minister of Health whether he had considered the report of the committee of the Central Health Services Council on the internal administration of hospitals. Miss PAT HORNSBY-SMITH, Parliamentary Secretary, stated on January 31 that the Minister had studied the report with great interest. It contained much useful material and many valuable suggestions, most of which were addressed primarily to the hospital authorities themselves and were for them to consider in the light of their own particular circumstances.

Mr. KENNETH ROBINSON (St. Pancras, North, Lab.) asked if the Minister was prepared to make a statement on the observations of the Central Health Services Council with regard to medical superintendents of mental hospitals. Miss PAT HORNSBY-SMITH replied that the Minister did not consider it would be appropriate at the present time to introduce model standing orders for the general government of mental, and mental deficiency, hospitals defining the functions of the medical superintendent.

Paying and Non-paying Patients

The MINISTER OF HEALTH informed Mr. SOMERVILLE HASTINGS (Barking, Lab.) on February 3 that at the end of 1953 the number of beds in England and Wales designated under section 5 of the Health Service Act was 1,559 in teaching hospitals and 3,697 in other non-mental hospitals. The average daily occupancy during 1953 was—teaching hospitals: paying patients, 967.5, non-paying patients, 217; other (non-mental) hospitals: paying 1,630, non-paying, 720. Figures for 1954 were not yet available.

Scottish Surgeries

Mr. W. HAMILTON (Fife, West, Lab.) asked the Secretary of State for Scotland on February 1 what progress had been made in the talks designed to effect improvements in conditions at doctors' surgeries. Commander T. D. GALBRAITH, Under Secretary, said that it had been arranged that executive councils in Scotland would undertake a review of consulting accommodation in all areas where adequate arrangements for this purpose had not already been instituted.

Mr. HAMILTON asked for an indication of when some positive action would be taken. There were complaints about unsatisfactory conditions in surgeries, and some firm action

¹ British Medical Journal Supplement, October 2, 1954, p. 1.

was necessary. Commander GALBRAITH said he could not give any assurance. He knew what the situation was, and he hoped the executive councils would get on as quickly as possible.

Cadmium Poisoning.—The question whether, in the light of the report by a member of the staff of the Medical Research Council, cadmium poisoning should be prescribed as an industrial disease, and if so, for what occupations, is being referred to the Industrial Injuries Advisory Council.

Universities and Colleges

UNIVERSITY OF OXFORD

The title of Clinical Lecturer in the Diseases of the Ear, Nose, and Throat conferred upon Dr. R. G. Macbeth for five years from the first day of Michaelmas Term, 1954, has been changed to Clinical Lecturer in Otolaryngology.

The following degrees were conferred in Congregation on December 11:

D.M.—C. P. Silver.
B.M.—J. Billingham, A. C. Markus, B. Clarke, R. R. Charlwood, G. Harris, B. L. D. Phillips, E. J. Bovett, D. J. Reid, J. H. Baron, M. P. Joyson-Bechal, P. H. Merry, D. C. Beckingham, F. W. Wright, G. Appleby, R. B. Chalmers, G. H. Fairley, J. Gerrard, D. Guttmann, L. J. Holmes-Smith, W. H. Mitchell-Banks, A. D. Jose, V. Marks, J. C. M. Wilkinson, E. J. Wimperis, C. M. S. Coppin, J. A. Mitchell, H. R. Overy, H. R. Dingle, M. Hartog, P. T. Pickens, H. J. Liebeschuetz, R. N. P. Sutton, P. J. Mitchell, D. T. Cousins, P. R. Samsworth, D. P. Woods, R. Akroyd, T. J. D. Cochrane, Mrs. Elspeth A. Beckett, Mrs. Jean O. Hunter, Ann C. M. Wickham, Patricia J. M. Cotter, *D. H. Crill, *H. L. Freeman.

* In absence.

UNIVERSITY OF CAMBRIDGE

In Congregation on December 11, 1954, the degree of M.D. was conferred on J. J. Fleminger.

On December 20, 1954, the degree of B.Chir. was conferred on:

I. N. Godlee, P. J. Burrows, M. S. Robson, P. J. D. Kirk, C. E. Salter, E. F. D. Gawne, D. W. Atkinson, I. H. Backhouse, I. McL. Flowers, A. C. Johanson, I. V. Longfield, D. B. R. Osbourne, R. J. C. Pearson, D. J. H. Prosser, W. Atherton, L. H. Blonstein, P. D. Crockett, R. H. S. Gibbs, A. M. Parfitt, M. J. Turner, J. F. Walker, R. D. Hyde, J. Ross Russell, W. L. Cordeaux, G. C. Spackman, A. H. Labrum, J. N. Bodger, P. G. T. Bye, W. S. Ogden, J. W. Blaxill, W. R. P. Bourne, J. A. Drviden, J. Fairley, L. H. Hurrell, C. F. Ridley, R. C. Nainby-Luxmoore, T. R. Clendon, J. S. Garfield, E. Redfern, I. R. Robertson, G. E. W. Swan, S. T. G. Butterworth, D. H. Cameron, J. R. Barwell, J. S. Miller, R. Shram, Inez R. Aldous, Claudia M. B. Grisson.

On December 22, 1954, the degree of M.B. was conferred on: G. H. Hilton, J. K. Snell, J. Crook, C. M. McGregor, G. F. B. Birdwood, D. J. Buttery, R. H. Gibbon, R. J. Knight, R. C. Lawson, W. A. Williamson, S. P. Lock, H. C. Masheter, J. T. Gibbs, P. D. W. Wickenden, S. G. Bayliss, J. W. Harding, H. Jacobs, I. G. Tait, W. H. Carling, D. E. Tunbridge, J. R. Wood, Mrs. Lucy M. Rochelle.

UNIVERSITY OF LONDON

The following candidates at the Institute of Psychiatry have been approved at the examination indicated:

ACADEMIC POSTGRADUATE DIPLOMA IN PSYCHOLOGICAL MEDICINE.—Valerie A. Cowie, I. J. MacDonald, *M. I. M. Pines. The following have passed in Part I only: G. P. S. Fernando, F. Grunberg, R. R. Mowat, I. C. L. Patch, B. P. Shah.

The degree of M.D. was awarded on December 15, 1954, to P. J. Hare.

The John Marshall Fellowship in Surgical Pathology, tenable for two years in the first instance at University College Hospital Medical School, has been awarded from October 1, 1954, to Mr. D. B. Griffiths, F.R.C.S., who will also hold the Whait Fellowship awarded by the Medical School.

The following candidates have been approved at the examinations indicated:

M.D.—Part I: H. Barkley, P. J. A. Butcher, J. A. Cheese, H. W. D. Davies, S. Dische, Yvette A. P. Franklin, Eva A. Frommer, A. A. Glynn, N. D. Gower, L. H. Harris, J. M. Hinton, N. B. Kreitman, S. Mattingly, A. R. May, Ariela Pomerance, M. E. A. Powell, A. Trueman, H. J. Wyatt, Joan F. Zilva.

M.S.—Part I: N. C. Rogers.

* Awarded a mark of distinction.

UNIVERSITY OF BRISTOL

The following candidates have been approved at the examinations indicated:

M.D.—A. G. W. Branch.
FINAL M.B., CH.B.—H. T. Apsimon, P. H. Barry, Catherine A. Clark, D. J. C. Felton, J. H. L. Griffin, M. L. Harvey, J. K. Howell, Antoinette R. Joseph, J. McC. Lalloo, Jean D. Matthews, T. N. Matthews, J. H. Orr, B. K. Palmer, B. A. Poley. In Group I completing the examination: Pamela M. Atkinson, K. G. Collins, E. C. Skeens. In Group II only: R. G. McCormick.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending January 22, (No. 3) and corresponding week 1954.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrar-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1955					1954				
	Eng. & Wales	London	Scot.	N. Ire.	Eire	Eng. & Wales	London	Scot.	N. Ire.	Eire
Diphtheria	8	0	6	0	1	18	0	9	0	
Dysentery	482	65	227	22	4	490	100	178	18	2
Encephalitis, acute	4	0	1	0		4	1	1	0

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Vital Statistics

Typhoid in Yorkshire

In December, 1954, and January this year an outbreak of typhoid occurred in Pickering, Yorkshire. Probably 29 people have been infected; of these, 23 are primary cases and the other 6 family or household contacts; 28 are adults. We are indebted for the following information to Dr. W. R. M. COUPER, M.O.H. of Pickering:

The date of the onset of the primary cases was between December 17 and 24. On December 13 an epidemic of what seemed to be an upper respiratory infection began in Pickering and was labelled influenza. Later the infection spread to the surrounding districts. At first children were affected; then older people had the infection in a rather more severe form. Pulmonary complications were treated with chloramphenicol. In due course some of the cases were diagnosed as typhoid fever. The clinical picture was of pyrexia, nose-bleeds, headaches, and prostration. Five patients who presented this clinical picture were sent into hospital between December 31, 1954, and January 16 last. By February 1 *Salmonella typhi* had been isolated from the faeces of one patient, and investigation of this patient and of four others showed that infection was recent.

The epidemiological picture was of a localized outbreak from a single source of infection within a short period. Examination of affected and suspected persons excluded the water supply and milk as cause of the outbreak. A common food was eaten by all patients identified as primary cases, and investigations are continuing to find out how the material became contaminated.

Influenza

In the great towns of England and Wales the number of influenza deaths (123) in the week ending January 29 showed a decrease of 13 compared with the previous week. There were small increases in London and the south-east and in the north, east, and west Ridings, north midland and south-western regions, and in Wales, which were more than offset by decreases elsewhere, mainly in the north-western and midland regions. There is little change in the situation.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the nine years 1946-54 (influenza, 1952-4) are shown thus ----, the figures for 1955 thus —. Except for the curves showing notifications in 1955, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest fluctuations in the trends of infectious disease in England and Wales during the week ending January 2 were decreases of 762 for measles, from 7,800 to 7,038, and 192 for acute pneumonia, from 1,121 to 929, and increase of 233 for whooping-cough, from 1,769 to 2,002, 185 for scarlet fever, from 465 to 650, and 80 for dysentery, from 402 to 482.

The largest falls in the number of notifications of measles were 135 in London, from 791 to 656, 122 in Lancashire, from 2,032 to 1,910, 110 in Essex, from 463 to 353, 99 in Cheshire, from 466 to 367, and 88 in Derbyshire, from 36 to 214. The largest increases in the incidence of whooping cough were 33 in Kent, from 108 to 141, and 31 in Yorkshire West Riding, from 51 to 82. A small rise in the incidence of scarlet fever occurred throughout the country, the largest was 22 in Essex, from 27 to 49. 8 cases of diphtheria were notified, being 6 fewer than in the preceding week.

24 cases of acute poliomyelitis were notified, and there were 1 more for both paralytic and non-paralytic cases than in the preceding week. The largest returns were 3 in each of the counties of Essex, Lancashire, and Gloucestershire (Bristol C.B. 2).

The largest centres of dysentery were Lancashire 103 (Liverpool C.B. 22, Manchester C.B. 18, Oldham C.B. 12), Yorkshire West Riding 80 (Leeds C.B. 55, Sheffield C.B. 13), London 65 (Southwark 18, Chelsea 11), Middlesex 28.

Medical News

Dr. E. D. Adrian, O.M., P.R.S., who was awarded a barony in the New Year Honours, becomes Baron Adrian, of Cambridge in the County of Cambridge.

New Midwives Rules.—Compulsory courses of instruction are ordered by the new midwives rules, issued as S.I. No. 120, 1955 (H.M.S.O. 1s. 3d.). Attendance at the courses is required of all practising midwives from 1958 every five years; midwives enrolled before 1938 must attend a refresher course within 12 months of giving notice to practise, unless they have attended one within five years. The rules also permit midwives to administer trichlorethylene.

New Journal.—The *Central African Journal of Medicine* makes its appearance as representative of medicine in the new Federation of Rhodesia and Nyasaland. It is a well-produced publication; its first number includes forewords by the Prime Minister of the newly formed Rhodesia and Nyasaland Federation (Sir GODFREY HUGGINS, F.R.C.S.), Sir RUSSELL BRAIN, P.R.C.P., and Dr. MORRIS, Federal Secretary of Health. Appropriately, a biographical note on David Livingstone appears, the first known medical man to practise in what is now Rhodesia and Nyasaland, and there are also papers on clinical subjects. Edited by Dr. M. GELFAND, the journal will appear six times a year at an annual subscription of £2 2s. Its editorial address is P.O. Box 2073, Salisbury, S. Rhodesia.

Dermatology Medal.—The Chesterfield Medal, with a cash prize of £25, is offered by the Institute of Dermatology for the best essay on a dermatological subject selected by the candidate. Full details from the Institute, at St. John's Hospital for Diseases of the Skin, Lisle Street, Leicester Square, London, W.C.2.

Essay on Health Visitors.—The Royal Sanitary Institute offers a prize of fifty guineas for an essay on "How the Health Visitor can help the family towards its full development." Full details from the Institute at 90, Buckingham Palace Road, London, S.W.1.

Scholarships Abroad.—Over 100 scholarships are offered to British students by 17 foreign countries for study abroad during the academic year 1955-6. The awards generally provide for free tuition and maintenance, and are tenable for periods varying from a few weeks to 12 months. The countries offering them are Austria, Belgium, Brazil, Denmark, Finland, France, Germany, Iceland, Italy, the Netherlands, Norway, Persia, Portugal, Spain, Sweden, Switzerland, and Yugoslavia. Closing dates for applications differ for each country, the earliest being March 7. Further information and application forms, for which a stamped, addressed foolscap envelope should be sent, may be obtained from the Education Division, British Council, 65, Davies Street, London, W.1.

Induced Hypotension.—The Edinburgh Postgraduate Board for Medicine will hold a fortnight's course of lectures and demonstrations on induced hypotension in anaesthesia at the Department of Anaesthesia, Royal Infirmary, Edinburgh, from March 21 to April 1 (see advertisement page 46). Applications to be sent before March 1.

D.D.T. Awards.—The Royal Commission on Awards has recommended an award of £6,000 for the manufacture of D.D.T., to be made jointly to J. R. Geigy, S.A., of Basle, and the Geigy Co. Ltd., of Manchester.

Dr. T. R. R. Mann, F.R.S., has been appointed director of the Unit of Reproductive Physiology and Biochemistry at Cambridge.

Dr. J. N. Hunt, senior lecturer at Guy's Hospital Medical School, has been appointed to the university readership in physiology tenable at that school.

Dr. P. M. Daniel has been appointed honorary consultant in neuropathology to the Army at home.

Glamorganshire 26 (Cardiff C.B. 14, Swansea C.B. 9), Norfolk 26 (Norwich C.B. 17), Northumberland 23 (Newcastle-upon-Tyne C.B. 9), and Durham 20.

The deaths from influenza in the 160 great towns numbered 136, being 2 more than in the preceding week. The largest return was 13 in Birmingham C.B.

Week Ending January 29

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 745, whooping-cough 2,237, diphtheria 23, measles 10,697, acute pneumonia 1,062, acute poliomyelitis 23, dysentery 678, paratyphoid fever 4, and typhoid fever 9.

Venereal Diseases

In England and Wales during the quarter ending September 30, 1954, 1,281 new cases of syphilis were reported as attending the clinics. Of these, 190 were classified as primary, secondary, or latent in the first year of infection, 9 cases of congenital syphilis in children aged under 1 year were reported, and 158 cases in persons over that age. New cases of gonorrhoea numbered 4,821, of chancroid 79, and of non-gonococcal urethritis (males only), 3,644.—*Monthly Bulletin of the Ministry of Health*, January, 1955.

Smallpox in France

The total number of cases so far reported in the Morbihan Department is 66, including 14 deaths. In addition, one case is reported from Rennes in the Ile-et-Vilaine Department, which adjoins Morbihan, and two cases in the town of Saint-Die, Vosges Department.

Death Rate Variations

Geographical differences in death rates are noticeable for many diseases in England and Wales. They are among the analyses of vital statistics included in the text volume of the *Statistical Review* for 1951 published this week, in which the pre-war practice is resumed of combining civil with medical statistics. In the age group 0 to 4 Greater London had the lowest general death rate and Wales the highest, while the north of England was in between. These disparities remain much the same for all age groups, though in some the south of England had slightly better statistics than Greater London. The differences by region are on the whole greater than the differences by density of population, and they are greater for males than for females. The lower death rates in Greater London and the midlands than elsewhere are thought possibly to be due to the benefits of suburban living.

Diseases of the respiratory system are well known to cause proportionately many more deaths in the north than in the south; so also do heart diseases, in particular coronary arteriosclerosis—Wales again showed a high incidence of this group of diseases.

Notifications of respiratory tuberculosis are more numerous in Wales, the north of England, and London and the south-east than in other parts of the country. The excess in Wales and the north is probably genuine; that in England and the south-east is thought to be a reflection of better diagnostic facilities. Mortality is exceptionally high on Merseyside, Tyneside, and in several midland cities. In 1951 the rate per million population was 512 in Liverpool, 463 in Sunderland, and 541 in Walsall, yet in London and the south-east it was 185, in Bath 177, and in Huddersfield 132.

A comparison of death rates from cancer of the lung with those from all forms of cancer shows that Greater London and the Merseyside cities have a higher proportion of deaths from lung cancer than other parts of England and Wales. Of the rural areas (where lung cancer is less prevalent than in cities), the south of England has the highest proportion of lung cancer deaths.

Registrar-General's Statistical Review of England and Wales for the Year 1951, Text Volume (H.M.S.O., 10s.).

COMING EVENTS

Symposium on Cardiovascular Surgery.—There will be 60 participants from 17 countries at the International Symposium in Cardiovascular Surgery to be held in Detroit from March 17 to 19. The following subjects will be discussed: Diagnosis and Treatment of Pulmonary Stenosis; International Septal Defects; Late Results of Mitral Commissurotomy; Hypothermia; and Substitutes for Arterial Segments. Sir RUSSELL BROCK will be the speaker at the dinner meeting on March 18.

International Congress on Embryology.—The editorial board of the *Journal of Embryology and Experimental Morphology* has arranged an international congress in Brussels from April 4 to 7. Details from Dr. D. R. NEWTH, Department of Zoology, University College, London.

Laboratory Animals Bureau Symposium.—The third symposium will be held at the Royal Society of Medicine, London, W.1, on May 9. The subject will be "The Breeding of Laboratory Animals." The symposium is primarily intended for medical, veterinary, and scientific graduates.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Friday, February 11

SOCIETY OF MEDICAL OFFICERS OF HEALTH: WELSH BRANCH.—At B.M.A. House, 195, Newport Road, Cardiff, 6.30 p.m., Dr. G. Grant: Student Welfare in the U.S.A.

Monday, February 14

CHADWICK TRUST.—At Royal Institution, 5.30 p.m., Sir Hugh Beaver: Clean Air.

LONDON UNIVERSITY.—At Senate House, 5.30 p.m., special university lecture in psychology by Professor Otto Klineberg (Columbia University): Psychology and International Relations.

MEDICAL SOCIETY OF LONDON.—8.30 p.m., discussion to be introduced by Dr. W. G. Oakley and Mr. S. M. Cohen: Diabetic Gangrene.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.—7.30 p.m., Dr. K. R. Capper, Ph.D., B.Pharm.: British Pharmaceutical Codex, 1954, and the National Formulary, 1955.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—4 p.m., Hunterian Oration by Sir Cecil Wakley: Hunter and Surgical Research.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.—At Physiology Theatre, 4.45 p.m., Dr. E. E. Snell (Texas): Relationship of Structure to Catalytic Activities of Vitamin B₆.

Tuesday, February 15

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor J. N. Davidson: Nucleoproteins in Cell Structure.

LIFORD MEDICAL SOCIETY.—At King George Hospital, Ilford, 8.30 p.m., Debate: That in the opinion of this House, the National Health Service is not in the best interest of the patient or the doctor. For the motion: Dr. J. L. McCallum; seconded by Dr. R. M. Noordin. Against the motion: Dr. Bruce Cardew; seconded by Dr. Arnold Elliott.

INSTITUTE OF DENTAL SURGERY.—At Eastman Dental Hospital, 5.30 p.m., Dr. H. M. Seldin, D.D.S. (New York): Oral Lesions of Interest to Dentist and Physician.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. J. Wallace: Bullous Eruptions.

LONDON UNIVERSITY.—(1) At University College Hospital Medical School, 5 p.m., special university lecture in medicine by Professor Jan Waldenström (Lund): Clinical Investigations in Hypergammaglobinaemia. (2) At Senate House, 5.30 p.m., special university lecture in psychology by Professor Otto Klineberg (Columbia University): Uses and Limitations of the Experimental Method in Social Psychology.

OXFORD UNIVERSITY MEDICAL SOCIETY.—At Radcliffe Infirmary, 8.15 p.m., general meeting.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor D. M. Pryce: Gynaecological Pathology.

SOUTH-WEST LONDON MEDICAL SOCIETY.—At Bellingbroke Hospital, 8.30 p.m., Professor Alan Moncrieff: Marasmus.

Wednesday, February 16

EUGENICS SOCIETY.—At Royal Society, Burlington House, W., 5.30 p.m., Mrs. Judith Hubback, M.A.: Fertility of Educated Women.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Clefts, Vesicles, and Bullae.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. A. C. Morson: Non-Tuberculous Infections of the Renal Tract.

LONDON UNIVERSITY.—At Warburg Institute, 5.30 p.m., Dr. D. P. Walker: The "Astral Body" in Renaissance Medicine.

MIDLAND MEDICAL SOCIETY.—At Queen Elizabeth Hospital, Birmingham, 8.15 p.m., clinical meeting.

NORTH-WESTERN TUBERCULOSIS SOCIETY.—At Aintree Hospital, Liverpool, 5.30 p.m., Mr. J. Cosbie Ross: Renal Tuberculosis.

ROYAL MICROSCOPICAL SOCIETY.—5.30 p.m., Dr. E. S. Horning: Hormones in Relation to Cancer. Demonstration by Mr. G. N. Byford and Mr. A. C. G. Best: New Type of Mercury-vapour Lamp.

ST. MARLEBOROUGH HOSPITAL FOR PSYCHIATRY AND CHILD GUIDANCE.—5.30 p.m., Dr. R. D. Newton: Indications for Psychological Treatment in Early Childhood.

Thursday, February 17

BAKINGSTON PLASTIC CENTRE MEDICAL SOCIETY.—At Rookdown House (Oak Fawcett Hospital), Basingstoke, 7.30 p.m., symposium: Fractures of the Long Bones with Soft-tissue Loss. Speakers, Professor J. Trueta, Mr. J. S. Ellis, Mr. A. J. Evans, and Mr. E. W. Peet.

BRITISH INSTITUTE OF RADIOLOGY.—8 p.m., Dr. A. Robinson Thomas: Technique of Sialography; Mr. R. T. Payne: Experiences of Sialography. **BRITISH POSTGRADUATE MEDICAL FEDERATION.**—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor J. H. Gaddum, F.R.S.: Effects of Alcohol.

EDINBURGH CLINICAL CLUB.—At 7, Drumshugh Gardens, 8 p.m., Mr. John Bruce: Surgery of the Stomach and Duodenum.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Techniques in Diagnosis of Fungous Infections.

LIVERPOOL MEDICAL INSTITUTION.—8 p.m., demonstration of specimens and cases.

ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Dr. W. H. Bradley: Man and Virus.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—At 26, Portland Place, London, W., 7.30 p.m., Colonel H. W. Mulligan: Recent Investigations on Trypanosomiasis in British West Africa.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Medical School, Small's Wynd, Dundee, 5 p.m., Mr. A. Logan: Benign Ulceration of the Oesophagus.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. M. A. Partridge: psychiatry demonstration.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.—At Physiology Theatre, 4.45 p.m., Dr. S. R. Eidsen: Respiratory Mechanisms in Bacteria.

Friday, February 18

BRITISH INSTITUTE OF RADIOLOGY.—5 p.m., meeting of medical members.

FACULTY OF RADIOLOGISTS.—At Royal College of Surgeons of England, 5 p.m., Dr. David Sutton: Thoracic Aortography by Percutaneous Trans-catheterization; Dr. Conway J. Don: Intravenous Cholangiography After Cholecystectomy.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. D. Williams.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., clinical demonstration by Dr. J. Smart: Pulmonary Tuberculosis.

INSTITUTE OF NEUROLOGY.—5 p.m., Dr. G. J. Romanes: Motor Cells of the Spinal Cord.

OSLER CLUB OF LONDON.—At 11, Chandos Street, W., 7.45 p.m., meeting in honour of Leonard P. Mark (1855-1930), author of "Acromegaly: A Personal Experience." Speakers: Dr. A. W. Spence and Sir James Paterson Ross.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—(1) 2 p.m., Mr. D. M. Wallace: Natural History of Bladder Tumours. (2) 4 p.m., Professor C. H. Stuart-Harris: Virus Diseases of the Respiratory Tract.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Mr. Iain McLennan: Some Surgical Aspects of Thyroid Disease.

ROYAL MEDICAL SOCIETY, Edinburgh.—8 p.m., Professor J. Chassar Moir: Confinements of Some English Queens and their Effect on History.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, 5.30 p.m., Professor F. Bergel: Attempts at Chemotherapy of Malignant Diseases.

Saturday, February 19

BIOCHEMICAL SOCIETY.—At London School of Hygiene and Tropical Medicine, 11 a.m., symposium: Biochemistry of Vitamin B₁₂.

APPOINTMENTS

MANCHESTER REGIONAL HOSPITAL BOARD.—F. Robinson, M.B., Ch.B., F.R.C.S., additional maximum part-time Consultant Plastic Surgeon to South Manchester Hospitals; G. Freeman, B.M., B.Ch., F.R.C.S., D.L.O., Part-time Consultant Ear, Nose, and Throat Surgeon to Lancaster and Kendal Hospitals; R. C. Woodcock, M.B., Ch.B., D.C.P., D.Path., Additional Consultant Pathologist, Bolton and District Hospitals; A. Kilpatrick, L.R.C.P.S. Ed., D.A., D.Obst.R.C.O.G., Assistant Anaesthetist, Lancaster and Kendal Hospitals; G. J. H. Hall, M.B., Ch.B., D.P.H., D.C.H., Assistant Physician (Infectious Diseases), Ladywell Hospital, Salford, and Asley Hospital, Wigan; G. H. Waddington, M.R.C.S., L.R.C.P., D.M.R.D., Assistant Radiologist, Lancaster and Kendal Hospitals; H. Fergusson, M.B., Ch.B., D.M.R.D., Assistant Radiologist, Blackburn and District Hospitals; G. H. A. Simmons, F.R.C.S., Consultant Surgeon to Crumpsall Hospital, Manchester; C. G. D. Martin, M.Ch., F.R.C.S.J., Senior Casualty Officer, Bury and Rossendale Hospitals.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Hainan.—On January 30, 1955, at University College Hospital, London, W.C., to Margaret (formerly Booth), wife of Dr. Keith Hainan, a daughter—Susan Mary.

Ringrose.—On January 23, 1955, at St. Brenda's Nursing Home, Bristol, to Doris (formerly Lemmon), M.B., B.Chir., wife of David F. Ringrose, L.D.S., of Bitton, Glos., a daughter.

Turner.—On January 31, 1955, at Burnley, Lancs., to Dr. Helen Turner, wife of Dr. Winston Turner, a daughter.

DEATHS

Acomb.—On January 21, 1955, in South Africa, John Acomb, M.B., B.S., D.L.O., of Linton, late of York, Yorks.

Allen.—On January 19, 1955, at Allendale, Coonoor, South India, Charles Harry Powell Allen, M.R.C.S., L.R.C.P., Lieutenant-Colonel, I.M.S., retired.

Aung.—On January 18, 1955, at Edinburgh, Shway Hla Aung, M.B., B.S., of Rangoon, Burma, aged 33.

Bell.—On January 29, 1955, at the Manor House, Buckden, Huntingdon, Arthur Sydney Gordon Bell, M.R.C.S., L.R.C.P., Surgeon Commander, R.N., retired.

Boone.—On January 27, 1955, at Hove, Sussex, William Brooke Boone, B.M., B.Ch., of Hillborough Terrace, Ilfracombe, Devon.

Brown.—On January 29, 1955, at the Long House, Little Strickland, near Penrith, Westmorland, Peter Otho Watkin Brown, M.B., C.M., late of Alderley Edge and Nethy Bridge, Inverness-shire, aged 88.

Burns.—On January 20, 1955, Henry Burns, O.B.E., M.B., Ch.B., Surgeon Commander, R.N., retired.

Butterworth.—On January 21, 1955, at Borth, Cardiganshire, John Butterworth, M.R.C.S., L.R.C.P., J.P., formerly of Middleton, Lancs., aged 83.

Castell.—On January 1, 1955, at his home, Finchley, London, N., Samuel Percy Castell, M.B., aged 61.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Collapse due to Adrenaline in Dental Analgesic

Q.—What is the most efficient dental local analgesic injection for a patient who is intolerant of adrenaline? The patient has twice had a serious collapse after these injections in the dentist's chair, but wants to avoid a general anaesthetic.

A.—"Cobefrin," an isomer of adrenaline, can be used as an alternative to adrenaline and is said to produce less general disturbance than the latter. Alternatively procaine can be used by itself, or better still the newer local analgesic solution "xylotox," which contains lignocaine hydrochloride in Ringer's solution. This itself produces a vasoconstrictor action and hence eliminates the need for adrenaline.

Diagnosis and Treatment of Psychosomatic Disorders

Q.—What are the positive points to look for in making a diagnosis of a psychosomatic disorder? I often see patients with vague complaints of pain, in whom every investigation is negative, and suspect that some of these pains are psychosomatic in origin. Having made such a diagnosis, what should I do then? Often a patient reacts very violently to any suggestion that he should be seen by a psychiatrist.

A.—The term psychosomatic is used in two ways: (1) To describe a disability dependent upon emotional factors (for example, anxiety) which are expressed either as a symptom without an objective organic lesion or as a physical disturbance (for example, peptic ulcer) whose existence may be verified by the usual methods. The emotional disturbance affects the soma through the autonomic system. (2) Of a disability, predominantly or wholly organic in origin, which leads to an emotional disturbance (for example, worry following the amputation of an arm).

An affirmative diagnosis of psychosomatic illness requires a careful history of the present illness, and in particular an atmosphere of emotion at the onset of the illness should be looked for. The emotion may be prolonged and figure largely in the clinical picture. The patient's description of the illness is generally overcoloured. Often, too, there will be a collection of medical reports with inconclusive diagnoses. A note should also be taken of the patient's reaction to past events such as the demands of school, work, marriage, and previous ill-health. Soon a picture of his personality will emerge. Happy and harmonious people do not develop psychosomatic complaints. The practitioner therefore should ask himself, What made this person ill? The answer will involve an assessment of the relative importance of those constitutional, environmental, and personal elements which predisposed the patient to develop the signs and symptoms he now has.

Vague complaints of pain, if persistent and without organic change, suggest a diagnosis of conversion hysteria or of an anxiety state. Presumably "every investigation" does not include a psychological investigation. Exhaustive physical examinations alone may induce an iatrogenic neurosis.

In treatment, a wise course is to affirm the reality of the illness, to state its nature as partly physical and partly emotional, and to explain that it is not due to "imagination" or "lack of will-power." Further, that for advice on treatment the help of a specialist—that is, a psychiatrist—would be desirable. Should the patient find this suggestion distasteful the physician should express regret and, without argument, he should recommend the patient to think it over.

If the patient, after reflection, still refuses the consultation it should be assumed that he has some misconceptions about psychiatrists or some shyness about the questions he fancies he might be asked. Both topics should be discussed frankly.

Treatment of Hodgkin's Disease

Q.—Would you kindly tell me if anything is known in this country about the treatment of Hodgkin's disease by a mould, actinomycin C? This substance is used, I believe, in Germany. What do you consider the best treatment for this disease?

A.—Actinomycin C, which is related to actinomycin A, was tried as a chemotherapeutic agent against human malignant disease in Germany. According to Schulte, the substance was inactive in carcinoma and in leukaemia, but had a temporarily beneficial effect in Hodgkin's disease. Most of the cases treated had concurrent radiotherapy; however, a few who were treated exclusively with actinomycin C showed a temporary reduction in the size of superficial tumours. Mediastinal masses, however, were unaffected. Recently a number of trials of actinomycin C ("sana-mycin") have been made in France. The results of these trials² showed a very limited response in a very small proportion of the cases of Hodgkin's disease. Its side-effects included stomatitis and diarrhoea.

In the author's opinion the published results with actinomycin C are inferior to those obtained with nitrogen mustard or T.E.M. (triethylene melamine). Both nitrogen mustard and T.E.M. will produce a remission of several months in most cases. Actinomycin C is said not to affect the veins on injection, as occurs with nitrogen mustard. This advantage can also be claimed for T.E.M., which is an oral preparation. The depressant effect on bone marrow is apparently less with actinomycin; this would be an advantage over both nitrogen mustard and T.E.M. if the clinical effectiveness of actinomycin was as great. This does not seem to be the case.

None of the chemotherapeutic agents so far described can yet replace radiotherapy in the treatment of the early or moderately early case of Hodgkin's disease. When radiotherapy can no longer be employed, or in the late generalized case, chemotherapy with nitrogen mustard or T.E.M. is valuable in affording one or more remissions of the disease. In the still later stages a further remission can be obtained in some cases with A.C.T.H. or cortisone.

Distended Bladder in a Child

Q.—When examining the abdomen of a boy aged 4 years 7 months who was suffering from diarrhoea and vomiting, I found his bladder distended almost to the umbilicus. With small encouragement he passed a pint (570 ml.) of urine without discomfort. He has no phimosis, pin-hole meatus, or obvious cause for retention of urine. His distended bladder seemed to cause him no discomfort. Are such cases unusual? Do they require watching or active treatment?

A.—A bladder as full as this is found now and then in the course of examining children, and is of no consequence provided that, as in this case, the child is able to pass urine normally. It probably results simply from the dislike of some children of asking to go to the lavatory, or if in bed of asking for the pot, until the very last minute. No treatment is indicated.

A distended bladder may occur in chronic constipation of severe degree, but the latter is then obvious on account of the faecal lumps in the loaded colon. Bladder neck obstruction or a urethral valve will cause chronic distension of the bladder. In this case, if micturition is watched the stream is seen to be feeble and intermittent, and the bladder is not usually fully emptied.

Prolapse in Young Women

Q.—Is it worth carrying out an operative repair in young women with prolapse, or does the likelihood of further pregnancies make this a waste of time?

A.—Youth and the possibility of further childbearing do not contraindicate operative treatment for prolapse, but they may call for modifications in surgical technique. In particular, every effort should be made to avoid amputating the cervix at the time of colporrhaphy, for this may lower fertility, cause abortion, or complicate labour. Indeed, every delivery following amputation of the cervix should be carried out in hospital.

If the operation is restricted to anterior and posterior colporrhaphy, subsequent pregnancies are not likely to be complicated and the risk of a recurrence of prolapse is not very high. It is usually advisable, however, to carry out episiotomy in labour. Even if the prolapse should recur after further childbearing and require another operation, the original operation is not to be regarded as a waste of time. It is unreasonable to condemn women to endure a prolapse for many of what should be their most active years, their only consolation being that they will be made comfortable when they reach an age at which the comfort means less to them.

The third book contains a cumulative index.

Sea Travel for the Elderly

Q.—Are there any special contraindications to elderly people undertaking long voyages by liner? Are any special precautions advised?

A.—There are no special contraindications to elderly people undertaking long sea voyages provided they are in average good health.

If the voyage involves passage through tropical waters it is desirable that they should travel at a cool period of the year. May and September are both trying months in the Red Sea, and in the period June to September when the S.W. monsoon is blowing conditions are hot and humid in the Indian Ocean. Apart from this the individual should be instructed to carry out on board so far as is practicable the normal routine he has been accustomed to in his own home, from the point of view of both exercise and diet. When the weather is hot he will be well advised to cut down exercise, perhaps spend one or two days resting in bed during the hottest period of the voyage, and throughout the hot-weather period he should drink water freely and add a little salt to this water.

The passenger should be reassured by the knowledge that in case of need there is on board a competent medical staff.

Is Chlorbutol a Dangerous Preservative?

Q.—Chlorbutol is used as a preservative for some types of injection. Have any untoward effects been ascribed to it when used in this way?

A.—Chlorbutol has been used for nearly 50 years as a preservative for solutions of adrenaline and of posterior lobe extract for hypodermic injection, being present in a strength of 0.5%, and has not produced untoward effects. The preservative. The Council of Pharmacy and Chemistry of the American Medical Association recommends it as the best preservative for ophthalmic solutions, as it is non-toxic, non-irritant, and free from a tendency to produce sensitization. Chlorbutol can be used orally as a sedative and antispasmodic, for which purpose the dose is 0.3–1.2 g. general view about chlorbutol is that it is a safe and useful

It was the main constituent of Mothersills' remedy for seasickness. Toxicity does not arise with amounts less than 6 g. (90 gr.) by mouth.

A Damp Cottage

Q.—A patient is worried because she has gone to live in an old cottage which in summer was dry but now shows a lot of damp patches on the walls of the ground-floor rooms. Is she running any real health risk, and, if so, of what?

A.—Tradition is in favour of this patient's fears. Science, however, has never demonstrated any direct deleterious result on a person in normal health living in a damp house. The fact that it is damp implies that the temperature inside tends to be less than that outside, owing to evaporation from the walls. The effect on the occupants will be to contract the skin capillaries, which some authorities consider may depress general immunity processes in some people, and in rheumatic subjects often to increase the pain suffered. But this can usually be counteracted by the installation of an adequate heating system.

Chickenpox, Zoster, and Poliomyelitis

Q.—Is there any evidence to suggest that an attack of chicken-pox or herpes zoster protects against poliomyelitis?

A.—No information is available on the question of whether previous exposure to varicella or zoster protects against poliomyelitis. It would seem unlikely on general grounds that such a widespread infection as chickenpox could protect against poliomyelitis without being noticed. It is certain that circulating antibody from previous infection with varicella-zoster virus is unlikely to have any protection against poliomyelitis, as the two viruses are antigenically unrelated.

NOTES AND COMMENTS

Fetishism.—OUR EXPERT writes: In your issue of January 29 (p. 302) Dr. Doris Odum comments on my reply to a question on this subject ("Any Questions?" January 15, p. 178). The female patients whom Dr. Odum considered to be suffering from fetishism were free from any kind of emotional disturbance and all were making a good adjustment to life. She adds that the condition—that is, fetishism—was not due to any morbid tendency but represented "an alternative or supplementary form of sexual gratification." She implies that any object which excites erotic feelings is a fetish. But this is not the sense in which the term is used in psychiatric literature. The true fetishist finds that coitus is impossible without the fetish object or the phantasy of it. There is no question of having the fetish as "an alternative or supplementary form of sexual gratification."

Dr. Odum implies that fetishism is common among women, but unrecognized because they do not talk of such socially unacceptable matters. This is not very convincing, for male fetishists have exactly the same reluctance and even during psychotherapy there is hesitation in mentioning the subject. One or two examples of fetishism in women have been reported in psychoanalytical literature; yet few psychoanalysts have been dogmatic about the existence of fetishism in females. Other workers with wide experience say that they have never come across an example or that it is extremely rare. The writer has made considerable inquiry in the past from psychiatrists of different schools of thought and so far has been unable to find a single authenticated instance of fetishism in women. Hence the statement that fetishism does not seem to occur in women.

VARIOUS COMBINATIONS OF ISONIAZID WITH STREPTOMYCIN OR WITH P.A.S. IN THE TREATMENT OF PULMONARY TUBERCULOSIS

SEVENTH REPORT TO THE MEDICAL RESEARCH COUNCIL BY THEIR TUBERCULOSIS CHEMOTHERAPY TRIALS COMMITTEE*

The fifth report of the Medical Research Council trial of isoniazid (isonicotinic acid hydrazide) contained a broad comparison of the effects of two combinations of drugs—streptomycin plus isoniazid compared with P.A.S. plus isoniazid—on a total of 391 patients after three months' treatment (Medical Research Council, 1953c). It was concluded that the combination P.A.S. (sodium salt) 20 g. daily plus isoniazid 200 mg. daily was of the same order of effectiveness as streptomycin 1 g. daily plus isoniazid 200 mg. daily, and as streptomycin 1 g. daily plus P.A.S. (sodium salt) 20 g. daily. There was, however, only limited information on whether the dosage of streptomycin or of P.A.S. in combination with isoniazid, could be reduced from the above levels. As a result of an increase in the total of patients to 588, it is possible in the present report to give a detailed comparison of the clinical and bacteriological effects of two dosages of streptomycin, and two dosages of P.A.S. in combination with isoniazid, after three months' treatment. These patients were admitted to the trial between September 5, 1952, and July 31, 1953, when admissions ceased. The scope of this report has been further extended by including bacteriological findings for 241 patients whose treatment was continued for six months. A list of the 51 hospitals and the names of the co-operating clinicians, bacteriologists, and pathologists are given at the end of the report. The trial was co-ordinated by the late Dr. Marc Daniels and by Dr. Wallace Fox, of the Council's Tuberculosis Research Unit; Dr. Fox and Dr. Ian Sutherland (of the Council's Statistical Research Unit) analysed the present results and prepared the report. Radiographic assessments were made by Dr. L. G. Blair. The isoniazid used throughout the trial was supplied as "nydrazid" by E. R. Squibb and Sons.

1. PLAN AND CONDUCT OF THE TRIAL

The plan and conduct of the trial are only briefly referred to here, as they have been described in detail in earlier reports (Medical Research Council, 1952, 1953a).

*Members of the Committee: Sir Geoffrey Marshall (chairman), Professor J. W. Crofton, Professor R. Cruickshank, Dr. Wallace Fox, Dr. J. E. Geddes, Professor F. R. G. Heaf, Professor A. Bradford Hill, Dr. J. V. Hurford, Dr. D. A. Mitchison, Professor W. D. M. Paton, Dr. J. G. Scadding, Dr. Norman Smith, Dr. P. D'Arcy Hart (secretary).

1. Type of Case

Certain basic requirements were laid down for all cases accepted into the trial. At the start of treatment:

- (a) Tubercle bacilli must have been demonstrated.
- (b) The tubercle bacilli, so far as was known, must not have been streptomycin-resistant or P.A.S.-resistant. (Any patient subsequently found to have had streptomycin-, P.A.S.-, or isoniazid-resistant organisms at the start of treatment has been excluded from the analysis: see Appendix.)
- (c) The patient must not have had more than 15 g. streptomycin or 300 g. P.A.S. (sodium salt) within the previous three months, and not more than 3 g. isoniazid at any time.
- (d) The patient must not have had any form of collapse therapy present on the side of the lesion requiring treatment.

Cases satisfying the above requirements were admitted to the trial in one of three main disease groups: (1) acute rapidly progressive pulmonary tuberculosis believed to be of recent origin; (2) other forms of pulmonary tuberculosis considered suitable for chemotherapy: *this group included a wide range of disease, and contained both acute and chronic cases*; (3) chronic forms of pulmonary tuberculosis expected to make only a limited response to streptomycin plus P.A.S.

2. Treatment

When a patient had been accepted for the trial, treatment was allocated by the Tuberculosis Research Unit from confidentially held prearranged lists based upon random sampling numbers.

After admission to the trial and a preliminary week of investigation, all patients were kept under observation for six months. During the first three months the prescribed treatment was followed for every patient. During the second three months patients in disease group 3 continued on the same combination of drugs. For other patients the clinician was free either to continue the original combination or to undertake any other treatment, chemotherapeutic or otherwise.

In the phase of the trial now reported, four treatments were studied concurrently—namely:

SH: Streptomycin 1 g. daily, in one intramuscular injection, plus isoniazid 200 mg. daily, in two equal doses by mouth.

S2H: Streptomycin 1 g. in one intramuscular injection, twice a week, plus isoniazid 200 mg. daily, in two equal doses by mouth.

20 PH : P.A.S. (sodium salt) 20 g. daily, in four equal doses by mouth, plus isoniazid 200 mg. daily, in two equal doses by mouth.

10 PH : P.A.S. (sodium salt) 10 g. daily, in two equal doses by mouth, plus isoniazid 200 mg. daily, in two equal doses by mouth.

In one important disease subgroup (1A—acute rapidly progressive bilateral pulmonary tuberculosis of recent origin, in patients between the ages of 15 and 30) patients were randomly allocated, for ethical reasons, only to the SH and 20 PH series. Every other patient was allocated at random to one of the four treatment series.

Prior to exclusions, 195 patients were allocated to the SH treatment, 151 to S2H, 184 to 20 PH, and 122 to 10 PH. The larger totals in the SH and 20 PH series are accounted for by the patients in subgroup 1A. The number of patients allocated to the S2H series was not intentionally larger than the number in the 10 PH series; the difference has arisen by chance as a result of the operation of random allocation within each of the 51 hospitals. Sixty-four patients (9.8%) were excluded from the analysis of the clinical results for reasons detailed in the Appendix. Of these exclusions, 29 (4.4%) were unimportant, since the patients either did not conform to the basic requirements for entry or did not complete the week of preliminary investigation. The remaining 35 (5.4%), though relevant, are few in number and so are unlikely to have seriously distorted the results. After exclusions, the numbers remaining in the clinical analysis were 182 SH, 142 S2H, 159 20 PH, and 105 10 PH

patients. The numbers in each disease group are set out in Table I. It will be noted that the numbers of group 3 patients are very small.

Since patients in subgroup 1A (acute bilateral disease in young adults) were admitted only to the SH and 20 PH treatment series, a valid comparison of the relative efficacy of all four treatments SH, S2H, 20 PH, and 10 PH can be made only after excluding the patients in this subgroup. In the first part of the tables which follow, the findings for the four treatments are presented first for all patients except those in subgroup 1A. The findings for all the SH and 20 PH patients, including those in subgroup 1A, appear in the second part of each table; the results for patients in this important subgroup may be obtained from each table by subtraction.

II. CLINICAL PROGRESS

1. Condition on Admission

The treatment received by patients before they entered the trial was investigated. Ten patients on SH (5%), 9 on S2H (6%), 6 on 20 PH (4%), and 3 on 10 PH (3%) had already received one or more courses of chemotherapy, but not within the preceding three months. Thus 95% of the patients in the present analysis were receiving their first course of chemotherapy. Most were also newly diagnosed cases.

Table II shows the condition of patients before the start of treatment as reflected by their general condition (assessment by the clinician in charge), temperature, erythrocyte sedimentation rate (E.S.R. Westergren 200 mm. reading at

* A patient was considered afebrile if every evening temperature in the pre-treatment week of investigation was below 99° F. (37.2° C.).

† Assessment on a single full-plate chest radiograph taken before treatment started. Tomograms were not taken into account.

‡ The sedimentation rate of one group 3 patient was not recorded.

one hour), and the extent of cavitation on a full-plate radiograph (as graded by the radiological assessor, who was unaware of the treatment series of any patient). It can be seen that, judging by the factors listed, the SH, S2H, 20 PH, and 10 PH patients had broadly similar distributions of severe and less severe illness; although the detailed figures are not presented in Table II, this applied to patients in disease groups 1 and 2 separately. When the patients in subgroup 1A were added the SH and 20 PH series still had very similar distributions of patients with severe and less severe illness.

2. Mortality

There were 7 deaths among the 588 patients (1.2%) during the three-month period of treatment—2 in SH patients, 3 in 20 PH patients, and 2 in 10 PH patients. Of these, 3 died within a week of starting treatment—a 20 PH and a 10 PH patient in group 1 and a 10 PH patient in group 2. Two others (both 20 PH, group 1) died within a month, the disease in each having pursued a steadily deteriorating course. One of these patients died after 21 days, the other after 30 days; for the latter, treatment was stopped 10 days before death because the patient was too ill to swallow. The remaining 2 deaths (both SH, group 1) occurred after 5 and 12 weeks. All the deaths were due to pulmonary tuberculosis except for the last patient, who died from renal failure secondary to acute nephritis, confirmed at post-mortem examination. This patient had slight clinical and radiographic deterioration at one month

and showed further clinical and radiographic deterioration at the end of two months. The nephritis was diagnosed in the third month. A specimen taken from the lung at post-mortem examination yielded a strain on culture which was sensitive both to streptomycin and to isoniazid.

3. Toxicity

There is nothing further to add to previous reports (Medical Research Council, 1952, 1953) of the absence of severe toxicity to isoniazid, in the dosage used, over a three-month period. There were also no noteworthy toxic manifestations in patients who continued to receive the drug for the whole six months. Treatment was stopped in 6 patients because of severe toxic reactions attributed to P.A.S., and in 1 patient with a severe toxic reaction attributed to streptomycin (see Appendix). Toxicity to P.A.S. must therefore be considered a disadvantage of treatment with the combination P.A.S. plus isoniazid.

4. The Comparison Between the SH, S2H, 20 PH, and 10 PH Treatments

Radiographic Changes in the First Three Months.—Table III sets out the radiographic changes at the end of three months' treatment. The assessments were made at a reading of full-plate chest radiographs by the radiologist, who was unaware of the treatment of any patient. In assessing improvement or deterioration three degrees were

" 7-13 lb. (3.2-6.3 kg.)	36	28	28	31	35	29
" less than 7 lb., or no change	23	12	24	19	20	24
Loss	4	2	6	2	3	7
Average gain in weight (lb.)	11.3	14.8	11.3	13.9	12.4	11.2
Temperature:						
Afebrile at 3 months (febrile at start)	(57) 79	(78) 72	(56) 82	(60) 73	(105) 75	(103) 83
Sedimentation rate:						
Fall to 10 or less from 21 or more, in 3 months	(72) 38	(100) 41	(64) 48	(72) 39	(127) 35	(118) 42

* The figures in parentheses indicate the total numbers of patients upon which the percentages are based.

allowed in each—namely, 1-plus, 2-plus, and 3-plus, and 1-minus, 2-minus, and 3-minus. Of 115 SH patients, 84% improved radiographically compared with 75% of 142 S2H patients, 76% of 100 20 PH patients, and 76% of 105 10 PH patients. Two-plus and 3-plus improvement also was more frequent under the SH treatment (54%) than under the other treatments (S2H 44%, 20 PH 33%, and 10 PH 38%). The differences between this percentage for the SH treatment and those for the 20 PH and 10 PH treatments attain statistical significance—that is, at the 5% level. There were no radiographic deteriorations and 2 deaths in the SH series, 6 deteriorations and no deaths in the S2H series, 2 deteriorations and 2 deaths in the 20 PH series, and 4 deteriorations and 2 deaths in the 10 PH series.

Changes in the other Clinical Assessments.—In Table IV are set out for the four treatment series the changes in the general condition and in the weight, and the resolution of pyrexia and the lowering of the sedimentation rate in the three-month period. Apart from weight changes the responses of the patients in the four treatment series were very similar. In the SH series, 38% of patients gained 14 lb. (6.4 kg.) or more, compared with 58% for the S2H series, 41% for the 20 PH series, and 48% for the 10 PH series. The average weight gains were 11.3 lb. (5.1 kg.) for the SH and 14.8 lb. (6.7 kg.) for the S2H patients, the difference being statistically significant. This difference may be related to disturbances associated with streptomycin injections in a proportion of patients (Riches, 1954). The corresponding averages were 11.3 lb. (5.1 kg.) for the 20 PH patients, and 13.9 lb. (6.3 kg.) for the 10 PH patients, the difference again being statistically significant. This difference is likely to be a result of greater gastro-intestinal disturbance to patients receiving the higher dosage of P.A.S.

The SH treatment was thus radiographically superior to any of the other three treatments. Otherwise the differences appear to be of little importance.

5. The Comparison Between all the SH and 20 PH Treated Patients

Radiographic Changes in the First Three Months.—The percentages of patients showing radiographic improvement were 84% for the 182 SH patients and 79% for the 159 20 PH patients (Table III). The proportion of patients showing 2-plus and 3-plus radiographic improvement was higher for the SH series (53%) than for the 20 PH series (38%), a difference that is statistically highly significant—that is, at the 1% level.

TABLE V.—Presence of Tubercle Bacilli at Single Examinations made at Monthly Intervals

		20 PH	150	99	35	23	8	5	39	26	68	45
	3	SH	166	100	18	11	5	3	30	18	113	68
		20 PH	147	100	19	13	3	2	25	17	100	68

All patients were bacteriologically positive before treatment—that is, at least one pre-treatment specimen showed bacilli on direct examination or was positive on culture.

* Even if culture-negative.

† Defined as follows: only a few clumps of acid-fast bacilli found after five minutes' search.

Changes in the other Clinical Assessments.—The changes in the general condition and in the weight, and the resolution of pyrexia and the lowering of the sedimentation rate, are set out in Table IV. There is a close similarity in the responses of patients on the two treatments.

The SH treatment is thus clearly superior to the 20 PH treatment on the radiographic assessment, but in other respects the differences are small.

III. BACTERIOLOGY DURING THE FIRST THREE MONTHS

The bacteriological findings for three months were analysed for those patients whose clinical progress has been reported above. The bacterial content of the sputum was determined after one, two, and three months of treatment, and the development of bacterial resistance after two and three months. Sensitivity to isoniazid was tested for patients under each of the four treatments, to streptomycin for SH and for S2H patients, and to P.A.S. for 20 PH and for 10 PH patients.

The procedure for taking specimens, the technique for sensitivity tests to each of the three drugs, and the definitions of resistance and sensitivity have been described in detail in previous reports (Medical Research Council, 1953a, 1953b). The examinations of bacteriological specimens and the sensitivity tests to isoniazid and to streptomycin were made in the co-operating laboratories. The P.A.S.-sensitivity tests were all made in the reference laboratory (see Acknowledgments).

The result of a bacteriological examination, or of a sensitivity test, for a given month was accepted only if it was performed on a specimen collected not more than seven days before or after the appropriate date. When more than one such result was available, the one referring to a specimen taken on or nearest to the appropriate date was selected to avoid bias. Thus in all the bacteriological tables each item represents a number of patients for each of whom a single test was selected, and not a total of all the tests performed on a smaller number of patients.

1. Exclusions

In addition to the patients already excluded from the clinical analysis, a further 5 patients (3 SH, 1 S2H, 1 10 PH) have been excluded from the bacteriological analysis. No tubercle bacilli were seen or isolated from pre-treatment specimens for any of these patients, and although there was

no doubt of the diagnosis they did not conform to the bacteriological requirements on entry to the trial. Eleven patients have already been excluded (see Appendix) because they were found to have had bacilli resistant to at least one of the drugs on entry to the trial. The bacteriological as well as the clinical analysis is thus confined to patients whose organisms were sensitive at the start of the trial to both of the drugs they were receiving.

2. Bacterial Content of Sputum

The results at one, two, and three months of the selected single examinations of the sputum for tubercle bacilli are set out in Table V. The incidence of negative cultures increased each month, and the proportions were very similar for all four treatments. At one month 40% of the SH patients, 33% of the S2H, 34% of the 20 PH, and 34% of the 10 PH patients yielded specimens negative both on direct examination and on culture. The corresponding percentages at two months were 55%, 53%, 49%, and 53%, and by three months the percentages had increased to 75%, 74%, 73%, and 75% respectively. The findings for acute disease (group 1) and for the other lesions, both acute and chronic, considered suitable for chemotherapy (group 2) were very similar, and have not been tabulated separately.

When the progress of all the SH and all the 20 PH patients was compared there was again a close similarity in the responses of the two series; 68% of 166 SH patients and 68% of 147 20 PH patients yielded specimens negative both on direct examination and on culture at three months.

3. Sensitivity Tests

Isoniazid Sensitivity.—The results of the isoniazid-sensitivity tests are set out in Table VI. Comparing the four treatments, it can be seen that at three months 2

resistant strains were obtained from 22 patients with positive cultures on SH, 12 resistant strains from 30 similar patients on S2H, none from 24 patients on 20 PH, and 2 from 25 patients on 10 PH. The results for the SH, 20 PH, and 10 PH patients were alike, and satisfactory. The figures for the S2H series were less satisfactory, since the resistant cultures at three months represented 40% of all positive cultures, compared with 9% for the SH series, 0% for the 20 PH series, and 8% for the 10 PH series. When expressed as percentages of all the patients for whom cultures were undertaken, resistant strains were isolated from 9% of 132 S2H patients compared with 2% of 105 SH patients, 0% of 92 20 PH patients, and 2% of 97 10 PH patients. At two months the results for the S2H series were already inferior to those of the other series, for 6 resistant strains were obtained from 59 positive cultures (10%), whereas no resistant strains were isolated from any of the patients on the other three treatments. The inferiority of the S2H series compared with the other three treatments at three months is statistically significant.

In the second part of Table VI are set out the results for all the SH and 20 PH patients. At three months there were 3 resistant strains among 52 positive cultures from 166 SH patients. In the 20 PH series there were no resistant strains among 44 positive cultures from 147 patients. Each treatment therefore proved effective in preventing the emergence of isoniazid-resistant organisms over a period of three months.

Streptomycin Sensitivity.—The first part of Table VII compares the results of streptomycin-sensitivity tests in the SH and S2H patients. At three months there were no resistant strains among 22 positive cultures from 105 patients in the SH series, compared with 3 resistant strains among 31 positive cultures from 132 S2H patients.

		S2H	132	100	1	31	28	2	3	10	2	2
All SH patients (including subgroup 1A)	2	SH	163	78	4	81	80	1	1	1	1	1
		SH	166	114	1	51	50	1	1	2	1	1

* Percentages based upon fewer than 25 observations are enclosed in parentheses as an indication of the small totals.

Full information on the ability of the SH combination to prevent the emergence of streptomycin-resistant strains is obtained when the results for the patients in subgroup 1A are included. At three months there was only 1 resistant strain among 51 cultures from a total of 166 SH patients.

P.A.S. Sensitivity.—The first part of Table VIII compares the results of P.A.S.-sensitivity tests in the 20 PH and 10 PH series. At three months 1 resistant strain was obtained from 22 positive cultures from 92 patients on 20 PH compared with 1 resistant strain from 23 positive cultures from 97 patients on 10 PH. Each combination is thus effective in preventing the emergence of bacilli resistant to P.A.S. over a three-month period.

When the results for the patients in subgroup 1A are included, there were 2 resistant strains among 75 positive cultures in the 20 PH patients at two months, and 1 resistant strain among the 40 positive cultures from 147 patients at three months.

IV. SENSITIVITY TESTS AT FOUR, FIVE, AND SIX MONTHS

During the second three months the original combination of drugs was continued for the few patients in disease group 3, and for other patients selected by the clinician. A total of 67 SH, 78 S2H, 58 20 PH, and 38 10 PH patients continued on their original drug combination, the majority doing so for the whole of the second three months. There were, however, some changes of dosage. In 29 of the 67 SH patients the dosage of streptomycin was reduced (to 1 g. three times or to 1 g. twice a week), and in 9 of the 78 S2H patients it was increased. In 3 of the 58 20 PH patients the dosage of P.A.S. was reduced, and in 2 of the 38 10 PH patients it was increased. Collapse therapy, usually a

pneumoperitoneum, was induced in the second three months for 45% of the SH patients, 33% of the S2H patients, 28% of the 20 PH patients, and 32% of the 10 PH patients.

The results of sensitivity tests for these patients have been used to study the subsequent course of the pattern of resistance which emerged for each combination of drugs in the first three months. Because the groups of patients who continued on their original combination were not drawn at random, they may not be representative samples from the four treatment series. Analyses were therefore undertaken to investigate this point. The clinical condition of the patients on admission to the trial is set out in Table IX. A comparison of this Table with Table II shows that the subgroups of S2H, 20 PH, and 10 PH patients who continued on their original drug combination had an initial distribution of severe and less severe illness which was similar to that of the groups from which they were respectively drawn. The subgroup of SH patients who continued on the combination was initially more ill than its parent group, notably in extent of cavitation; this slight disadvantage may have biased the results towards the emergence of bacterial resistance (Medical Research Council, 1948, 1952, 1954; Howlett *et al.*, 1949; Tucker, 1949; Bignall *et al.*, 1950; Lotte and Poussier, 1953).

The results of sensitivity tests at three, four, five, and six months for the four subgroups of patients are given in Tables X-XII. By comparing the three-month results for the patients who continued on the prescribed combination with the three-month results for the full series of patients in Tables VI-VIII respectively, it can be seen that the proportion of resistant strains isolated from each subgroup is similar at three months to the proportion in the parent group. As a consequence of the similarity in initial clinical

† Assessment on a single full-plate chest radiograph taken before treatment started. Tomograms were not taken into account.

‡ The sedimentation rate of one group 3 patient was not recorded.

condition, and the similarity in the results of sensitivity tests at three months, the analyses from four to six months have been regarded as continuations of the analyses for the first three months in the earlier tables. However, because the patients who continued on their original combination were not chosen at random at the end of the three months, the reliance which may be placed upon the conclusions for the second three months cannot be quite so firm as in the first three months.

For the patients in each series who stopped or changed chemotherapy before six months, the results are given for as long as the patient received the prescribed combination. The patients in disease subgroup 1A have been included in the Tables to increase the numbers.

Isoniazid Sensitivity.—Table X shows that at four, five, and six months very small numbers of positive cultures were obtained from patients on any of the four treatments and that only an occasional isoniazid-resistant strain was

* Percentages based upon fewer than 25 observations are enclosed in parentheses as an indication of the small totals.

isolated from the SH, 20 PH, and 10 PH patients. The experience of the S2H series was not so satisfactory; at four months 15 positive cultures were obtained from 70 patients, and 9 of these were resistant to isoniazid. At five months 5 of 9 positive cultures obtained from 62 patients were resistant, and at six months 8 of 9 positive cultures from 64 patients were resistant. It may be concluded that this further study of isoniazid sensitivity under the four treatments has yielded very few positive results for sensitivity studies, an observation which is in itself of considerable importance. But, in addition, such sensitivity results as are available confirm the unsatisfactory nature of the S2H treatment in that it fails to prevent the emergence of isoniazid-resistant organisms to the same extent as the other three combinations of drugs.

Streptomycin Sensitivity.—The results of the streptomycin sensitivity tests at three, four, five, and six months for patients in the SH and S2H series are given in Table XI. The SH patients fared very well. There was 1 streptomycin-resistant strain among 7 cultures at four months, none among 3 cultures at five months, and none among 2 cultures from 50 patients at six months. The results for the S2H patients were not quite so satisfactory. At five months 3 strains resistant to streptomycin were found among 9 positive cultures. At six months 3 streptomycin-resistant strains were again isolated from 9 positive cultures from 64 patients.

P.A.S. Sensitivity.—The results of the P.A.S.-sensitivity tests at three, four, five, and six months for patients in the 20 PH and 10 PH series are given in Table XII. Very few positive cultures were obtained after the third month in either series and none of the strains was resistant to P.A.S.

The Relationship of Resistance to Streptomycin and to Isoniazid in the S2H Series.—A further study was made of the 21 patients in the S2H series in whom resistance to streptomycin or to isoniazid emerged while the patient was receiving the combination. In 2 of these patients isoniazid and streptomycin resistance emerged simultaneously. In 1 patient streptomycin resistance alone emerged and there was no subsequent information. In the remaining 18 patients strains which were isoniazid-resistant but streptomycin-sensitive were obtained. No subsequent information was available for 8 of the patients. In the other 10 the strains were known to be sensitive to streptomycin in 3 patients one month later, in 1 patient two months later, and in 3 patients three months later; strains resistant to streptomycin emerged in 2 patients two months after, and in 1 patient three months after, the isoniazid-resistant strain.

The numbers of resistant strains with the other three treatments were too small for useful analysis.

V. ISONIAZID-SENSITIVITY TESTS IN PATIENTS WITH INITIALLY P.A.S.-RESISTANT STRAINS

Six patients, who were admitted, observed, and treated according to the requirements of the trial, were excluded from the above analysis because they were later found to have had bacilli resistant to P.A.S. on entry to the trial. Four received the 20 PH and 2 the 10 PH treatment for a period of at least three months. At two months there were 3 positive cultures, 1 of which was resistant to isoniazid. At three months 5 cultures were examined; 3 were positive and 1 of these was isoniazid-resistant. The 2 patients with isoniazid-sensitive strains at three months continued on the 20 PH treatment for two and for three more months respectively. At six months the former was culture-negative and the latter had an isoniazid-resistant strain. In all, 3 of the 6 patients yielded isoniazid-resistant strains while receiving P.A.S. plus isoniazid, at two, at three, and at six months respectively. In view of the association between the emergence of isoniazid resistance and the extent of initial cavitation (Medical Research Council, 1952, 1954; Lotte and Poussie, 1953), it is of interest to note that none of the 6 patients had extensive (3-plus) cavitation on admission to the trial. The result thus compares very unfavourably

with the total of 4 patients in whom isoniazid resistance emerged among the 264 20 PH and 10 PH patients with initially P.A.S.-sensitive organisms.

VI. DISCUSSION

In the fifth report of this trial (Medical Research Council, 1953c) a clinical and bacteriological comparison of streptomycin 1 g. daily plus isoniazid 200 mg. daily (SH) and P.A.S. (sodium salt) 20 g. daily plus isoniazid 200 mg. daily (20 PH) was presented for a period of three months. Larger groups of patients receiving these two treatments have now been studied, and it has been found that the treatments are of comparable efficacy in improving the general condition, in fostering weight gain, in resolving pyrexia, in lowering the sedimentation rate (Table IV), and in suppressing tubercle bacilli in the sputum (Table V). Both treatments are also very effective for three months in preventing the emergence of bacterial resistance to the drugs used (Tables VI-VIII). These findings confirm those in the fifth report. But it has now also been shown that the SH treatment is superior in the important radiographic assessment, 53% of the 182 patients showing substantial (2-plus or 3-plus) radiographic improvement, compared with 38% of the 159 20 PH patients, a statistically highly significant difference (Table III).

For 67 of the 182 SH patients and 58 of the 159 20 PH patients the clinician elected to continue the same drug combination beyond three months. For reasons given, the analysis of bacterial sensitivity for these patients during the second three months may be regarded as a continuation of the analysis in the first three months. At six months only 2 positive cultures, and these sensitive to both drugs, were obtained from 60 SH patients and there were no positive cultures from 47 20 PH patients. Combining the figures at four, five, and six months, a total of 12 positive cultures was isolated from the SH patients; one culture was resistant both to isoniazid and to streptomycin and another to isoniazid only; there were 2 isoniazid-resistant strains and no P.A.S.-resistant strains among the corresponding total of 9 positive cultures from 20 PH patients. Thus the bacteriological effectiveness of each combination was maintained for six months. The findings on isoniazid sensitivity for the subgroup of SH patients are particularly worthy of note, since the dosage of streptomycin in nearly half these patients was reduced at three months either to 1 g. three times or to 1 g. twice a week, and neither of the resistant strains occurred among these patients. Moreover, the SH patients who continued were in worse clinical condition on entry to the trial—particularly as regards extent of cavitation—than those in whom treatment was changed at three months.

In the phase of the trial reported here two other combinations were also studied, involving lower dosages of streptomycin or of P.A.S. These were streptomycin 1 g. twice a week plus isoniazid 200 mg. daily (S2H) and P.A.S. (sodium salt) 10 g. daily plus isoniazid 200 mg. daily (10 PH). A three-month clinical and bacteriological comparison of these two treatments, and of the SH and 20 PH patients admitted concurrently with them, is presented. For this comparison the patients in disease subgroup 1A (acute bilateral disease in young adults) have been excluded, since they were allocated only to the SH and 20 PH series. The analysis, which is based on 115 SH, 142 S2H, 100 20 PH, and 105 10 PH patients, shows that over a three-month period the four treatments were of similar efficacy, both clinically and in suppressing tubercle bacilli in the sputum, but the SH combination was radiographically superior to any of the other three treatments.

Judging from the results of bacterial sensitivity tests over a three-month period, the 10 PH treatment was of the same high order of effectiveness as the 20 PH treatment in preventing the emergence of strains resistant to either drug. There were no isoniazid-resistant strains among 24 positive cultures from 92 20 PH patients, although there were 2 among 25 cultures from 97 10 PH patients; each combination yielded 1 P.A.S.-resistant strain. (In view of the possible relevance of the dosage rhythm of P.A.S. to the

emergence of bacterial resistance to isoniazid, it should be noted that in both treatments each dose of P.A.S. consisted of 5 g. of the sodium salt.) On the other hand, at three months there were 12 isoniazid-resistant strains among 30 positive cultures from 132 S2H patients but only 2 among 22 cultures from 105 SH patients. The S2H treatment is thus much less satisfactory in preventing isoniazid resistance than any of the other three combinations, the differences being statistically significant. Moreover, streptomycin-resistant strains were found among 3 of the S2H patients and in none of the SH patients.

An analysis of sensitivity results for the 78 S2H and 38 10 PH patients who continued on their original drug combination beyond three months confirms these bacteriological trends. At four, five, and six months a total of 6 positive cultures was obtained from the 10 PH patients; none was resistant to either drug. The S2H treatment remained unsatisfactory; 9 of 15 positive cultures were isoniazid-resistant at four months, 5 of 9 at five months, and 8 of 9 at six months. There was 1 streptomycin-resistant strain at four months, 3 at five months, and 3 at six months.

There have been a number of other studies of streptomycin plus isoniazid, notably by the U.S. Public Health Service (Mount *et al.*, 1953; U.S. Public Health Service, 1953; Mount and Ferebee, 1954), by the U.S. Veterans Administration (1953, 1954), and by Pitts *et al.* (1953), in the main using streptomycin 1 g. twice a week. There is general agreement on the clinical effectiveness of the combination for periods of study of up to eight months. Bacteriologically, however, streptomycin 1 g. twice a week with daily isoniazid appears from these studies to be inadequate to prevent the emergence of resistance to isoniazid. The present trial gives the only information so far available on a comparison of daily streptomycin plus isoniazid and intermittent streptomycin plus isoniazid, in which the treatments were allocated concurrently and at random. The daily treatment is clearly superior when assessed bacteriologically for six months, and shows some radiographic superiority at three months.

Turning to the combination P.A.S. plus isoniazid, most other studies agree with the present report on its clinical value over a three-month period. Over a longer period of time there are differences of opinion. Favourable reports come from the U.S. Public Health Service (Mount and Ferebee, 1954) based on 303 patients treated for thirty-two weeks, from the U.S. Veterans Administration (1954), based on 75 patients treated for five to eight months, and from Thoren and Hinshaw (1952), based on 15 patients treated for six months. On the other hand, Ford (1953) reported initial improvement in 22 patients, "most of whom had reached the end of their therapeutic road," but the majority relapsed clinically during the second three months. However, 19 of the patients had received previous chemotherapy which included P.A.S., and no pre-treatment bacterial sensitivity tests were performed. Unfavourable reports also came from Joiner *et al.* (1954), based on 15 patients with chronic disease, but the authors state that the radiological assessments were inconclusive. It is reasonable to conclude, from the larger of these studies, that the clinical effectiveness of the combination P.A.S. plus isoniazid continues for many months.

There are also differences between the reports on bacterial sensitivity for patients on the combination P.A.S. plus isoniazid. The findings in the present study for a wide range of acute and chronic disease, in patients 95% of whom had received no previous chemotherapy and all of whom had sensitive organisms at the start of treatment, have been very satisfactory over a period of six months. They are in sharp contrast to the present findings for 6 patients with P.A.S.-resistant organisms initially, in 3 of whom isoniazid resistance subsequently emerged under treatment with P.A.S. plus isoniazid. The U.S. Veterans Administration (1954) also reported favourably on the combination for a period of five to eight months. As in the

present study, there was a lower incidence of isoniazid resistance with P.A.S. plus isoniazid than with streptomycin 1 g. twice a week plus isoniazid. Thoren and Hinshaw (1952), Ford (1953), and Joiner *et al.* (1954) gave unfavourable reports. However, neither of the first two studies presented pre-treatment sensitivity findings to P.A.S., so that it is difficult to appraise the unfavourable results of the isoniazid-sensitivity tests. Thoren and Hinshaw (1952) gave no information on the previous chemotherapy received by their cases, but 19 of the 22 patients in Ford's (1953) series had previously received chemotherapy which included P.A.S. Ten of the 15 patients treated by Joiner *et al.* (1954) had received previous chemotherapy, although all the strains were sensitive both to isoniazid and to P.A.S. at the start of the study. It may be concluded from the findings of the larger inquiries that the combination is satisfactory, both clinically and bacteriologically, for six or more months, at least in patients receiving their first course of chemotherapy.

This survey of the literature indicates the difficulty of assessing the value of a combination of drugs from studies of patients who have received previous courses of chemotherapy. Such patients are selected to some extent by virtue of failure to respond adequately to the earlier courses, and their response is thus likely to be prejudiced. Newly diagnosed cases of pulmonary tuberculosis are a much more suitable group for the study of the relative merits of chemotherapeutic combinations. First, whereas previously treated cases may have resistant organisms, there is at present a high degree of assurance that the organisms of newly diagnosed cases will be sensitive to any prescribed combination (though this must still be confirmed by sensitivity tests on pre-treatment specimens—Medical Research Council, 1953a; Thomas *et al.*, 1954). Secondly, newly diagnosed cases provide a wider variety of disease for study, ranging from minimal to far-advanced lesions, and from hyperacute to very chronic disease. Thirdly, they respond better to chemotherapy, and so will indicate the relative efficacy of different treatments more readily than cases in which chemotherapy has previously been used.

In conclusion, streptomycin 1 g. daily plus isoniazid 200 mg. daily is radiographically the most effective of the four treatments over a three-month period, though otherwise there is little to choose between them clinically. The treatment is also superior, but not greatly superior, to streptomycin 1 g. daily plus P.A.S. (sodium salt) 20 g. daily (Medical Research Council, 1953b). It thus represents the most effective combination studied at any stage of the trial.

On the other hand, treatment with streptomycin 1 g. twice a week plus isoniazid 200 mg. daily has proved less satisfactory in preventing the emergence of isoniazid-resistant organisms and, because of this, its use cannot be recommended as a primary chemotherapeutic measure. There is, however, evidence that it is bacteriologically effective as a continuation of a three-month course of daily streptomycin plus isoniazid.

The present report confirms the earlier finding (Medical Research Council, 1953c) that P.A.S. plus isoniazid is an effective combination, although it is not quite so powerful as daily streptomycin plus isoniazid. Further, there is little to choose between 20 g. and 10 g. P.A.S. (sodium salt) daily in combination with isoniazid 200 mg. daily, whether assessed clinically over a three-month period, or bacteriologically over a six-month period. Either combination of P.A.S. with isoniazid can therefore be considered a valuable form of combined chemotherapy in the treatment of pulmonary tuberculosis, and each has the great advantage that it can be administered entirely by mouth.

VII. SUMMARY

In the final stage of a clinical trial of isoniazid (isonicotinic acid hydrazide) in the treatment of pulmonary tuberculosis, 588 patients were studied in 51 hospitals: 182 were treated with streptomycin 1 g. daily plus iso-

niazid 100 mg. twice a day (SH); 142 with streptomycin 1 g. twice a week plus isoniazid 100 mg. twice a day (S2H); 159 with P.A.S., sodium salt, 5 g. four times a day plus isoniazid 100 mg. twice a day (20 PH); and 105 with P.A.S., sodium salt, 5 g. twice a day plus isoniazid 100 mg. twice a day (10 PH). When submitting a case the physician did not know which treatment the patient would receive, this being determined by random allocation. The present report analyses clinical and bacteriological results at the end of three months' treatment. Bacteriological results are also studied for 241 patients over a six-month treatment period.

The types of disease studied ranged from acute rapidly progressive disease to very chronic disease. Most of the cases were newly diagnosed; less than 5% had received previous courses of chemotherapy. All patients included in the analysis had organisms sensitive at the start of treatment to both of the drugs they were receiving.

Cases in an important subgroup (acute rapidly progressive bilateral disease of recent origin, in patients aged 15-30) were allocated only to treatment with SH (67 patients) or with 20 PH (59 patients). The report contains a comparison of the SH, S2H, 20 PH, and 10 PH treatments, excluding the patients in this subgroup, and a further comparison of the SH and 20 PH treatments, including these patients.

On admission, the four treatment series had similar distributions of patients with severe and less severe illness. At the end of three months' treatment the majority of patients had improved. In terms of general clinical condition, resolution of pyrexia, and improvement in the sedimentation rate, the differences between the four treatment series were small. The average weight gains were 11.3 lb. (5.1 kg.) for the SH, 14.8 lb. (6.7 kg.) for the S2H, 11.3 lb. (5.1 kg.) for the 20 PH, and 13.9 lb. (6.3 kg.) for the 10 PH patients.

Changes in radiographic appearances were independently assessed by a radiologist unaware of the treatment of any patient. Two-plus or three-plus improvement was seen in 54% of SH, 44% of S2H, 33% of 20 PH, and 38% of 10 PH patients. The differences between this result for the SH treatment and those for the 20 PH and 10 PH treatments attain statistical significance. There were no radiographic deteriorations and 2 deaths in the SH series, 6 deteriorations and no deaths in the S2H series, 2 deteriorations and 2 deaths in the 20 PH series, and 4 deteriorations and 2 deaths in the 10 PH series.

The proportions of patients bacteriologically negative, both on direct examination and on culture, at a single examination at three months were 75% in the SH, 74% in the S2H, 73% in the 20 PH, and 75% in the 10 PH series.

At three months bacillary resistance to isoniazid was found in 2 of 22 culture-positive SH patients, compared with 12 of 30 similar S2H patients, 0 of 24 20 PH patients, and 2 of 25 10 PH patients. Bacillary resistance to streptomycin was found at three months in 0 of 22 culture-positive SH patients and 3 of 31 S2H patients, and to P.A.S. in 1 of 22 culture-positive 20 PH patients and 1 of 23 10 PH patients.

The addition to the SH and 20 PH series of the results for the young adults with acute bilateral disease confirms both the radiographic superiority of the SH treatment and also the close similarity of the results with the SH and 20 PH treatments in other respects.

It is concluded, *judging solely from the results at three months*, that streptomycin 1 g. daily plus isoniazid 200 mg. daily is not only the most effective of the four treatments but also represents the most effective drug combination studied at any stage of the trial. Streptomycin 1 g. twice a week plus isoniazid 200 mg. daily is less satisfactory in preventing the emergence of isoniazid-resistant organisms, and its use as a primary chemotherapeutic measure cannot be recommended. P.A.S. plus isoniazid has proved itself a very effective combination of drugs, although it is not quite so powerful as daily streptomycin plus isoniazid. There is little to choose between the clinical and bacteriological efficacy of 20 g. and of 10 g. P.A.S. (sodium salt) daily plus isoniazid 200 mg. daily. Either combination of P.A.S. with isoniazid is a most valuable oral form of combined chemotherapy in the treatment of pulmonary tuberculosis.

A proportion of patients in each of the four treatment series continued on the same combination of drugs beyond three months. For reasons given the analysis of bacterial sensitivity for these patients during the second three months may be regarded as a continuation of the analysis in the first three months. The analysis, based on a total of 241 patients, confirms, for a period of six months, the adequacy of the SH, 20 PH, and 10 PH treatments, and the inadequacy of the S2H treatment, in preventing the development of bacterial resistance to isoniazid. Combining the figures at four, five, and six months, 2 of 12 positive cultures from SH patients, 2 of 9 from 20 PH patients, and 0 of 6 from 10 PH patients were found to be isoniazid-resistant. On the other hand, 9 of 15 strains from S2H patients were resistant to isoniazid at four months, 5 of 9 at five months, and 8 of 9 at six months.

A small group of patients with P.A.S.-resistant organisms on entry to the trial was not protected from the risk of development of isoniazid resistance during treatment with P.A.S. plus isoniazid.

APPENDIX

Exclusions from the Clinical Analysis

Nine patients were excluded before treatment was started:

- 2 died before the start of treatment (1 20 PH, 1 10 PH);
- 2 were too ill to be moved to hospital (1 SH, 1 S2H);
- 2 discharged themselves against medical advice (2 20 PH);
- 2 refused to go to hospital (2 SH);
- 1, although admitted, did not start treatment, because no positive sputum was obtained (SH).

Fifty-five patients were excluded after treatment had begun:

- 2 were found not to have had pulmonary tuberculosis (1 S2H, 1 20 PH);
- 4 were found to have had organisms resistant to streptomycin at the start of treatment (2 SH, 2 S2H);
- 6 were found to have had organisms resistant to P.A.S. at the start of treatment (4 20 PH, 2 10 PH);
- 1 was found to have had organisms resistant to isoniazid at the start of treatment (10 PH) (no check-test was performed in the reference laboratory);
- 7 were found to have had excessive recent chemotherapy (1 SH, 1 S2H, 4 20 PH, 1 10 PH);
- 5 were given the wrong treatment (1 SH, 2 S2H, 2 20 PH);
- 14 discharged themselves against medical advice—6 in the first, 7 in the second, and 1 in the third month (2 SH, 2 S2H, 3 20 PH, 7 10 PH);
- 2 were transferred to other hospitals in the first month for investigations of non-pulmonary complaints (1 20 PH, 1 10 PH);

- 1 was transferred to a mental hospital with a psychosis, in the second month (10 PH);
- 6 had severe toxic reactions attributed to P.A.S. (4 20 PH, 2 10 PH);
- 1 had a severe toxic reaction attributed to streptomycin (SH);
- 2 stopped treatment in the second month—one because of acute nephritis, the other because of persistent haemoptysis believed to be related to treatment (2 SH);
- 2 had a change of treatment in the first month: for one 10 PH patient streptomycin was added after eight days, and the dosage of P.A.S. was doubled, because of the serious clinical condition: for one 20 PH patient streptomycin was added after 18 days because of radiographic deterioration; this patient had 1-minus deterioration at one month, and the deterioration at three months was still classed as 1-minus;
- 2 had a change of treatment in the second month (2 20 PH): one patient had deteriorated both clinically and radiographically and the treatment was changed to SH at six weeks; at ten weeks a radiograph showed 1-plus improvement compared with the condition on admission: the other patient deteriorated radiographically and streptomycin was added at six weeks, but there was 2-minus deterioration at three months.

ACKNOWLEDGMENTS

The hospitals and the doctors co-operating in the phase of the trial reported here are as follows:

Hospitals.—Aberdeen City Hospital; Aintree Hospital; Ashludie Hospital, Monifeth; Ayrshire Central Hospital, Irvine; Bangour Hospital, West Lothian; Black Notley Hospital, Braintree; Brimston Hospital, West Hartlepool; British Legion Sanatorium, Nayland; Brompton Hospital; Broomfield Hospital, Chelmsford; Canadian Red Cross Memorial Hospital, Taplow; Clare Hall Hospital, Hertford; Connaught Military Hospital; Cumberland Hospital, Surrey; Donifree and Galloway Sanatorium; East Fife Hospital, East Lothian; Edgware General Hospital, Ayrshire; Cuy Hospital; Foxhall Hospital, Ipswich; Glenalton Spa; Heathfield Hospital, Ayrshire; Hillingdon Hospital; Holywood Hall Hospital, Bishop Auckland; Inverurie Hospital, Aberdeen; Kettlewell Hospital, Kent; King Edward VII Sanatorium, Midhurst; King George V Hospital, Godalming; King George's Sanatorium for Sailors, Hants; Lenham Sanatorium, Kent; Llangwyfan Hospital, Denbigh; Mearns Kirk Hospital, Renfrewshire; Mount Pleasant Hospital, Middlesex; Newcastle General Hospital; North Middlesex Hospital; Poole Sanatorium, Middlesbrough; Robroyston Hospital, Glasgow; Romsley Hill Hospital, Worcestershire; Royal Victoria Hospital, Edinburgh; St. Albans City Hospital; St. Helen's Hospital, Ipswich; St. Helier Hospital, Surrey; St. Wulstan's Hospital, Worcestershire; Seaham Hall Sanatorium, Sunderland; Southfield Hospital, Edinburgh; Westcliff Hospital; West Heath Hospital, Birmingham; Woodend Hospital, Aberdeen; Wooley Sanatorium, Northumberland; Yardley Green Hospital, Birmingham.

Physicians.—Drs. P. G. Arblaster, M. Barry, D. Bell, W. Biagi, W. M. Borthwick, J. T. Boyd, L. E. Burkeman, L. W. Carstairs, K. M. Chalmers, J. A. Chamberlain, C. W. Clayton, J. B. Cochran, R. C. Cohen, A. H. C. Couch, Professor J. W. Crofton, Drs. R. Cunningham, V. Davies, V. F. Dawkins, M. K. Dhole, J. W. Duerden, T. A. Watkin Edwards, I. Elmslie, W. J. Ferraby, P. Forgas, M. A. Foulis, R. Fraser, M. A. Gallagher, I. E. Geddes, I. W. B. Grant, J. S. B. Greenfield, L. A. Hardie, W. C. Harris, H. F. Harwood, M. Hemming, E. V. Hess, J. A. Hill, E. Hodgkiss, N. W. Jones, J. V. Hurford, G. Hurrell, J. E. M. Hutchinson, Lieutenant G. J. Jones, Dr. G. Penry Jones, R. Sinclair Kennedy, G. M. Lewis, G. M. Little, T. W. Lloyd, L. C. Lum, E. G. Sita Lumsden, G. R. W. N. Luntz, Lieutenant-Colonel J. Mackay-Dick, Drs. W. MacDermid, N. MacFarlane, D. G. McIntosh, G. R. McNab, A. C. P. Mason, W. T. Miller, K. Murray, W. A. Murray, P. J. O'Rourke, J. P. Parkinson (the late), Hayden J. Partington, W. C. Pinkney, A. C. P. Ritchie, J. B. Robinson, J. T. Nicol Roe, Hector J. T. Ross, I. D. Ross, J. D. Ross, J. B. M. Runciman, F. A. H. Simmonds, D. H. Smith, J. Morrison Smith, J. Stevenson, C. J. Stewart, P. Stradling, G. J. Summers, J. Sumner, J. O. Taubman, D. Teare, H. E. Thomas, O. F. Thomas, B. C. Thompson, H. R. Thomson, Sir Geoffrey S. Todd, Drs. H. J. Trenchard, F. W. A. Turnbull, M. Walton, W. F. Wheeler, A. B. White, F. L. Wollaston, W. L. Yell, D. van Zwannenberg, and the consultant staff of Brompton Hospital (registrars, R. N. Johnston and K. Citron).

Bacteriologists and Pathologists.—Drs. C. S. Anderson, D. F. Barrowcliff, R. Blowers, D. M. H. Cogman, R. T. Cooke, J. E. Craik, P. B. Crone, J. C. Dick, Professor A. W. Downie, Drs. J. M. Dunbar, W. J. Golden, T. E. W. Goodier, W. I. Gordon, J. Harper, J. F. Heggie, E. D. Hoare, Captain C. H. Jones, Drs. E. R. Jones, P. Kidd, M. Laidlaw, G. Laws, J. T. A. Lloyd, A. Macdonald, J. Marks, P. H. Martin, A. Messer, D. A. Michison, Squadron-Leader A. D. Moore, Captain H. D. S. Morgan, Drs. E. Nassau, J. W. Nicholas, W. H. A. Pictou, R. Pilsforth, Squadron-Leader J. S. Porterfield, Drs. A. I. D. Prentice, I. A. Purdie, K. Rafinski, R. W. Riddell, J. M. Robertson, B. R. Sandiford, F. E. T. Scott, A. G. Siny, T. Skeoch, J. Smith, P. J. Taylor, W. K. Taylor, A. T. Wallace, R. F. Welch, W. Whitelaw. The bacteriologists and pathologists formed a laboratory subcommittee under the chairmanship of Professor R. Cruickshank.

Dr. E. H. Bailey, Southern Group Laboratory, supplied culture medium where desired. Dr. D. A. Michison's laboratory, Postgraduate Medical School of London, served as reference laboratory for drug-resistance tests.

The above cannot be a comprehensive list of all the doctors who contributed to the results reported here, nor has it been possible to name the many laboratory technicians who did detailed and valuable work. The Tuberculosis Chemotherapy Trials Committee expresses its thanks to all members of hospital staffs who assisted in the investigation.

The Research Committee of the Tuberculosis Society of Scotland was of considerable assistance in initiating the trial in Scotland. The Edinburgh team was in receipt of a research grant from the Royal Victoria Hospital Tuberculosis Trust.

RESULTS OF SURGICAL TREATMENT OF CARCINOMA OF THE LUNG*

BY

T. HOLMES SELLORS, D.M., M.Ch., F.R.C.S.

Thoracic Surgeon, Middlesex, London Chest, and Harefield Hospitals

In the treatment of cancer of the lung it is generally accepted that surgery alone offers any real hope of success. Up to the present time radiotherapy has played a part that is largely palliative, and the experiences gained by the combined use of radiotherapy and surgery are too limited to be of value. There are now large enough numbers of surgically treated cases on which a rough estimate of long-term results can be based, and in this article an analysis of personal cases operated on between the years 1940 and 1950 is made. The follow-up was carried out up to the end of 1953, which gives a five-year survival figure for cases operated on prior to 1948 and three-year survival figures for those treated in the subsequent two years.

Excision of a tumour of the lung is a practicable proposition so long as the mass can be actually removed and so long as the patient can sustain the inevitable loss of lung tissue. Pneumonectomy is regarded as the standard operation in the treatment of pulmonary cancer, though a more limited resection in the form of lobectomy can be carried out in certain circumstances. Improvements in all branches of thoracic medicine and surgery have been responsible for making lung resection a relatively safe technical procedure and in reducing the post-operative mortality and complications to reasonable limits. The lapse of time has now been long enough to permit evaluation of the results of operation.

Incidence

The steady annual ascent of the recorded death rate in relation to carcinoma of the lung is indicated by the Registrar-General's figures given in Table I. and, even allowing for a much greater awareness of the disease and for

*Based on a paper given at the Sectional Meeting of the American College of Surgeons, London, May, 1954.

improved methods of diagnosis, these give some idea of the magnitude of the problem. Stocks (1947) believes that the incidence shows a true increase during the past two or three decades, and gives the standardized death rate in males as having increased from 1.1 in 1910 to 10.6 in 1938. More recently the crude mortality rate per million living has doubled in ten years.

TABLE I.—Mortality Per Million Living (Registrar-General's Figures)

	1938	1943	1948	1953
Carcinoma bronchus	113	162	238	343
" " stomach	311	337	337	323

Figures for carcinoma of the stomach are added for comparison.

The proportion of patients suitable for surgery is depressingly small; figures have been given for an operability rate of as high as 15 to 25%, but these figures come from surgical centres where there has been a considerable measure of pre-selection, and in all probability obviously inoperable patients have been excluded. Reasons for declining operation lie in the size and position of the growth, metastasis, and in the age and general condition of the patient. The figures produced by Brian Taylor and Waterhouse (1950) showed that in over 1,500 patients not treated by surgery the average expectation of life was four months. In consequence, if surgery can produce results which allow survival beyond the average expectation of the untreated case it will have performed some service. For this reason, in analysing the figures we have classified the follow-up into deaths that occurred up to two years after operation and then considered the survivals for a period of five years.

Factors Influencing Operability

General Condition of the Patient.—The most obvious contraindication is the inability of the patient's respiratory function to withstand removal of part or whole of a lung. A rigid chest, gross emphysema, and chronic bronchitis are examples, and the presence of persistent bronchospasm is a potent factor in rendering the post-operative course hazardous. Cardiac disability, unless severe, is not such a serious hazard to surgery as might be supposed, and many patients whose hearts have been suspect have supported the operation well. Straightforward clinical observation has been found to be the most satisfactory guide in assessing cardio-respiratory function.

Age.—As measured in years age is not important (see Fig. 1); many men of 70 and over have had younger tissues than their fellows in lower age groups and have supported the operation well.

FIG. 1.—Age incidence in 200 pneumonectomies.

Site of Growth.—A mass placed in the centre of the lung field is a better immediate risk for surgery than one located close to the mediastinum. Growths at the apex are more likely to invade pleura and traverse it than those at the base, where the tumour may spread along the pleural layers for a considerable distance without invading the chest wall. When a pleural effusion is caused by spread of growth over the membrane the chances of a radical excision are small, but a clear effusion or even empyema does not necessarily preclude operation. Involvement of mediastinal structures by the growth itself or by glands is one of the most frequent causes of inoperability. Practically no case which has developed a vocal cord paralysis can be excised completely; the same applies to involvement of the phrenic nerve. Obstruction of the superior vena cava and invasion of the left auricle with the development of fibrillation are further contraindications, though a number of these cases have been explored on the faint hope that excision will prove practicable. Oesophageal obstruction resulting from pressure of enlarged glands is suggestive of inoperability, but not always. Invasion of the pericardium is often associated with a considerable amount of effusion into that sac, which, when incised, shows bulging of the tumour into the pericardium without actual penetration of that membrane. Spread of the actual growth along the pulmonary veins is well recognized, and the risk of embolism of fragments of growth as a result of manipulation have been pointed out by Aylwin (1951).

Size of Growth.—It is not always the largest growth that gives the worst prognosis. Many large breaking-down tumours have been removed successfully, with good later results. Most of these tumours have an expanding rather than an infiltrative character, and, with a well-defined oval or circular outline, may easily be mistaken for benign growths.

Type of Growth.—In the present series no case of so-called adenoma of the lung or bronchus has been included. I regard these tumours as entities requiring separate consideration. The histological character of the tumour has a considerable bearing on the surgical selection and on the prognosis. D. M. Pryce and J. B. Walter (personal communication, 1954) have investigated the cell types in two consecutive series of cases; the one was taken from necropsies and the other from operation specimens, many of which are included in the material for this article. In the necropsy series squamous-cell tumours were recognized in 20.1%, adenocarcinoma in 28.3%, oat cell in 37.1%, and polygonal in 10.7%. In the pneumonectomy or excision series squamous-cell tumours were 60.4% of the total, adenocarcinoma 15.5%, oat cell 15.9%, and polygonal 7.7%. If the necropsy series is regarded as representative of all cases of lung cancer then the operability rate for squamous-cell carcinoma is infinitely superior to that for the other cell types—a feature that is well recognized; but it is not so well appreciated that adenocarcinoma is almost as common as oat-cell tumours. In the follow-up by Pryce and Walter the end-results of operation for squamous-cell growths are superior to those of the other types. An interesting commentary on the prognosis of adenocarcinoma and oat-cell tumours is that, while it is commonly supposed that the latter give consistently bad results and that adenocarcinoma is a less sinister type, an analysis of their figures suggests that both these growths are equally unfavourable for surgery.

Regional Metastasis.—The existence of secondary deposits in the regional glands has a considerable influence on prognosis. In the first place, they may have infiltrated adjacent mediastinal structures: this is particularly the case when the subaortic group of glands have invaded the aorta or main pulmonary artery, or when glands have infiltrated the main bronchial bifurcation. Such a circumstance may well preclude operation. Secondly, there may be enlarged glands which can be removed, but in which a full surgical clearance is unlikely. In this group of cases the operation is more of a palliative than of a radical nature. In a third

group of cases the glands may be grossly enlarged, but on histological examination they are found to be of a secondary inflammatory character without metastases.

Type of Operation

The accepted operation is a dissection pneumonectomy with removal of the lung and glands *en bloc*. In the earlier cases in this series the pulmonary arteries and veins were secured individually as they emerged from the pericardium. More recently incision into the pericardium has allowed these vessels to be taken closer to the heart and has enlarged the scope of the operation and even allowed excision of part of the left auricle if necessary. In all cases the division of the bronchus was made as close to the carina as possible and the closure carried out by interrupted non-absorbable sutures. Various methods have been used from time to time to cover the bronchial stump and reduce the incidence of bronchial fistula, which has now fortunately become a less serious complication than it was in former years. Excision of the parietal pleura is carried out over the mediastinum in all cases and over areas where lung is adherent.

Lobectomy, though a less radical operation, has produced excellent results, sometimes apparently superior to pneumonectomy. The operative mortality is lower and the loss of lung function less, but the cases chosen for this operation are carefully selected and largely consist of small central tumours without gross glandular involvement.

Segmental resection is an operation that is not often performed deliberately, but is sometimes carried out under the mistaken impression that the condition is tuberculous or that the tumour is benign.

In no case was a simultaneous or post-operative thoracoplasty performed unless the presence of an empyema required some measure of chest-wall collapse. The fate of the phrenic nerve was problematical: in most cases the nerve was divided, though in some instances, particularly on the left side, it was left intact.

In discussing the results of surgery over a period of years some points in the development of thoracic surgery should be recalled. Pneumonectomy was practised successfully on occasions in the late 1930's, but it did not become a common routine or established procedure until some years later. Towards the end of the recent war the introduction of penicillin coincided with a number of improvements in technique and experience, all of which contributed to a decrease in mortality and morbidity even though more extensive operations were being undertaken. The volume of material has also increased with the greater realization of the frequency of the disease and the wider application of chest radiology, including mass radiography. In spite of many endeavours to achieve an earlier diagnosis and consequently to improve the surgical results, the average delay in 1950 between the early symptoms and operation was six months. This contrasts more favourably than the nine months which was the period of delay in 1940, but still leaves much to be desired.

Results

In an analysis of the operations performed between 1940 and 1950 a total of 689 thoracotomies were recorded and

TABLE II.—Type of Operation

	1940-8	1949-50	Total
Thoracotomy only	155	88	243
Pneumonectomy	227	137	364
Lobectomy	46	36	82

243 thoracotomies; 446 resections.

excision was undertaken on 446 occasions (Table II); this gives an approximate figure of two cases out of every three explored being operable. The "operative mortality" was taken to cover all patients who died in hospital or within

four months of operation. Of those who were submitted to resection 81 (18%) died; the figure for the period 1940-8 was 24%, but this fell in the subsequent two years to 9% (Table III, Fig. 2). There was one death in the lobectomy;

FIG. 2.—Survival rate.

TABLE III.—Results of Resection

	Resections	Deaths			Survivals			
		Following Operation	4-12 Months	1-2 Years	At End of 2 Yrs.	At End of 3 Yrs.	At End of 4 Yrs.	At End of 5 Yrs.
1940-48	273	66 (24%)	78 (28.5%)	36 (13%)	93 (34%)	81 (30%)	65 (23.5%)	57 (21%)
1949-50	173	15 (9%)	53 (31%)	35 (20%)	70 (40%)	59 (34%)	—	—

series, which consisted of 82 cases. A number of the patients included under the heading operative mortality had indeed recovered from the actual operation, but succumbed from respiratory complications or from distant metastases which were not recognized at the time of operation. In an analysis of a number of these early deaths it can be mentioned that death occurring within a week was largely caused by heart failure, pneumonitis, or respiratory insufficiency. A later complication sometimes leading to fatality, particularly in the earlier cases, was empyema consequent on a bronchial fistula.

Deaths which occurred within 4 to 12 months of the operation amounted to 131 (29%). The majority of these deaths followed early local recurrence or a distant secondary. Brain and suprarenal glands were common sites for these metastases, and there is little doubt that some of the former were caused by direct embolism of growth as a result of operative manipulation. In all, 47.5% of the patients who had the growth excised did not survive a year, and a further 16% were dead before a further two years had lapsed.

When dealing with survival figures two analyses have to be made: the period 1940-8 gives survival up to the end of five years, but the 1949-50 group can only give a three-year figure. It will be noted from Table III and Fig. 2 that the figures from this more recent group are superior to the earlier ones, largely as a result of the reduction of operative mortality; but as more advanced cases were undertaken there is a percentage increase in the deaths occurring before two years had passed. In the 1940-8 group 34% of the patients were alive at the end of two years, 30% at the end of three years, 23.5% at the end of four years, and 21% at the end of five years. At one time it was thought that if a patient survived operation without recurrence for two years his chances of long-term survival were good, but it would appear that three years must elapse

before there is any feeling of security. In the 1949-50 series 40% of the patients were alive at the end of two years and 34% at the end of three years. If these figures follow the pattern of the other group it would seem reasonable to suggest that a 25% survival at five years might be expected.

Many of those who have died are known to have died from causes other than recurrence of cancer of the lung; suicide, accident, and old age have all played some part in reducing the number of survivors. A number of those who have exceeded the five-year period are known to have lived longer than this arbitrary limit. My longest survivor is 15 years (a case not included in this analysis), and there are four who have lived 10 years, and a greater number who have passed the seven-year mark.

An analysis of any surgical results in the treatment of cancer is bound to be disappointing, and there would seem to be an impression that the results of treatment in lung cancer are so poor that surgery is not worth while. This is suggested by the number of patients who are treated conservatively or are referred for radiotherapy without being seen by a thoracic surgeon, who alone can give the best advice regarding the chances of operation in an individual case. In spite of the many disappointments there is a kernel of success and satisfaction in that at least 21% of the patients operated on survive the five-year period, and indeed in the more recent cases there is every reason to expect that this figure may be appreciably raised.

Summary

An analysis of personal cases of cancer of the lung operated on between 1940 and 1950 is made.

Of a total of 689 thoracotomies, 446 were found suitable for excision—an operability rate of about two-thirds of the cases explored.

A follow-up to the end of 1953 gave for cases operated on prior to 1948 a survival rate of 34% at the end of two years, 30% at three years, 23.5% at four years, and 21% at five years. In the 1949-50 series 40% were alive at the end of two years and 34% at three years.

It is thought that there is some satisfaction that at least 20% of these patients survived the five-year period. Moreover, the more recent cases suggest that this figure may be improved upon.

Taylor, A. Brian, and Waterhouse, J. A. H. (1950). *Thorax*, 5, 257.

According to the Annual Report for 1952 of the Chief Inspector of Mines, recently published, the number of persons killed in 1952 was a new low record, being 420, comparing with 487 in 1951 and an average of 583 in the previous ten years. Much of the improvement in 1952 was due to the absence of any great disasters: Deaths due to falls of ground were fewer than in the previous year's, but deaths due to haulage increased by 22 over the previous year's. "The numbers of fatalities in shafts and on the surface have shown no improvement in the last ten years or so—a state of stagnation which constitutes both a reproach and a challenge." The number of accidents required by law to be immediately reported involved 2,109 injured people, as compared with the 1951 figure of 1,942. People injured in accidents not immediately reportable but causing disablement for more than three days numbered 238,100, as compared with 234,400 in the previous year. But as more people were employed there was little change in the accident rate, which was one accident for every three employees. In the last decade fatal mining accidents have fallen by 52% and non-fatal by 25%. The safety organization of the National Coal Board continued to grow, but there were 33 vacancies in the mining inspectorate.

INTERMITTENT POSITIVE-PRESSURE RESPIRATION IN BULBO-SPINAL POLIOMYELITIS

USE OF THE RADCLIFFE RESPIRATION PUMP

BY

J. R. HARRIES, M.D., M.R.C.P., D.C.H.
D.T.M.&H.

Acting Medical Specialist, Colonial Medical Service, Kenya Colony

AND

W. E. LAWES, F.F.A.R.C.S., D.A., D.T.M.&H.

Anaesthetic Specialist, Colonial Medical Service, Kenya Colony

The use of positive-pressure respirators driven either by hand or by machines has been described by Lassen (1953), Smith *et al.* (1954), and Macrae *et al.* (1954) in the treatment of bulbo-spinal poliomyelitis, where postural drainage combined with some form of tank respirator is not sufficient to prevent inhalation of secretions. Recently we have treated three such cases in the poliomyelitis unit at Nairobi, Kenya, all in male adults, and the Radcliffe respiration pump (Russell and Schuster, 1953) was used. One patient died from shock and hyperpyrexia; one died suddenly on the twenty-fifth day of illness, no cause

Recent modifications in the Radcliffe respiration pump (P), and accessories. The pump has alternative motors—one for 230 volts A.C. and the other for 12 volts D.C. The latter is very suitable for transporting patients by air or road. The gas meter (M) replaces the cumbersome spirometer. H=Humidifier. V=Expiration flutter valve. G=Gauge. T=Cuffed tracheotomy tube.

being found at necropsy; while the other was flown to Oxford, still using the Radcliffe pump, at the end of the eighth week and is making satisfactory progress.

Christie (1954) has pointed out the difficulty of clinical assessment and has emphasized the importance of being able to call on the services of the physiologist, the biochemist, the clinical pathologist, and the pharmacologist. Such assistance is generally available only at the larger medical centres, and the aim of this article is to point out to those working in more remote centres that simple clinical methods can be passably successful.

For a general description of the machine and method the reader is referred to the article by Smith *et al.* (1954). This machine has since been modified as shown in the accompanying illustration (Ritchie Russell, 1954, personal communication).

Type of Case.—Intermittent positive-pressure respiration (I.P.P.R.) through a cuffed endotracheal tube inserted into a tracheostome was reserved for those cases having respiratory embarrassment, an ineffective cough, inability to swallow, and pooling of secretions in the pharynx.

Tracheotomy

Andersen and Ibsen (1954) have described how local analgesia was abandoned as unsatisfactory in the Danish epidemic of 1952, and as this agreed with our previous experience it was decided that general anaesthesia should be used. All cases received thiopentone and succinylcholine chloride; atropine, 0.6 mg., was the only pre-medication. Small doses of thiopentone, 0.15-0.3 g., were used, but the usual dose of succinylcholine chloride, 2-3 ml. in divided doses, as the procedure took ten to fifteen minutes. In one case in which the operation was performed elsewhere and the services of an anaesthetist were not available, the dose of succinylcholine chloride was too small and disaster very nearly followed. The anaesthetist must have full immediate control of the patient, who may be in poor condition.

The steps of the procedure were as follows: (1) Aspiration of stomach with the Levine tube: this we regard as important, as regurgitation can occur without warning and a fatal outcome may result. (2) The patient's lungs were inflated with oxygen through a Waters to-and-fro unit from which the canister had been removed. (3) Thiopentone was given in a sleep dose only, followed by succinylcholine chloride, 1-1.4 ml., other syringes containing 0.5-0.7 ml. of succinylcholine chloride being available as required. In only one of our cases was there any weakness of the jaw muscles. (4) Laryngoscopy and laryngopharyngeal toilet. (5) Bronchoscopy and bronchial toilet. (6) Intubation with a plain endotracheal tube. (7) Tracheotomy, which under these circumstances can be done quietly and deliberately. Our surgical colleague commented on the difference between the ease of the operative procedure under this method and the difficulties he had experienced in previous cases under local analgesia. No window was made as suggested by Lassen (1953), and Macrae *et al.* (1954).

General Management and Treatment

Physiotherapy.—All joints were passively moved through their full range once daily. Splints were applied where necessary to prevent deformity. After about a month active exercises were instituted.

Antibiotics.—From admission, antibiotics were given in full doses, the choice depending on the sensitivity of organisms cultured on bronchial swabbing.

Other Drugs.—Phenobarbitone, 32 mg. t.d.s., and ephedrine hydrochloride, 16 mg. t.d.s., were given. Chloral, 1.3 g., was given at night. Paraldehyde intramuscularly or by mouth was used occasionally. Aspirin was used to allay the muscular pains and vitamin-B complex was given daily.

Investigations.—Blood urea estimations were done twice weekly. Bronchial swabs for culture were taken weekly. Urine chlorides were estimated daily. Total blood counts were performed at weekly intervals. Plasma proteins were estimated from time to time.

Fluid Intake and Diet.—Feeding was by means of a Levine tube. The aim was 3 litres of fluid and 2,500 calories daily. The salt intake was governed by the Fantus test for urinary chlorides and the protein intake by the blood urea.

Specific Management and Treatment

The endotracheal tube was changed every three days and deflated four-hourly. Macrae *et al.* (1954) have pointed out the danger of overinflation of the cuff. The cuff should be inflated slowly until air ceases to pass round it; this end-point can be detected by auscultation over the trachea, though sometimes it is not easy. If air enters both apices equally then the tube is not too far in. The management of the tube caused some difficulty at first, as it was not possible for an anaesthetist to be present all the time. The nursing staff quickly learned the dangers of these tubes, as attested by the fact that, during the three months in which the machines have been in continuous use, only on three occasions have emergencies arisen specifically from the cuffed tube. Twice the tube slipped into the right main bronchus, completely blocking the left; on the third occasion an old tube was used, and the very soft cuff herniated over the end of the shortened tube, giving a ball-valve effect. Air could be forced past the herniation but very little could escape. Releasing the cuff had little effect, and the herniation persisted even after the tube had been withdrawn from the trachea. This emergency almost ended in disaster, and since that time no tube has been used more than twice.

Pharyngeal, Tracheal, and Bronchial Toilet.—Suction was performed through the mouth and the endotracheal tube at regular intervals, also before and after turning, and whenever there was any evidence of pulmonary collapse or whenever the stroke of the pump seemed to be impeded. Posturing of the patient, especially into the prone position, with percussion and squeezing of the chest at the end of expiration, brought the secretions within range of the catheters. Bronchial catheters, soft rubber catheters, and Tieman catheters were used; the last-mentioned tended to cause some bleeding unless used very gently. Bronchoscopy was needed during treatment on only four occasions apart from the original surgical procedure: twice when the humidifier had been set at too low a figure and secretions had become dry and sticky; once when it had been thought that a considerable amount of secretion had run down past a deflated cuff; and once for pulmonary oedema, but bronchoscopy in this last condition seemed to do little if any good. The site of the cuff was inspected on each occasion, and appeared to be normal, except on one occasion when the left main bronchus showed a minor degree of excoriation, probably resulting from the too vigorous use of a Tieman catheter. Bi-weekly x-ray pictures were taken to check the clinical findings.

Humidification.—The apparatus described by Marshall and Spalding (1953) proved satisfactory. The temperature of the thermostat was originally set at 110° F. (43.3° C.), but was later increased to 130° F. (54.4° C.), as the sputum became too sticky at the lower figure. A fair amount of condensation occurred in the lagged tube, and care was taken to ensure that it sloped away from the Stott valve towards the humidifier.

Pressure Gauge.—It has been shown that if the pressure in the trachea does not fall to atmospheric level at the end of expiration the circulation will be affected (Courmand *et al.*, 1948; Motley *et al.*, 1948). The gauge at times needed readjusting by disconnecting it from the machine and resetting the pointer. The pressure on inspiration was not allowed to exceed 16 cm. of water. Common sites of leakage, as shown by a reduction of pressure, were round the cuff and at the Stott valve.

Increased Oxygen Percentage.—At first we tended to give extra oxygen through the side tap of the machine. This was later discontinued, as on only a few occasions was oxygen really needed and high flows upset operation of the valve. When oxygen is required it is best to lead it into a reservoir bag attached to the main intake of the inflating bellows.

Control of Respiration.—Spirometer readings of expired air are essential, as the volume delivered each minute by the machine does not all reach the lungs. The difficulty

of deciding the optimum ventilation for each patient has been stressed by many writers (Smith *et al.*, 1954; Macrae *et al.*, 1954; Astrup *et al.*, 1954). Overventilation upsets the circulation and causes alkalaemia. Underventilation causes CO₂ excess with or without anoxia. Some degree of hypertension would suggest CO₂ retention and a rise of urinary pH alkalaemia. Clinical assessment we found to be difficult. Various clinical signs have been reported as being indicative of CO₂ excess. Ibsen (1954) describes a rise in blood pressure, cold clammy skin, gagging and bucking of respiration in cases in which spontaneous respiration is present, and increased secretions in the mouth and nose—all the symptoms being relieved when respiration is increased. Case and Haldane (1941), working on conscious volunteers breathing 6% CO₂, describe hyperventilation, relatively little mental impairment, but some mental distress, slight headache, photophobia, and nausea.

The problem of CO₂ could not be investigated by elaborate methods as described by Astrup *et al.* (1954). A simple CO₂ meter of German manufacture (Dräger) was obtained from Messrs. Garthur, and was used to measure the CO₂ content of the expired air. Sampson Wright (1945) gave a figure of 4% for CO₂ in expired air. It was decided that a figure of 4% should be regarded as the maximum permitted for samples collected in a bag at the respiratory vent. As the meter gave slightly different readings from the same sample, the mean of three readings was used. There were, however, occasions when the figures seemed somewhat bizarre, and the meter readings were used only as a guide. On a few occasions attempts were made to obtain figures for air at the carina, but the figures were very variable, possibly owing to turbulence, and this method was abandoned. Routine urinary pH examinations were done as a check against hyperventilation.

The respiration pumps were used at speeds of 20 to 26 a minute, and the readings for expired air on the spirometer varied from 9 to 14 litres a minute. The higher figures were used on a heavily built man with an axillary temperature of 42.2° C. (108° F.) in whom it was exceedingly difficult to get the CO₂ readings down to 4%. These spirometer readings are higher than those recommended by other writers (Smith *et al.*, 1954; Astrup *et al.*, 1954; Macrae *et al.*, 1954), but on only one occasion was the urine alkaline.

Case 1

A European air-pilot aged 33 was admitted to the Infectious Diseases Hospital, Nairobi, on September 4, 1954. He had been flown from Mweiga, a distance of some 300 miles (480 km.). One week before admission he had suffered from epigastric pain, which continued for five days, when he developed frontal headache and aches across the shoulders and behind the knees. He had lost his appetite and had had several bouts of vomiting.

On admission he was found to have stiffness of the neck and back, horizontal nystagmus, and slight weakness of the flexors of the right hip. On the following day the nystagmus had increased and there was weakness of the left masseter and palate. He was cyanosed and no movements of the intercostals were detected. The flexors and extensors of the elbow-joints on both sides were weak. He was unable to raise his legs from the bed. The respiratory embarrassment increased, and at 1.50 p.m. he was put into a tank respirator. The next day his condition remained about the same. On September 7, 36 hours after being put into the tank respirator, he was found to be cyanosed, and the left side of the face and the left masseter were paralysed. He was unable to swallow, and secretions had collected in the hypopharynx. Both the intercostals and the diaphragm were paralysed, and all the limb muscles were paralysed to a greater or lesser degree. It was decided at this stage to institute intermittent positive-pressure respiration by means of the Radcliffe pump. The operative procedure and routine management employed have already been described.

His progress was marked by the frequent occurrence of pulmonary collapse. On one occasion this was caused by the endotracheal tube slipping down the right bronchus. On all other occasions plugs of mucus were the causative factor. These were dealt with rapidly and satisfactorily by turning, tipping, percussion, and squeezing of the chest combined with bronchial suction. The relief of collapse in these cases could only be referred to as dramatic. In almost all cases the collapse occurred in the left lung. On two occasions early on it was necessary to have recourse to bronchoscopy.

His temperature took about three weeks to settle. The first week it slowly fell from 103 to 101° F. (39.4 to 38.3° C.), the second week there were occasional spikes to 100° F. (37.8° C.), and the third week to 99° F. (37.2° C.).

On September 19 he was able to make short attempts to breathe alone, but not for more than 30 seconds at a time. On the 21st the Levine tube was removed, as ability to swallow was completely recovered. On the 22nd an attempt to replace the I.P.P. respirator by the Paul-Bragg pulsator was unsuccessful. After three hours in the pulsator the CO₂ in his expired air had risen to 6.2% and his blood pressure had increased from 135/80 to 172/105. Normally his CO₂ levels for expired air were between 2.5 and 3% and his blood pressure was about 135/80.

The usual ventilation given was 10 litres a minute, but this was increased to 12.5 litres a minute on October 11, by which time his blood-pressure level had slowly risen to 150/100. The increased ventilation caused a slow decline to the previous level.

On October 5 weaning to a Monaghan type of cuirass respirator was tried. This again was unsuccessful. After five minutes in the cuirass his blood pressure had risen to 225/105 from 130/85, his pulse had fallen from 100 to 40 and had become irregular, and the CO₂ in his expired air was 5%. Both blood pressure and pulse returned to their previous levels eight minutes after restarting I.P.P.R. Similar results were obtained on repeating the procedure, with elevation of blood pressure to 220/120, pulse 60, and CO₂ 4.2%. In an attempt to explain the mechanism of these changes, we carried out the following experiment.

The patient was inflated with pure oxygen at a slow rate (2.5 litres a minute) in order to produce CO₂ accumulation. After eight minutes the blood pressure showed a slight rise to 160/105, the pulse remained constant, and the CO₂ was 4.1%. The oxygen was then stopped and he was allowed to breathe by himself. After one and a half minutes his blood pressure had further risen to 190/115, and his pulse had fallen to 60. The Radcliffe pump was restarted and after about 10 minutes the blood pressure, pulse, and the CO₂ readings settled to 135/85, 96, and 2.5% respectively. After a rest, the patient was then allowed to breathe by himself, but this time he was given pure oxygen. After eight minutes there was a slight rise in blood pressure to 158/105, but the pulse remained constant. However, after stopping the oxygen and allowing him to breathe air, the blood pressure rose slowly during the first three minutes to 162/110, and the pulse dropped to 84. In the next three minutes the blood pressure rose rapidly to 190/115 and the pulse fell to 60. No cyanosis was observed.

We concluded that these anomalies of elevation of blood pressure and fall in pulse rate were probably due to a certain degree of anoxia. We thought it possible that he had a hypertensive vasomotor centre or carotid sinus which responded to hypertension by causing a marked slowing of the pulse rate. In an attempt to wean the patient from the Radcliffe pump, he was allowed to breathe pure oxygen on his own, and when he was evacuated to England he was able to breathe for 13 minutes at a time. By December 2 we understand that he could breathe without assistance for eight hours a day.

When he left Nairobi recovery from the cranial nerve palsies had occurred, he had a fair amount of power in all the arm and shoulder muscles, and there was movement in

all the muscles of the left leg and in the hamstrings and gastrocnemius of the right leg. The sacrospinalis showed some muscle recovery.

On October 24 he was flown to the Radcliffe Infirmary, Oxford, a distance of some 4,500 miles (7,240 km.), in a pressurized plane to the Respiration Unit directed by Dr. W. Ritchie Russell. He was accompanied by a team consisting of a physician (J. R. H.), a hospital superintendent, and a nursing sister. The machine was run from batteries by means of a dynamo to provide 240 volts. Oxygen was carried but not used. The journey of 21 hours' flying time was uneventful, apart from a collapse of the entire left lung due to secretions. The collapse was rectified by suction, posturing, and slapping. The team was met at London Airport and the patient transferred to Oxford by ambulance under the care of Dr. Crampton Smith. The latest Radcliffe respiration pump has since been modified so that it may be run from 12-volt batteries (Ritchie Russell, 1954, personal communication) (see Fig.).

Case 2

On October 15 a male Chinese electrician aged 46, working at Musoma, Tanganyika Territory, developed fever, headache, and a sore throat. On the following day the left leg became paralysed. On the 17th the right leg followed suit, and he was unable to pass urine. On the 18th he was transferred to Nairobi by plane—a distance of some 400 miles (640 km.).

On admission he had slight difficulty in swallowing; the right side of the chest moved poorly and paradoxically. Both legs were paralysed with the exception of the dorsi and plantar flexors of the right ankle-joint. His bladder was distended. At this time there was no involvement of the arms or of the diaphragm. He was nursed in the lateral positions with the foot of the bed raised. He would not tolerate the semi-prone position. The following day (October 19) he developed nystagmus, and had marked impairment of deglutition and weakness of the shoulder girdles. His respiratory rate was 40, with abdominal respirations. The intercostals on the left side were now involved. Some secretion was accumulating in the pharynx. At this time his temperature was 100° F. (37.8° C.), pulse 132, and blood pressure 115/85. A Levine tube was passed into his stomach at 2.15 p.m. This had to be done under anaesthesia (thiopentone and succinylcholine chloride). At 11 p.m. his temperature rose to 105° F. (40.6° C.), pulse 162, and respirations 38. At 1.30 a.m. he was noticed to have periodic respirations, his pulse being difficult to palpate, with blood pressure 85/70, and pulse 162. The pharyngeal secretions had increased and he became very restless. Cyanosis was not observed. The Paul-Bragg pulsator was found to be of little help, so it was decided to institute I.P.P.R. by means of the Radcliffe pump rather than the tank respirator—compare experiences quoted by Macrae *et al.* (1954).

Three hours after starting the I.P.P. respirator his blood pressure had risen to 104/80, and pulse to 158. He became very restless after recovering consciousness and was given 6 ml. of paraldehyde intramuscularly three and a half hours after the tracheotomy had been performed. He lapsed into unconsciousness after the paraldehyde, and did not recover until 15 hours later. At 10.30 a.m. on October 20 his temperature was 103.2° F. (39.6° C.), and he was given 25 mg. of chlorpromazine hydrochloride intramuscularly. In the afternoon of the same day his blood pressure fell to 60/50, and a noradrenaline drip was set up, which maintained the pressure at about 105–120 mm. Hg systolic, with occasional drops to 80. He had pulsus paradoxus, the fall in pressure during inspiration being about 10 mm. Hg. This improved when the stroke volume of the machine was reduced and the rate increased.

In the evening his temperature again rose to 105° F. (40.6° C.). The noradrenaline was stopped after nine hours, but had to be restarted as his systolic pressure fell to 45 mm. Hg. After restarting at a slower rate, his blood pressure was maintained at about 80 and gradually rose to 90, when

the drip was finally discontinued after 17 hours. At 9.30 p.m. he was given 25 mg. chlorpromazine hydrochloride intramuscularly in an attempt to reduce his temperature. Later the same day the machine was discontinued for two intervals of ten minutes as he was fighting against it. Shallow abdominal respirations were present, but in a short time the blood pressure rose to 145/100, and the CO₂ was 4.3%, so the machine was restarted.

By October 26 his temperature had gradually settled to normal and his blood pressure averaged about 115/70, pulse 100. From this day onwards he was tried for gradually increasing periods without the machine. On the 28th he developed pulmonary oedema for some 16 hours.

On November 2 he suddenly collapsed and became cyanosed, and was so for 20 minutes until medical aid was at hand. The cuff tube was at once removed, with dramatic recovery. The accident was thought to be due to a herniation in the cuff covering the opening of the endotracheal tube, producing a ball-valve effect. A bronchoscopy was performed, when a large amount of pus was found in the right bronchus. Two days later he began to bring up frothy sputum, several ounces a day, with signs of pulmonary oedema, which continued until his death.

On November 9, after breathing by himself for 16 hours, he became a little restless and the I.P.P. respirator was restarted at 10 p.m. He was given 6 ml. of paraldehyde as a sedative by mouth and 0.6 mg. of atropine subcutaneously, as he was bringing up a fair amount of frothy sputum. At 1.15 a.m. his condition was recorded as good. At 2 a.m. his pulse was said to have become thready. Medical aid was summoned, but the patient was found to be dead, with post-mortem mottling of the skin.

Pulmonary Complications.—Throughout the whole course of the illness large amounts (several ounces) of mucus were aspirated daily. Only on one occasion, however, did a pulmonary collapse occur—in the left lung. After the advent of pulmonary oedema the amount of mucus decreased considerably and was replaced by frothy pink-hued sputum. X-ray films of his chest revealed an old quiescent tuberculous lesion of the right apical region and elevation of the left diaphragm.

Mental State.—Great difficulty was experienced in communicating with this patient owing to the language difficulty. His knowledge of English was slight and of Swahili little better. He became very agitated when trying to explain his wants, and suffered from marked depressive phases. At night he used to pull out the Levine tube and pull off the bedclothes and was most irrational. We noticed with European patients that though these phases occurred they tended to be much less marked.

Investigations.—An electrocardiogram was taken on November 4, when the patient was breathing by himself and again while breathing on the machine. The following is an extract of a report which was given by Dr. A. D. Charters, consultant cardiologist to King George VI Hospital, Nairobi: "The electrocardiogram during unaided respiration shows marked clockwise rotation of the heart with low-voltage QRS in all leads, particularly in CR₁, which shows flattened T waves. Rhythm regular, rate 100. P-R interval 0.16 second. QRS 0.08 second. R-T 0.28 second. T wave inverted in VR and upright in the other leads. Comparison of tracings while in the respirator with those during unaided respiration: The voltage in the respirator is less in Leads II, CR₁, and CR₄, with smaller T waves in Leads II, CR₁, CR₄, and VL. The voltage is higher in the respirator in VR and CR₂, with a higher T wave in CR₂. P, R, and T waves are all taller in Lead III during unaided respiration."

Case 3

A male European, aged 40, weight approximately 90 kg., was admitted to Kitale Hospital, some 300 miles (480 km.) from Nairobi, on October 22, 1954, suffering from respiratory weakness. Respiration was so embarrassed that he was placed in a tank respirator on admission. He had

been ill for one week beforehand, but had carried on working, as he thought he had "flu." We were later informed that on the day previous to admission he was so ill that he could barely drag himself from his car, and his temperature had been 102.5° F. (39.2° C.).

A team consisting of a physician, a hospital superintendent, and a nursing sister flew to Kitale within a few hours. Bulbar signs had already appeared when the team reached Kitale, and the patient was cyanosed. A tracheotomy was performed and I.P.P.R. started. He was very restless and irrational during the night despite 8 ml. of paraldehyde intramuscularly. The blood pressure fell to below 100 mm. Hg systolic and sweating was profuse. One litre of 0.9% saline was given, as he was considerably dehydrated. No method of tube feeding was available. The temperature rose slowly from 102 to 105° F. (38.9 to 40.6° C.); sponging reduced it to 103.5° F. (39.7° C.).

The Radcliffe pump was hand-operated for two and a half hours during the return flight. The pilot deliberately flew at the lowest possible altitude, 9,000 to 11,000 ft. (2,700 to 3,350 m.). A foot-pump-operated sucker was used during the journey to aspirate the bronchi.

On arrival at the poliomyelitis unit at 9 a.m. on October 23, his general condition was fair and the flight did not appear in any way to have affected him adversely. He was conscious and somewhat restless, he could not swallow, and there was complete paralysis of the intercostals and diaphragm, and of the shoulder girdle and arms; but full movement was present in both legs. His pulse rate was 120, blood pressure 130/90, and temperature 102.3° F. (39.1° C.) in the axilla. Temperature readings from then on were taken every half-hour in the axilla. Chlorpromazine hydrochloride, 25 mg., was given intramuscularly. One hour later bronchoscopy was carried out under 0.3 g. of thiopentone and succinylcholine chloride (the previous evening he had needed 2 g. of thiopentone in addition to succinylcholine chloride). The tracheostoma was enlarged and a No. 10 cuffed tube inserted. His temperature fell slightly after the chlorpromazine, but rose again within an hour and continued to rise sharply to 104° F. (40° C.) that evening, his blood pressure remaining at 140/90, pulse 120. The CO₂ readings were high—just under 5%—in spite of increasing the minute volume from 11.5 litres to 12.7 litres. The CO₂ readings fell to 2.2% when the minute volume was further increased to 14 litres. A second dose of chlorpromazine, 25 mg. intramuscularly, was given, but without much effect on the temperature. A cold sponge shortly afterwards, however, reduced it to 102.6° F. (39.2° C.). No fall in blood pressure followed the chlorpromazine.

The next morning the temperature was up to 105.2° F. (40.7° C.), the blood pressure being 134/90, and his condition remained reasonable. A third dose of chlorpromazine, 25 mg. intramuscularly, was followed by a cold sponge, and the temperature fell to 101.8° F. (38.8° C.). The blood pressure dropped to 100 mm. Hg systolic, pulse 136. The temperature soon rose again, and by midday was over 105° F. (40.6° C.), CO₂ concentration being 4.5%. At this point the patient suddenly collapsed, became unconscious, and remained so until he died 36 hours later. Engström (1954) has described the appearance of circulatory symptoms occurring suddenly at high temperatures followed by rapid death. From now on, the axillary temperature readings were taken every four minutes. His lips and mucous membranes were grey; the blood pressure was 70/50, pulse 160, temperature 105.8° F. (41° C.). The oxygen flow was increased and his general condition slowly improved, the ashen-grey appearance disappearing. The temperature rose slowly to 107° F. (41.7° C.), but the blood pressure remained low, 85/50; the pulse rate was 140. Cold sponging had no effect on the temperature. The humidifier had by this time been turned off.

Lassen (1954) reported a mortality rate of 93% in cases of hyperpyrexia and temperatures of over 102° F. (38.9° C.) for five days. It was felt that a further dose of chlorpromazine was justified, and 50 mg. was added to 540 ml. of

glucose and an intravenous drip set up. The temperature fell to 103.8° F. (39.9° C.) when approximately 130 ml. had been run in, but rose again rapidly to 107° F. (41.7° C.) within an hour. The pulse was extremely poor and very rapid—170 to 200—the blood pressure being 60 mm. Hg systolic (by palpation). Covering the patient with chipped ice and allowing a fan to blow over him did not bring down the temperature. He had now been hypotensive for five hours, and we decided to give noradrenaline intravenously. As we had had a poor response with noradrenaline following chlorpromazine previously, we set up a drip of 4 ml. in 500 ml. of 5% glucose, but with little effect. Three pints (1.7 litres) of this solution was eventually run in.

By 7.30 p.m. on October 24 the axillary temperature had risen to 108° F. (42.2° C.) in spite of chipped ice and a very strong breeze from the fan; blood pressure 70 mm. Hg systolic, pulse 128, pupils pin-point. A fourth dose of chlorpromazine, 25 mg. intramuscularly, was given, and within an hour the temperature had fallen to 101° F. (38.3° C.). For the next 16 hours the temperature remained on an average at 100 to 102° F. (37.8 to 38.9° C.), rising to 105° F. (40.6° C.) on one occasion and falling to 98° F. (36.7° C.) for three short periods. During this time the skin, except in the axilla, was cold to the touch, with stagnant cyanosis, but could be made a reasonable colour by rubbing. The capillary refill test was fair. As the noradrenaline had not been effective, methylamphetamine hydrochloride, 20 mg. intravenously, was given at three-hourly to four-hourly intervals, but with no effect. The pulse could not now be felt at the wrist, and the only sign of life, apart from the apex beat, was the screwing up of the face which followed tracheal suction; this reaction to stimulation of the tracheo-bronchial reflexes persisted up to within a few minutes of death.

Towards the evening of October 25 the temperature again started to rise to 105° F. (40.6° C.), and the apex beat could be heard only with difficulty. The pupils became widely dilated and did not react to light towards midnight. An attempt to give an intra-arterial blood transfusion failed, as neither the femoral nor the subclavian artery could be palpated. In a further unsuccessful effort to insert an intra-arterial needle 8 ml. of noradrenaline was added to 540 ml. of 5% glucose and the drip run in fairly quickly for a few minutes. The pulse became palpable, the blood pressure rose to 80/60, and the pupils became half-dilated and reacted to light. The drip was then slowed, but the circulation finally collapsed completely and the patient died within 20 minutes. Necropsy showed the usual changes of poliomyelitis in the cord, medulla, and pons.

Discussion

To date there are reports of five cases of bulbo-spinal poliomyelitis occurring in England (Smith *et al.*, 1954; Macrae *et al.*, 1954), and these three more in Kenya which have been treated with I.P.P.R. Of these eight patients five have died. In the English series one died of the effects of inhalation of vomit (Smith *et al.*, 1954) and two from pulmonary infection (Macrae *et al.*, 1954). In our series the cause of death in Case 2 was unknown, though during the course of his illness he developed the following complications: (a) hyperpyrexia as defined by Lassen—mortality rate 91% (Lassen, 1954); (b) shock—mortality rate 67% (Lassen, 1954); (c) pulmonary oedema—mortality rate 93% (Lassen, 1954). He survived the first two complications, and it would appear from the post-mortem findings that pulmonary oedema was not the direct cause of his death. Case 3 developed hyperpyrexia—axillary temperature, 108° F. (42.2° C.)—and shock, both carrying a high mortality rate as mentioned above.

Shock.—The causes of shock in bulbo-spinal poliomyelitis are: (a) anoxia; (b) CO₂ retention; (c) virus invasion of the brain; (d) interference with venous filling of the heart; (e) central damage due to hyperpyrexia (Christie, 1954; Engström, 1954). Engström points out that high pressures and long inspiratory phases interfere with cardiac output,

and that hyperpyrexia above 105.8° F. (41° C.) is followed by rapid circulatory failure. In Case 2 a fall in systolic pressure of 10 mm. Hg occurred during the inspiratory phase of the machine, indicating interference with the venous return to the heart (Lewis, 1942); this was supported by the electrocardiographic changes. There was no evidence of anoxia or of CO₂ retention, though central damage remained a possibility. It was noted, however, that there was an improvement in the blood pressure and a decrease in the inspiratory fall in pressure on increasing the rate of the machine, so decreasing the time of the inspiratory phase. The pressure recorded on the machine during inspiration remained constant at 16 cm. of water. In Case 3 the shock was presumably due to damage to the vasomotor centre by hyperpyrexia and direct damage by the virus.

Mental State.—All cases showed some degree of mental distress. In Case 1 the patient, who was most co-operative, tended to be very emotional and would burst into tears for no apparent reason. At the beginning of treatment he wanted to pull out the endotracheal tube. He became very intolerant of pain and had marked depressive phases, which were most noticeable about the third week, from which time he became more cheerful. In Case 2 the added difficulty of communication exaggerated the mental symptoms. At all times the patient was restless and agitated, and tended to fight the machine with his remaining respiratory muscles. He slept poorly, and at night, especially latterly, he became very irrational and was always pulling out the Levine tube and pulling off the bedclothes. After the second week he became very depressed and wanted to pull out the endotracheal tube. Case 3 tended to be restless and irrational at night. In none of these cases were the mental changes due to the accumulation of CO₂ or to anoxia. In Case 1 reassurance helped considerably; this has been stressed by Daley and Miller (1952).

Pulmonary Oedema.—This appeared rapidly in Case 2 on three occasions. We are unable to suggest the exact mechanism. Anoxia and CO₂ accumulation did not appear to be relevant. This patient was, however, exceedingly apprehensive and agitated, and had been breathing on his own for considerable periods. The serum proteins were low (total 5.3 g.%), but the oedema persisted even when the total proteins had risen to 6.5 g.%. Treatment with atropine, 0.9 mg. twice daily, aminophylline, 0.5 g. twice daily intramuscularly, oxygen, bronchial suction, and anaesthetizing the bronchi with cocaine were disappointing. The pulmonary oedema on two occasions disappeared suddenly; once for no apparent reason and once 20 minutes after 0.9 mg. of atropine had been given.

Chlorpromazine.—This was tried on two of these cases because of its supposed pharmacological actions of (a) protection against shock (Laborit and Huguenard, 1953); (b) potentiation of sedatives (restlessness was a prominent feature of these cases); (c) reduction of temperature and of the oxygen requirements (Laborit and Huguenard, 1951); and (d) depression of respiratory reflexes. Its use in asthma has been reported by Robinson and Zuck (1954). Bronchial suction was frequent, and it was thought that this action would be particularly useful in view of the occurrence of widespread rhonchi in all cases. Chlorpromazine did not seem to have any appreciable effect on the temperature unless ice and a breeze from a fan were used in addition. These two measures in conjunction did bring down the temperature, but the reduction was inconsistent and no definite conclusions could be drawn. Shackman *et al.* (1954), using promethazine as part of a "lytic cocktail," have shown that unless cooling measures are added no fall in temperature occurs in non-pyrexial patients under anaesthesia. The anti-noradrenaline action of this drug was shown, as has been described by Foster *et al.* (1954). In the two cases in which noradrenaline was used to combat the hypotension, large doses were needed and in higher concentrations than are generally recommended. Higher concentrations were used, as we feared that the circulation might be overloaded by larger amounts of 5% glucose.

Transport.—We experienced no particular problems in the transport of these cases by air, using the Radcliffe respiration pump. A sucker of some kind is essential. Oxygen cylinders were carried, but were not needed in pressurized planes. The team consisted of a physician, a hospital superintendent, and a nursing sister.

Staff.—It was soon realized that a specially trained team of doctors and nurses was essential. Ideally, a doctor should be in attendance throughout the day. In particular we would emphasize that the nursing is arduous and that, as this is a new technique, every detail must be carefully explained to every member of the team. The members should not be changed if this can possibly be avoided. It is unfair to expect a nurse, new to this type of work, to be able to learn the details "as she goes along." An error of judgment may be fatal, and a call for help must be answered promptly.

It is obvious that this treatment can be carried out only in properly equipped centres, and no one should be tempted to undertake these measures unless the following minimum personnel are readily available: a physician, an anaesthetist, and nine nursing staff. Even with these requirements medical personnel must be prepared for a day's work of 16 hours over long periods.

Conclusions

(1) Even with the advance of I.P.P. respiration in the treatment of bulbo-spinal poliomyelitis the mortality remains high when complications enter the picture.

(2) It is important to have a specially trained team of nurses and doctors, and constant supervision for 24 hours a day.

(3) It is necessary for an anaesthetist to be a member of the team used for the transport of acute cases.

(4) General anaesthesia is advisable for tracheotomy.

(5) We would emphasize the difficulty of treating the various complications—shock, hyperpyrexia, and pulmonary oedema—and of ascertaining the exact aetiological factors involved.

Summary

The treatment of three cases of bulbo-spinal poliomyelitis with the Radcliffe respiration pump is described. All cases showed inadequate respiration combined with inability to swallow, ineffective cough, and pooling of secretions.

Experience of these Kenya cases has shown that even acutely ill patients may be flown safely over long distances with this apparatus.

The importance of maintaining a clear airway in the lower respiratory tract coupled with the inflation of air at the correct pressure, humidification, and temperature, and in adequate volume, is stressed. A simple bedside method of measuring the CO₂ content of expired air is suggested, coupled with pH estimations of the urine to detect hyperventilation.

The different features of each of the three cases emphasized the difficulties in the management of this condition. An adequately trained team of doctors and nurses is essential. These patients cannot be left unattended at any time, as critical emergencies may occur without warning.

"Shock," hyperpyrexia, and pulmonary oedema occurred in the two fatal cases. Chlorpromazine and noradrenaline were used to combat "shock" and hyperpyrexia.

Abnormalities of the mental state were prominent in all cases but responded well to reassurance when this was possible.

We wish to thank the matron and the nursing staff of King George VI Hospital and the Infectious Diseases Hospital, Nairobi.

for the long hours of arduous duty given willingly and without complaint. We also acknowledge the invaluable help given to us by Mr. F. Owen, hospital superintendent, the Infectious Diseases Hospital, Nairobi, and Mr. Austen, Government Electrical Engineer. We are indebted to the United States Air Force for their prompt answer to a call for assistance. A cuirass respirator and a technician were flown out to us from Tripoli. We have to thank the Director of Medical Services, Kenya Colony, for his help and permission to publish this article. The Radcliffe pumps were manufactured by H. G. East and Co., Longworth Road, Oxford.

CLINICAL USES OF INTRAVENOUS HYDROCORTISONE

BY

F. DUDLEY HART, M.D., F.R.C.P.

Assistant Physician, Westminster Hospital

Cortisone therapy is now an important part of day-to-day therapeutics. Whatever the argument may be for its use in rheumatoid arthritis, ulcerative colitis, and asthma, there is little difference of opinion when it comes to adrenal insufficiency; for in Addison's disease, Simmonds's disease, and in the adrenalectomized subject it is the most useful drug now available. In acute adrenal insufficiency, however, oral cortisone may not be enough; though the drug is rapidly absorbed from the intestinal tract when taken by mouth, in adrenal crisis a vomiting and dehydrated patient may need rapidly effective parenteral therapy. It is to meet this need that intravenous hydrocortisone has been produced, for the ordinary issue of cortisone or hydrocortisone acetate for oral, intramuscular, or intra-articular use cannot be given intravenously.

The use of intravenous hydrocortisone may be considered in the following conditions:

1. **Addisonian crisis.**—The dehydrated, vomiting, critically ill patient with Addison's disease may be unable to tolerate oral cortisone, and intramuscular injections may be too slow in action to help him. An intravenous drip of 10–20 mg. hydrocortisone per hour for some six to eight hours will usually effect marked improvement and allow the institution of oral or intramuscular cortisone therapy. This dosage can be increased, if response is unsatisfactory, to 30–40 mg. per hour or even higher.

2. **The adrenalectomized patient,** usually in the face of infection or some other form of stress, may become ill, weak,

and hypotensive. Such patients may not show the usual signs of adrenal insufficiency, but appear merely to go downhill rapidly and alarmingly. Nausea is frequent and vomiting commonly occurs. The use of intravenous hydrocortisone may be life-saving, and if in doubt the general rule should be to treat as for a probable adrenal failure.

3. **The cortisone-treated patient with intact adrenal glands,** whether he be a sufferer from rheumatoid arthritis, asthma, or any other condition, may, in the face of infection or any other form of acute stress, experience symptoms of partial adrenal insufficiency. One common form of stress is major operative surgery. A surgical operation may precipitate adrenal failure in a gland suppressed by weeks or months of cortisone therapy, and, if there is no time for 24–48 hours' full pre-operative cortisone treatment, intramuscular cortisone may be augmented by intravenous hydrocortisone. It is well recognized that after stopping cortisone therapy, if such treatment has lasted more than a few days, the adrenal glands may be unable to react normally to operative stress for some weeks or months subsequently. In such patients it is wise to "cover" the operation two days before and a week afterwards by full cortisone therapy. Intravenous hydrocortisone may in these instances also play a part if such "cortisone cover" has been neglected or the dosage insufficient.

4. **The Waterhouse-Friderichsen syndrome.**

5. **Simmonds's disease.**—In the face of stress these patients may develop signs of acute adrenal insufficiency. Allott and Simmons (1951) report a case of Sheehan's syndrome which responded only to cortisone. In such cases intravenous hydrocortisone should be considered. Such cases are rare, however, compared with the hypoglycaemic episodes which are common in this condition and which respond usually satisfactorily to intravenous glucose.

6. **The above list of indications is not to be regarded as exclusive.** Black and Harken (1954), for instance, discussing "the safe conduct of a patient through cardiac surgery," state that in a few cases intractable hypotension after operation appeared to be due to adrenal failure. The patient, alert and orientated despite the absence of a detectable blood pressure, responded to intravenous hydrocortisone though not to intramuscular cortisone or corticotrophin (A.C.T.H.). In severe status asthmaticus, acute disseminated lupus erythematosus, or overwhelming allergic reactions, the use of intravenous hydrocortisone could legitimately be considered.

The following cases are instructive.

Case 1

The patient was a woman aged 47. Bilateral total adrenalectomy was performed by Sir Stanford Cade for metastatic malignant disease secondary to carcinoma of the breast. The immediate post-operative progress was uneventful, no noradrenaline infusion being required. On the seventh post-operative day her condition deteriorated rapidly, swelling and induration became apparent at the medial end of the left incision, and her temperature rose to 104° F. (40° C.), her pulse to 150 a minute. She became drowsy, almost comatose, and her blood pressure unrecordable. As her condition was critical, intravenous hydrocortisone was started that night and 100 mg. was given over a period of six hours. After some two hours her blood pressure rose and her general condition improved dramatically; by morning her temperature had dropped to 99° F. (37.2° C.) and her pulse to 110. Oral cortisone, 25 mg. six-hourly, was given for the next six days and then gradually reduced to the usual maintenance dose of 50 mg. a day. There were no marked changes in serum electrolytes, sodium and chlorides being normal or just below normal throughout.

Comment.—In this case a wound infection rapidly precipitated a degree of adrenal insufficiency which seemed

likely to prove fatal. The improvement was sufficiently rapid and dramatic to make it probable that the hydrocortisone given was responsible for that improvement.

Case 2

This patient was a woman aged 44. Total bilateral adrenalectomy was performed by Sir Stanford Cade in April, 1954, for advanced metastatic disease secondary to carcinoma of the breast. Before operation she had been subject to occasional mild attacks of nausea and vomiting. In May, one month after discharge from hospital, she was readmitted, vomiting and ill; B.P. 85/75. Serum electrolytes were within normal limits. Only slight improvement occurred on L-noradrenaline and hydrocortisone (100 mg.) infusions, and it was felt that her gradual improvement was natural and essentially uninfluenced by therapy. Her next vomiting bout occurred in July; again it was felt that improvement was unrelated to L-noradrenaline given, but it was noted that the marked tachycardia settled only when the cortisone daily dosage was increased to 112.5 mg. by mouth.

In late November, 1954, she caught a severe cold and vomiting restarted. She became critically ill, pulse 140-150 a minute; the blood pressure dropped and became unrecordable. She became rapidly very weak and felt "numb." Her reflexes were normal. Hydrocortisone hemisuccinate, 50 mg., was given rapidly intravenously, followed by intravenous saline infusion. Within an hour she was distinctly better, blood pressure being 95/70. A further 50 mg. of hydrocortisone hemisuccinate was given intravenously three hours after the first injection, saline infusions were continued, and her daily dose of cortisone was increased to 200 mg. intramuscularly. Next morning she was much improved, the blood pressure was 120/90, and vomiting had stopped. Plasma chlorides and serum sodium, which were just below normal (93 and 131 mEq per litre respectively) on admission, dropped to 75 and 110 mEq as her condition deteriorated, then rose to 97 and 121 mEq two days after starting treatment.

Comment.—An upper respiratory infection apparently precipitated an attack of vomiting, a symptom to which this patient was predisposed. Her rapid deterioration seems to have been due partly to adrenal insufficiency and partly to dehydration and electrolyte upset. Intravenous hydrocortisone, abundant saline infusions, and an increase in the daily dose of cortisone appeared responsible for the improvement, which started soon after 50 mg. of hydrocortisone had been given intravenously and before more than a very small amount of saline had been infused. In this case it seems likely that in the previous episode hydrocortisone dosage had been inadequate.

Case 3

This patient, a woman aged 56, had had adrenalectomy performed by Sir Stanford Cade, the left side on March 16, 1954, the right on March 30. In the early morning of April 25 she suddenly collapsed and the blood pressure became unrecordable on the sphygmomanometer. She was sweating and the skin was cold; she was not cyanosed. For the previous three days her condition had been deteriorating and she had had nausea and vomiting, with some hypotension. Blood chemistry had been normal. The cause of this collapse was uncertain, and she was given 100 mg. of hydrocortisone by intravenous infusion over a period of six hours, purely empirically. She improved to some extent, but a greater improvement followed an intravenous infusion of noradrenaline subsequently. On May 2 her general condition had greatly improved.

Comment.—In this case hydrocortisone appeared to be less effective than the noradrenaline subsequently infused, though it may have initiated the improvement in the patient's condition. Many conditions apart from cortisone

insufficiency may cause sudden deterioration in these critically ill malignant cases—dehydration, electrolyte imbalance, and spread of the malignant process. Any infection, however trivial, may upset their somewhat precarious balance.

Discussion

Rukes, Orr, and Forsham (1954) have reported the use of intravenous infusion of the free alcohol of hydrocortisone at rates up to 50 mg. an hour in over 50 instances without untoward effect, though they note that epileptic seizures can be precipitated in susceptible patients. Thorn and his associates (1953) have shown that considerable sodium retention occurs in the normal subject during intravenous continuous infusion of 12 mg. an hour in saline. Over the short periods needed for the treatment of adrenal crisis, sodium retention and oedema are not a very real danger, however, and the use of 5% glucose in water will minimize this hazard. Rukes *et al.* advise that saline should be used only when an increase of blood volume is required, as in shock. They regard the use of intravenous hydrocortisone as justified in "selected cases of shock which are not relieved by transfusion or vasopressors."

Intravenous hydrocortisone is rapidly eliminated from the body; after its use oral or intramuscular cortisone must be given in full dosage. It is common practice to give a large intramuscular injection of cortisone acetate at the same time as the intravenous infusion is started so that it may gradually take effect when the infusion is discontinued. The patient should be very closely watched for some hours after the intravenous infusion has been stopped.

During the treatment of any condition in medicine or surgery with large doses of cortisone a close watch is always kept for signs of infection, and antibiotic therapy instituted as required. This applies particularly to adrenalectomized patients with metastatic malignant disease who are in such a frail condition that episodes such as post-operative infection are often poorly tolerated. If there is any possibility of cortisone deficiency playing a part resort is had to the use of intravenous hydrocortisone. We have not, to date, needed to use intravenous infusions of this drug over the operative period; we regard it as our main stand-by when any symptoms occur which might be construed as being the result of acute cortisone insufficiency after operation. The adrenalectomized patient may respond atypically to wound or chest infection, becoming hypotensive and ill, not responding satisfactorily to antibiotics, and going rapidly downhill. Cases such as Case 1 above should, I feel, be given intravenous hydrocortisone. Although only some may be helped, it is unlikely that the rest, seriously ill patients with advanced malignant disease, will be harmed by this treatment, which in some cases appears to be life-saving.

Summary

Intravenous hydrocortisone is a most useful weapon in the treatment of acute adrenal insufficiency; it marks a real advance in therapeutics. Its use is discussed in a number of different conditions. It should be always available when total adrenalectomy is performed and throughout the early post-operative period.

My thanks are due to Sir Stanford Cade for permission to publish details of his cases, and to Messrs. Merck & Co., Rahway, New Jersey, for supplies of hydrocortisone (free alcohol) and for hydrocortisone infusion concentrate for intravenous use. Case 2 was treated with hydrocortisone hemisuccinate kindly supplied by the Roussel Laboratories.

TREATMENT OF PROGRESSIVE MYOCLONIC EPILEPSY WITH MEPHENESIN*

BY

R. E. KELLY, M.D., M.R.C.P.

Physician, Department of Neurology, St. Thomas's
Hospital, London

AND

D. R. LAURENCE, M.D., M.R.C.P.

Senior Lecturer in Applied Pharmacology at University
College and University College Hospital Medical
School; Late St. Thomas's Hospital Medical
School, London

During an investigation of the effect of mephenesin on certain cerebral dysrhythmias it was found that the drug abolished myoclonus in two cases of progressive myoclonic epilepsy, and it has since proved possible to control this hitherto intractable symptom of the disease by using very heavy dosage of mephenesin.

The disease was first clearly described by Unverricht (1891). The patients have occasional attacks of grand mal, but their major disability is myoclonus, in the production of which there is a strong reflex element (Dawson, 1947). The disease progresses until they exist in "status myoclonicus" and die of exhaustion and inanition within four to five years of the onset. Often there are signs of a cerebellar disturbance (Ramsay-Hunt, 1921), and cerebellar changes are found at necropsy (Hodskins and Yakovlev, 1929).

Early in the course of the disease the myoclonus may respond to the usual anticonvulsants, but it soon becomes resistant to and uncontrollable by drugs without producing incapacitating cerebral depression. Bradshaw (1954) reported that myoclonus may be partially suppressed by phenacemide ("phenurone"), but this is the only drug that has appeared to offer any relief, and the relief afforded was apparently not striking.

Case 1

A girl aged 16 was admitted to St. Thomas's Hospital in March, 1952. She had previously been a patient at the National Hospital, Queen Square, under the care of Dr. S. P. Meadows. She had suffered from grand mal for eight years and myoclonus for seven years. She had been helpless for four years, could not feed herself or leave her bed, and her speech was slow and jerky. Many days were passed in status myoclonicus. Phenobarbitone, phemitone, phenytoin sodium, bromides, troxidone, and phenylmethylbarbituric acid ("rutonol") had been tried and a combination of phenobarbitone and phenytoin found to be the most helpful in preventing grand mal and perhaps slightly reducing the myoclonus.

The patient, during a period when severe facial and general myoclonus was constant, was placed on a couch and an electroencephalographic record was taken for 30 minutes (see Fig.). This showed many cortical spikes and high-voltage slow waves; there was also a moderate amount of muscle artifact in the frontal leads. An intravenous infusion of 1% mephenesin in normal saline was begun, and within 50 seconds the cortical spikes and muscle artifact had disappeared and the record had become dominated by high-

voltage slow waves. Myoclonus ceased. In 35 minutes 1.75 g. mephenesin had been given. The patient felt a little sleepy during the latter part of the infusion. The E.E.G. began to revert and myoclonus began to return 20 minutes after the infusion ended. The experiment was repeated seven days later, when the patient had been deprived of anti-convulsants for three days. The results were similar except that epileptic activity in the E.E.G. was not totally abolished.

Oral treatment with mephenesin was started and the myoclonus was well controlled. She was deprived of mephenesin on four occasions, and each time she relapsed dramatically but was readily controlled again, first by an elixir containing 2 g. of mephenesin per oz. (30 ml.) in about 30% alcohol, and later by a suspension of mephenesin carbamate.

The patient left hospital in May, 1952, taking 1 gr. (65 mg.) of phenobarbitone thrice daily and 1 oz. (30 ml.) of mephenesin elixir four times a day. She was now well enough to dress herself partially, to feed herself, write, knit, and walk with assistance. Reflex myoclonus still occurred but was

mephenesin intravenously.

infrequent, whereas previously it had prevented every voluntary act. During the following 18 months she had five minor and two major grand mal seizures.

In November, 1953, she developed an acute attack of vomiting, and, probably correctly attributing this to the mephenesin, she stopped taking it and within 24 hours relapsed completely and became speechless and helpless. She was readmitted to hospital five days later in status myoclonicus and having had a grand mal attack on each day of relapse. She had six major fits during her first 12 hours in hospital. She had been vomiting her phenobarbitone also. Paraldehyde, 5 ml. intramuscularly, failed to control the myoclonus, so she was given 2 g. of mephenesin intravenously as a 1% solution in normal saline in 20 minutes. Within five minutes of the start of the infusion the myoclonus ceased. She relapsed an hour later and the mephenesin was repeated with the same result. Four hours later she relapsed yet again and was given 8 ml. of paraldehyde intramuscularly and 0.75 g. of mephenesin carbamate by mouth; she then slept. She went home 16 days later, taking 1.25 g. of mephenesin carbamate four times a day and 1 gr. (65 mg.) of phenobarbitone three times a day. She was then better than she had ever been. She has since been liable to attacks of "gastritis," which are attributed to the mephenesin carbamate. She is now taking about 15 g. of mephenesin carbamate a day either as 20% suspension or as tablets.

Case 2

A woman aged 29 was admitted to St. Thomas's Hospital in January, 1954. Facial myoclonus had begun five months previously and had spread, so that for three months she had been confined to bed and unable to feed herself. Occasional grand mal attacks occurred from this time. She had two

*A summary of this paper was read and a film demonstrating the first two patients shown at a joint meeting of the Swiss Neurological Association and the Association of British Neurologists at Interlaken in June, 1954.

periods of remission; the first, lasting one week, occurred when she was given 1 gr. (65 mg.) of phenobarbitone and 1½ gr. (98 mg.) of phenytoin thrice daily; the second, of 10 days, followed an attack of grand mal. Grand mal attacks were always followed by remissions, which became shorter and shorter until there was only a few minutes' quiescence before the myoclonus recommenced and gradually increased in violence until another major fit occurred hours later.

An electroencephalographic record in January, 1954, when she had had no anticonvulsant drugs for three days, showed random spikes in association with slow wave activity. A second record when taking phenobarbitone showed much low-voltage fast activity with random spikes. The spike activity was greatly reduced after an intravenous infusion of 1.5 g. of mephenesin.

Oral treatment was begun, and 15 minutes after 3 g. of mephenesin as elixir both the spontaneous and the reflex myoclonus ceased. She became practically normal, but relapsed in three hours and was readily controlled again by 3 g. of mephenesin. This sequence of events was repeated many times. A control elixir containing no mephenesin was substituted and proved ineffective. She was then allowed to take 3 g. of mephenesin as elixir whenever she felt the myoclonus returning, and in a few days she was taking 27 g. a day. She was mildly drunk on this dose, as the elixir contains about 30% alcohol. It was therefore decided to try mephenesin carbamate in the hope that a lower dose could be used, since it is more potent than mephenesin when tested on animals (Berger, 1952). This was given as a suspension and contained only 1% alcohol.

On the first day she took 9 g. of mephenesin and 12 g. of carbamate, on the second day 24 g. of carbamate; on the third day she relapsed, returned to taking the elixir on demand, and became drunk again. The myoclonus of the throat was the first to return after each dose and so she had to swallow the elixir in sips. This resulted in anaesthetization of the throat (mephenesin is a local anaesthetic), and inhalation of the drug and of food. The resulting lung infection was treated with penicillin, and a stomach tube was passed for medication and feeding. When she recovered mephenesin was given partly as the elixir, for rapid action, and partly as crushed tablets, so that her alcohol consumption was reduced, although the tablets seemed rather less effective. A few days after this regime began she had increased her daily total to 48.5 g. of mephenesin, but it soon fell to an average of 30 g. a day, 10 g. as the elixir and 20 g. as tablets.

She left hospital in February, 1954, on a regime of mephenesin, phenobarbitone (33 mg. t.d.s.), and primidone (250 mg. b.d.). The latter drug alone had not prevented relapses of myoclonus. She could walk, dress, and feed herself, but had a slight irregular tremor of both hands which made her writing illegible. A month later she reported that she had had no grand mal since leaving hospital. She had been doing her shopping and housework, but was still unable to write clearly and feared to carry saucepans lest she should drop them. She had been taking 2 g. of mephenesin as elixir on waking, when the myoclonus was fairly severe. The elixir controlled the myoclonus sufficiently to enable her to swallow 3.5 g. in tablets 30 minutes later. She had been taking 3.5 g. in tablets once or twice between meals with 2 g. as elixir at meal times. Her daily requirements had varied, being about 30 g. total—8–10 g. as elixir and 20–22 g. as tablets. During April and May she reported that she had had no myoclonus and that she was reducing her mephenesin dosage.

The common side-effects of mephenesin—dizziness, drowsiness, and vomiting—are less severe if the drug is taken after food, and in this case are not troublesome.

Other Cases

After it had become clear that the drug was effective in these two cases Dr. E. Arnold Carmichael, of the National Hospital, very kindly allowed us to give intravenous infusions to three of his cases.

Case 3.—This patient, a young woman aged 21, had never been normal. From the age of 4 irregular jerking movements of all four limbs had been noted. The condition progressed until myoclonus was constantly present, and for the past eight years she had been confined to her bed totally incapacitated by the myoclonus. Mephenesin, 1.5 g., was given intravenously in 15 minutes. There was a complete abolition of the myoclonus as in the previous cases and of a similar duration. She has since been treated with oral mephenesin, which appears to be effective, but the correct dose has not yet been determined, as she has great difficulty in tolerating the drug, although it was clear that it was enabling her to get on to her legs.

Case 4.—A woman aged 41 had suffered from myoclonus for three years. She had been confined to her bed for one year and had been for the most part totally disabled, but there was a marked periodicity in her condition. Mephenesin, 2 g., was given intravenously in 20 minutes, and this had a less dramatic effect than in the other cases. The myoclonus did not disappear completely, but the movements were sufficiently reduced to enable her to sit up and get off the bed on to her legs. This had previously been impossible. Oral mephenesin has since produced enough relief to allow her to walk and to sit up in an armchair. The duration of its effect is short and, unfortunately, when the effect wears off the myoclonus is more violent than it was before treatment was begun.

Case 5.—A youth aged 19 had suffered from attacks of grand mal and myoclonus, causing ataxia for six years. Although never able to work, he was much less incapacitated than the previous patients and was able to care for himself and to walk, although unsteadily. As the myoclonus was mild the effect of intravenous mephenesin was not marked. He has, however, started to take the drug orally and he appears to be slightly improved.

Cases 3, 4, and 5 have been treated for a few weeks only, and it is too early to assess their response.

Mephenesin

Mephenesin was introduced by Berger and Bradley in 1946, when they showed that its principal action is depression of the spinal cord. It was later shown by Berger (1947), Henneman *et al.* (1949), and Kaada (1950) that the site of action is probably on the spinal cord internuncial neurones. Polysynaptic neural circuits are easily depressed and monosynaptic circuits withstand large doses. Henneman *et al.* (1949) also found that mephenesin decreases or abolishes facilitation and inhibition, reaching anterior horn cells from all levels of the central nervous system, and that the electrical activity of the bulbar reticular substance is reduced. Reversible paralysis sparing respiration can easily be produced in animals by large doses, and it is not due to a peripheral effect. A neuromuscular blocking action can be demonstrated only by toxic doses (Berger, 1947), and there is no record of this effect having been achieved in man.

That the drug has actions high in the central nervous system of man may be inferred from the slight drowsiness and invariable nystagmus which follow the intravenous infusion of the pure drug in saline, and also from the observation that spike-and-wave activity in the E.E.G. in cases of petit mal can be reduced (Gammon and Churchill, 1949). We have confirmed this in some cases, but have found others which were resistant to the drug given intravenously. The highest concentration of mephenesin following intravenous injection is in the brain (dogs) (Morrison *et al.*, 1948). However, there is at present no evidence of the site of action above the brain stem, and the mechanism of the beneficial effect in myoclonic epilepsy remains obscure. It has been observed (Hunter and Waterfall, 1948) that mephenesin can subdue status epilepticus.

Mephenesin has a poor reputation in this country, largely owing to its failure to produce good relaxation in surgical anaesthesia and to the occurrence of haemolysis when given intravenously as a 10% solution. It has also proved to be

relatively unsuccessful in the treatment of spastic paralysis, for which condition it was particularly indicated on theoretical grounds. Its failure is due chiefly to the difficulty in getting enough of the drug into the patient without causing gastric or cerebral side-effects and to its brief action: intravenous administration in adequate dosage usually gives complete or almost complete relaxation of the most severe spasticity without any concurrent loss of power, although the effect by this route is too brief to be therapeutically useful.

In the treatment of myoclonic epilepsy we have found it necessary to give up to 48.5 g. of mephenesin a day, and, although this is exceptional, doses of that order should be fairly easily achieved, for short periods at least, if attention is given to the timing of the doses. Where possible they should be given on a full stomach, some as alcoholic elixir and some as tablets, although the latter are absorbed less readily and possibly less completely than the elixir.

In a series of 27 spastic patients one of us found that the maximum tolerated dose of the elixir alone varied between 6 and 18 g. of mephenesin a day; these were high doses at the time (1951), and it is now clear that they can be greatly exceeded in some patients and are safe for a period of months at least.

When mephenesin is given intravenously it should be as a 1% solution in saline. At this strength significant haemolysis does not occur and haemoglobinuria has never been reported. The risk of this complication increases as the solution strength rises, but is probably not serious until 4% has been reached. For solutions of over 1.5% it is necessary to use alcohol or propylene glycol to aid solution. The drug is metabolized very rapidly, and the clinical effects of a single intravenous injection may last as little as 30 minutes, or an oral dose only 60 to 90 minutes.

Mephenesin is also a local anaesthetic, and if a patient cannot swallow easily and sips the elixir this may lead to anaesthetization of the throat and inhalation of the drug (Case 2 above and Newhouse *et al.*, 1950).

Summary

It has hitherto been impossible to control the myoclonus of progressive myoclonic epilepsy with drugs.

Five cases are reported, in four of which helpless patients were restored to activity temporarily by intravenous mephenesin; one less severe case was helped by oral mephenesin.

Owing to the very large doses necessary, various side-effects occurred; these were largely overcome.

The mechanism of the action of mephenesin in this disease remains unknown.

We wish to thank Dr. S. P. Meadows for permission to treat Case 1; Dr. M. J. McCormack for referring Case 2 to one of us; and Dr. E. Arnold Carmichael for permission to treat Cases 3-5. We also wish to thank Dr. J. St. C. Elkington for his help and encouragement in carrying out this work; Dr. J. T. Hutchinson for the E.E.G. reports; Messrs. E. R. Squibb and Son, who supplied the mephenesin carbamate; and British Drug Houses, who supplied the control elixir.

SPONTANEOUS REGRESSION OF A MALIGNANT MELANOMA

BY

V. B. LEVISON, M.B., F.F.R.

Senior Registrar, Radiotherapeutic Centre, Addenbrooke's Hospital, Cambridge

Cutaneous malignant melanoma has a characteristically unpredictable behaviour, and a melanoma which has already metastasized may undergo spontaneous regression (Willis, 1953).

Bennett (1899) described two such cases. The first was in a woman aged 52 who had a malignant melanoma of the foot treated by local excision, followed by Syme's amputation for a local recurrence. She then developed widespread skin and glandular metastases, and the prognosis was regarded as hopeless. Six months later there was no evidence of malignancy. His second case showed spontaneous disappearance of glandular metastases and skin nodules following removal of the primary tumour, a malignant melanoma of the foot.

Gould (1906) saw a man aged 35 who developed widespread skin recurrences following excision of a malignant melanoma on the chest. The liver was enlarged, there were glandular metastases, and melanogen was present in the urine. He was treated with turpentine and sulphur pills, with considerable local and general improvement and disappearance of the skin deposits lasting for five months, though during this time the melanogenuria persisted. Renewed activity then occurred and he died eight months later. Mathews (1915) saw a man aged 45 who had a malignant melanoma over the scapula, with enlarged axillary glands and a fullness above the corresponding clavicle. After incomplete surgery, when the primary tumour and the axillary glands were removed, he remained well for two years and the supraclavicular swelling disappeared.

The histogenesis of intraocular melanoma is unsettled; amongst other hypotheses Willis (1953) suggests that they are of epithelial origin, arising from split-off epithelial cells analogous to the naevus cells of the skin, and that there is a general similarity between the intraocular and cutaneous melanomas. Ocular melanoma behaves slightly differently from the cutaneous type in producing frequent though long-delayed metastases, and in not usually disseminating so widely throughout the body. If, however, Willis's hypothesis is acceptable, then it is reasonable to expect metastases from a malignant melanoma of the choroid to exhibit the same anomalous behaviour as if the primary tumour were in the skin.

Case Report

The patient, a man aged 60, had the right eye excised at Moorfields Eye Hospital on February 21, 1951. The pathological report on the specimen was as follows: "Arising from the choroid in the superonasal quadrant of the eye is a large lightly pigmented mixed-celled malignant melanoma. Many blood sinuses are present in the growth and the reticulin content is light. There is some infiltration of the adjacent deep scleral lamellae, but in the sections examined there is no evidence of extraocular extension. The retina overlying the melanoma has been invaded and there is a retinal detachment on both sides of the growth. Microscopically this is a malignant melanoma of the choroid."

The patient was first seen at Addenbrooke's Hospital on February 26, 1953, when there was no clinical evidence of recurrence and the liver was not palpable. An x-ray film of the chest showed multiple small opacities at the base of the left lung, and examination of the urine at the same time showed melanogens to be present, and he was accordingly regarded as having pulmonary metastases. The presence of melanogens in this urine was shown by the ferric chloride in hydrochloric acid test, and by Thormählen's nitroprusside reaction (Harrison, 1947). No treatment was given.

Re-examination on July 8 showed disappearance of the pulmonary metastases and no melanogens in the urine. Since then repeated clinical and radiological examinations have shown no evidence of recurrence, and melanogens have not been present in the urine.

Discussion

Melanogen, the colourless chromogen of melanin, is excreted in the urine when there are extensive secondary deposits of malignant melanoma. Urine containing melanogen reduces sodium nitroprusside to ferric ferrocyanide (Thormählen's reaction) and reduces ferric chloride to ferrous chloride. Haden and Orr (1924) and Peters (1923) describe cases with apparent melanogenuria with no malignant melanoma in the body, but it seems doubtful if melanogen was really present in the urine in these cases. von Jaksch (1905) claims that a positive Thormählen reaction may be obtained in urine free from melanogen and has seen it in children suffering from chronic constipation; he says an abundance of melanogen occurs in the urine of wasted patients. Harrison (1947) states that he has tested many pathological urines and has never obtained a positive Thormählen reaction except in melanogenuria, and he concludes that if both the ferric chloride test and the nitroprusside reaction are positive it is safe to diagnose melanogenuria. In the case reported here it is considered that, as the choroidal tumour removed was a proved malignant melanoma, the pulmonary opacities were metastases and responsible for the presence of melanogens in the urine.

Spontaneous disappearance of a malignant tumour is a rare phenomenon of considerable interest, and several theories regarding the aetiology have been put forward. Rohdenburgh and Bullock (1918) collected 302 cases in which temporary or permanent regression of a malignant growth occurred. In this series the greatest number of spontaneous regressions followed incomplete surgical removal of the tumour or acute infections with prolonged pyrexia such as erysipelas, and a smaller number were associated with a profound upset of the patients' metabolism such as the menopause. He considered it probable that these conditions act by depressing the proliferative energy of the malignant cell until the defensive forces of the body are able to accomplish its final destruction. Ewing (1940) says the only explanation of many cases of spontaneous cure of highly malignant tumours is a local or general immunity. It is recognized that necrosis, probably starting because the tumour outgrows its blood supply, is a prominent feature of choroidal melanoma, and out of 106 tumours described by Samuels (1934) 24 were completely necrotic. Reese (1951) saw spontaneous necrosis occur in a malignant melanoma of the iris.

In the case reported here there was no obvious cause for the regression of the metastases such as an acute infection. As necrosis can bring about regression and apparent cure of the primary choroidal tumour, it is thought probable that this is the cause in this case rather than the other theories discussed.

Summary

A case of spontaneous regression of pulmonary metastases from a malignant melanoma of the choroid is described. Several theories concerning the aetiology are discussed, necrosis due to the tumour outgrowing its blood supply being considered the most probable.

I am grateful to Professor J. S. Mitchell for permission to publish details of this case and for his help, to Dr. N. R. Lawrie for assistance with the biochemical details, and to Dr. N. Ashton for supplying me with the pathology report.

THERAPY IN EXPERIMENTAL HEPATIC FAILURE

BY

P. C. REYNELL, D.M., M.R.C.P.

Medical Tutor, Radcliffe Infirmary, Oxford

It is difficult to assess the effect of any drug in the treatment of acute hepatic failure in man. A few patients will recover spontaneously, and any method of treatment used will then be given credit for the successful outcome. No satisfactory therapeutic trial comparing similar groups of treated and untreated cases has ever been carried out, and the difficulties in the way of such a trial are formidable, for the condition is uncommon and may be due to a variety of causes.

A controlled trial of the efficacy of some of the measures advocated for the treatment of acute hepatic failure in man has therefore been carried out on rats in which the syndrome has been reproduced experimentally.

Methods

It has been shown that the injection of 0.02 to 0.04 ml. of carbon tetrachloride into the mesenteric vein of the rat will reproduce many of the clinical and pathological features of the syndrome of acute liver failure seen in man (Reynell, 1953). A large proportion of the rats so treated will die within 48 hours. The procedure was designed to produce severe hepatic necrosis without damaging other tissues. Adult male rats of the Wistar strain (200-400 g. body weight) and free of Bartonella infection were used in these experiments.

Experiment I: Vitamin Supplements by Mouth.—Thirty-four rats reared on stock diet were each given 10 g. of a synthetic diet daily for two days before the injection of carbon tetrachloride into the mesenteric vein. The diet was made up as follows: cornstarch, 71 parts; casein, 26 parts; and salt mixture, 3 parts. During the three days after operation each rat was offered 5 g. a day of the same diet, although even this reduced amount was not always consumed. Half the rats were given the following vitamin supplement, which was mixed with the diet: 2 mg. of nicotinic acid, 1 mg. of thiamine, 1 mg. of riboflavin, 1.5 mg. of tocopherol, and 30 mg. of choline chloride per rat daily. This supplement resembles the parenteral vitamin mixture advocated by Latner (1950) for the treatment of hepatic failure.

Experiment II: Large Doses of Parenteral Liver Extract.—Of 24 rats fed on stock diet and subjected to the injection of carbon tetrachloride into the mesenteric vein, 12 were given 0.25 ml. of commercial liver extract daily by subcutaneous injection for two days after operation.

Experiment III: Sodium Gluconate.—Of 28 rats fed on stock diet and subjected to the injection of carbon tetrachloride into the mesenteric vein, half were given 50 mg. of the monosodium salt of glutamic acid eight-hourly by subcutaneous injection for 48 hours after operation.

Experiment IV: Cortisone.—Of 40 rats fed on stock diet and subjected to injection of carbon tetrachloride into the mesenteric vein, 20 were given 2 mg. of cortisone per 100 g. body weight twice a day by intramuscular injection for two days after operation.

Results of Treatment

Treatment	Treated Animals		Controls	
	Surviving	Dead	Surviving	Dead
Vitamin supplements ..	10	7	11	6
Liver extract ..	5	7	4	8
Sodium glutamate ..	4	10	5	9
Cortisone ..	6	14	7	13

Results

In none of these experiments was there any significant difference between the mortality of the treated rats and that of the controls (see Table). Vitamin supplements by mouth, large doses of liver extract parenterally, sodium glutamate, and cortisone all separately failed to improve the chances of survival of rats with experimentally induced hepatic failure.

Discussion

Polyvitamin therapy (Latner, 1950), large doses of liver extract (Snell and Butt, 1941), glutamic acid (Walshe, 1953), and cortisone (Ducci and Katz, 1952) have all been advocated for widely differing reasons in the treatment of hepatic failure. Though these measures may sometimes be followed by symptomatic improvement, claims that they increase the patient's chances of survival should be examined critically. Although there are possible dangers in applying the results of animal experiment to man, no adequately controlled human therapeutic trial has been done, and one is obliged to draw conclusions from human observations which are relevant but inconclusive and from animal experiments which are conclusive but of uncertain relevance.

The clinician faced with a patient suffering from acute liver failure has to deal with a liver which is already severely damaged, and treatment is probably effective only in so far as it will protect the organism against the effects of liver damage until regeneration can occur. Since the metabolic effects of liver injury are so extensive, it is unlikely that any single chemical substance will do this completely, and, as in acute renal failure, the object of treatment must be to maintain chemical homeostasis until spontaneous recovery occurs. There is a need for more fundamental knowledge of the biochemistry of liver failure in order to plan rational therapy.

Summary

Acute hepatic failure has been produced in rats by the injection of small quantities of carbon tetrachloride into the mesenteric vein.

Vitamin supplements, large doses of liver extract, sodium glutamate, and cortisone all failed to reduce mortality in this type of experimental liver failure.

I am grateful to Miss Shirley Thomas for technical assistance and to Professor L. J. Witts, in whose department this work was done.

SURGICAL EMPHYSEMA AS A COMPLICATION OF ANAESTHESIA

BY

J. OZINSKY, M.B., Ch.B.

AND

A. B. BULL, M.B., Ch.B., D.A.

(From the Department of Anaesthesia, University of
Capetown)

Surgical emphysema is that condition in which gas is present in the tissues. This gas may be air or, during anaesthesia, any of the gases used in induction. The first case of surgical emphysema occurring as a complication of anaesthesia was reported by Woolsey in 1912. Thereafter sporadic reports of cases have been published.

Two factors are concerned in the aetiology: (a) the presence of gas under pressure, and (b) some form of trauma permitting entry into the tissues. During anaesthesia, trauma may be produced on any portion of the surface lining of the respiratory tract, including the nose and pharynx, and is usually due to instrumentation (Barrett and Thomas, 1944; Gordon, 1950). Laceration of the mucosa permits gases in the lumen of the respiratory tract to gain access to the submucosal connective tissue and to spread from there.

Gas under pressure in the lumen of the respiratory tract may itself produce the trauma and spread in the connective tissue. Normally the weakest point of the respiratory tract is the alveolar wall, and raised pressure will cause trauma here. In man, a case has been reported in which an intrabronchial pressure of only 12 mm. Hg caused emphysema (Heidrick *et al.*, 1940; Marcotte *et al.*, 1940), and a pressure above 80 mm. Hg will almost always rupture the alveolar walls and their contained vessels, causing air embolism (Haldane and Priestley, 1935). This excess pressure may be exerted by the anaesthetist with his machinery easily enough nowadays, when controlled respiration is so commonplace. Tuffier (1906) showed that a pressure of 6 mm. Hg was enough to maintain distension of the lungs, and 15 mm. Hg has been advocated as the maximum pressure that should be employed in controlled respiration (Thornton *et al.*, 1944). The patient may himself raise the intrabronchial pressure, as by coughing or straining (Hamman, 1945).

The mechanism involved is (Macklin, 1937): The alveolar wall ruptures and gas passes perivascularly along the vessels to the hilum and mediastinum, producing mediastinal emphysema, which becomes the focal point for the further spread of the gas. The gases may (a) spread with the large vessels up to the neck and present as subcutaneous emphysema, (b) spread with the vessels down into the retroperitoneum, or (c) rupture the mediastinal pleura, thus producing pneumothorax. The important point is that pneumothorax does not result directly from rupture of the alveolus.

Clinical signs and symptoms depend on the site and the amount of gas present. Mediastinal emphysema (Hamman, 1945) causes obstruction to the return of blood to the heart and thus lowers the cardiac output, showing clinically as dyspnoea, cyanosis, engorged veins, obliteration of the cardiac dullness, and crackling sounds

on auscultation of the heart. These signs of mediastinal emphysema are generally not marked, the gases usually spreading with comparative ease and presenting as subcutaneous emphysema, with or without pneumothorax. With mediastinal emphysema an associated pneumothorax is present in one-third of the cases.

Case Report

A boy aged 8 years was admitted to hospital for enucleation of an eye. Pre-operative examination revealed a plump child, weight 58 lb. (26 kg.), height 3 ft. 9 in. (114 cm.), nose blocked, pigeon chest, emphysematous vesicular breathing. Premedication consisted of chloral, 8 gr. (0.5 g.), at 9.25 a.m., and atropine, 1/100 gr. (0.65 mg.), at 10.15 a.m.

At 11 a.m. 200 mg. of thiopentone sodium as 2½% solution, followed immediately by 20 mg. of succinylcholine chloride ("scoline"), was given intravenously. After the usual fibrillations of the muscles, a size 8 "portex" endotracheal tube was passed easily through the mouth into the trachea under direct vision, using a Macintosh laryngoscope. The endotracheal tube was connected to a Boyle machine, and inflation of the lungs with oxygen was begun pending the return of spontaneous respiration.

As the bag was compressed, the sudden rapid appearance of subcutaneous emphysema of the face and neck was noticed. The Boyle machine was immediately disconnected from the endotracheal tube, the laryngoscope was inserted, and the tube was removed from the larynx and immediately replaced. The patient was still apnoeic as a result of the succinylcholine chloride, so the tube was reconnected to the Boyle machine and very gentle rhythmic compression of the oxygen-filled reservoir bag was restarted. The subcutaneous emphysema had spread superiorly up to the eyebrows and inferiorly on the anterior abdominal wall down into the scrotum. At this time the pulse could not be palpated, but it rapidly returned to full volume in less than two minutes at a rate of about 150 beats a minute. The mucous membranes were pink throughout, except for a period of about one minute following the appearance of the subcutaneous emphysema, when they were cyanosed. Spontaneous respiration began again in about five minutes.

In view of the patient's condition the operation was cancelled and he was returned to the ward with the endotracheal tube *in situ*. At about 11.15 a.m. he started to object to the presence of the endotracheal tube, but was restrained from removing it, and amethocaine 2% solution was sprayed down and round the tube. Portable x-ray examination of the chest revealed a bilateral pneumothorax, retroperitoneal gas, and subcutaneous emphysema. Bilateral puncture of both pleural cavities was performed with needles attached to tubes leading under water. Gas bubbled out rapidly and x-ray examination showed re-expansion of both lungs. The patient was then sedated with paraldehyde, and three and a half hours after the onset of the surgical emphysema the endotracheal tube was removed. Penicillin, 500,000 units, and streptomycin, 0.5 g., were given twice daily as a prophylactic against the possible development of mediastinitis, and the patient made an uneventful recovery, the subcutaneous emphysema being almost entirely reabsorbed by the following day.

Comment

The cause in this case appears to be the institution of positive pressure, leading to the sequence of events described by Macklin: rupture of the alveoli and perivascular tracking of the oxygen to the mediastinum, with extension from there to the neck to present as subcutaneous emphysema, and rupture of the mediastinal pleura to give bilateral pneumothorax with collapse of the lungs.

Trauma to the tracheal mucous membrane, as has been described by others (Barrett and Thomas, 1944; Gordon, 1950), seems to be unlikely, in view of the ease with which the endotracheal tube was passed.

Summary

The causes, mode of production, and treatment of surgical emphysema as a complication of anaesthesia are discussed, and a new case is reported.

Medical Memoranda

Winged Scapula Caused by a Solitary Exostosis

Solitary exostoses of the scapula of sufficient size to cause symptoms occur very rarely. Du Mortier and Halpert (1934), who reported two cases, could find only 18 further cases in the literature covering the previous 100 years; Mouchet, who showed one case to the Société d'Anatomie de Paris in December, 1927, had personal knowledge of two further cases (quoted by Pouzet and Labry, 1929). Five other isolated cases have since been reported (Pouzet and Labry, 1929; Hartmann, 1930; Lunardi, 1934; Taylor and Schaffer, 1937; Leffmann, 1947). In a survey of the causes of "snapping scapula" collected by Milch and Burman (1933), subscapular exostosis was mentioned, these authors citing the case described by McWilliams (1914), which is included in the series of Du Mortier and Halpert.

In 15 of the cases in the series of Du Mortier and Halpert the exostosis grew from the subscapular surface, thus causing winging of the scapula or interference with shoulder movement. Of the remaining five cases, four were inadequately described by the original writers, and in one instance (Heurtaux, 1886) the exostosis arose from the spine of the scapula. In the five further cases now collected from the literature, the situation of the exostosis was at the medial angle or the vertebral border of the scapula, except in one, in which it was attached to the axillary border (Taylor and Schaffer, 1937). There appears to be no sexual predominance, 14 being male and 12 being female.

In all but four cases symptoms occurred before the age of 20, and in the remainder it is likely that the condition had existed for some years before advice was sought. Because of its rarity it was thought worth while reporting a case of subscapular exostosis with some unusual features.

CASE REPORT

A bus driver aged 23 attended the out-patient clinic complaining of aching pain in the left shoulder and limitation of shoulder movement.

On examination an extensive deep-brown pigmented naevus was found to be situated over the left shoulder and a pronounced winged scapula which could not be passively corrected. The deformity had apparently been present for about 10 years, recently becoming more noticeable. The arm could be abducted to 160 degrees, this being accompanied by a creaking sensation over the scapula. Palpation deep to the vertebral border of the scapula revealed a large bony mass. X-ray examination showed this to be an exostosis growing from the subscapular fossa and impinging on the uppermost three ribs, which bore slight indentations at the points of contact. At operation the exostosis was approached by a longitudinal incision over the vertebral border of the scapula. The exostosis was easily excised and was found to be pear-shaped, 3½ in. (9 cm.) in length

by 2 in. (5 cm.) at its greatest width. It was attached by its narrower extremity to the costal aspect of the vertebral border. The wider end bore rounded facets indicating the points of contact with the ribs.

The pathological report stated that the specimen consisted of normal compact and cancellous bone, covered by a layer of hyaline cartilage at its wider end, and without any evidence of haemopoiesis or malignancy.

The post-operative recovery was uneventful, a full range of painless movement, together with disappearance of the "winging" of the scapula, being obtained in eight weeks.

COMMENT

In only two cases of the present collected series of 26 instances of exostosis of the scapula were the exostoses found to be present at a site other than the medial angle or vertebral border. Du Mortier and Halpert (1934) believed the exostosis to grow from an accessory centre of ossification, but Lunardi (1934) thought it to be due to an overgrowth of the epiphysis of the vertebral border.

Treatment consisted in excision of the exostosis as close to the scapula as possible, and sometimes a portion of the scapula may need to be resected with it. The results of operation appear to be uniformly good, and even in cases in which winging has been present for many years, as in the case here described, correction of the deformity and return of full function is the rule.

I wish to thank Mr. G. Hyman, under whose care this case was admitted and who performed the operation, for permission to publish and for encouragement and advice; and Dr. R. A. Garson, assistant pathologist to the Halifax Group of Hospitals, for his examination of the specimen.

STANLEY HULMAN, M.B., Ch.B.,
Formerly Orthopaedic Registrar, Halifax Group of Hospitals.

Topical Analgesia for the Urethra

Topical analgesia for urethral instrumentation has been practised for many years, during which time cocaine and a large number of synthetic derivatives have been tried with varying results. All of these drugs have a small but undeniable mortality risk from toxic absorption. The blame for this must be attributed to the operator who, with complacent disregard for the risks, instils the drug into the urethra. Although cocaine has fallen into disrepute for nerve blocks or infiltration techniques, it still retains an important place as a topical agent, and if due regard is paid to the maximum dose it is as safe and efficient as its synthetic rivals.

Only too frequently are local analgesic drugs used with unwarranted abandon; and since, in efforts to produce perfect analgesia, the solution is instilled too liberally, accidents still occur. Recently a preparation, "xylocaine gel" containing xylocaine (lignocaine hydrochloride) 2% w/v, has appeared on the market, supplied in 15-ml. tubes for urethral application. The total quantity of xylocaine in any one pack amounts to 300 mg., and, just as it is impossible to empty a tube of toothpaste completely, so also will the amount of xylocaine which can be administered be appreciably less than the total dose available. With such a packing, some protection is offered against overdosage.

The efficiency of 2% xylocaine solution in providing good topical analgesia for the urethra has been attested by many workers. In a series of more than 800 cases Persky and Davis (1953) limited their dose to 10 ml. and reported good results with only one doubtful toxic reaction, while Haines and Grabstald (1949) observed no untoward effects in 250 cases. The results obtained with xylocaine gel

appear to have been equally good (Romanus, 1951; Nesbitt and Baum, 1952).

I have now administered xylocaine gel to 150 patients, ranging in age from 16 to 84 years, for a variety of per-urethral instrumentations with good results and no toxic reactions.

TECHNIQUE

Males.—The bakelite nozzle (supplied in each package and sterilizable by boiling) is screwed on the end of the tube of gel and a small amount is squeezed beyond the tip to lubricate the nozzle. The penis is cleaned in the usual fashion and the nozzle inserted into the meatus. The contents of the tube are then expressed gently into the urethra. As the nozzle is removed, the penis is compressed with a penile clamp or rubber band to prevent leakage. The gel is massaged gently into the posterior urethra and 10 to 15 minutes are allowed to elapse before proceeding with the operation.

Females.—A throat swab with enough wool to cover the terminal 1 to 1½ in. (2.5 to 3.8 cm.) is dipped in xylocaine gel which has been expressed into a dish. The genitals are cleaned, and the prepared swab is inserted into the urethra and kept there for 10 minutes.

RESULTS

The methods described have been used on 100 males and 50 females for cystoscopy, retrograde pyelography, passage of sounds, and a few cases of simple cystodiathermy.

Males.—In the male group the directions given must be followed with care. In most cases good surface analgesia was provided, but this in itself does not suffice where a narrow urethra has to be stretched, causing sensations of deep pressure. A stricture, an enlarged prostate, and a contracted urogenital diaphragm all provide obstructions to the passage of an instrument, and are therefore causes of discomfort. When the urethra is essentially normal a good result can be expected. The result was satisfactory in 89 out of 100 cases.

Females.—Commonly no analgesia is used for cystoscopy in the female, but there is no doubt that discomfort is caused by the passage of a rigid instrument whose position is constantly changing. Most of the females in this series had previously been catheterized in the ward; the majority volunteered that cystoscopy with xylocaine gel was no more unpleasant than the simpler ward procedure carried out without analgesia. The result was satisfactory in 48 cases and unsatisfactory in 2; one of the latter had a large neoplasm encroaching on the internal meatus, and the other was a nervous girl of 16, for whom any form of local analgesia would have been unsuitable.

The method is not recommended as a general rule for cystodiathermy, as the pain from this is not abolished by topical analgesia of the urethra. However, where it has been necessary merely to fulgurate one or two seedling papillomata on the fundus of the bladder, many patients have found the procedure quite tolerable.

The advantages of topical analgesia for urethral instrumentation include the simplicity of the method, the lack of general disturbance to the patient, and the retention of consciousness, which allows a supervising nurse to be dispensed with, as, for example, when retrograde catheterization is being carried out in the x-ray department.

Toxic Reactions.—Although no toxic reactions were seen in this series a second type of reaction was encountered in a man who complained of nausea and faintness when the gel was injected too rapidly, causing localized distension of the urethra. This reaction, although not dangerous, may cause considerable distress to the patient.

Justin-Besançon *et al.* (Pp. 502. No price.) Thérapeutique, sous la direction de MM. les Professeurs Guy Laroche et L. Justin-Besançon *et al.* (Pp. 188; illustrated. No price.) Paris: Expansion Scientifique Française. 1954.

Symposia and annual reviews have recently been described as having become a literary incubus in their own right. *Advances in Internal Medicine* is the third annual survey of medicine which we have reviewed in the last few weeks; nevertheless, it is not a newcomer, this being the sixth volume, and it has previously been reviewed favourably in these columns. Each of the annual volumes contains nine or ten articles of about 10,000 to 15,000 words on subjects of topical interest. The subjects included in the present volume are uropepsin, glucagon—the hyperglycaemic hormone of the pancreas—the Papanicolaou technique of cancer diagnosis, spatial vectorcardiography, the L.E. cell phenomenon, biopsy studies of the liver and kidney, thrombotic thrombocytopenic purpura, porphyria, diaphragmatic hernia, and the determination of insulin in blood. The authors are expert and well chosen; for example, Hargraves writes on the L.E. cell phenomenon. The book is well produced, and this sixth volume will consolidate the position of the series as a valuable help to the physician wishing to keep up to date in the theory and practice of medicine and to the student working for the higher medical examinations.

The Bichat Postgraduate Lectures are a series of annual publications which are widely used and much esteemed in the French-speaking world. They form the basis of a postgraduate course which is given in the amphitheatre of the Salpêtrière in Paris. Not all the lectures are actually spoken, though the text is available for discussion. They are about 2,000 words in length, and there are some 80 lectures each on medicine and on surgery and the specialties, and some 50 lectures on therapeutics. About them all it can be said, as the preface itself says of the lectures on therapeutics, that they have at the same time an up-to-date character and a practical tendency. The series gives a splendid picture of the renaissance and vitality of French medicine since the war; and, although the language difficulty will prevent these volumes from having a wide public in this country, they can nevertheless be strongly recommended, if only for skimming, to our medical and surgical travelling clubs, and to our British teachers and consultants in general, nourished as they are almost exclusively on Anglo-American literature. I should certainly like to have them on my own shelves for preparing clinical lectures and case demonstrations.

L. J. WITTS.

ANTIBIOTIC THERAPY

Principles and Practice of Antibiotic Therapy. By Henry Welch, with 16 collaborators. Specially edited by Felix Marti-Ibanez. (Pp. 699+xix. \$12.) New York: Medical Encyclopedia, Inc. 1954.

This book is a successor to *Antibiotic Therapy* by Henry Welch and Charles N. Lewis, which was somewhat critically reviewed in these columns (June 21, 1952, p. 1339); it has been much improved. The more superfluous accounts of clinical features and general treatment of diseases have been omitted, as have the unsatisfactory diagrams indicating variations in bacterial sensitivity: these are replaced by extensive tables containing much important and positive information. But the chief change has been made by deputing the clinical chapters to leading authorities in special fields. It is invidious to mention only a few names, but to say that Finland writes on staphylococcal infections, Hinshaw on tuberculosis, and Woodward and Smadel on

virus and rickettsial diseases will show their quality. Multiple authorship has one disadvantage: it may entail inconsistency. Thus in Chapter XXIV carbomycin is given as the first choice for treating certain infections, whereas in Chapter XXV it is dismissed as inferior to other antibiotics. The time before dental extraction for beginning penicillin administration to prevent bacterial endocarditis is stated as two days on page 661, as one day on page 318, and as 30 to 60 minutes on page 664; there are strong reasons, which have been ventilated in this *Journal* (for example, March 31, 1951, p. 656), for choosing the shortest of these intervals.

The book is well up-to-date, including, for example, a full account of tetracycline. Both for the extensive information about the pharmacology and biological activity of individual antibiotics in the earlier chapters, and for the accounts which follow of their clinical use in almost every condition in which they are applicable, this work will be of great use both to clinicians and to laboratory workers.

L. P. GARROD.

THE CAUSES OF CRIME

Who are the Guilty?: A Study of Education and Crime. By David Abrahamsen, M.D. (Pp. 340. 13s. 6d.) London: Victor Gollancz Ltd. 1954.

The Roots of Crime. Edited by the late Sir Norwood East, M.D., F.R.C.P. With a foreword by the Rt. Hon. Sir David Maxwell Fyfe, G.C.V.O., Q.C., M.P. (Pp. 181+ix. 30s.) London: Butterworth and Co. Ltd. 1954.

"Masturbation in a boy," writes Dr. Abrahamsen, "is like playing for sexual excitement. . . . When a man starts gambling, that also begins as a sort of play. Another similarity is that in many forms of gambling as well as in masturbation the person uses his hands." The question Dr. Abrahamsen asks in his title is a pertinent one; and the implied answer—that, in so far as we do not make efforts to guard children against the effects of unsatisfactory home life and other defects of the society in which we live, we are all among the guilty—will awaken sympathy. But he does not advance his argument by a consistent looseness of thinking, of which an example has been given above.

The British symposium edited by Sir Norwood East has the advantage over the American *cri de cœur* that the authors have tried to come to grips with the problem at a realistic level. To offset the exaggerated claims, both for treatment and for prophylaxis, which are made by some psychotherapists Dr. Curran quotes the results of an American experiment. The names of 650 boys between 6 and 10 who were notified as likely to become delinquent were matched in 325 pairs by a number of characteristics, including age, intelligence, and educational, ethnic, and social background. By a toss of a coin one member of each pair was sent for psychotherapy—anything from "big brother" guidance to formal psychoanalysis—while the other was watched as a control. The boys were followed up for an average of 50 months. Out of the treatment group 96 appeared in court for 264 offences; out of the control group 92 for 218 offences. When faced with these results the therapists insisted that the relationships established had their value in themselves, irrespective of their possible effect on the boys' behaviour.

Mr. F. J. Powell, in his chapter on "The Magistrate and the Psychiatrist," estimates that mental abnormality entered into the causation of only 11% of all cases tried at the Clerkenwell Court during a complete year (1951). This may well be an underestimate, as if psychiatric abnormality is unsuspected it will not be looked for. Nevertheless the figures lend support to the view that in most cases of the commoner crimes, such as larceny, psychological explanations will be found in ordinary rather than psychopathic mental processes. We can be sure that the contribution which psychiatry can make to the elucidation of the causes of crime is important, but is most unlikely to be decisive.

In his introductory chapter Sir Norwood East points out that the peak age for crime in both sexes is 13–14; the risk of criminality rapidly diminishes with age. With "finger-

printable" offences, 81% of those without and 59% of those with proved previous offences had not returned to prison 14 years later. Sir Norwood concludes that "prison treatment can justly claim a considerable degree of success"; but this is a *non sequitur*. It can safely be claimed for "prison treatment" that while it is going on it substantially reduces the risk of crime; but, curiously enough, there appears to be no evidence at all, in a scientific sense, that imprisonment is any more successful than psychotherapy.

ELIOT SLATER.

CONGESTIVE HEART FAILURE

A Primer of Congestive Heart Failure. By George E. Burch, M.D., F.A.C.P. (Pp. 126+xi; illustrated. 30s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1954.

This book of 126 pages has four chapters. The first is devoted to a review of the mechanisms of heart failure, while the remaining three are concerned with its treatment. Although primarily intended for medical students, young graduates, and general practitioners, there is little description of the clinical features and varieties of congestive heart failure. The current theories of the mechanisms of heart failure are clearly presented in the first chapter. Fact and theory are separated, and experimental work is appraised in its relationship to the findings in man. The emphasis is on the heart and circulation as a double pump system, and the effects of forward and backward failure are described; but Dr. Burch points out that they are an inadequate explanation of the clinical syndrome.

Advice on management and therapeutics is detailed and sound, though not always applicable to conditions in Great Britain. Home treatment is considered to be at least equal to a hospital regimen. The dangers of hyponatraemia and other toxic effects of administering mercurial diuretics appear to be slightly overemphasized. Most physicians are more impressed by their extraordinary safety. The third chapter, on digitalis, contains a useful table describing the various preparations of this and related drugs. The many diagrams are clear and there is a reasonable bibliography at the end of each chapter. The crisp opening sentence of this book—"Congestive heart failure constitutes one of the enigmas of medicine to-day"—is supported by seven references and characterizes the form and substance of the book. It is one to be confidently recommended to those for whom it is written.

WALLACE BRIGDEN.

CLINICAL BIOCHEMISTRY

The Biochemistry of Clinical Medicine. By William S. Hoffman, Ph.D., M.D. (Pp. 681+xx; illustrated. 90s.) Chicago: Year Book Publishers Inc. London: Interscience Publishers Ltd. 1954.

This is an ambitious book, as it aims at dealing with some of the essential aspects of biochemistry as well as with the pathological, biochemical, and therapeutic aspects of most diseases of biochemical interest. The difficulty of compressing all this within some 650 pages is obvious, but the author has very largely succeeded in his efforts, and he is to be congratulated on producing a useful and readable book. This is perhaps the nearest approach in recent years to the well-known *Quantitative Clinical Chemistry* by Van Slyke and Peters, though it differs from the earlier work in omitting all technical details.

The volume opens with a discussion of proteins, carbohydrates, and fats, and proceeds to a consideration of diseased states arranged mainly on an anatomical basis. Chapters are included on such subjects as nucleic acids, biological antagonists, and isotopes. References are not so numerous as might be expected, but a useful list is given at the end of each chapter. Relatively more space is devoted to endocrine disturbances than to some other subjects. Sections on the liver, kidney, and electrolytes are also excellent. On the other hand idiopathic steatorrhea is hardly mentioned and is not given as a cause of osteomalacia. There is a lack of reference to recent work on the 17-keto-steroid excretion in gout, and the modern dietary treatment

of uraemia is not discussed. Nevertheless this book can be strongly recommended both to the clinician and to the chemical pathologist as a valuable work of reference and a stimulating account of this special field.

N. F. MACLAGAN.

SURGICAL HANDBOOK FOR STUDENTS AND NURSES

Demonstrations of Operative Surgery: A Manual for General Practitioners, Medical Students and Nurses. By Hamilton Bailey, F.R.C.S., F.A.C.S., F.I.C.S., F.R.S.Ed. Second edition. (Pp. 387; illustrated. 24s.) Edinburgh and London: E. and S. Livingstone Ltd. 1954.

This is indeed a remarkable book and will appeal to a wide circle of readers. Written originally for the benefit of the nursing staff, it has grown into a manual in which the medical student, the theatre sister, the general practitioner, and indeed all those who wish to know how operations should be carried out will find all that they require. To describe an operation accurately and yet to avoid the elaborate detail with which the surgeon himself must be familiar is no easy task, but here it has been accomplished with complete success.

The first chapters deal with the minute care of instruments and the complicated appliances which the modern nurse is expected to maintain. There follow a series of short but accurate descriptions covering practically every operation in the most modern fields of surgery, including even mitral valvotomy. The descriptions are so clear and so admirably illustrated that no one could fail to appreciate the steps of each operation or the reasons for the precautions which are so carefully explained. Many an experienced surgeon will be only too glad to refresh his memory in the case of some unusual situation with which he has to deal.

The illustrations are most aptly chosen and well produced and add greatly to the value and clarity of each article. Hamilton Bailey is to be congratulated on a brilliant achievement in co-ordinating the contributions of some thirty authors, all of them acknowledged leaders in surgery, in a volume for which so many will be grateful.

HENRY SOUTTAR.

PARKINSONISM

Parkinsonism and its Treatment. Edited by Lewis J. Doshay, M.D., M.A., Ph.D. (Pp. 152; illustrated. 24s.) London, Philadelphia, and Montreal: J. B. Lippincott Company. 1954.

In recent years increasing interest has been taken in Parkinsonism, and this short book adequately covers various aspects of the subject. The outstanding chapters are those by Professor Wolf on the pathology of the various types of Parkinsonism and by Professor Denny-Brown on the aetiology of the condition. In this latter chapter the suggestion is made that idiopathic Parkinson's disease may basically be due to a disorder of metabolism, and Denny-Brown cites evidence indicating that it may be a "limited form of cumulative metabolic neuronal lipoidosis." The description of the clinical aspects by Dr. Doshay is excellent, but it is disturbing to find adiadochokinesis mentioned as an important sign of the condition. If this cumbersome word is to be used at all, it should surely be applied to incoordination of rapid movements such as occurs in cerebellar disease, and not to the slow, but not incoordinate, type of movement seen in Parkinsonism.

Over one-third of the book deals with treatment; there is a useful chapter on the drugs, including the newer synthetic chemicals, which are valuable in improving symptoms, and this is embellished by a coloured plate showing the various tablets and capsules. A considerable number of surgical procedures have been used in an effort to reduce rigidity and tremor, and these are reviewed by Dr. Schlesinger; his conclusion is that no surgical treatment "has approached the status of a standard clinical procedure."

This book is easy reading and should be helpful to all who look after patients suffering from this common disorder.

SATURDAY FEBRUARY 19 1955

COMBINED CHEMOTHERAPY IN TUBERCULOSIS

Of all the drugs recently found to be effective in the treatment of tuberculosis, isonicotinic acid hydrazide (isoniazid) stands in a class by itself. While not the "wonder drug" that some hoped it might prove to be, three years' experience has fully confirmed the original American reports that it has a remarkable effect *in vitro* and *in vivo* against the tubercle bacillus.¹⁻³ It was therefore disappointing when early reports on isoniazid showed that both in the laboratory and in the treatment of patients (especially with pulmonary tuberculosis) tubercle bacilli developed resistance to the drug even more quickly than to streptomycin,^{3,4} and the indiscriminate use of isoniazid alone in the treatment of tuberculosis was generally condemned.⁴⁻⁶

This condemnation has not been universal. Isoniazid alone has been given with success to many patients with miliary and meningeal tuberculosis.^{7,8} Even for pulmonary tuberculosis W. McDermott and his colleagues⁹ have claimed that isoniazid alone, over a period of one year, was "in the same general class as the multiple drug regimens," and tubercle bacilli could be cultured from the sputum of only 11 out of 32 patients treated for that length of time. There was no great deterioration in clinical condition even in those patients whose sputum still contained tubercle bacilli, often highly resistant to isoniazid. Now many strains of isoniazid-resistant tubercle bacilli isolated both in the laboratory and from patients have been shown to be relatively avirulent, at all events to certain experimental animals,¹⁰⁻¹³ and McDermott and his colleagues, while recognizing

the great value of combined therapy, suggest that in at least some cases of pulmonary tuberculosis the administration of isoniazid alone may not be so disastrous as was at one time feared. Even so, in some patients bacteriological relapse, with the re-appearance in the sputum of isoniazid-resistant tubercle bacilli, is associated with serious clinical relapse¹; such organisms may perhaps be of reduced virulence in the sense of initiating new lesions in certain experimental animals, but they seem to be capable of causing serious harm to the patients in whose lungs they are growing, and these people may be a danger to contacts.

Many reports have shown that excellent results can be obtained by suitable combinations of isoniazid with P.A.S. or streptomycin.^{6,14,15,16} The latest report of the Medical Research Council, published in the opening pages of the *Journal* this week, gives further information about the effectiveness of certain of these combinations. Four methods of treatment were compared in 588 patients. All received 200 mg. of isoniazid daily; 182 of them received in addition streptomycin, 1 g. daily (SH), 142 streptomycin 1 g. twice weekly (S2H), 159 P.A.S. 20 g. daily (20 PH), and 105 P.A.S. 10 g. daily (10 PH). "Judging solely from the results at three months," the report concludes that "streptomycin 1 g. daily plus isoniazid 200 mg. daily is not only the most effective of the four treatments, but also represents the most effective drug combination studied at any stage of the trial." Streptomycin 1 g. twice weekly plus isoniazid 200 mg. daily was less effective in preventing drug resistance; isoniazid plus P.A.S. in either of the doses used was effective, though not quite so good as daily streptomycin plus isoniazid. It is not always realized, though it is explicitly stated, that full clinical and laboratory information was available for only three months of treatment, and therefore these Medical Research Council reports, although they contain valuable information about the response to three months' treatment, cannot be expected to tell us what happens with longer courses of chemotherapy. It is true that in 241 patients bacteriological results are available for courses of treatment lasting for six months, and these confirmed the adequacy of the SH, 20 PH, and 10 PH treatments, and the inadequacy of the S2H treatment in preventing bacterial resistance to isoniazid. But it is unfortunate that clinical information is not available for periods of treatment longer than three months, since it is precisely in the period between three and six months that differences between different treatments may reveal themselves, at least in some forms of pulmonary tuberculosis. Such information is urgently needed for the combination isoniazid plus

P.A.S. There is no doubt that this method of treatment is effective over short periods, and the Medical Research Council's report shows that drug resistance is greatly delayed by the use of isoniazid plus P.A.S. for six months. But, as the report points out, its clinical value over periods longer than six months is in doubt. Much of the disagreement can perhaps be explained by differences in the type of case studied by different groups of workers. In some studies, for example, isoniazid alone, isoniazid plus streptomycin, and isoniazid plus P.A.S. have appeared to be about equally effective. Yet in advanced fibrocaceous disease isoniazid plus streptomycin is clearly better than isoniazid alone. Isoniazid plus P.A.S. may be between these two regimens in the benefit it gives.

The best combination of these three drugs remains uncertain. It is possible that changes in treatment may be more effective than any one combination. C. L. Joiner *et al.*¹⁷ obtained satisfactory results with isoniazid, streptomycin, and P.A.S. in rotation, each pair of drugs being used for one month at a time. Whether in the end this will be more or less effective in delaying drug resistance is not known. The use of all three drugs together has the disadvantage that resistance might develop to all of them. The importance of continuing the search for new drugs is plain. Two which show promise are terramycin (oxytetracycline) and pyrazinamide. Terramycin by itself has some activity against the tubercle bacillus, and it is interesting to note that G. B. Mackaness and N. Smith¹⁸ found that, like isoniazid, terramycin was effective in killing tubercle bacilli inside macrophages as well as in the test-tube. There is little information about its effect *in vitro* in combination with other drugs. But several workers have claimed that in the treatment of chronic pulmonary tuberculosis excellent results could be obtained by combining streptomycin with terramycin. More recently Sheila Stewart, F. W. A. Turnbull, and J. W. Crofton in this *Journal*¹⁹ have attempted to assess the value of terramycin together with isoniazid in the treatment of chronic fibrocaceous tuberculosis. Thirty-three patients were treated. All received isoniazid (100 mg. twice daily) and terramycin in daily doses of 1 g. (10 patients), 2 g. (13 patients), or 5 g. (10 patients). The progress of these patients was compared with the progress of 17 patients who received isoniazid alone (100 mg. twice daily). The authors conclude that terramycin in the lower doses has little to offer, even in conjunction with isoniazid, but that in a dose of 5 g. daily it does seem to delay the onset of isoniazid resistance. Resistance to terramycin was not observed in any of the groups. The authors themselves suggest that these results are not impressive, but that terramycin may

have some place in combination with isoniazid when other drugs for any reason cannot be given. Some recent American reports suggest that pyrazinamide is more promising. McDermott and his colleagues⁹ go so far as to say that pyrazinamide with isoniazid "provides probably the most effective therapy known." Pyrazinamide is a drug of considerable interest. Chemically it resembles nicotinamide, but has a pyrazine instead of a pyridine ring. Like nicotinamide, it is not very active in the test-tube against tubercle bacilli except in special conditions, but showed promise in experimental animals. When first used in man it was found to be too toxic for prolonged administration in effective dosage, but if the recent American reports are confirmed its combination with isoniazid is an important step forward.

One of the real problems in this field is the nature of the disease, whose progress or relapse is difficult to test reliably. A given course of treatment may produce disturbingly different results in different groups of patients, even though every care has been taken by one group of investigators to make them as comparable as possible. It is therefore not surprising that results obtained by different groups of workers are sometimes even more conflicting. When several good methods of treatment are available, it is not easy to devise tests which will clearly indicate the best of them. Here it is well to remember how quickly the chemotherapy of tuberculosis has advanced. Only a few years ago tuberculous meningitis was a disease with a 100% mortality, and no drug could be relied upon to influence the course of any form of tuberculosis. To-day the drug control of tuberculosis is established and is already greatly reducing the mortality and the infectiousness of the disease.

GRANTS FOR NEW HOSPITALS

The Minister of Health's statement last week on a new building programme for hospitals in England and Wales, together with the Secretary of State's similar statement for Scottish hospitals, will have brought a feeling of relief to all responsible for the working of the hospitals. The programme will not be started until the financial year after next, and the sums of money to be made available will be small in relation to the needs; but at last a start will be made on the physical expansion of the hospitals made necessary by the growth of their services since 1948.

The new programme, which is divided into two parts, will not replace the existing capital works programmes of hospital boards. These, under which a certain amount of expansion and renovation have already taken place, and nurses' homes been provided, will go forward as planned. In the current financial

year, £12m. has been voted for the capital expenditure of hospitals in Great Britain, and, according to the statements made last week, much the same sums will be available in 1956-7 and 1957-8. What the main part of the new programme will do is to inaugurate the building of entirely new hospitals for the first time since before the war. Parliament will be asked to vote a sum of £7½m. for England and Wales in 1956-7 and £10m. in 1957-8 to enable major building projects to be undertaken.

Compared with expenditure in the decade before the war, when a vast amount of hospital building was carried out from voluntary funds and by public authorities, these sums, as Mr. Macleod pointed out, are not large. On the other hand, much of the building by the voluntary system in the 'thirties took the shape of small hospitals, scattered haphazardly over the country according to the wishes of the benefactors, local enterprise, and local wealth. In the public system, similarly, energetic local authorities were busy putting up new hospitals or converting their old public assistance institutions. But here, too, though such relatively well-off public authorities as London and Middlesex carried out some big hospital schemes, some of the poorer authorities were impeded by lack of funds. Now that all hospital expenditure is met from central funds, there should be a much better chance of the new building taking place where it is most needed and of the money available being put to better use. Certainly the list of projects given by Mr. Macleod that will be included in the first year's programme looks as if absence or shortage of existing accommodation in relation to population has been the main criterion in deciding priority. Thus a new town like Harlow and a greatly to be expanded old town like Swindon are to have new general hospitals. West Cornwall and West Cumberland, at present without adequate general hospitals, are to have them. The present shortage of mental hospital accommodation in the Midlands is reflected in the new mental hospital to be built at Wolverhampton, and four regions are to have major extensions to their mental deficiency hospitals. The rebuilding of Charing Cross Hospital at Harrow, possibly to start in 1957-8, had been decided on long ago; it is an obvious advantage to disperse some of the teaching hospital facilities of Central London to areas of growing population outside.

In other cases, however, the reason for priority seems less clear, at least to those not privileged to know what guides a regional board in coming to a decision. Four hospitals were mentioned by Mr. Macleod as being allowed to start building new out-patient departments in 1956-7. Their need for them is not disputed. But what the staffs of other hospitals whose need is apparently no less great would like to

know is why their hospitals' claims have again been postponed. Publication of the reasons for postponement might help to allay the customary suspicion that priority is given to those who make most fuss.

The second smaller part of the new programme is a special allocation of money to be used for plant replacement and "redeployment," whatever that may prove to be. For this purpose Parliament will be asked to vote £2m. in 1956-7 and £4m. in 1957-8. The replacement of antiquated plant in boiler rooms and laundries has long been recognized as a means of economizing in maintenance expenditure, and the new financial provision is intended to give a fillip to schemes of this sort, which can already—subject to Ministerial approval—be carried out under the Boards' ordinary capital programmes.

Nevertheless, such economies as are obtained in this way must be small in relation to the hospitals' total maintenance expenditure. This is bound to be increased when the new hospitals are ready to be staffed and used. Here, too, a point arises. Will the additional staff be forthcoming? Mr. Macleod seemed to have no qualms about this on being questioned, because, he said, hospital staffs had been steadily increasing since 1948, and it would be easier to attract staff to new hospitals. Nevertheless, there is a danger, particularly in the mental hospitals and mental deficiency institutions, which are already short of nurses, that the new hospitals will not recruit additional staff but merely attract staff away from the old.

The new schemes are only a foretaste of what needs to be done. But at least a beginning is to be made, and at last hospital boards have been given a long-term period for planning—and, moreover, a definite undertaking that, subject to Parliament's approval, the necessary funds will be forthcoming.

RESULTS OF TREATING CANCER OF THE LUNG

Carcinoma of the bronchus is a disease with a bad prognosis: often no treatment is possible, and in other cases only temporary palliation can be hoped for. But when radical surgery is possible a substantial hope of a long survival can be offered; and in the majority of cases life is prolonged. The benefits of surgery, disappointing though it often is, are greater than is generally believed. Elsewhere in this issue Mr. T. Holmes Sellors reviews the results of surgery in the cases he has himself treated. Between 1940 and 1950 he undertook 689 thoracotomies, and found excision possible in 446. Of 273 resections performed between 1940 and 1948, 24% of the patients died within four months of operation, but 34% survived

two years, and 21% five years. Of 173 resections performed in 1949 and 1950, 9% of the patients died within four months of operation, and 40% survived two years, and 34% three years. Results of surgery are thus better than they used to be and are still improving. In 1946 Tudor Edwards¹ published his personal results in the first number of *Thorax*: of 1,016 patients seen with bronchial carcinoma, 173 were operated on and excision carried out on 70. Operative mortality was 17%; 27% of the patients survived two years, and 7% five years. Another recent series, published in 1954 by Boyd and his colleagues² from Boston, Mass., gave results comparable to those of Holmes Sellors: resection was done in 104 cases out of 403 seen, with 8% operative mortality and 32% surviving for five years. Gibbon³ reported a five-year survival rate of 26%; and Ochsner⁴ found resection possible in 442 cases out of 1,365, with an operative mortality of 19% and a five-year survival rate of 34%. In considering survival rates, it must be remembered that most of these patients are in late middle or old age and that the onset of other diseases would in any event be tending to raise the mortality rate in such a group. Nevertheless many of those surviving for five years eventually die from recurrence or metastases of the original growth.

Taylor and Waterhouse,⁵ reporting on 1,592 cases of carcinoma of lung, found an average survival of only four months from the time of diagnosis in patients not treated by resection. Boyd and his colleagues² also reported that patients treated only medically survived four months; and Lea⁶ found the average duration of life to be six and a half months from the first symptom. The range of variation in the time of survival of untreated patients is wide, and occasionally, as with all cancers, patients survive several years. A case of spontaneous regression has even been reported,⁷ but the natural course of the disease is almost always extremely short. Cure is always hoped for, though it cannot be confidently predicted even after several years' survival, but the patient who has had a resection has more than a 50% chance of surviving for a year, and so of trebling his life expectation.

Radiotherapy, which is mainly used as a palliative, also prolongs life. As Smithers⁸ has pointed out, the patients who would most benefit from radical radiotherapy are also suitable for surgery and so usually treated by resection. Brooks and his colleagues⁹ found that 129 patients given a radical course of radio-

therapy survived for an average period of 10 months, and that 176 given palliative therapy lived, on average, for five and a half months. The temporary palliation of symptoms achieved by the lesser course, which, unlike radical therapy, can usually be given without causing radiation sickness, is most valuable, particularly for the relief of haemoptysis, superior vena caval obstruction, or the pain of secondary bone deposits (but not of direct bone invasion).

The advice of a surgeon should be sought whenever extension of the growth beyond the thorax has not been proved. Operation will occasionally be contraindicated by the patient's general condition (especially if respiratory function is reduced by previous disease), but more often by invasion of glands or mediastinal structures—the heart or superior vena cava, the recurrent laryngeal or phrenic nerves, or the proximal great vessels. Holmes Sellors confirms the general belief that the histological type of the carcinoma influences the operability and prognosis, squamous-celled growths being more readily and more successfully treated than adenocarcinoma or oat-celled carcinoma. The same tumour, however, may contain areas of different cellular types. Unfortunately operability cannot always be determined before exploration, and a large number of useless thoracotomies must inevitably be done if as many patients as possible are to be given the benefit of a resection. A radical operation nearly always entails a pneumonectomy, since it is usually essential to remove the main bronchus. Sometimes in peripheral growths without glandular involvement a lobectomy is enough, and in other patients with poor respiratory function it must be accepted as a palliative.

ARTIFICIAL RESPIRATION AND CARBON DIOXIDE

When a healthy man breathes air or oxygen mixed with 5% of carbon dioxide his breathing markedly deepens and quickens. This incontrovertible observation led to the emergency use of carbon dioxide in attempts to stimulate breathing when it had stopped. Haggard and Henderson¹ in 1921 advocated, for many respiratory emergencies, the use of 5% carbon dioxide with oxygen in conjunction with artificial respiration. Since then cylinders containing this mixture of gases have been widely used. There are few forms of treatment about which it is harder to obtain direct clinical evidence, for in these emergencies those present must strive urgently for the patient's life and critical observation is almost impossible. Yet it has been suspected for some time that to give carbon dioxide to a patient who needs and is receiving artificial respiration is not only irrational but may be harmful.

When a healthy man breathes 5% of carbon dioxide the breath-regulating mechanism responds and ventilation of the lungs increases greatly, with the result that the pressure of carbon dioxide in the arterial blood increases only very slightly. This is not so when the patient has been exposed to narcotics or deprived of oxygen, for then the breath-regulating mechanism is damaged and depressed and the earliest of its functions to be impaired is the ability to respond to increasing concentrations of carbon dioxide. Thus by the time that artificial respiration becomes necessary the tension of carbon dioxide in the alveoli and arterial blood will already be abnormally high and the pH of the arterial blood may be abnormally low. If 5% of carbon dioxide is given to a patient in real need of artificial respiration breathing will not be stimulated. Ventilation of the lungs will continue to depend upon the artificial respiration, and in emergency conditions this is unlikely much to exceed normal resting levels. In consequence the alveolar carbon dioxide concentration will rise to 15% or 20%, and at this level carbon dioxide is poisonous. Such concentrations of carbon dioxide depress respiration, cause coma, and damage the cardiovascular system.

The hazard and confusion which can be caused by high alveolar concentrations of carbon dioxide have now been recognized in respiratory disease² and after anaesthetic procedures which seriously interfere with breathing.³ Failure of commencement of spontaneous respiration after the administration of a muscle relaxant may be due to this cause if artificial respiration has been inadequate during the operation. In a recent issue of the *Journal* we published a report⁴ to the Medical Research Council by its Committee for Research on Breathing Apparatus on the subject of gases to be administered in artificial respiration. The authors of the report, Dr. K. W. Donald and Professor W. D. M. Paton, have marshalled the evidence in favour of the committee's conclusion that "carbon dioxide should not be administered with oxygen in the resuscitation of subjects requiring and receiving artificial respiration." It is recommended that oxygen should be given, when possible. Much of the evidence is experimental, but in this field experiment can often closely mimic practice. The evidence and argument are impressive, and no other conclusion seems reasonable.

THE FUGITIVE CATHETER

A polyethylene catheter has been found a practical alternative to the cannula in giving intravenous fluids. It is particularly useful when a hypertonic solution is to be given intravenously, such as hypertonic glucose in the treatment of anuria. The fluid can be delivered directly into the superior vena cava by advancing the tip of the catheter to this point; whereas if a cannula in a peripheral vein is used thrombosis in the vessel will probably ensue as a result of hypertonicity of the fluid. The polyethylene catheter has, however, one serious disadvantage—it is difficult to anchor securely to the skin. This is usually overcome by having a sufficient length of catheter both outside and inside the vein, so that small changes in position of the catheter do not

matter. Turner and Sommers¹ now report a serious mishap to a patient with myocardial infarction being treated with intravenous fluids: a 22-cm. length of polyethylene catheter which had been tied into the right median antecubital vein and strapped to the skin escaped from the vein and passed into the right auricle. At necropsy two days later, in addition to extensive myocardial infarction resulting from recent coronary occlusion, the polyethylene catheter was found lying in the right atrium and superior vena cava, with its tip resting against the tricuspid valve ring. A mural thrombosis overlying an area of myocardial necrosis was found on the anterior wall of the right atrium at the level reached by the end of the catheter. The catheter itself was surrounded by a thin layer of antemortem blood clot and the entire right side of the heart was filled with clot also. A similar layer of blood clot sheathing the entire length of the catheter has occasionally been found at necropsy on patients who have died from anuria after treatment for several days by hypertonic glucose through a polyethylene catheter in the superior vena cava. Hence intravenous therapy by this method should not be continued longer than is absolutely necessary. The endocardial lesion in the case reported by Turner and Sommers was probably caused by atrial contraction against the tip of the catheter. No direct parallel can be drawn with cardiac catheterization, since in this procedure the tip of the catheter is only in the same position in the heart for a matter of minutes, as opposed to 48 hours in the case reported. Goodwin,² however, reporting a fatality after cardiac catheterization, found a small area of subendocardial necrosis lying beneath an endocardial thrombus in the outflow tract of the right ventricle, and he stressed the need for caution and gentleness when performing cardiac catheterization. The necropsy findings in Turner and Sommers's case lend further weight to his warning.

POST-TRAUMATIC PERSONALITY CHANGES

Interest in the personality changes following frontal lobe injury in man has grown progressively since Phineas Gage received his head injury from a crowbar just over one hundred years ago, and was converted from a popular hard-working man into a "childish kind of crook."³ The increase in the number of patients with head injury, due to the two world wars and to automobile accidents, and the steady growth of neurosurgery have enlarged the clinical experience of neurologists and psychiatrists. It was, however, the results of animal experiments which led to the introduction of prefrontal leucotomy, by which those character changes caused by frontal lobe injury might be expected to balance certain symptoms—in particular, emotional tension and pre-occupation—occurring in patients with mental disorder.

Various groups of patients have been studied in order to determine the fundamental disturbances resulting from frontal lobe injury, and each of these groups has its advantages and disadvantages as research material. In 1937 Jefferson⁴ commented on some of the mental changes observed in eight patients operated on for

frontal lobe tumours. Rylander⁴ also recorded his findings in patients who had had a frontal lobectomy for tumour or abscess, and found fairly consistent changes in spite of the variations in amount of tissue excised and the possibility that in some patients the tumour had not been completely removed. There were mental changes in almost all of his 32 patients with frontal lobe ablation, an alteration in mood and a decrease in social tact being prominent. Partridge,⁵ in his outstanding contribution to knowledge about prefrontal leucotomy, recognized the difficulty of separating the effects of the mental illness and the effects of the operation. He therefore paid special attention to the group of patients who had recovered from an affective illness, and found some character change in all except one. The most remarkable changes were diminution in activity, a decrease in the tendency to worry, and a more permanent lack of restraint in behaviour—often “the freer post-operative expression of some subdued hostility which the patient has formerly held in check.”

The group of patients with frontal lobe damage due to penetrating wounds presents certain advantages for the study of personality changes, in that it comprises for the most part people who were previously in good health and in whom the lesion is static. Jarvie⁶ has recently made a close study of the changes after wounds of the frontal lobes in six patients. He compared their personality before and after injury and found that they had a much less firm control of their behaviour in its social aspects, and that this might appear independently of intellectual or other changes and was often quite apparent to the patient. Further, antisocial tendencies present before injury which had required a continuing conscious inhibition found a more ready expression after injury. He used the term “disinhibition” to describe this change, and pointed out that this mechanism gives an explanation of why such personality changes are seen only in certain patients, and why they involve different aspects of the personality in different people. Similar intensive studies of small groups of patients—particularly the study of personality, with its rich variation from person to person—are likely to throw more light on frontal lobe dysfunction and psychological mechanisms.

ROCKEFELLER INTERNATIONALISM

It is usual for the president of the Rockefeller Foundation to preface the annual report with a review intended to inform the public on broad lines of the Foundation's activities and interests. In the annual report just to hand, for 1953, the president, Mr. Dean Rusk, has had to devote half his space to a rebuttal—unnecessary as this must appear to many non-American observers—of charges against the Foundation and other philanthropic bodies made by a Congressional committee. The committee has been investigating tax-exempt institutions, and opportunity has been taken to make charges of “subversion” and the promotion of “left” ideas inimical to the American social system and government. The report of the committee had not been published when the president wrote his review, but he was aware of its likely tenor and made in advance a dignified defence. The activity under suspicion seems to

be that the Foundation has promoted internationalism, but what else, asks the president in effect, could it do? The attack upon medical and allied problems must cross national boundaries. Moreover, the general body of knowledge, scientific and other, is an international heritage, depending on the labours of scientists and scholars in many schools, in many laboratories, in many countries.

It is refreshing to turn from this political murkiness to what the Foundation achieved in 1953. In work of such variety it is difficult to take any short measurement except the financial one. The benefactions amounted to not far short of fifteen million dollars, which at the rate of exchange prevailing is between five million and six million pounds. This was divided for the most part between the four provinces of the Foundation—medical and public health projects, science and agriculture, social sciences, and the humanities. The medical interests of the Foundation in 1953 lay mainly in three directions. The first was the improvement of medical education by support given to medical faculties and teaching institutions in twelve countries. The second was a virus research programme, including intensive research on viruses whose attack upon man up to now has not been severe but may become so with changes in the genetic and environmental situation. The third was medical care, including a survey of general practice in an area of the United States with a view to throwing light upon the training of doctors for work in rural communities. There is no clear dividing line between medical and social science, and the Foundation is supporting investigations into the relationship between physiological and psychological factors and social behaviour. Grants were made in the expectation that the biochemist, the physiologist, the neurologist, the endocrinologist, the geneticist, and their colleagues in closely related fields can throw more light on human conduct. The Institute of Psychiatry of the University of London and similar departments at Cardiff and Birmingham were included as recipients.

In 1953 the Rockefeller benefactions assisted eleven British universities and numerous other institutions in this country. Out of the 321 persons holding the Foundation fellowships—163 of them in medicine and public health—19 were from Great Britain and 50 more from other countries in the British Commonwealth. A total of one million dollars was made available for fellowship activities during 1953. These fellowships, for postgraduate study, are awarded to outstanding men and women who show promise of making important contributions in their various fields. Eighty years ago, long before the Foundation was established, Charles W. Eliot, the famous president of Harvard, declared that in England and the United States “the method of doing public work by means of endowments managed by private corporations has been domesticated for several centuries; and these are the only two nations which have succeeded on a great scale in combining liberty with stability in free institutions.” It is to be hoped that no “barbaric indictment,” to quote the words of one of the dissenting members of the Congressional committee, will result in inhibiting the work of the Rockefeller Foundation or restricting its international adventures.

EMERGENCIES IN GENERAL PRACTICE

CRISES IN MYXOEDEMA

BY

RICHARD ASHER, M.D., F.R.C.P.

Physician, Central Middlesex Hospital

Myxoedema is a chronic rather than an acute disease, and therefore rarely presents with a crisis. It only does so when the disease has progressed to a very advanced stage, or if an acute complication develops.

I shall start by describing how to recognize the disease, for whatever the crisis the clinical picture of myxoedema is the same. The most important thing is to keep the possibility of the diagnosis in mind, for once the diagnosis has been thought of it is usually not difficult to establish it with the appropriate questions and observations.

Signs

I put signs first because appearance, voice, or demeanour often initiate the idea of the diagnosis before the history does.

Face.—The most helpful sign is the appearance of the face. This is hard to describe but easy to recognize once a case of myxoedema has been encountered, because affected people resemble each other as closely as if they were near relations. The patient is usually a woman, but the condition can occur in men. In advanced cases the features look bloated and the normal contours of the face are smoothed away just as the wrinkles of a balloon disappear when it is blown up. Oedema collects in the lips, broadening them, and around the eyes, narrowing the palpebral fissures and forming little bags of flesh beneath them. The colour is yellowish and waxy with a contrasting burgundy-coloured flush over the cheeks; in addition, the hair is dry and scanty, with a receding hair margin that leaves a wide forehead and, in some cases, partial baldness. The eyebrows are sparse and sometimes the lashes too. The classical loss of hair over the outer third of the eyebrows is an unreliable sign because so many normal people show this deficiency.

Neck.—Feeling for the absence of thyroid tissue is not clinically rewarding—besides, myxoedema can occur with a goitre; but the presence of a thyroidectomy scar is a helpful confirmatory sign when present.

Speech.—The essential characteristics of the speech are that it is low, it is slow, it shows nasal obstruction, and has a thick indistinct quality. In a gross case the words are punctuated by peculiar grunting, snorting sounds, and sound like a bad gramophone record (running down) of a drowsy, slightly intoxicated person with a bad cold and a quinsy. In less severe cases a husky thickness is all that is observed.

Oedema.—The myxomatous infiltration gives the body tissues a spongy, swollen feel somewhat resembling ordinary fluid oedema, but not pitting on pressure. This can be best felt on the front of the upper chest, where the sensation on pressure reminds one of rubber sponge. The textbook supraclavicular pads are not at all constantly present. In the legs the myxomatous oedema may be blended with true oedema due to heart failure.

Heart.—Though bradycardia is the textbook finding, it is unusual to get a pulse rate below 70. The heart is usually somewhat enlarged, but the frequent presence of pericardial effusion makes it seem larger. It is unlikely that the size of the heart or the presence of pericardial fluid will be detected clinically, because of the thickened integument of the chest wall.

Skin.—This looks coarse and feels cold, dry, and scaly; in a gross case the observer feels as if he were touching a lizard.

Mentality.—The patient with myxoedema thinks, speaks, and moves slowly. She may sleep much of the day and night, dropping off unintentionally whenever she sits in a chair. Her memory is faulty and she is too drowsy to pay much attention to anything. Psychotic symptoms may occur (see below) even when the myxoedema is not gross.

Symptoms

The history may give little help in making the diagnosis, though it greatly helps in confirming it once suspected. The symptoms are admitted to rather than complained of, and are discovered only when the right questions are asked. Often relatives notice the changes more than the patient because the illness itself smothers self-criticism. The following symptoms are common: general tiredness and sleepiness, gain in weight, vague pains in the limbs, poor memory, constipation, deafness, falling out of hair, dryness of the skin, and a feeling of perpetual cold. The myxomatous blocking of the air passages makes the patient complain of a chronic cold, and during sleep snoring may be unusually loud. The puffiness of the face and the change in the quality of the voice may be noticed by relatives. The drowsiness may be so great that the patient drops off to sleep at all hours of the day. The feeling of coldness may be so striking that a patient with myxoedema may use an inordinate number of blankets and hot-water bottles even in summer; the position in bed is often characteristic for the same reason—the bedclothes pulled up high, with only the top of the head visible, in an effort to get warm (Fig. 1).

FIG. 1.—The “snug” sign. A case of gross myxoedema showing the typical position in bed.

Diagnosis

Essentially myxoedema is a diagnosis made by clinical observation rather than by investigations; it is unlikely in a crisis that the practitioner would need more than the blood cholesterol level (and perhaps the basal metabolic rate and a photograph if easily available). For the sake of completeness here is a fuller list of investigations that may be helpful in supporting the diagnosis in doubtful cases.

Photographic Test.—Take a photograph of the face before and after six weeks' thyroid treatment. The change in appearance is usually sufficient to leave no doubt of the diagnosis (see Figs. 2 and 3). One patient, for instance, was not recognized by her grocer, with whom she had dealt for years, because her appearance had so greatly changed with treatment.

Blood Cholesterol.—The normal value is usually between 100 and 200 mg. per 100 ml. In nearly all cases of myxoedema there is a rise in this value to between 300 and 400 mg., or even higher. However, a normal value does not exclude the diagnosis.

Basal Metabolic Rate.—Classically the basal metabolic rate is lower than minus 30 to 40% by the time symptoms appear. The basal metabolic rate is a difficult thing to estimate accurately both because myxoedematous patients are often uncooperative and because the test demands special conditions, faultless apparatus, and repeated estimations by a very experienced observer. For these reasons a misleading figure is sometimes obtained, but this should not exclude a diagnosis made on clinical grounds.

Electrocardiogram.—The dry skin makes good records hard to get. The record sometimes shows bradycardia and usually reveals a low voltage of the QRS complex with flattening or inversion of the T wave. After treatment the electrocardiogram becomes normal.

Chest Radiography.—This reveals an apparently enlarged heart, but aspiration will show that much of the enlargement is due to pericardial effusion. With thyroid treatment the enlarged cardiac shadow returns to normal.

Iodine Excretion.—The urinary excretion of radioactive iodine is followed for 48 hours after a dose of 10 mc. of I^{131} with

FIG. 2

FIG. 3

Fig. 2.—A case of myxoedema admitted with an acute psychosis, before treatment. Fig. 3.—Same patient as in Fig. 2 after six weeks' treatment. (The loss of facial hair after treatment was only an indirect effect of the administration of thyroid. The improvement in the patient's social consciousness led to the use of a razor.)

10 mg. of potassium iodide. When hypothyroidism is present the values in the 24-48-hour period are abnormally high because the thyroid gland is less greedy for iodine than normally, but in myxoedema caused by antithyroid drugs the avidity of the thyroid for iodine is increased unless the antithyroid drug is still being given.

Temperature Chart.—There may be a low temperature, ranging between 96 and 97° F. (35.6-36.1° C.). A chart of this kind may help in suggesting the diagnosis, but the inconstancy of low temperature in myxoedema makes it of little value as a diagnostic test.

Blood Count.—Anaemia is usually found. In the blood count alone there is nothing diagnostic, for any of three types of anaemia may be shown: (1) a true macrocytic pernicious anaemia responding to liver in the usual fashion; (2) true hypochromic iron-deficiency anaemia responding to iron; and (3) a normochromic anaemia which responds neither to liver nor to iron but improves very slowly with thyroid.

Other Tests.—Among other tests the urinary ketosteroid excretion may be lowered, the protein-bound blood iodine diminished, the cerebrospinal fluid protein increased, the blood carotene raised, and the response of the blood sugar to intravenous insulin delayed. These tests are not essential for diagnosis.

What the Patient Says

Usually, despite all the diagnostic tests, the most convincing confirmation of the diagnosis lies in the spontaneous remarks of the patient or her relatives after treatment. For example: "My husband says I look ten years younger";

"I feel different, I speak different, and I am like what I used to be." A barmaid said to me, "I usen't to know how many light ales the boss had ordered and my customers used to say, 'What's come over you, Lyd? You're like an old frog,' but now they say, 'You're back to your usual self, Lyd.'" This same barmaid told how before treatment she found she had lost her power of repartee which she found so necessary in dealing with jovial regulars, and it was the return of this gift which pleased her more than anything.

Crises

1. Advanced Myxoedema

Any patient with advanced myxoedema is liable to die suddenly in the first few weeks of treatment before normal metabolism has been restored. The exact cause of death is not usually clear. The diagnosis of advanced myxoedema is easy if the patient is seen for the first time, but when a patient has been known for years the advanced condition may develop so slowly that a practitioner long acquainted with the patient can fail to notice it; the clinical newcomer has an advantage.

Before describing treatment, it must be underlined that in this (and the other crises of myxoedema) the ideal treatment is to prevent the condition ever reaching so gross a stage by diagnosing and treating myxoedema earlier.

The patient should be kept warm with plenty of bedclothes and hot-water bottles, because she is liable to develop hypothermia and go into an irreversible coma. Because of the liability to sudden collapse the patient should be moved as little as possible. People with gross myxoedema lie huddled in a torpid hibernating condition, and they should be allowed to stay thus without bothering them with much washing, visiting, or investigations. Thyroid should be started with a dose of $\frac{1}{2}$ gr. (32 mg.) twice daily for ten days and then be increased to $\frac{1}{2}$ gr. three times daily for the next week. After that the dose can be increased slowly to that level which maintains clinical improvement without overdose. This dose usually lies between 2 and 3 gr. (0.13 and 0.2 g.) a day. The clinical improvement and the blood cholesterol level help to assess the dose. Palpitations, anginal pain, diarrhoea, and undue loss of weight are indications that the dose is too large. Thyroxine has recently come on the market and can be used instead of thyroid. It has the theoretical advantages of a pure substance—certainty in action and constancy of dosage, 0.1 mg. corresponding roughly to 1 gr. (65 mg.) of ordinary thyroid; however, thyroid tablets in practice seem so efficient and certain that their general use continues.

The complications of myxoedema which can lead to crises are: myxoedema coma, acute psychosis, heart failure, intestinal obstruction, anaemia, gall-stones, and relapse.

2. Coma

This condition occurs only in fairly gross myxoedema and is often fatal. V. K. Summers reported five cases, all of them fatal. The coma may develop within a few hours, or deepen gradually for two days. The cause of the coma is uncertain, most cases have a very low temperature and the condition occurs more often in winter, so hypothermia may play a part.

It is hard to be dogmatic about treatment, because the coma is so often irreversible and treatment ineffective. Of the two cases I have seen that recovered, one came round from her coma in a few hours before thyroid had been given and thereafter progressed on $\frac{1}{2}$ gr. (16 mg.) of thyroid

twice a day, whereas the other case (which Dr. C. G. Barnes, of Hillingdon Hospital, kindly invited me to see) made a good recovery after being given 10 gr. (0.65 g.) of thyroid on the first day. Probably all that can be done is to treat the patient as already described for severe myxoedema, but if she is too deeply comatose to swallow, thyroxine sodium, 0.05 mg., can be injected subcutaneously instead of giving thyroid $\frac{1}{2}$ gr. (32 mg.) by mouth.

3. Acute Psychosis

Quite commonly an acute psychosis may result in the patient being first diagnosed as a mental case and dealt with under the Lunacy Acts. A. J. Cronin gave a vivid account of this complication in his book *The Citadel*, and it was clearly described in 1888 by the Clinical Society of London. I reported 14 cases in 1949 and have encountered eight more since. Almost any type of psychosis may occur, and the diagnosis is made on the myxoedematous appearance of the patient and not on the kind of mental symptoms. The commonest variety of psychosis is general confusion and disorientation, with persecutory delusions and hallucinations.

As there is a prospect of mental recovery within one or two weeks, the patient need not be transferred to a mental hospital if she can be managed at home or in a mental observation ward. Thyroid can be started at $\frac{1}{2}$ gr. (32 mg.) twice a day, or, if the myxoedema is not very severe, at 1 gr. (65 mg.) twice a day. Amylobarbitone, 3 gr. (0.2 g.), or paraldehyde, 2 dr. (7 ml.), may be needed at night to allay restlessness. Within a week or two the psychotic symptoms may have cleared almost completely, though if the condition has been long established mental improvement may be incomplete.

4. Heart Failure

Heart disease can occur in myxoedema because the heart is enlarged by myxoedematous infiltration of the heart muscle and because there is quite often a pericardial effusion. In addition, there may be coronary atheroma because of the high blood cholesterol. The clinical picture is that of myxoedema with the addition of dyspnoea, venous distension of neck veins, and pitting oedema.

If the myxoedema is gross it is probable that the heart failure will respond to thyroid; this should be given as already described in the treatment of gross myxoedema. In addition, digitalis should be given, 3 gr. (0.2 g.) three times during the first day, 2 gr. (0.13 g.) three times during the next day, then 1 gr. (65 mg.) three times a day for a week. If there is a pericardial effusion it should not be aspirated as it will absorb with thyroid treatment. Patients with myxoedema sleep well, so no sedative may be needed. If necessary, phenobarbitone, 1 gr. (65 mg.), can be given at night; morphine should not be given, as it may produce stupor.

5. Intestinal Obstruction

Subacute intestinal obstruction can occur as a complication of myxoedema owing to the constipation which is part of the disease and also to the myxomatous infiltration of the gut wall. One of my patients (the woman shown in Fig. 1) came in as a surgical emergency with subacute intestinal obstruction, and three other such cases have been seen at the Central Middlesex Hospital. The condition clears up with thyroid treatment. Naturally it is important to see that the obstruction is not caused by some unrelated condition such as strangulated hernia or carcinoma of the colon.

Thyroid is given as described already and a saline enema of 1 pint (570 ml.). Digital evacuation of the rectum is necessary if there are very hard scybala there.

6. Anaemia

It is unlikely that anaemia will be severe enough to be labelled as a crisis, but it may by its presence add to the critical condition of the patient.

Thyroid should be given whatever the type of anaemia if myxoedema is present. Other treatments depend on the

kind of anaemia. If there is iron deficiency the blood picture is that of hypochromic microcytic anaemia, and iron should be given by mouth as ferrous sulphate tablets, 6 gr. (0.4 g.) three times a day. If the blood picture shows true pernicious anaemia with macrocytosis and megaloblasts in the peripheral blood the case should be treated with vitamin B₁₂, 200 μ g. by intramuscular injection monthly. Before initiating treatment with vitamin B₁₂ it is advisable to confirm the diagnosis of pernicious anaemia by a sternal puncture and by reticulocyte counts, which should rise to a peak on the sixth day after treatment. Transfusion should not be given for the anaemia of myxoedema, because of the liability to heart failure.

7. Gall-stones

The incidence of gall-stones is increased in myxoedematous people, so the crises of gall-stones—that is, cholecystitis and gall-stone colic—may complicate the picture of myxoedema. The treatment of gall-stones is not a matter for this article, but the associated myxoedema should be treated in the usual way.

8. Relapse

It is, unfortunately, common for people with myxoedema to stop taking their thyroid and relapse into a condition of advanced myxoedema complicated by any of the crises which have just been outlined. The reason is that patients feel so well after a few months' treatment that they think there cannot still be any need to continue it. Once a patient stops taking thyroid the mental slowing prevents her noticing her own deterioration. It is important, therefore, to explain most carefully to the patient and her relatives that the illness requires treatment indefinitely, because, unlike most illnesses, it is caused not by something wrong being present, but by something right being absent.

(Fig. 1 is reproduced by permission of *Medicine Illustrated*.)

Next article on Emergencies in General Practice.—"Fits," by Dr. Denis Williams.

THE B.P.C. AND THE NATIONAL FORMULARY

A PHARMACEUTICAL SOCIETY LECTURE

The publication of the *National Formulary*, 1955, which was the subject of a leading article in our last issue (p. 402), a few weeks after that of the *British Pharmaceutical Codex*, 1954, has been arranged so that both compilations can be accepted for National Health Service purposes on the same date. In a lecture delivered by Dr. K. R. CAPPER, Ph.D., B.Pharm., a member of the Codex Revision Committee, at the Pharmaceutical Society of Great Britain on February 14, an interesting account was given of the work which lay behind both these publications.

Dr. CAPPER reminded his audience that to a large extent the *Codex* was produced by pharmacists for pharmacists, although many doctors served on the revision committee, and many doctors consulted the *Codex* for information, especially on the newer drugs. On the other hand, the *National Formulary* was a joint production by doctors and pharmacists, and was in fact a prescribers' handbook, easy to use in the crowded surgery hours of the general practitioner and in the dispensary of a retail pharmacy.

English or Latin Titles

The *Codex*, following the lead of the *British Pharmacopoeia*, had used English for the main titles of its monographs, whereas the *National Formulary* had reverted to an arrangement based on Latin titles and abbreviations of Latin names. Dr. Capper explained that this was the result of differently constituted committees dealing with similar

but not identical problems. Latin was officially discarded for medico-pharmaceutical purposes when the first *British Pharmacopoeia* used English instead of Latin for everything except titles. Latinized titles had some value because some of them, although by no means all, were identical with those used in other countries, but many of the traditional drugs to which these titles applied had fallen into disuse, and the newer drugs had never had such titles. The antibiotics, the antihistamines, the newer hypnotics, and narcotics, and the sulphonamides and other drugs were known only by their English names, and thus the advantage of retaining Latin titles for the older drugs became less than the disadvantage of coining Latinized names, which would never be used, for the newer ones. Many of the monographs in the *Codex* referred to *British Pharmacopoeia* substances some of which had not been given Latin titles in the *Pharmacopoeia* itself.

In the *National Formulary* the arrangement had reverted to that used in the 1949 edition. The Joint Formulary Committee, said Dr. Capper, bowed to the resolutions of many important medical and pharmaceutical bodies. The Committee was not backing Latin in the *Formulary*, but it was recognizing "that by far the greater number of prescriptions are written in a type of shorthand which is often an abbreviated Latin, but sometimes could equally well be abbreviated English. It is these abbreviations to which practitioners and pharmacists are really attached—the abbreviations which appear on prescriptions, on the shop rounds in dispensaries, and, with some irrelevance, on the little drawers behind the counter."

Some 400 formulae had been deleted from the formulary section of the *Codex*; over 900 had disappeared from current editions within a few years. The omissions consisted mainly of preparations of vegetable drugs, and of pills, effervescent granules, and other types of preparation which had largely fallen into disuse. To look through the formulary section of the *Codex* of 1934 was to realize the great changes which had occurred in the nature of pharmaceuticals in two decades. Of the 86 new formulae included in the new edition many were identical with or similar to those which had been deleted from the recent *British Pharmacopoeia*.

New Monographs in the "National Formulary"

In the *National Formulary* 45 new monographs had replaced 62 deleted from the 1949 edition. The reaction of the medical press to some of the additions, said Dr. Capper, deserved special consideration. This concerned in particular certain mixtures deleted from previous editions which had been reinstated either because frequency-of-prescribing surveys had shown that they were still often prescribed or because there had been strong requests from medical practitioners for their inclusion. The Committee had, in fact, reinstated only a few of very many formulae from old formularies that were still prescribed—in two counties alone there had been 96 mixtures and 67 other preparations in this category—and only when the evidence that these preparations were greatly in demand was indisputable. Dr. Capper welcomed what the *British Medical Journal* had said about the new *National Formulary*. "It may stimulate a discussion which will help the Joint Formulary Committee and eventually the pharmacists who have to use the book it produces."

Another criticism of the *Formulary* was that it contained no equivalents for certain popular proprietaries composed of freely available drugs. It could hardly be expected that the Committee would include these formulae if it did not consider them therapeutically sound. "In any case," said Dr. Capper, "it is a much better procedure if the medical men on the Committee decide how they want the drug presented for use, in tablet, injection, mixture, or linctus, and let the pharmacists develop a suitable formula. Such a formula may or may not resemble a proprietary medicine; if it does, it can be taken as an indication that great minds think alike." The idea that a patient would have no

confidence in what his doctor prescribed unless it resembled some well-known proprietary medicine seemed to be based on a completely unreal conception of the doctor-patient relationship.

The lecturer concluded by remarking on the immense amount of work put in by the members of the revising committees. The Codex Revision Committee had 16 members, and its subcommittees a membership of nearly one hundred.

JOHN HUNTER AND SURGICAL RESEARCH SIR CECIL WAKELEY'S ORATION

The Hunterian Oration was delivered before a large assembly at the Royal College of Surgeons on February 14 by Sir CECIL WAKELEY, whose theme was "Hunter and Surgical Research." He described Hunter as a pioneer in experimental surgery and the first to establish an experimental research station. This was at Earl's Court, then largely open country, where in 1763 he purchased 3½ acres of land, which had increased to 52 acres by the time of his death 30 years later. The orator read an impressive list of staff who came to be employed on the estate. Many species of animals were maintained, and Hunter's study overlooked a lion's den and a pond where he kept fish and frogs, eels and river mussels. How cheerful he was in this research environment was shown by a letter to his brother-in-law in 1775 in which he said, "My business is very nearly what I want because it very nearly gives me what I want," and added that he was "one of the happiest men alive." For a great part of his life Hunter seemed to be in some financial embarrassment, and, although when his estate was sold it realized over £10,000, yet after payment of debts and redemption of mortgages the amount at the disposal of his family was only a little over £1,000.

Some of the early experiments at Earl's Court were designed to prove what the surgeon could accomplish by grafting. Hunter believed that life in all animals was of the same nature however far apart zoologically they might be. It was natural to dwell on Hunter's successes, but perhaps an equal amount of instruction was gained from his failures. He was disappointed, for example, in his temperature experiments. He had the idea that life might be almost indefinitely preserved by refrigeration. The experiment failed, and yet freezing had now long been used in minor surgery and more recently in major surgery. Hunter, by the way, regarded 99° F. (37.2° C.) as the normal temperature of man. Readers of Hunter's lectures were inclined to smile at his explanation of how and why a useless piece of bone was absorbed, but the subject was still obscure, and it was necessary to postulate a susceptibility to some form of stimulation as yet unexplored. He studied the growth of antlers in deer, and came to the conclusion that in the animal body there was something which gave a new supply of blood to an actively growing part. One of his successful experiments followed an accident to himself in 1767, when he ruptured his tendo Achillis. This led to several experiments which laid the foundation of the modern practice of tenotomy. In 1785 he performed the operation of tying the femoral artery for the treatment of popliteal aneurysm.

After speaking of some of Hunter's pupils and how they had carried their master's teaching and methods to other schools and countries, Sir Cecil Wakeley said that were Hunter alive to-day his first concern would be the fate of his museum, which he desired to be preserved intact, not sold piecemeal. The Royal College had reason to be very grateful to the faithful guardians of the museum throughout the years, especially, in recent times, to Sir Arthur Keith and Professor Wood Jones, also to that great benefactor Sir Buckston Browne, who had made possible the research station at Downe, in Kent, an establishment after Hunter's own heart. Two priceless possessions Hunter would wish them to preserve, said the orator in conclusion, were his museum and his ideal of research.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Whither Natural Childbirth?

SIR.—Certain trends in maternity work are taking shape rapidly, and I would like to ventilate some of the problems before it is too late. The country is coming to demand for its expectant mothers elaborate explanation and instruction, with classes to increase the suppleness of the pelvic joints, to teach relaxation, and to rehearse for labour. There is a tendency to-day to introduce all these as a national policy as if benefit therefrom were an established fact, whereas I believe there are many who are uncertain of the wisdom of such a course. Has the matter been carefully enough thought out, discussed, and tested, or are we in danger of being rushed into its precipitate acceptance? Does childbearing require special training to be natural? To any other generation such a suggestion might seem absurd. Yet it is on just such a supposition that vast sums of public money are being expended to-day.

A baby does not have to be trained to defaecate, yet rehearsals for the second stage of labour are being taught all over the country.¹ In a normal labour the natural impulse to strain comes into action irresistibly when the head presses on the pelvic floor. The mother, without giving any elaborate thought to it, expels the foetus using the same mechanism as she has used day by day all her life for evacuation of the bowel. In both processes faulty timing, straining too soon, too hard, or for too long at a stretch, can impede progress. Surely, then, preconceived ideas about bearing down and practice beforehand will make it more difficult and not easier to achieve truly spontaneous evacuation. Cases where the second stage is not capable of being completely spontaneous are relatively few, provided patience is practised by those in attendance (a feat beyond the capacity of many doctors and midwives even to-day). Where teaching is required it can be given quite satisfactorily when the need arises—this would seem preferable to sacrificing the chances of an easy natural birth for the majority by training them antenatally just in case they should be in the minority group.

The first stage is not so easy to rationalize. It calls for considerable fortitude and endurance in many and varies enormously from person to person, and even from confinement to confinement in the same person. Any idea or ideal which can serve as a charm or banner during this ordeal may be given the credit by the patient for helping her win through. It is resignation as much as relaxation that is required, although the two may well go together. Practice beforehand may help some, but given implicit confidence in the attendant and the correct atmosphere of calm and reassurance, aided perhaps by sedation at the appropriate time, resignation and relaxation come naturally to a considerable proportion of mothers. This number includes many who are exceedingly tense personalities normally. Should we then be teaching relaxation as a necessary but difficult accomplishment which must be learned beforehand if a gruelling and painful labour is to be avoided? Is there not a danger that a fear of failure may be instilled in the mind of some mothers?

Does special training in fact increase the incidence of natural childbirth? Statistics can be misleading, but even more misleading are impressions on such a variable factor as morale. Many authoritative statements have been made²⁻⁶ pointing out that statistically⁷ no significant difference has been proved as between trained and untrained mothers in relation to length of labour, instrumental deliveries, or lacerations. Despite such strong backing this evidence still seems to require wider publicity. Only morale is then left. It hardly seems worthy of the mothers to-day and to-morrow that these very extravagant aids purely for their morale should be deemed necessary. Rather is it not a censure on those who look after them and whose duty it is to win their confidence?

There is, too, the possibility that the usual antenatal classes may in some cases actually do physical harm. The hazards of

instability of the pelvic girdle are of far-reaching importance and it may be that they are not receiving sufficient attention to-day. The widespread and time-honoured idea that increased mobility of the pelvic joints is so desirable is open to doubt.⁸

Another problem should be discussed. It is becoming customary to go into considerable detail in classes about the processes of pregnancy and labour and to illustrate them by pictures and diagrams. Is this intimate knowledge really necessary for an atmosphere of resignation and confidence in the first stage and for doing as nature dictates in the second? Knowledge when first acquired is seldom in perspective, but that is the quality of knowledge with which our mothers are in danger of being armed for their first confinement. It is unlikely that anyone without a previous background could obtain a balanced grasp of midwifery in a few months, still less should we expect a pregnant woman, who is already in a biased position, to keep a sense of proportion.

What training then, if any, is desirable for childbirth? There is one argument for antenatal classes which merits its full measure of praise. This is the opportunity to train women in good posture and muscle control. Although important, it may be questioned whether the antenatal period is the best time to introduce these problems. If we as a nation were more physique- and posture-minded, and if the physical education given in schools, and even better in evening classes in adolescence, were more enthusiastically supported, it would not be necessary to begin the teaching in pregnancy. The extra postural precautions necessary as the result of increased weight and altered centre of gravity could then be taught without special classes and post-natal rehabilitation would be more readily achieved. It might even be argued, as Nixon⁹ has already suggested, that the training required for childbirth is mainly the training which is desirable for life in general.

I am not writing to put forward any new theory; many authorities, as I have tried to show, have indicated somewhat similar lines of thought. Nor do I wish to underestimate the valuable pioneer work which has been done to wean women away from demanding painless labour, however artificial. I am writing because I believe more general and open discussion might be wise at this juncture.—I am, etc.,

Hove, 3.

Thinking Differently

SIR.—As many others must have done, I read with interest and delight in its literary style, scholarship, and clinical brilliance Sir Charles Symonds's Harveian Oration (*Journal*, January 15, p. 119). I felt as I finished the peroration, with its earnest exhortation to research, that under such leadership the future of medicine could not be as gloomy as that which Sir Heneage Ogilvie depicted for surgery in an address you published a few weeks previously (*Journal*, December 18, 1954, p. 1435).

But, as I thought about it, his suggestion that the State should now in the names of research pay physicians to sit and think started an ugly train of thought. Is this privilege to be extended to all consultants or only some? The context excluded the possibility that it was to be given to hard-pressed young registrars, the class most likely to produce new ideas were they able, like consultants, to shed their overload of routine work.

Most particularly in neuropsychiatry, the field in which Sir Charles so well earned his knighthood, the need, it seems to me, is not for more thinking or training along established lines but for new thinking. If we want new thinking without each man having to rediscover everything for himself teachers must give young men opportunity and encouragement, not only to dot the "i's" and cross the

"t's" of their own work, but to think differently from them, to make mistakes and try again, for "error is opinion in the making" (Bacon). Such a policy is inconsistent with a State service, and I venture to suggest that Sir Heneage's interpretation of the trend of the times is the correct one, and that as a historian Sir Charles is too long-sighted. If he plans further historical research he might consider the factors that led to the decline of the spiritual influence of the Established Church when good committee work and adroitly turned platitudes became the passport to rich benefices. More simply let him try and imagine Hughlings Jackson or any of his successors, whose original research still carries neurology, allowing attendance in committees to interfere with their work, or doing their thinking by the paid session.

I conclude regretfully that the effect of the oration is to adorn rather than advance the art of medicine, and would remind anyone to whom the proposal seemed attractive that it was written long ago that man cannot serve God and Mammon—in the same session.—I am, etc.,

Sistrans, Austria.

J. F. TUTHILL.

Surgery in Octogenarians

SIR,—In his article on surgery in octogenarians (*Journal*, January 29, p. 266), under the heading of "Anaesthesia," Mr. Ronald W. Raven mentions that respiratory depression is easily induced. Every anaesthetist will agree with this. I feel certain, however, that there are many who will consider that the doses of respiratory depressant drugs that he then recommends are surprisingly large.

In my experience with these old people the dose of "omnopen" for premedication should never exceed $\frac{1}{2}$ gr. (10 mg.) or pethidine 50 mg., and usually it is better to give atropine only. Sodium thiopentone may be used for induction, but should be given very slowly in a 2.5% solution with a maximum dose of 0.25 g. The intravenous injection of 50 mg. of pethidine following omnopen or pethidine premedication and thiopentone induction suggested by Mr. Raven will induce severe respiratory depression, at least in my hands. It is safer to give single doses of 10 mg. of pethidine in dilute solution and to assess the effect of each for 10 minutes before giving subsequent similar amounts. I appreciate that details of anaesthetic technique cannot be given in an article of this nature, but consider that inexperienced anaesthetists may have been misled by the dosage recommended.—I am, etc.,

London, E.C.1.

ROBERT I. W. BALLANTINE.

Recurrent Abdominal Pain

SIR,—The recent correspondence on the subject of chronic appendicitis and the résumé by Mr. A. Henry Millard (*Journal*, January 22, p. 230) failed to consider a particularly frequent cause of recurrent abdominal pain in the young. I refer to non-specific mesenteric adenitis. As reported elsewhere,¹ I have seen more than 100 cases of this syndrome in one year in hospital practice. Due to the recurrent nature of the symptoms, the usual diagnosis before admission to hospital was that of chronic appendicitis. Awareness of the frequency of mesenteric adenitis, however, and of its presenting features, enables a clinical diagnosis to be made in almost every case. Particularly important in this connexion is a deliberate attempt (bimanual pressure if necessary) to palpate the firm, bean-sized nodes through the abdominal wall.

Further, there does appear to be a significant relationship between mesenteric adenitis and appendicular disease. Gross abnormality of the appendix was a feature of 19% of 588 cases culled from the literature. Therefore, without inserting a finger towards the mesenteric root, the surgeon cannot be satisfied that an abnormal-looking appendix (unless it be acutely inflamed) is the source of the patient's symptoms. It is worthy of note that of 700 cases of mesenteric adenitis in the literature 84% had no recurrence of symptoms after laparotomy.

Dr. H. R. E. Wallis (*Journal*, January 15, p. 128) has illustrated the importance of tuberculous mesenteric adenitis as a cause of recurrent abdominal pain. It must be borne in mind, however, that the non-tuberculous form is many times more common. The radiologist must be the arbiter in distinguishing between the two. With regard to laparotomy findings, Heusser² and Freeman³ have shown that if the glands are not typically tuberculous to the eye or finger they are not tuberculous in origin. The plea raised by Aird,⁴ Apley,⁵ and others for a wider recognition of the non-specific mesenteric adenitis syndrome must again be reiterated.—I am, etc.,

SIR,—It is not often that a general practitioner actually sees the cause of recurrent abdominal pain, and this case might therefore be of interest.

The patient concerned first consulted me when she had right-sided abdominal pain for ten days, with nausea but no vomiting. On examination she was slightly tender in the right iliac fossa; her temperature was normal. I diagnosed a subsiding appendicitis and treated it accordingly. The pain became very much less and so did the tenderness, but I made an appointment for her to see a surgeon at the local hospital. One month after the first onset of pain she again complained of acute abdominal pain, this time more central, again with nausea but no vomiting, and no disturbance of the bowels. Her temperature again was normal, but this time she was admitted to the local hospital as a possible acute appendicitis. Again the pains subsided, and she was discharged after two days, but asked to return for a barium enema at the hospital. After the enema she came to see me and reported that two days before the enema she had felt something sharp when defaecating and on investigation had found a piece of glass, which she showed me. It was a jagged piece of clear glass about $\frac{1}{2}$ in. (12.7 mm.) long by $\frac{1}{4}$ in. (6.4 mm.) wide, such as might have come from a milk bottle or glass jar.

It is now five weeks since she passed the glass per rectum, and she has remained completely pain-free. The barium enema showed nothing abnormal. It seems probable therefore that the glass was indeed the cause of the pain, and the patient was rather fortunate in the outcome of the incident.—I am, etc.,

Purley, Surrey.

MAUREEN B. ADAMS

Obstruction from Orange Pith

SIR,—I have read with interest the cases reported by Mr. D. H. Sandell (*Journal*, December 18, 1954, p. 1484) and by Mr. N. H. Antia (*Journal*, January 22, p. 229), but do not agree that a bolus consisting of an unmasticated "quarter" of an orange could not pass through a normal pylorus. In 1941, while acting as Emergency Medical Service surgeon at St. Mary's Hospital, Highgate, a woman aged 50 was admitted suffering from obvious acute intestinal obstruction. She gave a history of similar (though milder) attacks over the previous 20 years. She was admitted during a night of almost continuous air raids, but her condition was so serious that it was decided to operate at once in the small emergency theatre. On opening the abdomen I found a stony hard mass in the lumen of the small intestine about 15 in. (38.1 cm.) from the ileo-caecal valve. The gut proximal to the obstruction was engorged and dilated. The intestine was opened and the mass removed. It was found to be a "quarter" of an orange fibrosed in the centre and covered with a dense layer of calcification. The patient made an uninterrupted recovery, and, on being told the findings, volunteered that she knew she had swallowed a large lump of orange when in her "teens." Subsequently she has had no recurrence of the colicky attacks she had suffered from previously. It would appear likely that the foreign body had been present longer than in the previous cases recounted.—I am, etc.,

London, W.1.

G. M. SANDES.

Bleeding from Tumours of the Small Bowel

SIR,—The interesting paper by Mr. T. A. Ogilvie and Mr. H. M. Shaw (*Journal*, January 15, p. 142) indicates clearly the various clinical manifestations of these tumours. May I emphasize more particularly one aspect of their presentation—that is, the occurrence of severe melaena? Two illustrative cases are as follows.

(1) A woman aged 38 had a right nephro-ureterectomy for tuberculous infection of the kidney in 1941. In 1949 she had a partial gastrectomy carried out for attacks of melaena due to duodenal ulcer. At the time of operation there was no evidence of a small bowel neoplasm. Her subsequent convalescence was uneventful until 1951, when she complained of attacks of central abdominal pain. In 1952 she was admitted as an emergency, having had a severe melaena stool, the first noted since the time of operation on the stomach in 1949. At the time of her admission her Hb was 8.2 g./100 ml. A barium meal and follow-through showed a high partial gastrectomy with some tenderness over the stoma, but no obvious ulcer. She had a further severe melaena and after massive blood transfusion the abdomen was explored. There was some thickening around the stoma but no obvious ulcer, and a vagotomy was carried out. Further exploration of the abdomen, however, revealed a mass in the terminal ileum with adjacent enlarged glands in the mesentery. The affected ileum and mesentery were resected and bowel continuity restored. Subsequent convalescence was uneventful, and the pathological report stated that the tumour was an ulcerated argentaffinoma with secondary deposits in the regional nodes of the mesentery. The particular point of emphasis is that the operation became a matter of urgency owing to the severity of the melaena while she was being investigated as an in-patient.

(2) A man aged 67; this patient complained of attacks of faintness and discomfort after food, associated with flatulence, for two to three years prior to admission. He was admitted with severe melaena as an emergency. There was no abdominal tenderness. There were no physical findings on examination of the abdomen, although his obesity rendered palpation difficult. His blood pressure was 160/65. It was considered that he had had a peptic ulcer with a recent exacerbation of inflammation, leading to melaena. He bled again soon after admission and operation was advised. At operation a pedunculated growth in the lumen of the gut about 3 in. (7.6 cm.) distal to the duodeno-jejunal flexure was palpated. Resection of the gut with end-to-end anastomosis was carried out. Convalescence was tardy owing to diarrhoea and some wound dehiscence. Pathological report on the tumour was that it was a simple fibroma.

It is not infrequent that prior to operation, and even afterwards, the final diagnosis of the cause of bleeding in the management of cases of severe melaena may be in doubt. As more cases of severe haematemesis and melaena are treated by immediate surgery, in the absence of obvious peptic ulceration or portal obstruction, the possibility of a neoplasm of the small bowel as being the cause of symptoms should be borne in mind.—I am, etc.,

St. Albans.

P. STRINGER.

"Rugger"

SIR,—Dr. J. Montgomery (*Journal*, February 5, p. 353) betrays a lack of appreciation which, in the twentieth century, is astonishing. Rugby football may cause occasional physical injury, but it differs strikingly from "Association" in that it never causes psychological trauma. Soccer is the supreme example of perpetual frustration. A player no sooner gets the ball than someone takes it away from him. The deprived person has no redress except to bump into his adversary (called "barging," I believe). Furthermore, 20 men have frequently to stand in impotent fury whilst one or other of two specially favoured players (called "goalies") handle the ball just as much as they like. If you want the ball in Rugger you go and get it, whilst in soccer you have to await its arrival in your part of the field.

But there are up-to-date reasons for thinking that Rugger actually confers psychotherapeutic benefits. There is a school of thought which believes it to be intensely beneficial for tired human beings to assume a healthy foetal position from time to time. I attribute my tranquillity of mind largely to the frequency with which, as a front row

forward, I assumed the vertex position, properly immersed in fluid medium, whenever the scrum collapsed on top of me on the Rugger pitch of a school famous for its mud (and its Rugger). At the most, soccer players never get beyond a few moments in the transverse lie—one that any psychologist would admit to be bad.

Let Dr. Montgomery should reply that the I.Q. of Rugger players is too low for the infliction of psychological trauma. I would add that when they play other games like cricket they have been found to develop depression and schizoid and paranoid tendencies in approximately similar proportions.—I am, etc.,

London, N.W.8.

J. C. HAWKSLEY.

SIR,—I am surprised that Dr. John Montgomery (*Journal*, February 5, p. 353) appears to take it for granted that more physical injury is produced by Rugby football than by Association football. Perhaps he can produce figures for this statement. I am also uncertain of the significance of the adjective "chivalrous" in relation to the more ancient game. Does he suggest that Rugger is not chivalrous, or does he really expect us to believe that all soccer players are inspired by a nobility of character unknown in other games?

I have always given extra credit in examinations to any student who has shown proficiency in some non-academic university activity, whether it be in games (especially "rough" games) or in such activities as debating, acting, or playing musical instruments. I am sure all sane teachers do the same by one method or the other. What kind of people does Dr. Montgomery desire to have as practitioners of medicine—a pack of lily-livered knights out of a Burne-Jones painting? Finally, I would be interested in Dr. Montgomery's reactions to Irish hurley, which perhaps as much as any other game trains the eye and muscles to act in perfect co-ordination. Many a good surgeon owes his skill to playing such games as much as to reading textbooks or listening to lectures. As for Rugby being responsible for the class war, let us introduce it to the Russians.

Would they tremble in the Kremlin,
Would they shudder on the Don,
Would the homeland break asunder,
Comrades rise in wrath and wonder,
If Russia took to Rugger
And won the triple crown?

(England having dropped out in order to return to her ancient, chivalrous, and noble national game.)—I am, etc.,

Belfast.

JAMES SCOTT.

SIR,—Dr. J. Montgomery writes (*Journal*, February 5, p. 353), no doubt, with his tongue in his cheek, and we are grateful for the entertainment value of his letter. But after the laughter has subsided we must pause to consider whether too much emphasis is being placed on the dangers accompanying activities which most of us have believed to be both health-giving and character-forming. And in any case, according to statisticians, two of the most dangerous occupations available at present are (1) crossing the road, and (2) staying at home. What can we do to be really safe?—I am, etc.,

Birmingham, 14.

P. R. KEMP.

SIR,—I sincerely trust that Dr. John Montgomery (*Journal*, February 5, p. 353) is edentulous in case his tongue should remain in the position it surely occupied in his cheek when he wrote under the above heading. Otherwise, had he the misfortune to meet one of these sadistic monsters of Rugger players he might suffer one of the injuries mentioned in Mr. O'Connell's article, referred to in your leading article (*Journal*, January 15, p. 154).—I am, etc.,

London, S.W.1.

J. C. DOWSE.

* * We understand that, teeth apart, Dr. Montgomery's tongue was partially displaced.—Ed., *B.M.J.*

Influenza

SIR.—I would like to support the views of Professor C. H. Stuart-Harris (*Journal*, February 5, p. 348) that there are in reality few, if any, clinical differences between the A and the B types of influenza. I say this from experience in general practice of three epidemics in 1950 (A), 1953 (A), and the recent 1955 B epidemic. The total number of cases is almost 650. It was quite impossible to detect any clinical differences in the symptoms and signs in these three epidemics; the only epidemiological difference was the fact that the maximal incidence in the one B epidemic was in children under 10 and in the two A epidemics it was in the young and middle-aged adults. In further support of the lack of difference between the two types an examination of the incidence and types of chest complications shows little difference.

Incidence and Nature of Chest Complications in Three Influenza Epidemics

	1950 A	1953 A	1955 B
No. of cases	233	264	150
Chest complications	43 (20%)	29 (12%)	15 (10%)
Acute bronchitis	6 (3%)	12 (5%)	4 (3%)
Pneumonia with clinical consolidation	4 (2%)	4 (2%)	4 (3%)
Pneumonia with no clinical consolidation	33 (15%)	13 (5%)	7 (5%)

These numbers are necessarily few, as they emanate from one single general practice and care must be taken not to draw any false conclusions, but there do not seem to be any real marked differences in the liability of the lungs to be affected in the two types of flu.—I am, etc.,

Beckenham, Kent.

JOHN FRY.

Subacute Oedematous Nephritis Treated with Malaria

SIR.—In her report of a case of subacute oedematous nephritis successfully treated with malaria (*Journal*, December 11, 1954, p. 1398) Dr. Ruth Porter states: "The explanation for the effectiveness of various infections, such as measles and malaria, in improving the course of oedematous nephritis remains obscure."

In my original report¹ I stated that the effect of acute febrile infection might be due to stimulation of the active defence phase of the general adaptation syndrome in which—among other observed effects—there occurs a greatly increased production of A.C.T.H. Support for this explanation is given by the findings of McCall and Singer,² who showed that there is a correlation between the level of corticoid excretion in the urine and the diuretic response to A.C.T.H. Children in whom the urinary corticoid levels failed to show a marked increase with A.C.T.H. did not discharge their oedema, while those patients whose excretions were high at some time during therapy underwent complete diuresis. They also observed that in nephrotic children who contracted severe infection the urinary corticoid excretion was within the same range as that reached by nephrotic patients who were receiving treatment with A.C.T.H. and who subsequently cleared their oedema. The corticoid excretion observed in minor infection was comparable with that obtained in patients receiving A.C.T.H., but whose subsequent diuretic response was unsatisfactory. The above-mentioned workers felt that their findings might explain why spontaneous loss of oedema is a frequent outcome of severe infection in nephrotics, whereas diuresis rarely results from a mild or moderate degree of infection.

The patient whose case I reported in 1952 has maintained a normal renal function since his treatment with malaria in 1949, and in two other cases, similarly treated, normal renal function has been restored, apart from a slight but transient albuminuria occurring in the course of acute infections.—I am, etc.,

Lancaster.

Kaposi's Varicelliform Eruption

SIR.—Drs. A. Girdwood Fergusson and W. A. Dewar (*Journal*, February 5, p. 352) are correct in asserting that Kaposi's varicelliform eruption occurs on skin damaged by conditions other than eczema. Dr. G. I. Barrow's paper (*Journal*, February 27, 1954, p. 482), to which I drew attention in my letter (*Journal*, January 15, p. 167), deals with this point in some detail. I must confess, however, that I am not very impressed by the other basic conditions quoted by my Glaswegian colleagues—impetigo, seborrhoeic eczema, infectious eczematoid dermatitis, and ichthyosis. Eczema occurs in two of the four conditions mentioned, and it is well known that the ichthyotic easily ecematizes (see Dr. Barrow's Case 3). I would suggest that it is as rare for Kaposi's varicelliform eruption to occur on basic pathological conditions other than eczema as it is for the Scot to recross the Tweed through failure to make a living amongst the English.—I am, etc.,

Bradford, 8.

ALLAN BIGHAM.

Agranulocytosis

SIR.—The interesting case of agranulocytosis recorded by Drs. H. E. Hutchison and Hugh Conway (*Journal*, January 22, p. 207) raises some interesting features. Many years ago, when amidopyrine was used very effectively in ameliorating the attack of measles, agranulocytosis was not recorded, but in these cases it was used only for four or five days. Accordingly, 50 adult volunteers were given 10 gr. (0.65 g.) of amidopyrine three times a day after meals for seven days, and the leucocyte count made every day. At the end of this time all were well and none showed any reduction in the count either then or subsequently. This suggested that, as has been pointed out by others, the majority of cases arise after marrow poisons have been taken for some time, and often in quite small doses.

With regard to the immediate treatment, in addition to penicillin the transfusion of fresh blood is of great value for obvious reasons, and this may have to be repeated in a few days' time.—I am, etc.,

Bristol, 8.

FREDERICK SUTTON.

The New Insulins

SIR.—The articles by Drs. J. M. Stowers and J. D. N. Nabarro (*Journal*, January 8, p. 68) and Dr. K. J. Gurling *et al.* (p. 71) represent an admirably full and critical survey of the clinical action of the insulin zinc suspensions. They show these preparations in perspective and allow an assessment of their value. The fact impresses itself that insulin zinc suspension is by no means the ideal insulin it was hoped to be. However, Drs. Stowers and Nabarro, having reviewed and compared the features of soluble insulin, protamine zinc insulin, globin insulin, and isophane insulin, in their summary maintain that insulin zinc suspension has definite advantages over the other preparations.

Their conclusions do not appear to me to be justified where they concern isophane insulin. This preparation, introduced in the U.S.A. about 1948, and in Britain late in 1953, has oddly enough received hardly any publicity in this country, probably owing to the simultaneous introduction of I.Z.S. Having used isophane (with the kind encouragement of Drs. D. E. Meredith and G. H. T. Lloyd) since November, 1953, and in more than 60 diabetics, I find it easily the most satisfactory one-shot-a-day insulin available and fully deserving its established popularity in the U.S.A. It has all the advantages claimed for G.I., I.Z.S., and S.I.-P.Z.I. mixtures, and practically none of their drawbacks. Direct comparison in some half-dozen patients who responded poorly to I.Z.S. showed smooth and rapid stabilization on isophane in the majority, generally on a lower dose.

Drs. Stowers and Nabarro allege two disadvantages of isophane: (1) early morning hyperglycaemia in some cases—I have not encountered this in any significant degree; and

(2) local sensitivity reactions in some cases. I recall two patients with mild rashes; these were transient and did not necessitate any modification of treatment. Moreover (as mentioned by Gurling *et al.*), I.Z.S. is not free from local reactions. More could be said in favour of isophane insulin, but your space is valuable and the only valid proof is, after all, practical trial. I feel sure that anyone who uses this preparation will rapidly become conscious, as I have, of handling the most smoothly effective insulin available at the present time.—I am, etc.,

Rhyd.

E. B. KRAUS.

Princess Louise Children's Hospital

SIR.—I note with dismay your announcement (*Journal*, January 29, p. 299) that proposals are being made to convert the Princess Louise Kensington Hospital for Children for adult use. I had the pleasure of working there at the time when the fate of Paddington Green Children's Hospital was in the balance. The outcry against that proposal was sufficiently vehement to achieve results, and I hope history can be repeated.

The practice of judging the work of children's hospitals by the size of their waiting-lists is widespread and cannot be too strongly condemned. Have the authorities not yet realized that children do not get waiting-list diseases? Do they not appreciate that, generally speaking, they are either acutely ill or not ill at all? If the paediatric beds in the country were decimated, the waiting-lists for them would scarcely increase.

The only fair criteria by which to judge the work of a children's hospital is by bed occupancy, and even then allowances must be made for seasonal variations in demand and closures due to infectious diseases which do not occur in adult wards. A visit to the less fortunate paediatric wards and hospitals, especially at this time of year, will often reveal children being discharged home prematurely and extra cots being put up in odd corners to accommodate acute cases. But there is still no waiting-list.—I am, etc.,

Leeds, 7.

R. W. SMITHELLS.

Disk Lesions and Low Backache

SIR.—The admirable clinical and pathological picture of the disk syndrome described by Mr. John Charnley (*Journal*, February 5, p. 344) is not, I think, so unorthodox as he would suggest. It certainly agrees very closely with my own teaching. But, though we are now getting a much clearer idea of what happens during the course of this condition, we are still in the dark as to why it happens.

An important point that he brings out is that all derangements of an intervertebral disk are primarily pathological in nature and can only occur after the tissues of the disk have become softened as a result of degenerative changes. We know that degenerative changes in the intervertebral disk are part of the normal ageing process. A generation ago, when "lumbago" and "sciatica" were almost the prerogatives of middle age, the clinical picture was a reasonable one—of an intervertebral disk in which degenerative changes were present finally giving way under stress. Now, however, an increasing proportion of cases seen are in the third decade or even younger. To explain such cases one must postulate the presence of some abnormal pathological process, and this is borne out by the soft "pulpy" condition of the tissues that is usually noted if operation is carried out in young people. The infective theory has now been discarded, and it is generally considered to be most likely that the cause is a metabolic one, and that it may possibly be incited by nutritional defects. But, since we are told that the nation as a whole has never been better fed than during the last 15 years, how can we explain the changing incidence of these conditions on any such basis?

Professor B. S. Platt's masterly article (*Journal*, January 22, p. 179) seems to pierce the gloom with the first real shaft of daylight. I use the word "gloom" thinking of the

sense of frustration that we all feel in treating an endless succession of symptoms without any real understanding of their cause, and hence no means of dealing with it. As an orthopaedic surgeon I believe that the investigations he describes will prove to be more important for the advancement of knowledge in my own subject than any other work now being carried out, and I would commend their study to all those who have to deal with these and allied conditions.

Incidentally, the publication of his paper at the moment provides a happy example of that most important function of your columns—namely, to help parallel lines of thought to meet.—I am, etc.,

London, S.E.1.

T. T. STAMM.

SIR.—Mr. J. Charnley does a great service by his paper on acute lumbago and sciatica (*Journal*, February 5, p. 344), which I have read with great interest. His theory of the mechanism of pain suggests to me two lines of treatment which have been advocated by Dr. Cyriax for some years—namely, spinal traction and manipulation. In paragraphs (4) and (5) under the heading "A Theory of Disk Pathology," the figures 5 and 6 would seem to be crying out to have their arrows illustrating centrifugal force reversed to a centripetal force by spinal traction. Who knows, this reversal might cut short the "tension episode." In paragraph (7) Mr. Charnley states that manipulation sometimes relieves the sequestrum type of lumbago. Although no mention is made of dural pain, could not a ruptured fragment of the annulus which is pressing on the dura be moved to a position of more comfort by manipulation? The time-honoured Kernig's sign and neck rigidity demonstrate that the dura is not insensitive to pain when pressure and tension are applied to it.

The protagonists in this correspondence seem to have resolved themselves into two camps (with some waverers): those who have tried Dr. Cyriax's methods and those who have not. I feel confident that Mr. Charnley's article will bring recruits to the Cyriax technique, for at the moment Mr. Charnley has nothing to offer but rest, morphine, and surgery. I make these comments with the plea that the prejudices which have surrounded manipulations of the spine for so long be cast aside, and that all those who have to deal with backache and allied conditions will not disregard the evidence¹⁻³ which so plainly points the way to easing the suffering of many.

Lastly, I wish to apologize to Mr. Charnley (*Journal*, January 15, p. 163) if my previous letter (*Journal*, December 18, 1954, p. 1488) suggested to him that orthopaedic surgeons were failing in their responsibility or that they were tending towards a dog-in-the-manger attitude. This suggestion, of course, was not intended.—I am, etc.,

Brough, Yorks.

LEONARD S. CALVERT.

SIR.—I would like to back up the letters of Dr. Leonard S. Calvert (*Journal*, December 18, 1954, p. 1488) and Dr. David B. Ramsay (*Journal*, January 8, p. 105) concerning the treatment of backache, acute and chronic, due to disk lesions together with sciatica as on the lines of the Dr. Cyriax technique. I myself would not go so far as to say that every case of lumbago is caused by a disk prolapse. I visualize that many patients in middle life who get sudden backache are suffering from sudden cracking or fissure of a desiccated disk with accompanying oedema or local haemorrhage. These are the cases which get well after a week or so of resting in bed, but which are cured quickly if treatment is carried out on manipulative lines as advocated by Dr. James Cyriax (*Journal*, January 15, p. 140). Before a diagnosis of a prolapse of a lumbar intervertebral disk lesion is made there must be a history of sudden pain and click while in the act of spinal flexion and compression, followed

by inability to stand erect. Lumbago is not a disease entity but a symptom and a sign of protective painful muscle spasm of the erector spinae protecting a spinal joint.

Before the derangement—be it a prolapse, a displacement, oedema, or adhesions about the damaged disk—can be manipulated or loosened, the guarding muscle spasm must be temporarily abolished so as to give the manipulator a better chance of localizing his manoeuvres to the affected intervertebral joint. For a year or more, in a hospital physiotherapy department of which I have charge, I have been giving all acute lumbago and sciatica cases having spasm of the back muscles—the erector spinae being seen as tight cords on forward flexion—mephenesin ("myan-esin"), 11 0.5-g. tablets a day for three days. While under the effects of this drug the patient attends the physiotherapy department daily and is given 15 minutes of infra-red and gentle massage to the back muscles; then, with the patient lying on his back, rotation of the lumbar spine is carried out by the patient and the physiotherapist fully flexing and adducting each hip across the abdomen five times, so that the patient's pelvis and lumbar spine are tilted backwards and rotated first to one side and then to the other (Cyriax manoeuvre). The hip in turn is then fully flexed by the patient grasping the knee, and, on a word from the assistant, who grasps the ankle, the leg is forcibly pulled out straight, thus jerking the leg, hip, pelvis, and lumbar spine. Doing this on the unaffected leg in sciatica is not painful, but the jerk is quite painful when the leg with the sciatic pain is pulled. This longitudinal jerking is repeated three times on each leg. Other manipulation manoeuvres are described by Dr. Cyriax in his book,¹ but we have found that, if a patient is going to respond to manipulation therapy, these two manoeuvres produce rapid improvement. A bad "lumbago" of a week's duration responds within a few days—often better after six treatments. A sciatica of a week or so's duration responds so that the sciatica is practically gone after a week except for residual tingling (evidence of root oedema), which may, however, persist for up to a month. If a case fails to respond after a fortnight, manipulative therapy is stopped and a plaster cast applied for two weeks. If this fails to relieve the sciatica, rest in bed with weight traction on the affected sciatic leg for ten days usually cures.

Laminectomy is a rarity now. With a fairly large annual turnover of backache and sciatica cases in several hospitals, I perform one or two laminectomies a year. Statistics showing control cases treated by manipulative, other physiotherapy methods, or rest in bed are difficult to produce until we can further define and be certain of the pathological conditions which we are treating—e.g., muscle sprain; disk lesion, fissure, or prolapse; osteoarthritis; sacro-iliac strain; or even fibrositis.—I am, etc.,

London, S.E.1.

G. O. TIPPETT.

SIR.—Having read the recent mass of correspondence from many experts on lumbago, I feel it is time some general-practitioner sense was cast on the problem of disk lesions.

I do not think that any general practitioner would deny that a cold draught can produce "fibrositis," but I would defy any orthopaedic specialist or physical medicine expert to state that a cold wind can prolapse a disk. As I see it, the pain which I still refer to as "fibrositis" is an end-product of prolonged constant tension of skeletal muscle and may well be a fatigue phenomenon. This can obviously be produced in a variety of ways, the most important being: (1) overworking (usually for about a month); (2) an underlying lesion which requires protection by immobility—for example, bone and disk lesions; (3) nervous tension; (4) stimuli from the skin (cold draughts, wettings, etc.). These can obviously operate singly or in any combination. In my experience it usually takes two to cause trouble.

It seems that the majority of cases of lumbar ache which occur in my practice get better in about a week, and seem to get some relief from heat, gentle massage, and aspirin. These do not seem to recur very easily unless the stress recurs. Those which do not so respond I presume to have an underlying lesion and usually refer to hospital, where they are nearly all diagnosed and confidently treated as disk lesions by the orthopaedic specialist. If an orthopaedic specialist were therefore to assess fibrositis on the basis of cases which I refer to him, he would undoubtedly

form the opinion that over 90% of cases are due to prolapsed disks. I am sure that the consultant here concerned realizes that he is seeing a highly selected group.—I am, etc.,

*Workington.

R. N. R. GRANT.

Tuberculous Patients in General Hospitals

SIR.—Dr. J. F. Brailsford (*Journal*, January 15, p. 164) strongly recommends that patients suffering from pulmonary tuberculosis be expelled from general hospitals in order to protect the nurses from infection. He suggests that the ideal place for the patient is his own home. I wonder if he has seriously thought how this could be carried out?

A man needing absolute rest for many weeks must present a very difficult problem in the home. How could he really rest and relax if he saw his wife becoming worn out looking after him, family, and house? How can Dr. Brailsford's conscience allow a tuberculous patient to be removed from adult nurses for their protection and yet be put into the home where, as like as not, there may be young children? The chances of their being able to receive the same full care and protection must be far less than the nurses'. How can the busy general practitioner possibly have time to cope with the numerous investigations and treatment that a tuberculous patient needs?

I can answer Dr. Brailsford from personal experience that no matter how capable and efficient the general practitioner is, no matter how good home conditions are, the patient cannot receive the same feeling of assurance and optimism that hospital and sanatorium give him, and I know that where I was fortunate enough to be treated the charming and capable nurses were looked after with great care. Finally, I would agree with Dr. A. B. Cowan (*Journal*, November 20, 1954, p. 1227) that the real answer to the problem is to "declare an all-out war against tuberculosis," but until that time comes the general hospital must still play its part.—I am, etc.,

Watton-on-Thames.

P. B. SCHOFIELD.

Sudden Death in Labour

SIR.—Dr. Patricia E. Campbell (*Journal*, January 8, p. 87) reported sudden death following an injection of procaine penicillin. This tragedy was ascribed to anaphylactic shock. While this may have been the cause, I think that it is more likely to have been due to the accidental injection of the substance into a vein.

Elsewhere a report was published¹ of the effect of deliberate intravenous injection of procaine penicillin into the saphenous vein of cats, and a whole range of symptoms from a transitory disturbance up to death were obtained, depending upon the amount of the drug injected in relation to the weight of a cat. The median lethal dose was found to be 100,000 units per kilogram of body weight and this finding was remarkably constant. Procaine penicillin is a suspension with particles ranging in size from 5 μ to 70 μ which appear to cause multiple small emboli in the pulmonary capillaries. Further intramuscular injections of procaine penicillin following severe but not lethal intravenous injections did not cause any systemic disturbance in the animal. This appeared to rule out the possibility of anaphylactic phenomena.—I am, etc.,

Consett, Co. Durham.

R. C. BELL.

REFERENCE

- ¹ Bell, R. C., *Lancet*, 1954, 2, 62.

Scurvy

SIR.—May I add yet a further case of scurvy to the one described by Dr. S. E. Levin (*Journal*, January 1, p. 46), but this time in a boy of 7 years? This must be an extremely rare occurrence nowadays, and the diagnosis was particularly surprising, as the lad was otherwise well nourished.

The boy was seen by me late one evening as an emergency, complaining of bilateral painful paralysed legs which had been

swollen all day. Actually there had been some aching behind the knees for nearly a week, but the puffiness had come up suddenly and the child could not bear to have his legs touched, and claimed that he could not walk. The legs were oedematous from just above the knees down to the ankles, and were tender to touch. Scattered petechiae were present around the lower third of the shins; temperature 99.4° F. (37.4° C.); pulse 96. The reflexes were normal. He was neither anaemic nor undernourished and there were no other abnormal physical signs. On questioning the parents, it appeared that he had had no fresh fruit for four months apart from an occasional apple; he had always refused to eat green vegetables and practically never drank fresh milk. X-rays of the legs were negative—even after a month. But the results of the ascorbic acid absorption test (dichlorophenol indophenol dye method) were confirmatory.

Ascorbic Acid Absorption Test, 300 mg. Intramuscularly

	Urine Concentration (mg./ml.)		
	Initial	After 2 Hours	After 5 Hours
Onset of illness	0.030	0.020	0.025
One month later	0.125	0.195	0.123

Clinically he improved on bed rest, tab. ascorbic acid 100 mg. daily, and orange juice *ad lib.*, but the absorption test after one month suggests that he is not fully saturated with vitamin C.

I wish to thank Dr. B. W. Powell, consultant paediatrician at the North Cambridgeshire Hospital, for his advice and for arranging the investigations.—I am, etc.,

Wisbech.

PETER CAVE.

Tests of Hearing

SIR.—The title of the statement about hearing tests to which Dr. Edith Whetnall refers (*Journal*, January 22, p. 227), and which you published for the Medical Research Council (*Journal*, January 1, p. 41), was "The Sweep-frequency Method of Making Screening Tests of the Hearing of Schoolchildren." The council did not ask me to draft a comprehensive statement on the ascertainment of defective hearing in childhood. The sweep-frequency method was recommended, in my statement and with the council's authority, for use by school medical officers in detecting defects of hearing among children which have escaped ascertainment during their pre-school life or have occurred without having been otherwise ascertained after their admission to school.

With financial support from the Medical Research Council, a clinic in which special provision is made for testing hearing in infancy and early childhood was established by the University of Manchester in the Department of Education of the Deaf in 1934. This research unit appears to have been the first of its kind, and the procedures that my wife and I have evolved for testing the hearing of children aged 3 months to 5 years have been reported in the *Journal of Laryngology and Otology*¹ and in our books.²⁻⁴ As Dr. H. Binysh says (*Journal*, February 5, p. 354), these procedures are being used in local authority clinics. Further study of deafness in childhood, in which senior members of the staffs of the Department of Otolaryngology and Education of the Deaf in this university are taking part, is at present in progress.—I am, etc.,

Manchester, 13.

Foreign Body in Kidney

SIR.—The cases described in your issue of January 22 (p. 205) by Dr. Duncan Macaulay and Mr. Thomas Moore remind me of the case of a child, aged 2, who demonstrated that "kirbigrips" can perforate other areas of the intestine than the duodenum.

Two years ago she was referred to the orthopaedic surgeon here because she was limping and had pain in the right knee and was unable to straighten the right hip. On

examination the knee movements were full but there was incomplete extension of the hip-joint, and a routine x-ray of the hip-joint showed a kirbigrip lying obliquely in the right iliac fossa with its blunt end about the middle of the iliac bone and the double end 1 in. (2.5 cm.) above and to the left of the umbilicus. Operation disclosed that it was lying in the ileum with the lower end passing through the ileocaecal valve and piercing the posterior wall of the caecum, forming an abscess in the ilio-psoas muscle. It was removed at operation in one piece with some little difficulty, as it had become so soft and eroded, but the child made a normal recovery after draining pus for some ten days or so. Post-operative leg movements were full and painless.

The feature of interest in this case was that the kirbigrip was so long relative to the size of the child that it is surprising that it was able to pass round the duodenal curve and did not present as a perforated duodenum with penetration of the kidney as described by Dr. Macaulay and Mr. Moore. Owing to the parents being immigrants with practically no English, no history could be obtained of the time when the pin had been swallowed, but its condition suggested that it had been present for a considerable time.—I am, etc.,

Rochdale.

A. M. McMASTER.

Eclampsia

SIR.—Marked interest in the subject of eclampsia has lately been shown in the correspondence in this *Journal* and by the refresher course article by Professor W. I. C. Morris (*Journal*, January 29, p. 279). It might be more profitable from the clinical point of view to establish the source of the toxin rather than to discuss conflicting hypotheses which have been forced into the Procrustean frame of endocrinology.

Having been interested for some 30 years in the origin of the toxins of eclampsia, I have tried to arrive at conclusions by taking into account a number of different observations which have been established independently. Among these, the absence of eclampsia among primitive tribes suggests that the toxin originates in environmental factors. Of these factors, the nutritional seem to be of prime importance. This is suggested by the long-established observations concerning on the one hand the relationship between eclampsia and the excess consumption of rich foods, and, on the other hand, the disappearance of eclampsia during the starvation period in Central Europe between 1916 and 1922. In my own practice I have not yet seen any case of eclampsia among subjects who were under strict dietary control during pregnancy. I have, however, noted in cases of eclampsia referred to me that invariably there has been some gross dietary error. It would seem that the detoxicating mechanism which may be adequate in non-pregnant women is not able to cope with excessive demands during pregnancy.

I have always advised low intake of overheated fats and salt. On the positive side, I have recommended liberal helpings of raw fruit, salads, and vegetables (roughage and vitamins), with proteins supplied by milk and lean meat.¹

It is likely, however, that the subject of eclampsia has been significantly advanced by the observations of Grauert.² This author noticed many years ago that, on opening the skull during necropsy of eclampsia cases, a typical smell of prussic acid (HCN) became noticeable. Following up this observation Grauert developed the view that endogenous cyanides may be involved in the aetiology of eclampsia.

In the normal course of metabolism of the foetus, cyanocompounds are produced in the breakdown of purine-rings. These compounds are normally innocuous, because they react with the sulphur of the HS-group of cystein to yield thio-compounds, a process which also takes place with the HCN formed in the intestines in the course of digestion. In the normal organism we find the innocuous potassium ferricyanide, which originates by combination of ferrous cyanide and ferrous cyanurate with potassium cyanide. This complex formation, neutralizing the liberated HCN, is

missing in the eclamptic condition. In the urine, serum, and saliva of the eclamptic patient thiocyanic acid—a product produced by the detoxication of HCN—is significantly raised. For instance, in the 24-hour urine it amounts to 0.15 to 0.35 g. (normally 0.03 to 0.05 g.), as precise qualitative and quantitative analyses have incontestably proved. For the rough clinical test the deep red colour obtained on the addition of diluted ferric chloride to the urine or saliva, which flow amply from the mouth during a fit, is sufficient.

The conversion of cyanide into thiocyanide—the actual detoxication—can be successfully brought about with the help of thiosulphate and/or cobaltinitrate. The specific action of the HCN is annulled by the nascent sulphur which combines with the cyanide radical when sodium thiosulphate is administered intravenously. Thus the noxious element of eclampsia is neutralized. In the pre-eclamptic, a few intravenous injections of 5 ml. of a 2½% sodium thiosulphate solution suffice. In severe cases, intravenous injection of 2 ml. of a 50% sodium thiosulphate solution in 10 ml. of a 20% dextrose solution are administered one to three times daily. The fits stop gradually or at once. There are no side-effects. In mild cases, one injection every second day is sufficient. Of 34 cases, including some seemingly moribund women, where this method was used, 32 were cured, followed by successful termination of the pregnancy.

The claims made by Grauert are so definite that the method deserves to be subjected to tests in this country.—I am, etc.,

London, W.1.

Tetanus Immunization

SIR.—In your annotation "Tetanus Immunization" (*Journal*, January 29, p. 278) you mention the difficult task of weighing the risks of horse serum against those of tetanus. Surely the risk of serum reactions would be greatly diminished by the routine subsequent active immunization of all patients who have received tetanus antitoxin. They would then just be given a booster dose of tetanus toxoid if prophylactic measures were required on a subsequent occasion (reactions following the injection even of tetanus toxoid do, however, rarely occur).

I do not know how many casualty departments pursue such a policy, which presents certain administrative difficulties, but it is a policy which we have in mind for the rather injury-prone population of a colony for mental defectives. It is to be hoped that the triple vaccine (whooping cough, diphtheria, tetanus) will prove its value and become more widely used. In the meantime, following the recommendation of Mr. T. C. J. O'Connell, referred to in your leading article (*Journal*, January 15, p. 154), football players might be added to the list of groups carrying a special risk of tetanus and thus being worthy of active immunization.—I am, etc.,

St. Albans.

M. P. NELSON.

Operator and Anaesthetist

SIR.—I think Dr. E. Schofield (*Journal*, February 5, p. 351) is either very unfortunate or else he grossly overstates his case. He says that competent dental anaesthetists "outside London and one or two other centres . . . do not exist."

I admit that the art and technique of dental anaesthesia in the chair is not an easy one to acquire, but it has a fascination of its own and it has attracted the attention of some of the most active minds among anaesthetists. The literature on the subject is copious and there must be few places in Great Britain where there is not someone who has not given thought, attended demonstrations, and acquired some proficiency in the art of dental anaesthesia.

The remuneration under the N.H.S. is inadequate, but many dental surgeons do their best to mitigate this by grouping their gas cases at a time convenient to the anaes-

thetist of their choice. By such co-operation I feel sure Dr. Schofield could avoid the added risk and heavy responsibility that he incurs in acting as both anaesthetist and operator in the majority of his cases.—I am, etc.,

Hove, 2.

REX BINNING.

SIR.—Dr. Eric Schofield has some very useful points to make in his letter (*Journal*, February 5, p. 351) on the subject of dental anaesthesia. There is, however, one part of his letter which I feel cannot pass without comment.

As a final-year student I feel qualified to write on current instruction in at least one big London teaching hospital. Dr. Schofield will, I am sure, be glad to know that there at any rate all medical students get special instruction in dental anaesthetics during their three-month appointment on anaesthetics in general. The instruction includes lectures and clinical work consisting of the giving of between 15 and 20 dental anaesthetics. Incidentally, they are also instructed in local dental analgesia and the extraction of teeth—including practical experience of both.—I am, etc.,

London, W.14.

J. ZORAB.

A Case of Pheochromocytoma

SIR.—The pre-operative localization of a pheochromocytoma is important in determining its surgical approach. In the patient described by Mr. R. A. C. Owen and Dr. G. H. Murray (*Journal*, February 5, p. 331) x-ray examination after perirenal air insufflation failed to show a tumour which at operation was found to be 3 in. (7.6 cm.) in diameter. As they imply, perirenal insufflation often fails to achieve its object, and in addition it carries a very definite risk of an air embolism.

Retroperitoneal (presacral) pneumography is a much more satisfactory alternative, its advantage being that both kidneys and suprarenal regions can be visualized with a high degree of certainty, and it is free from the risk of air embolism.¹ The procedure as described by Blackwood² was used in a case previously reported by my colleagues and myself.³ No difficulty was experienced, and the result was entirely satisfactory, since not only was the tumour accurately localized but the contralateral suprarenal was seen to be normal in size and contour. For the pre-operative localization of a pheochromocytoma retroperitoneal pneumography is, in contrast to perirenal air insufflation, a safe and a more reliable investigation.—I am, etc.,

Nuneaton.

Chloroquine Sulphate in Chronic Discoid Lupus Erythematosus

SIR.—We read with interest the article by Dr. H. J. Lewis (*Journal*, February 5, p. 329) on chloroquine sulphate in the treatment of chronic discoid lupus erythematosus. His results agree with our own published a year ago.¹ Since the publication of these, further trial with chloroquine sulphate has confirmed our opinion that it is the drug of choice in early cases of chronic lupus erythematosus.

We also note with interest his findings regarding the erythrocyte sedimentation rate (E.S.R.) during treatment. One of us² used this test in a series of 85 cases of chronic lupus erythematosus and found that as the disease improved the E.S.R. gradually decreased. It was shown that special attention should be paid to cases in which an E.S.R. of 10 mm. or over remained after apparently successful treatment, as these cases were most prone to relapse.—We are, etc.,

Obituary

G. E. MALCOMSON, M.D., M.R.C.P.

The sudden death in the street of Lieutenant-Colonel G. E. Malcomson, on January 24 came as a shock to his many friends, the more so as he was just about to go to Switzerland for his annual ski-ing holiday. He was 76 years of age.

Greer Edmund Malcomson, who was born at Belfast on September 30, 1878, came from a well-known Ulster family, and was educated at Owens College, Manchester, subsequently completing his medical training at Guy's Hospital. He graduated M.B. in 1902 and proceeded to the M.D. two years later. After holding house appointments at Guy's he joined the Indian Medical Service in 1906 and was posted to the 114th Mahrattas, serving on the North-west Frontier. Later he was attached to the 26th Punjab in Hong Kong, where he left the Service in 1913 on being appointed the first professor of physiology in the then New University.

On the outbreak of the first world war Malcomson asked to be relieved of his post, and in 1915 he re-entered the I.M.S. to serve in Mesopotamia until 1917. In 1919 he returned to India as superintendent of the Military Hospital, Karachi, but in 1921 he transferred to the civil side of the I.M.S. and became first physician to the Government of Madras and subsequently professor of medicine, with beds in the Government General Hospital. Here he gained a considerable reputation as a singularly astute diagnostician, and his services as a consultant were much sought. On study leave in 1927 he took his M.R.C.P.

When retirement was forced upon him in 1930 he found himself, like so many, at a loose end. The typical club life of a retired Army officer irked him badly, and in answer to an advertisement he began work at King's College, London, where he worked very full time with assiduous care checking the 7,000 references of McDowall's *Control of the Circulation of the Blood*, on the title-page of which his name appears. Later he assisted in research. His wealth of knowledge, his loyalty, his cheerfulness, and his patient hard work were a great example and made him beloved by all. From 1939 wartime conditions again found him engrossed in multifarious and voluntary duties, and in recognition of his work in the radium department he became a life governor of the Royal Free Hospital. During the last 10 years he continued to see a few old patients (some even came from India to see him), and he read voraciously. Always abstemious in his habits, he prided himself on his physical fitness, and continued to ski until quite recently. All who knew him will cherish his memory and regret his passing.

We are indebted to Lieutenant-General Sir ERNEST BRADFIELD for the following appreciation: Before Lieutenant-Colonel Malcomson became professor of medicine at Madras College he succeeded Colonel Donovan as professor of physiology there. In this appointment he maintained the high standard which his predecessor had built up in a department of preclinical teaching which could bear comparison with any in England. Malcomson was a quiet, unassuming officer, a first-class clinician, and a good teacher. He was popular with the students and had a large practice among both Europeans and Indians in Madras, where his devotion to his profession and to his patients was much appreciated. At one time he suffered from a detached

retina, and spent many anxious weeks of uncertainty, but seemed to recover completely. Until this eye trouble he hunted regularly with the Madras Hounds, and enjoyed the snipe shooting which was a feature of the cold-weather season in Madras. Since his retirement he maintained his interest in his profession by assisting in the writings of others, but published nothing himself. He had a small practice consisting of old patients, for whose benefit he never spared himself. His wife, a former Guy's sister, survives him.

F. BOLTON CARTER, M.D., M.S., F.R.C.S.

Mr. F. Bolton Carter, honorary consulting surgeon to Leicester Royal Infirmary, died on February 5, nine days before his 82nd birthday.

Felix Bolton Carter was born at Gravesend, Kent, on February 14, 1873, and received his medical training at University College Hospital, London. He qualified M.R.C.S., L.R.C.P. in 1895, but, with his mind set on a surgical career, he determined to widen his experience as well as to acquire higher qualifications. As the first step in this direction he took the London M.D. in 1897, and this was followed by the F.R.C.S. in 1899, the London B.S. (with first-class honours) in 1901, and the M.S. degree in 1902. For a time he worked as a ship surgeon, and his other early appointments included those of senior obstetric assistant at University College Hospital and senior house-surgeon at Halifax Royal Infirmary. He began his long association with the Leicester Royal Infirmary as a house-surgeon in 1901, retiring from the active staff 31 years later. When the British Medical Association held its Annual Meeting at Leicester in 1905 he held office as honorary local general secretary jointly with the late Dr. Astley V. Clarke, who died in 1945. To Bolton Carter and Clarke much of the success of the meeting—the only Annual Meeting of the B.M.A. to be held at Leicester—was due.

We are indebted to Mr. J. C. BARRETT for the following appreciation:

Mr. F. Bolton Carter came to the Leicester Royal Infirmary as house-surgeon in 1901 after a very distinguished academic career. He was appointed to the consulting staff in 1906 and was the first consulting surgeon as such, his predecessors having been general practitioners at one time or another, including his very well known senior colleague, the late Colonel C. J. Bond. Carter's brusque manner, decisiveness, and speed in operating are well remembered, and also his intense loyalty to his house-surgeons when medical matters were in dispute. He was essentially a general surgeon, for at this time there were no special departments at the Royal Infirmary other than the ear, nose, and throat and ophthalmological departments. He served with the R.A.M.C. in the first world war, principally at the 5th Northern General Hospital, which was situated in the buildings which are now the home of Leicester University College. He became senior surgeon of the Royal Infirmary in 1930 and was chairman of the medical staff committee until his retirement in 1932. From this time he was a regular attendant at the meetings of the board of governors until the inception of the National Health Service in 1948. Carter was a keen golfer and an equally keen bridge player all his life and was captain of the Leicestershire Golf Club from 1911–13 and president in 1914. Our sympathy goes out to his widow, three daughters, and son, who is now first assistant in the surgical unit at University College Hospital.

Dr. MURDO MACLEAN died suddenly on December 25, 1954, four years after his retirement from general practice and 48 years after graduating M.B., Ch.B. at Edinburgh University, and with his death there has passed one of the old

school of family doctors. He was 75 years of age. The second son of the late Mr. K. A. Maclean, headmaster of Tarradale Public School, Muir of Ord, he was himself originally destined for the teaching profession. After taking the M.A. in 1899 he turned to medicine and graduated M.B., Ch.B. in 1906. He then came to England as a resident at the Sunderland Royal Infirmary, and after a period as an assistant he settled in general practice in the mining town of Ashington, Northumberland, where he remained until within three years of his death. A member of the British Medical Association for 46 years, Dr. Maclean was chairman of the Morpeth Division in 1924-5 and again in 1938-9, and he was elected a vice-president of the North of England Branch in 1936. Having been a member of the Northumberland Panel Committee, he later served on the Northumberland Executive Council. During the first world war he held a temporary commission in the R.A.M.C.

H. S. B. and W. M. write: Fond as he was of the place of his adoption and of the people whom he served so faithfully for 40 years, Murdo Maclean never ceased to be a Highlander, making regular visits to Inverness, where one of his family still resides. His gentle voice with the soft Highland accent, coming strangely to English ears from so large a man, his never-failing interest in people and their doings, his strong conviction of the supernatural, all distinguished him as a Highland Scot. Though he played his part in administrative affairs it could not be said that he was a keen medical politician, but he could be relied upon to express a well-considered opinion on any important subject under discussion. He will, however, be better remembered by his friends and by his patients as a skilful and conscientious doctor, quiet, gentle, dignified, sympathetic to those in trouble, ready to enjoy a joke with the merry, upright in his dealings, and most generous to his friends. To a generation glibly talking of doctor-patient relationship and busying itself with form-filling or improved pay and working conditions, Murdo Maclean presented an example of the true ideal which is founded on the vocation to the service of the sick. It can indeed be said of him that he will continue to live in the memory of his friends in all stations of life. His wife died in 1952, but he is survived by his daughter, Dr. Mary Maclean, to whom we extend our sympathy.

The news of the accidental death from an electric shock of Miss GRACE LUKOSE on December 26, 1954, at the early age of 36 came as a great blow to her many friends, who believed that she was destined for a surgical career of exceptional distinction in her native country of India. Grace Mary Lukose was born in India on April 21, 1918, the daughter of Dr. Mary Poonen-Lukose, surgeon-general to the Government of Travancore. After graduating B.Sc. at Madras University, she followed in her mother's footsteps and entered as a medical student at the London School of Medicine for Women, where she graduated M.B., B.S. in 1946. She showed a special bent for surgery, and after returning to India and working at the Lady Hardinge Medical College, New Delhi, for two years she came back to England in 1949 to study for the F.R.C.S., which she obtained in 1951. Not long afterwards she was appointed assistant professor of surgery at the Lady Hardinge Medical College. She had recently been ill, and it was in Travancore that she was killed.

Dr. KATHLEEN M. LANE writes: Singularly free from any self-consciousness, Grace Lukose quickly made friends and entered into every aspect of university life. It was during the years of her second visit to England, when she resided at Canterbury Hall, that many of us came to recognize her unique qualities and to catch some of the gaiety of her infectious laughter. No one could be more jealous than she was for the position and dignity of medical women, nor more loyal than she to her friends and to the institutions to which she gave her affection.

The warden of Canterbury Hall writes: It is difficult to write of Grace Lukose without seeming to exaggerate her

lovely qualities, but the concern with which the news of her death was received by those who had known her in England showed the deep impression that her rich, vital personality had made on all who came into contact with her. We went to her with joys and troubles, and with her invigorating common sense and fine understanding, springing from her own inner serene faith, she was able to give us what we needed. Sincere, forthright, courageous, she spoke her mind or took action in the cause of truth or right wherever she felt it necessary. In her there was no sense of any difference between East and West: in her were the best qualities of each. Yet there was never undue seriousness: nobody could ripple into laughter and nonsense more easily than Grace. I was privileged to live for a while at her home in Travancore in 1952 and also to see her in Delhi, and I know how well loved she was in her own country and what a great future there seemed to be for her work in India.

Dr. G. R. F. STILWELL died at Beckenham Hospital on January 22 at the age of 87. George Robert Fabris Stilwell was born at Beckenham on August 30, 1867, the son of Dr. R. R. Stilwell, who was in practice there from 1857 until his death thirty years later, and the grandson of Dr. George Stilwell, of Epsom. G. R. F. Stilwell was educated at Epsom College and St. Thomas's Hospital, qualifying in 1891 and graduating M.B. London two years later. After holding house appointments at his teaching hospital and spending a year at sea as a ship surgeon, he entered general practice at Beckenham, where he was to remain in active practice for more than sixty years. He soon began what was to be a lifelong association with Beckenham Hospital, being made honorary medical officer to the hospital in 1900 and honorary consulting medical officer in 1911. He was early a member (later chairman) of the committee of management, and in 1934 he was made vice-president of the hospital. He was chairman of the medical staff committee for a number of years, and played a major part in planning the rebuilding and extension of the hospital during the 1930's. One of its wards was named after him in 1951. He was also chairman of the Beckenham and Penge Joint Maternity Home Committee which built for these two co-operating local authorities the hospital that is now the Beckenham Maternity Hospital. Dr. Stilwell was an active member of the British Medical Association, being chairman of the Bromley Division in 1924-5 and again in 1938-9. He was also president of the Kent Branch in 1930-1 and from 1943 to 1947. During the first world war he held the rank of captain in the R.A.M.C. and was in charge of a war hospital established in the district. In addition he was chairman of the local medical war committee, and for his wartime services was appointed O.B.E. in 1919. During the second world war he was again the mainstay, as chairman and secretary combined, of the local medical war committee, and this in spite of the fact that his own practice duties were considerably increased by the absence of his son on service. Dr. Stilwell was for many years chairman of the Kent local medical and panel committee. In this busy life he still found time to play a full part in the social life of the town. He helped to organize the Beckenham tennis tournaments, now one of the most important of the pre-Wimbledon fixtures, and he was a life-long member of the cricket club and a keen golfer. Horticulture and bell-ringing were among other hobbies which he followed and inspired others to follow. His was a full life, active to the end. He will be greatly missed and long remembered for all he achieved in extending the facilities for medical practice in Beckenham. He married Miss Edith Perks, and she survives him, together with a son and two daughters. The son, Dr. G. Denison Stilwell, joined, and now succeeds, his father in the family practice.—A. T. R.

The death of Dr. A. R. RENDLE on January 22 at his home at Godalming, Surrey, has severed a long connexion between his family, for some generations established at

Plymouth, and the medical profession. He was in his 84th year. Born at Saxmundham, Suffolk, on June 19, 1871, Arthur Russel Rendle was the fourth son of Dr. C. B. Rendle and the grandson of Dr. Edmund Rendle; his uncle was Dr. E. M. R. Rendle; his cousin, Dr. C. E. R. Rendle; and his elder brother, Dr. A. C. Rendle. An entrance scholarship took A. R. Rendle from Marlborough College to St. George's Hospital for his medical training, and he qualified M.R.C.S., L.R.C.P. in 1893. After holding the post of assistant surgical registrar at St. George's and a similar appointment at Leicester he went into general practice at Devonport, where, being keenly interested in the volunteer movement, he became surgeon-captain in the 2nd (Prince of Wales's) Volunteer Battalion of the Devonshire Regiment. He was also surgeon to out-patients at the Royal Albert Hospital. In 1902 he moved to the City of London to become a medical examiner for insurance companies, but in 1906 he gave up this work to join the Colonial Medical Service. Employed in Southern Nigeria, he gained much varied surgical experience, but he remained in Africa for only a few years. He took the Brussels M.D. in 1908, and in the following year re-entered general practice at Chichester. During the first world war he served as a captain in the R.A.M.C. in Malta, India, Mesopotamia, and Russia, where he was in command of the military hospital at Petschenga. While there he improvised out of a tobacco tin a practical form of ear speculum and mirror, which he described in the *British Medical Journal* in 1918. After the war he was in practice at Folkestone and Blackpool before he finally settled, in 1924, at Godalming, where he practised until 1946. In conjunction with a busy practice he held several medical appointments in the town, including those of examining surgeon under the Factory Acts and Admiralty surgeon and agent. He was also medical officer to St. George's Hill Military Hospital at Weybridge, and surgeon to Walton-on-Thames Cottage Hospital. One of the general practitioners of a more gracious age, Dr. Rendle had a whimsical sense of humour, and his scrupulous attention to the needs of his patients, coupled with unostentatious benevolence and a punctilious regard to the niceties of professional etiquette, contributed to his popularity with patients and colleagues. All his long life he enjoyed foreign travel and visiting the art galleries in Europe. As a young man he was a keen Rugby footballer and rifle shot, and in later life he enjoyed his game of bridge. He married his cousin, Miss Enid E. Cardew, the younger daughter of the Rev. F. C. Cardew, in 1897, and she survives him, together with the two sons and two daughters of the marriage.

Colonel GEORGE A. MOORE died on January 29 at the Princess Beatrice Hospital, Kensington, aged 85. George Abraham Moore was born in Dublin on March 24, 1869, the fourth son of Dr. William Moore, physician in ordinary to Queen Victoria and Edward VII in Ireland. His brother, the late Sir William Moore, was the Lord Chief Justice of Northern Ireland. Educated at Charterhouse School and at Trinity College, Dublin, he graduated M.B., B.Ch., B.A.O. in 1891 and proceeded M.D. seven years later. Immediately after qualification he entered the Army Medical Services. He served on the North-west Frontier of India and in the Tirah campaign of 1897, obtaining the medal with two clasps. Then he served throughout the South African war of 1899-1902, being decorated with the Queen's Medal and four clasps and the King's Medal and two clasps. When the first world war broke out he was allotted the task of organizing the ambulance train service for the B.E.F. As the authorities had not envisaged such luxuries as ambulance trains, this meant hasty improvisation with rolling stock begged or borrowed wherever it could be found—chiefly by conversion of the French vans with the familiar inscription, "Hommes 40, Chevaux 10." The result was a service which for some months was far below a proper standard—but better than nothing at all.

In the collection of rolling stock there is little doubt that some of his subordinates did not hesitate at what the Army called "scrounging." To this the French authorities objected strongly, and just as new and properly designed coaches, built in England, began to appear, Moore, who had done wonders with the slender resources at his disposal, was transferred to command No. 1 Base Hospital at Etretat, and later on became an A.D.M.S. That the Army valued his services was shown by his appointment as C.M.G. in 1916 and D.S.O. in 1918. In 1921 he retired with the rank of colonel, and started in general practice in Kensington, where he worked until his death. He took a special interest in ear, nose, and throat work. Moore was a remarkably handsome man with a splendid soldierly bearing, very good manners and address, and typical Irish *bonhomie*. He soon made many friends among his professional colleagues in London. He married in 1899 Helena Catherine Georgina, daughter of the late Deputy Surgeon-General G. Whitla; she died in 1946, leaving three sons and a daughter.

Dr. A. G. JAMES, of Castleford, Yorkshire, died in Pontefract General Infirmary on January 30, within a few days of his 58th birthday. Alan Gilbert James was born in Leeds on February 3, 1897. In the first world war he served as a combatant and was wounded. Rather later in life than usual he became a medical student at Leeds University, where he graduated M.B., Ch.B. in 1932. Having held resident appointments at the General Infirmary at Leeds and the Leeds Public Dispensary, he settled in general practice at Castleford in 1934, in partnership with his twin brother, Dr. E. James, who died six years ago. At the time of his death he was honorary secretary of the Wakefield, Pontefract, and Castleford Division of the B.M.A., an office he had held since 1947.

T.G. writes: The sudden and unexpected passing of Dr. Alan G. James was a shock to all his friends and colleagues. For twenty years his genial personality had endeared him to a wide circle. In addition to the work of a strenuous industrial practice, his activities, among other things, included membership of the local hospital management committee and medical committee of the West Riding of Yorkshire, as well as the council of the Association of Police Surgeons of Great Britain. He was a very efficient honorary secretary of his B.M.A. Division, and will not easily be replaced. The deep sympathy of all who knew him is extended to his widow and two children.

Dr. BERNARD MYERS writes: All old friends of Mr. J. HARDIE NEIL—whose obituary was printed in last week's *Journal*—will deeply regret his passing. During the first world war he held the reputation in the field of being an efficient and able officer for whom no trouble was ever too much, even in the great stress of work on the Somme: he was esteemed by officers and men alike. In the intervals between the fighting Hardie Neil went to much trouble to organize entertainments for the troops, which they greatly appreciated. I was A.D.M.S. to the 1st N.Z.E.F. at the time and aware of his fine qualities as a man, a surgeon, and a good fellow. After Neil's return to Auckland, New Zealand, he did some fine work on the anatomy of the lung and gave unstinted services to the New Zealand League for the Hard of Hearing. He will be sadly missed by his many friends.

Dr. R. J. C. HUTCHINSON died suddenly at his home at Wiveliscombe, Somerset, on January 25 at the age of 42. Ralph John Charles Hutchinson was born on March 30, 1912, and qualified by taking the L.M.S.S.A. in 1945. After qualification an appointment at Willesden General Hospital was followed by short periods of practice in various parts of the South of England, until finally he settled at Wiveliscombe, near Taunton, towards the end of 1949.

R.S.H. writes: The sudden loss of John Hutchinson deprives the West Country of one of its most able general practitioners and a man of sterling quality. Not only was

he most fully versed in the techniques of his profession, but he had "the root of the matter in him." Each case was an individual problem to be considered in all aspects, and his notes—in that crabbed and difficult hand—were complete in all essentials. To be consulted by John was both an honour and a test. He was loved and trusted by his patients—and with justice. Their interests were his, and he brought a critical but most charitable and fearless mind to bear upon their problems. Life was not always easy for him, but he met it with gallantry and fortitude. His spirit will live on in the loving memory of his friends. We are the richer for having known him: the poorer for his passing.

Medico-Legal

DAMAGES FOR LOSS OF WIFE

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On February 9 in the Queen's Bench Division of the High Court Mr. Justice Devlin gave judgment¹ for £2,650 damages for the loss of his wife and dancing partner to Mr. Robert William Burgess. Mrs. Burgess had died in January, 1953, as the result of an injection of what was admitted to be an accidentally lethal dose of adrenaline by Miss Emily Catherine Lewis, F.R.C.S., at the Florence Nightingale Hospital. The issue before the court was not liability but damages.

Mr. Burgess had started dancing with the deceased in 1942 when he was 25, and after considerable success as amateurs they turned professional in 1948. By January, 1953, when Mrs. Burgess died, the couple were nearly at the peak of their professional success. Mr. Burgess had found his wife's skill as a dancing partner substantially irreplaceable and was losing professionally as a result of her death some £500 to £750 per year.

Mr. Justice Devlin assessed Mrs. Burgess's value as a dancing partner in terms of gross income at £2,500, her value as a wife at £1,000, and the loss to Mr. Burgess of her contribution out of their joint income to their joint living expenses at £1,000. The value of her contribution to the support of her mother and daughter was assessed at £300 and £350 respectively.

Mr. Justice Devlin held that the damage suffered by Mr. Burgess for the loss of his wife as a dancing partner was not recoverable under the Fatal Accidents Act. To recover, it had to be shown that the benefit which the plaintiff had enjoyed arose out of the relationship. In this case the relationship of husband and wife was incidental to and superimposed upon their business partnership, and, if the claim under this head was allowed, logically any partner whose prospects were affected by the death of a partner, whatever their relationship, ought to be allowed to recover. The husband, however, was entitled to recover for the loss of the wife's contributions to their joint income. No doubt a century ago husbands paid all the expenses and a wife's earnings were treated as pin money, but that conception did not fit in with the way Mr. and Mrs. Burgess's life had been conducted. Both earned and contributed equally, and Mrs. Burgess was in the same position as if she had kept her money separately and then handed it over.

Where a husband and wife had a joint income and lived together and shared expenses and so had expenses which were less than if they had lived separately, each conferred on the other a benefit arising out of their relationship of husband and wife and its loss was therefore recoverable under the Fatal Accidents Acts.

The Medical Protection Society instructed Messrs. Le Brasseur and Oakley, solicitors, to act for Miss Lewis.

¹ *The Times*, February 10, 1955.

Medical Notes in Parliament

HOSPITAL BUILDING PLANS ANNOUNCED

The MINISTER OF HEALTH told Parliament on February 9 of the Government's plans for increasing the rate of hospital building in England and Wales. In sum they represent estimated Exchequer expenditure in 1956-7 of some £13m. and in the following year of £18m.—an increase on current expenditure in the first period of about 50% and in 1957-8 of 100%.

Mr. IAIN MACLEOD stated that it was proposed to expand the building programme in two ways, first by the starting of a number of new major building projects, including new hospitals, and, secondly, by a special allocation of money for a plant replacement and redeployment programme. It was not thought that any significant increase in capital expenditure on major schemes could be achieved in the 1955-6 programme, which remains unaltered.

It was proposed in 1956-7 and 1957-8 to start major new building projects to a total value of £7½m. and £10m. respectively. For the plant replacement and redeployment programme £2m. would be available in the first of these years and £4m. in the second. Quite apart from these amounts, there would be £9m. available in 1956-7 and £10m. in 1957-8 for capital expenditure on other works. The Minister said that these figures covered only work financed from Exchequer funds. He hoped that a fair amount of hospital building work would be financed from other sources during this period, but he could not give an estimate of what this figure might be.

The Minister explained that full discussion with the hospital boards would be necessary before all the projects could be settled. The boards concerned had already been asked to bring to completion the planning of a first batch of major projects, to a total value of some £7m., and these would almost certainly be among those started. They included new general hospitals, or the first stages thereof, for Welwyn, West Cumberland, West Cornwall, Harlow, and Swindon; the development of the Glangwili Hospital, Carmarthen; a new mental hospital near Wolverhampton; major extensions at mental deficiency hospitals in the Newcastle, Sheffield, and Liverpool regions, and in Wales; new out-patient departments at the Royal Victoria Infirmary, Newcastle, the Leeds General Infirmary, the Lewisham, and North Middlesex Hospitals; a new block at St. James's Hospital, Balham, and major extensions to the Peterborough Memorial Hospital. Considerable expenditure was also likely to be needed during the period for making good structural defects at the Manchester Royal Infirmary.

Examples of the type of project he had in mind to start within the next few years were the new Cardiff teaching hospital, the rebuilding of Charing Cross Hospital at Harrow, a new ward block at Guy's Hospital, new general hospitals at Slough, Boston (Lincolnshire), Coventry, and Sheffield, and new mental hospitals in Lancashire and Yorkshire, but he could not at present say which of these would be started in 1956-7 and 1957-8. He added that the Government believed that these outline proposals represented what could reasonably be achieved over this period, and they represented also the first programme of new hospital building in this country since before the war.

New Allocations

The cheers with which this announcement was welcomed were followed by a string of questions seeking to amplify points in it. In his answers to these Mr. MACLEOD made it clear that the new programmes were distinct from the normal capital allocations to regional boards, which would be maintained and in the second year increased by £1m. The teaching hospital at Cardiff retained its first priority in England and Wales for a completely new teaching hospital. But it was an enormous project, nowhere near ready

yet—the architectural competition had not taken place—and it would therefore be the wildest guess to say when it would be started. Whether the new Charing Cross Hospital, to be built on the site already obtained at Northwick Park, Harrow, would get into the 1957-8 programme was uncertain, but it stood a very good chance. He was not unduly worried about the staffing side of the new building and extensions. With all the difficulties, there had been a steady increase since 1948 in the numbers of staff, and it would be easier to attract staff to good new hospitals than to old ones.

Scottish Hospitals

A corresponding increase in the rate of hospital building in Scotland was announced by Commander T. D. GALBRAITH, Under Secretary, Scottish Office. He said the total provision would be increased from the present level of £1.9m. this year and next to £2.2m. in 1956-7 and £2.5m. in 1957-8. Of the extra funds thus made available £50,000 in the first year and £150,000 in the second would be used to supplement the programme of plant renewal, on which £800,000 would be spent in the three years 1955-8. The balance would be used to increase the number of major building schemes, and he expected it would be possible to put in hand schemes to a total value of £3m. during these three years.

In 1955-6 a start would be made on a new maternity hospital at Bellshill, Lanarkshire, a new surgical block at Kirkcaldy, and the reconstruction of a mental hospital in Dundee. Details of the subsequent programme had still to be settled in consultation with the regional boards, but among the projects to be considered were extensions to mental deficiency institutions in Banff and in the Glasgow area, a new treatment unit at Glasgow Western Infirmary, reconstruction of the Edinburgh Royal Mental Hospital, and improvement of hospital facilities in Shetland. Detailed planning work would also be put in hand for other schemes to start in 1958-9 and succeeding years, including the provision of a completely new teaching hospital in Dundee.

M'NAGHTEN RULES DEBATED

The House of Commons, having at long last on February 10 debated the report of the Royal Commission on Capital Punishment, decided that the death penalty must remain. It did so by a majority of 31 votes, rejecting by 245 to 214 on a free vote the only alternative before it—the proposal, moved by a Labour Member and seconded by a Conservative, that for an experimental period of five years convicted murderers should be sentenced to life imprisonment.

The arguments pro and con have been widely canvassed since the issue arose in the debates on the Criminal Justice Bill in 1948, and little new was added by those who spoke on this occasion. Some, but not many, had changed their opinions. Among these were the Home Secretary, Major G. Lloyd-George, and his Labour predecessor, Mr. Chuter Ede, who introduced a touch of personal drama by the admission that in the case of Evans, found guilty of the murder of his infant daughter but not tried on the second charge of murdering his wife, he had made a mistake and sent to the gallows a man who was not guilty as charged.

Major LLOYD-GEORGE, stating the Government's provisional views on the major recommendations of the commission, accepted the minority view that there were strong objections to raising from 18 to 21 the age below which the death sentence might not be imposed; and rejected as unworkable the proposal that juries should be given discretion to decide whether there were extenuating circumstances to justify substituting life imprisonment for the death sentence.

The third main recommendation related to the criterion of criminal responsibility when a defence of insanity was raised. The majority of the commission, he recalled, took the view that the present criterion in the M'Naghten Rules was so defective in the light of modern medical knowledge that it ought to be changed, and that the best course would

be not to frame a new criterion but to dispense with any criterion and leave it to the jury to decide whether, at the time of the act, the accused was suffering from any disease of the mind or mental deficiency to such a degree that he ought not to be held responsible. Three members of the commission dissociated themselves from this recommendation on the ground that, while the Rules were in some respects inadequate, a formula had the advantage of limiting the arbitrary element and promoting uniformity, but to have no formula would leave the decision to the uncertain variation of ethical standards and emotional reaction which might influence the minds of the jury. These members set out their own formula in the commission's report. The Government's view was that in England some formula was essential. They recognized that the M'Naghten Rules were open to criticism (although the commission recognized that their theoretical defects led to little hardship or injustice in practice); they were impressed by the difficulty of framing a satisfactory amendment on the Rules and the wide differences of opinion, and they took the view that no advantage would be gained by disturbing the present position and that it was better to leave matters as they were.

Defect of Will

Mr. BASIL NIELD (City of Chester, Con.), Recorder of Salford, said the fundamental and perplexing problem was what must be proved to establish insanity which would amount to a defence. The M'Naghten Rules said that there should be shown to be a disease of the mind—which was clearly right—but that, having established a disease of the mind, the defence must continue so as to prove a "defect of reason" of the sort described. It was around these words that controversy had raged. Might there not be not merely a defect of reason but a defect of will which should constitute a defence? He had always doubted the rightness of the decision that an uncontrollable impulse was not a defence. If there was a disease of the mind which rendered a man incapable of resisting an impulse, he could not in logic see why that was not a defence. The principal argument against any alteration of the M'Naghten Rules seemed to be: they have worked well for a long time; they have been liberally interpreted, and indeed stretched by the jury if circumstances appeared to require it. He could not support the proposal that the Rules should be abrogated and the question left to the jury to say whether they found insanity or no. A formula should be devised so that the jury might have an objective standard by which to decide, and he inclined to the other proposal that the Rules should be extended to add that insanity was proved if disease of the mind rendered the accused incapable of preventing himself from committing the offence.

Irresistible Impulse

Dr. REGINALD BENNETT (Gosport and Fareham, Con.), who said he had been in practice as a psychiatrist examining offenders on remand—although not on capital charges—said it must be faced that the M'Naghten Rules were dangerous and misleading and only approximately did the job for which they were intended. He used as an illustration of how misleading they could be the case of a man suffering from a depressive psychosis. But no substitute formula could be found. The concept of the irresistible impulse (which was suggested by the B.M.A. in para. 264) immediately raised the point of the irresistible impulse and was not the best way to evaluate the less obvious forms of derangement. The idea of the principle of irresistible impulse was a good one, but it would entangle a jury in a welter of hypothetical motivations and provide a happy hunting-ground for insincere pleas of irresistibility. It was too subjective a test. Juries were not qualified to split hairs on psychiatric issues, but they were qualified to judge sanity and to recognize conduct within normal limits, and could be expected to see the prisoner objectively. He suggested, as a modification of the M'Naghten Rules, that if the answers to the first two existing questions—whether the man knew

Vital Statistics

Influenza

In the great towns of England and Wales the number of reported influenza deaths was 106 in the week ending February 5, a decrease compared with the preceding week of 17. Most of these deaths were of people aged 65 and over. Decreases were reported in all regions except the north-western, midlands, and London and south-eastern. There is still no sign of any spread of virus-A infection.

Smallpox in France

Up to February 9 the number of cases reported in the Vannes area of the Morbihan Department was 67, including 15 deaths. 52 of the cases are among hospital patients. The last cases were notified on January 31. Over 2 million persons have been vaccinated in Morbihan and the four adjacent Departments. No additional cases have been reported from the Vosges Department since the two cases notified last week.

Smallpox in Belgium

Up to February 10 two confirmed cases of smallpox have been notified at Spa (on January 31 and February 2).

Week Ending February 5

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 791, whooping-cough 2,213, diphtheria 16, measles 12,729, acute pneumonia 1,157, acute poliomyelitis 13, dysentery 979, paratyphoid fever 7, and typhoid fever 8.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the nine years 1946-54 (influenza, 1952-4) are shown thus - - - - -, the figures for 1955 thus ———. Except for the curves showing notifications in 1955, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The incidence of infectious diseases rose in England and Wales during the week ending January 29. The largest increases in the number of notifications were 3,659 for measles, from 7,038 to 10,697, 235 for whooping-cough, from 2,002 to 2,237, 196 for dysentery, from 482 to 678, 133 for acute pneumonia, from 929 to 1,062, and 95 for scarlet fever, from 650 to 745.

The largest increases in the number of notifications of measles were 656 in Yorkshire West Riding, from 808 to 1,464, 481 in London, from 656 to 1,137, 477 in Lancashire, from 1,910 to 2,387, 292 in Derbyshire, from 214 to 506, 240 in Cheshire, from 367 to 607, 187 in Essex, from 353 to 540, 150 in Nottinghamshire, from 319 to 469, 147 in Gloucestershire, from 120 to 267, 138 in Surrey, from 138 to 276, 105 in Warwickshire, from 267 to 372, and 104 in Lincolnshire, from 128 to 232. The largest fluctuations in the trends of whooping-cough were rises of 36 in Lancashire, from 181 to 217, and 31 in Essex, from 52 to 83, and a fall of 42 in Kent, from 141 to 99. The largest rises in the incidence of scarlet fever were 22 in London, from 37 to 59, and 22 in Yorkshire West Riding, from 55 to 77. 23 cases of diphtheria were notified, an increase of 15 on the total for the preceding week. Multiple cases of diphtheria were notified in Yorkshire East Riding (Kingston-upon-Hull C.B. 6), Cheshire (Birkenhead C.B. 3), Devonshire (Plymouth C.B. 2), and Lancashire (Whiston R.D. 2). 5 of the 9 cases of typhoid fever were notified in London (Islington 4, Hampstead 1).

23 cases of acute poliomyelitis were notified, and these were 1 fewer for non-paralytic and the same for paralytic cases as in the preceding week. The largest returns were Essex 5 (Braintree R.D. 5) and Yorkshire West Riding 4.

The increase in dysentery was mainly contributed by Lancashire, where 121 more cases were notified than in the preceding week. The largest centres of infection were Lancashire 224 (Oldham C.B. 51, Manchester C.B. 31, Royton U.D. 21, Liverpool C.B. 17, Blackpool C.B. 16, Stretford M.B. 14, Morecambe and Heysham M.B. 10), London 74 (Southwark 12, Chelsea 11), Yorkshire West Riding 54 (Sheffield C.B. 18, Leeds C.B. 14), Norfolk 44 (Norwich C.B. 20, Blofield and Flegg R.D. 18), Durham 37 (Whickham U.D. 9), Lincolnshire 28 (Scunthorpe M.B. 26), Leicestershire 23 (Leicester C.B. 20), Glamorganshire 23 (Cardiff C.B. 19), Northumberland 22 (Newcastle-upon-Tyne C.B. 14), Middlesex 21 (Edmonton M.B. 13), and Berkshire 20 (Easthampstead R.D. 20).

Medical News

Hunterian Society.—Dr. W. S. C. COPEMAN presided over the annual dinner of the Hunterian Society on February 10, when the health of the society was proposed by the Lord Chancellor, Viscount KILMUIR, who said that Hunter was still a figure that enthralled us "over the arches of the years." He recalled that it was in 1819 that the society took its present name three weeks after a meeting in a City tavern called the King's Head. After Dr. COPEMAN had replied Dr. W. GORDON SEARS proposed the toast, "The Lord Mayor and Corporation of the City of London." Sir SEYMOUR HOWARD responded. Professor A. E. RICHARDSON, the President of the Royal Academy, replied to the toast of "The Guests," proposed by Sir ARTHUR PORRITT.

Hunterian Festival Dinner.—On February 14, for the first time, the Hunterian Festival Dinner at the Royal College of Surgeons was attended by Fellows and Members of the College as well as by the College council and their guests. For the first time also the dinner was held in the Great Hall of the College, where some hours earlier the Hunterian Orator, Sir CECIL WAKELEY, had delivered his oration (see p. 474). The large and distinguished company included two of the visiting Commonwealth Prime Ministers and two Ministers of the Crown. After the President of the College, Sir HARRY PLATT, had proposed the Loyal Toasts and "The Memory of John Hunter," which was honoured in silence, Lord ADRIAN, O.M., P.R.S., proposed the health of the College. He foresaw a time when to match the advances of an electronic age the objectives of surgery would have to change. The College might find itself organizing a great replacement service for worn-out organs of every kind. The surgeon would be found sitting at his desk surrounded by punch-cards and electronic devices. But, reassuring his audience, Lord Adrian predicted with equal confidence that there would still be patients and they would still continue to be grateful. Replying, the President of the College spoke on the meaning to surgeons of the Hunterian tradition. It was not true that after 150 years John Hunter was a mere shadow and the Hunterian tradition something of a mystique. Hunter had lived a life of insatiable curiosity and experiment—"an empiricist in a splendid age of reason." "British surgery," said Sir Harry Platt, adapting a phrase of Whitehead about current philosophy, "consists of a series of footnotes to John Hunter." Since Moynihan's day the College had returned to experimental surgery in the Hunterian tradition, and the future of the College lay in its ability to maintain its leadership in ideas. Professor LAMBERT ROGERS then proposed the health of the many guests, who included the Prime Minister of New Zealand (Mr. S. G. HOLLAND), the Prime Minister of the Federation of Rhodesia and Nyasaland (Sir GODFREY HUGGINS, a Fellow of the College by examination), the Minister of Health (Mr. IAIN MACLEOD), Lord WAVERLEY, and the High Commissioners for Australia, India, New Zealand, and Rhodesia and Nyasaland. Lord WOOLTON, Chancellor of the Duchy of Lancaster, replied. The evening concluded

with the proposal of the health of "The Hunterian Orator," coupled with the name of Lady WAKELEY, by Mr. JULIAN TAYLOR, and a brief reply by Sir CECIL WAKELEY.

World Health Organization.—The W.H.O. Executive Board has had to be content with recommending acceptance by the Eighth World Health Assembly of a budget for 1956 of a little over 9.6 million dollars. Although this is a small increase on this year's figure, it will not maintain the Organization's programme at so high a level, and the Board is dissatisfied with the position. Reflecting its anxiety about current methods of malaria control, the Board passed the following resolution among its other business: "In view of the fact that certain types of malaria-carrying mosquito are already showing resistance to insecticides, all threatened countries should be urged to plan total malaria eradication before it is too late." Another decision is to call, with the United Nations Food and Agriculture Organization, a conference of experts on food additives. The Board declares as the reason for this conference "the potential health danger from the increasing number of chemical substances added to various foodstuffs." Other activities of the Board were described in our issue of February 5 (p. 365).

Edinburgh Mental Health Week.—In Edinburgh February 6-12 was designated a Mental Health Week, with the objects of interesting the public in mental health and sickness and of recruiting nurses to the mental hospitals of the region. The Ministry of Labour and the regional hospital board were initiators and co-ordinators of the recruiting campaign. publicity was handled by the Scottish Information Office, and the staffs of the hospitals concerned were responsible for the detailed planning and performance of its main features of public interest. Many statutory bodies and voluntary organizations assisted. The two principal events were a cinema show, where an address was given by a psychiatrist, laymen's questions were answered by a medical team, and films were shown (including "The Troubled Mind"); and an exhibition, entitled "Mental Nursing To-day," which ran for four days in a large shop in the centre of the city. Over 7,000 people visited the exhibition in its first three days.

Hospital of St. John and St. Elizabeth.—On February 9 Cardinal GRIFFIN, Archbishop of Westminster, opened a new 18-bedded children's ward at the Hospital of St. John and St. Elizabeth, St. John's Wood, London. The ward cost £27,000.

Royal College of Surgeons.—At the Council meeting on February 10 Honorary Fellowships were awarded to Dr. LOYAL DAVIS (Chicago), Mr. WILLIAM DOOLIN (Dublin), Professor ROBERT JAMES (Toronto), and Professor PAUL SANTY (Lyons). Professor A. B. MACGREGOR (Birmingham) was appointed Charles Tomes Lecturer for 1955, and Dr. N. M. CASS lecturer in physiology. The annual meeting of Fellows and Members will be held this year in Manchester on December 10, when there will also be clinical demonstrations and a scientific discussion.

Tuberculosis Grant.—The Scottish Branch of the National Association for the Prevention of Tuberculosis offers a grant of £250 for postgraduate study abroad to a doctor working in Scotland. Details from 65, Castle Street, Edinburgh, 2, not later than April 1.

The Duke of Edinburgh has accepted an invitation to become the first Honorary Fellow of the Pharmaceutical Society of Great Britain.

Cortisone for Acute Leukaemia.—On a recommendation from the Medical Research Council, the Ministry of Health will supply to hospitals cortisone and A.C.T.H. for the treatment of acute leukaemia.

Mental Health Research.—£3,300 has been raised by a B.B.C. appeal for the Mental Health Research Fund.

Music Therapy.—The renowned violinist, FRITZ KREISLER, and his wife have given \$500 (£180) to the Music Service in Hospitals, which is an organization established to encourage and provide musical therapy in British hospitals.

Medical Orchestra.—The London Medical (and Dental) Orchestra, conductor Dr. H. Ucko, will welcome more players. Details from Dr. E. V. SLAUGHTER, 6, Oxford Court, London, W.3. The next concert will be a performance of Haydn's Passion, "The Seven Last Words," on Good Friday.

Sir Earle Page has been elected the first Chancellor of the recently established University of New England, New South Wales.

Dr. J. L. Blonstein has been appointed to the Medical Commission of the Association Internationale de Boxe Amateur.

Journal Index.—The half-yearly indexes to Volume II of the *Journal* and the *Supplement* for 1954 are now being sent to members who receive them regularly and to subscribers. Members who have not previously asked for the indexes can obtain copies, post free, on application to the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

COMING EVENTS

Doncaster Dinner.—The Doncaster Medical Society will hold a dinner and dance at the Danum Hotel on February 24 at 7 for 7.30. Tickets (£1.11s. 6d.) from Dr. P. J. SHIELDS, Roxboro' House, Carcroft, Doncaster.

Brompton Hospital Association.—Fourth dinner at the Waldorf Hotel, Aldwych, London, W.C.2, on April 15. Dr. G. E. BEAUMONT will preside. Inquiries to hon. secretary, Brompton Hospital, London, S.W.3.

Joseph Clover Lecture.—Professor W. W. MUSHIN will lecture on "Measurement in Anaesthesia" at the Royal College of Surgeons, Lincoln's Inn Fields, on March 23, at 5 p.m.

Daiby Memorial Lecture.—Mr. TERENCE CAWTHORNE will lecture on "Otosclerosis" at the Royal Society of Medicine on March 3 at 8.30 p.m.

National League of Hospital Friends.—Annual meeting and conference at Caxton Hall, Westminster, on March 9. The theme of the conference will be, "Leagues of Hospital Friends in Special Spheres" (The Aged and Chronic Sick; The Mentally Sick). Details from the secretary at 23, Knightsbridge, London, S.W.1.

Boat Race.—Messrs. Vitamins Limited have available a number of tickets for doctors who may wish to view the Oxford and Cambridge Boat Race on March 26 from the Bemax premises. Early application should be made to Dept. B.R.1, Vitamins Limited, 23, Upper Mall, London, W.6.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Sunday, February 20

GREY TURNER SURGICAL CLUB.—At Postgraduate Medical School of London, from February 20 to 23 inclusive, meeting.

Monday, February 21

HUNTERIAN SOCIETY.—At Mansion House, 8.30 p.m., Hunterian Oration by Mr. Lionel E. C. Norbury: Some Aspects of Life in the Time of John Hunter.

INSTITUTE OF PSYCHIATRY.—5.30 p.m., Dr. E. Stengel: lecture-demonstration.

Tuesday, February 22

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor A. C. Frazer: Fat Metabolism.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. E. J. Moynahan: Carcinogenesis.

LONDON UNIVERSITY.—At Anatomy Theatre, University College, 1.15 p.m., Dr. R. P. Kelvin: Missing the Point in Psychology.

MIDDLESEX COUNTY MEDICAL SOCIETY.—At Edgware General Hospital 3 p.m., Dr. F. E. Camps: Brute Force and Murderous Ignorance.

Members of the Harrow Division, B.M.A., are invited.

OXFORD UNIVERSITY MEDICAL SOCIETY.—At Radcliffe Infirmary, 8.15 p.m., Sir Cecil Wakeley: Surgery Through the Ages.

ROYAL STATISTICAL SOCIETY: STUDY CIRCLE ON MEDICAL STATISTICS.—At Westminster Medical School, 6 p.m., Dr. A. L. Cochrane: Medical Field Surveys.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Professor H. C. McLaren: Carcinoma of the Uterine Body.

SURREY INTER-HOSPITAL PSYCHIATRIC ASSOCIATION.—At Long Grove Hospital, Epsom, Surrey, 6 p.m., clinical meeting. Papers by Dr. A. Gillie: A Safe Technique in Modified E.C.T.; Dr. A. B. Monro: A Concept of Mental Health Derived from Recent Research.

Wednesday, February 23

BIRMINGHAM MEDICAL INSTITUTE: SECTION OF PSYCHIATRY.—At Child Guidance Clinic, 29, George Road, Five Ways, 5 p.m., clinical meeting. BRITISH PSYCHOLOGICAL SOCIETY: MEDICAL SECTION.—At Royal Society of Medicine, 8.30 p.m., Dr. R. A. J. Asher: Talk, Tact, and Treatment. INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Squamous Cell Epithelioma.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., Professor F. C. Ormerod: Hoarseness.

INSTITUTE OF ORTHOPAEDICS.—6 p.m., Dr. C. H. Lack and Dr. H. A. Sissons: Clinical Pathological Conference.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Dr. S. B. Osborn: Radiotherapy in Urology.

NOTTINGHAM MEDICO-CHIRURGICAL SOCIETY.—8.30 p.m., Dr. T. F. Fox: Medicine in Russia.

ST. MARYLEBONE HOSPITAL FOR PSYCHIATRY AND CHILD GUIDANCE.—5.30 p.m., Dr. C. C. Edwards: Functional or Organic? Differential Diagnosis.

THURSDAY, FEBRUARY 24

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. R. A. Kekwick: Plasma Proteins.

GLASGOW UNIVERSITY MEDICO-CHIRURGICAL SOCIETY.—At Glasgow University Union, 7.30 p.m., B.M.A. Lecture by Dr. W. N. Pickles: Epidemiology in Country Practice.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Mr. H. S. Williams: Physical Principles of Radiation Therapy.

LIVERPOOL MEDICAL INSTITUTION.—At Walton Hospital, Liverpool, 3 p.m., afternoon clinical demonstration.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Medical Society of London, 8.30 p.m., pictorial survey: Ocular Manifestations of General Disease; short film: Myasthenia Gravis. Speaker, Mr. Joseph Mintea.

NUFFIELD ORTHOPAEDIC CENTRE.—At Wingfield-Morris Orthopaedic Hospital, 8.30 p.m., Mr. J. C. Scott: Results of Conservative Treatment of Fractures of the Femoral Shaft.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Arnold Demonstration by Dr. F. Stansfield: Growth and Development of Bone.

ROYAL EYE HOSPITAL.—5.30 p.m., Dr. T. H. Whittington: Some Aspects of Refraction Work: (1) Normal Vision. Headache and Asthenopia.

ROYAL MEDICAL SOCIETY, Edinburgh.—At Charlotte Rooms, 8 p.m. to 1.30 a.m., annual ball.

ROYAL SOCIETY.—4.30 p.m., Dr. Wilson Smith, F.R.S., Dr. G. Belyavskiy, and Dr. F. W. Sheffield: Host Tissue Component of Influenza Viruses.

Dr. H. Halliday: Absorption of Antibodies from Immune Sera by the Gut of the Young Rat.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Medical School, Small's Wynd, Dundee, 5 p.m., Dr. D. P. Cuthbertson: Work of the Rowett Research Institute.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. J. H. Paterson: neurology demonstration.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.—At Physiology Theatre, 4.45 p.m., Dr. S. R. Elden: Respiratory Mechanisms in Bacteria.

FRIDAY, FEBRUARY 25

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. R. T. Brain: Precancerous and Epitheliomata.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., clinical demonstration by Dr. J. Smart: Pulmonary Tuberculosis.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—3.30 p.m., Mr. J. C. Hogg: Dysphagia.

●LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.—6.30 p.m., Dr. J. H. Sheldon: Old Age.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.—At 11, Chandos Street, London, W., 7.30 p.m., Dr. A. E. Wilkinson: Use of T.P.I. as a Verification Test in Suspected Latent Syphilis; Dr. P. J. L. Sequeira: Studies on the Reproducibility and Specificity of T.P.I.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—(1) 2 p.m., Mr. D. Lamb Stevenson: Some Illustrations of General Surgical Principles. (2) 4 p.m., Dr. J. J. R. Duthie: Systemic Manifestations of Rheumatoid Disease.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH.—3.30 p.m., Mr. Ian Fraser: Problems of Tumours of the Small Intestine.

●ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Professor Stanley Alstead: Therapeutics: Tropical Diseases.

ROYAL MEDICAL SOCIETY, Edinburgh.—8 p.m., Dr. A. G. MacGregor: Atomic Medicine.

ROYAL SANITARY INSTITUTE.—At Town Hall, Rhyd, 10.30 a.m., Dr. B. Rhyddwen: Whither Public Health? Afternoon, Mr. E. L. Lloyd Jones: Food Poisoning—Why?

SATURDAY, FEBRUARY 26

CAMBRIDGE UNIVERSITY MEDICAL SCHOOL.—10.30 a.m., Symposium: Infectious Diseases.

MEDICAL ASSOCIATION FOR THE PREVENTION OF WAR.—At 45 Russell Square, London, W.C.1, 8 p.m., Professor Taitai (Osaka University): Medical Aspects of the Atomic Disaster in Japan (illustrated).

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Ambrose.—On February 9, 1955, in London, to Sheila, wife of Dr. Gordon Ambrose, a son.

Feldman.—On February 4, 1955, to Nora, wife of Dr. A. Feldman, of 70, Petersfield Avenue, Harold Hill, Essex, a son—Mark Rosslyn.

Hamilton.—On Christmas Eve, 1954, at the Toronto Western Hospital, to Rosemary, M.B., B.S., wife of Thomas R. Hamilton, M.B., B.S., a son.

Price.—On February 8, 1955, in Calcutta to Kathleen (formerly Shaddick), wife of John Price, F.R.C.S., a daughter—Jane Elen.

DEATHS

France.—On January 16, 1955, Robert Scouler France, M.B., Ch.B., late of Merthyr Tydfil, Glam.

Geddie.—On January 25, 1955, in hospital, Colin More Geddie, M.B., Ch.B., of 59, Preston New Road, Blackburn, Lancs, aged 71.

Gimson.—On January 29, 1955, at Witham, Essex, Edward Carwardine Gimson, D.S.O., M.B., Ch.B., aged 77.

Hill.—On January 19, 1955, at the London Hospital, London, E., Nelson Wood Hill, F.R.C.S.Ed., aged 75.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Tin Poisoning

Q.—What are the signs and symptoms of tin poisoning? What records are there of poisoning by tin from the consumption of tinned foods?

A.—It is pretty generally agreed that tin and its simple compounds have little or no toxicity. As Von Oettingen¹ states, acute tin poisoning is very rare, but it has been reported from the ingestion of acid-canned herrings containing about 156 mg. of tin. The toxic symptoms started after a latent period of 5 or 6 hours and were characterized by severe colic, meteorism, oppression in the chest, and later by a metallic taste and constipation. In a few instances the continued absorption of small quantities of tin was followed by abdominal pain, nausea, constipation, and loss of weight. Some patients complained of sore throat and chilliness, mild fever, myalgias, and arthralgia, and some showed a moderate anaemia. The symptoms cleared up when no more tin was ingested. The elimination of tin from the body may be helped by the administration of sodium iodide.

Fairhall² states that tin is one of the least toxic of the common metals when ingested in the form of its salts. Relatively large quantities can be dissolved from acid materials preserved in tin cans without conferring any taste or flavour to food materials and without producing toxic symptoms. In an investigation made by Schwartz and Clarke,³ of the U.S. Department of Agriculture, four individuals were fed on canned pumpkin for five days, during which time they ingested as much as 2.75 grammes of tin. The quantity of tin absorbed was small and no adverse effects were noted. The intravenous injection of stannic and stannous salts in animals shows that the organs tolerate relatively high concentrations of tin and that the injected tin is rapidly excreted. The inhalation of tin oxide dust and fume over a long period produces marked radiological changes in the lungs simulating silicosis. The condition is known as stannosis and no symptoms have been noted as a result of it. It is comparable with the siderosis of welders and other workers inhaling iron oxide.

The subject of tin as a poison was reviewed recently in the *Journal*⁴ and attention was drawn to the toxic properties of organic salts of tin such as di-ethyl tin diiodide combined with linoleic acid or vitamin F. It is clear that such salts are much more toxic than the inorganic ones.

The Metallic Contamination Subcommittee of the Foods Standard Committee has set up a new limit of tin in canned foods of 250 parts per million, whereas the one recommended in 1908 was 286 p.p.m. It is pointed out that this limit has generally been regarded as satisfactory and that there was practically no evidence of cases of poisoning attributable to excessive tin content in tinned foods. Even so it was thought desirable to lower the limit until more decisive information is available on the subject of the toxicity of tin.

Testosterone and Growth

Q.—I was shown a press cutting by a patient in which it was reported that an adult male had grown by three inches (7.6 cm.) after a prolonged course of testosterone had been given by mouth. Is there any scientific basis for this claim?

A.—Testosterone undoubtedly has growth-promoting properties and is responsible for the marked growth spurt

seen in boys at the time of puberty. (Girls have a less marked growth spurt at puberty.) However, as part of its action on growing bone, testosterone also brings about epiphyseal fusion, which leads to cessation of growth, so that only a limited growth increment can result from its administration. Testosterone given to an adult though hypogonadal male whose epiphyses have not yet fused will usually produce a definite increase in stature. But clearly no growth can be produced by testosterone, or by anything else, once epiphyseal fusion has taken place. Presumably, therefore, the "adult male" referred to in the question must have been hypogonadal when treatment was begun.

Morphine for Patients with Coronary Thrombosis

Q.—One commonly provides the patient suffering from coronary thrombosis with trinitroglycerin tablets for use in the event of pain; occasionally one wishes to give them some form of morphine so that they may use it themselves in case of a severe attack. What preparation of morphine is recommended as being best for this purpose, and what dose should be given?

A.—Suppositories containing 15 mg. ($\frac{1}{2}$ gr.) morphine would appear to be the most suitable and safe preparation for this purpose.

The Fish Tape-worm

Q.—Could you kindly tell me whether there is any danger of infection by fish tape-worm from eating raw pickled herrings? Which species of fish are concerned in the transference of these worms to human beings?

A.—There is no danger of human infection with the fish tape-worm from eating raw pickled herrings. The infective larval stages (plerocercoids) of this parasite (*Dipyllobothrium latum*) occur in Europe only in fresh-water fish, such as perch, pike, salmon, miller's thumb, trout, grayling, etc. Other kinds of fresh-water fish are involved in Africa, Japan, North America, and Canada.

Desensitization to Penicillin

Q.—I should be grateful if you could give me details of the best method of attempting desensitization to penicillin in a nurse who develops an allergic rash on the face and hands after giving the drug by injection, although every care is taken in injection technique. If success is achieved, how long would the benefit be expected to last?

A.—The method of desensitization to penicillin which it is recommended to adopt is the one used by Crofton.¹ Crofton described in detail desensitization to streptomycin with daily intramuscular injections starting with 10 mg. and gradually increasing to 1 g. The whole treatment in Crofton's cases took from one to three months, and it seems likely that the same methods are applicable to penicillin. Severe reactions may be encountered, but may be minimized if points mentioned by Crofton are carefully studied.

Periodical Lactation at Menstruation

Q.—A patient of mine aged 42 years had her only child 14 years ago. Seven years ago and on two occasions during the last year she has lactated at a time corresponding to her periods. What are the possible causes and what treatment, if any, should be given?

A.—Women who have borne and suckled children can often express a small amount of "milk" from the nipples for many years afterwards. The breasts are normally affected to some extent by the hormone cycle of the ovary, and during the premenstrual phase are usually slightly larger, more vascular, and tender, if not painful. The amount of discomfort varies from one individual to another, and from time to time in the same individual.

The occurrence of such symptoms might cause a woman to examine her breasts more closely and to attempt expression and thus reveal some secretion which would not otherwise have been noticed. This sort of explanation of the finding of secretion about the time of a period is tentatively suggested. It assumes that the amount of secretion is small. If, however, there is a free supply of milk such as would warrant the term galactorrhoea, and which occurs in the absence of manipulation of the breast, the explanation might not be acceptable. Galactorrhoea sometimes occurs as a sign of a corpus luteum retention cyst or of a disturbance of pituitary function (including tumour formation). The latter is not likely in this case, because the phenomenon has been intermittent over the course of years. A temporary disturbance of the ovarian cycle is more probable.

If no evidence of pituitary or ovarian disease can be found, the occurrences should be regarded as being of no importance and as not requiring any treatment other than advice to avoid interfering with the breasts.

Refractive Changes in Diabetics

Q.—It has been stated that the presence of diabetes should be considered in adults requiring frequent changes of glasses, since a tendency to myopia is associated with a high blood sugar level, and hypermetropia may be observed concomitant with a low concentration of sugar. Why is this? Is it due to a varying concentration of glucose in the fluid media of the eye?

A.—It has long been known that refractive changes occur in diabetics in whom the sugar content of the blood varies rapidly; the tendency is for myopia to develop with a high sugar level in the blood, hypermetropia with its sudden decrease. The actual mechanism determining these changes is unknown, but it is not due to a varying concentration of glucose in the fluid media of the eye. The evidence is fairly conclusive that the changes in refraction are associated with alterations in the lens, possibly due to osmotic effects; but it is not clear how these act.

Sterilization of Rug Made by Tuberculous Patient

Q.—I have a patient with pulmonary tuberculosis who has a positive sputum. As a hobby he has started making wool rugs. The first one is completed and I should be grateful if you would let me know how this can be sterilized without damaging it.

A.—It is probable that hanging the rug out in the fresh air and sunshine for four days in succession would render it quite harmless. For maximum safety, however, exposure to steam at a pressure of 5 lb. per square inch (0.35 kg. per square cm.) for 30 minutes is advised. The local chest clinic will probably have an arrangement with a hospital or the local authority for getting this done.

Laburnum and Other Poisonous Plants

Q.—What is the active poison in laburnum seeds? The seeds when eaten cause vomiting, diarrhoea, drowsiness, and collapse. Can you advise a suitable reference to poisonous plants and shrubs, which includes antidotes?

A.—The poisonous principle of *Cytisus laburnum* is the alkaloid cytisine, $C_{15}H_{15}ON_2$. Some years ago Laidlaw¹ reviewed recorded cases of poisoning and produced evidence for the responsibility of cytisine, emphasizing the narcotic-irritant action and similarity to nicotine. As with most poisonous plants, treatment is directed to elimination of the poison rather than to application of an antidote, and he states: "The treatment of laburnum poisoning in man resolves itself into removal of the poison by emetics or stomach-tube and the treatment of symptoms as they arise. Radziwillowicz has shown that cytisine is readily excreted in the urine; diuretics, therefore, seem to be indicated. In a number of cases hot baths seem to have been beneficial." Later investigations have added little or nothing to this work; no therapeutic application of cytisine has been made.

The best small book on poisonous plants in Europe, including all important species occurring in Britain, their pharmacology, and treatment of cases of poisoning, is by O. Gessner,² but it is unfortunately in German. In English there is a popular work of some age by the Rev. Professor G. Henslow³ which has no up-to-date successor. Much information, but only incidentally referring to human poisoning, is to be found in the books by H. C. Long,⁴ the first of which has detailed references.

Supernumerary Kidneys

Q.—In a recent post-mortem examination a small accessory kidney was seen on the left side. I would like to know the approximate frequency of this finding, and I would be grateful for a reference to any recent review on the subject.

A.—Supernumerary or accessory kidneys are very rare. The reported cases have been collected and reviewed by H. E. Carlson.¹ He traced records of 51 cases, of which 4 were diagnosed pre-operatively and 32 came as a surprise to a surgeon when operating. Supernumerary kidneys are generally smaller than their companion kidney. Their function is always greatly reduced and they are generally found below the normally located and functioning kidney. The ureters are generally bifid, but complete duplication is not infrequent and ectopic ureteral orifices are not uncommon. Carlson points out that there is wide variation in the pathological findings in both the supernumerary and non-supernumerary kidneys, and he summarizes these in the tables which accompany the article referred to above.

Incidence of Hydronephrosis in Prostatic Obstruction

Q.—What proportion of cases of prostatic enlargement with symptoms have hydronephrosis or hydroureter? Is there any difference in incidence on the two sides?

A.—Figures given by Kretschmer and Squire¹ showed that in the period 1933–7 44% of their patients with prostatic obstruction had hydronephrosis or hydroureter, and in the period 1945–7 33%. They claimed that the incidence was diminishing with earlier treatment. There was only a small difference, at the most 1%, in the incidence on the two sides in their cases; unilateral hydroureter is, however, sometimes seen and can be related to unilateral prostatic enlargement in a few instances. As a rule dilatation of the ureter precedes dilatation of the pelvis and calyces.

Corrections

We regret that in the *Journal* of February 5 (p. 362) Mr. Eric Johnson, M.P., was recorded in our Parliamentary report as being a member of the Labour Party instead of the Conservative Party.

The tuberculosis attack rates were wrongly quoted as per 100 instead of as per 1,000 in the penultimate paragraph of the leading article in last week's *Journal* (p. 403) commenting on the Rhondda Fach survey.

FACTORS INFLUENCING ADRENOCORTICAL ACTIVITY IN HEALTH AND DISEASE*

BY

R. I. S. BAYLISS, M.D., M.R.C.P.

Assistant Physician, Westminster Hospital

The heightened interest in the adrenal cortex and its secretory products over the last few years is largely due to two factors—the belief by some workers that several diseases of unknown aetiology, such as rheumatoid arthritis, are caused by an imbalance in the various hormones secreted by the adrenal gland, and the advent of pure adrenal steroids and corticotrophin (A.C.T.H.) in sufficient amounts for use in clinical medicine. There can be no doubt that these agents are of considerable value in the treatment of certain diseases, particularly in the control of status asthmaticus and rheumatoid arthritis, and also in testing adrenocortical function so that the diagnosis of certain endocrine diseases can be more accurate and founded on a truly scientific basis. The proper use of these agents requires some knowledge of the mechanism by which they and other factors influence adrenocortical function.

The many different hormones secreted by the cells of the suprarenal cortex can be classified under five main headings according to their chief physiological actions. These five categories comprise glucocorticoids, androgenic steroids, mineralocorticosteroids, oestrogenic steroids, and progestational steroids: very little is known about the last two groups, and they are not discussed further. These subdivisions are somewhat arbitrary, because the actions of these hormones often overlap. For example, glucocorticoids, which include such compounds as hydrocortisone (also known as cortisol and compound F) and corticosterone (Albright calls them the "S" or sugar hormones because of their influence on carbohydrate metabolism), not only affect protein, carbohydrate, and fat metabolism but influence salt and water metabolism as well. There is evidence, however, for a specific mineralocorticoid which controls salt and water metabolism—namely, aldosterone, a hormone recently isolated by Simpson *et al.* (1954). Little is yet known about its role in health and disease, although there is enough evidence to indicate that the factors which control its secretion are different from those which promote the formation of hydrocortisone (Simpson and Tait, personal communication; Prunty *et al.*, 1954). Androgenic steroids, which Albright has called the "N" or nitrogen-retaining hormones because of their ability to promote anabolism of protein in addition to their action on the secondary sexual mani-

festations, also appear to be controlled to some extent by different factors from those concerned with the formation of glucocorticoids and aldosterone. Thus in considering the factors which influence adrenocortical activity in health and disease it is necessary to define which particular adrenal function is under discussion. This report is concerned chiefly with the secretion of glucocorticoids: our knowledge is far from complete, and in a rapidly developing field of research this is inevitably in the nature of an interim report on work in progress in several different centres.

INDICES OF ADRENOCORTICAL ACTIVITY

Glucocorticoid Secretion

Research into the secretion of corticosteroids has been beset with difficulties largely owing to lack of satisfactory methods. In the past much valuable information has been obtained from animal experiments in which assessment of adrenocortical activity has been based on such indirect indices as the degree of ascorbic acid or cholesterol depletion in the adrenal glands—changes which have been accepted as evidence of increased secretion of corticosteroids. However, the significance of these changes is still uncertain, and in endocrinology, perhaps more than in any other subject, it is unwise to translate from animal experiments to man. In man, too, indirect indices of adrenocortical activity have been used. Some of these, such as the fall in eosinophils, have proved under certain circumstances to be misleading. The significance of these eosinophil changes is discussed later.

More direct assessment of adrenocortical function is obtained by measuring the concentration of corticosteroids in the blood and in the urine. In principle the technique of estimating plasma corticosteroids is simple. A sample of 15 ml. of plasma is extracted with chloroform. The extract is dried and then purified by column chromatography. The steroids are estimated by a colour reaction with phenylhydrazine in sulphuric acid which is specific for C-17 dihydroxy-ketones (Porter and Silber, 1950; Nelson and Samuels, 1952; Bayliss and Steinbeck, 1953). By working up large volumes of fresh plasma it has been found that the bulk of the material measured is hydrocortisone (Nelson and Samuels, 1952), although some of the colour is produced by metabolites such as tetrahydrocortisone (Bayliss and Steinbeck, 1953; unpublished observations). The identification of the compounds present has been made by paper chromatography, eluting the steroids off the

*A lecture given to the Postgraduate Medical School and the Institute of the British Postgraduate Medical Federation as part of the course on "The Scientific Basis of Medicine." Delivered at the London School of Hygiene and Tropical Medicine on November 25, 1954.

paper and then recording the characteristic absorption spectra they give when reacted with concentrated sulphuric acid (Zaffaroni, 1950, 1953).

There are certain shortcomings in using the plasma concentration of 17-hydroxycorticosteroids as an index of adrenocortical activity. First, the method does not measure corticosterone, which is a normal, but probably not a major, constituent of adrenocortical secretion. The second, and in this context the more important, shortcoming is that the concentration of 17-hydroxycorticosteroids in the plasma may not necessarily be an index of adrenal activity. The level in the plasma is

Diagram to illustrate some of the factors which influence the plasma level of 17-hydroxycorticosteroids.

the resultant of several factors (see Diagram)—the quantity being secreted by the adrenal glands, the quantity being metabolized and utilized in the tissues, and the quantity being excreted in the faeces and urine.

Secretion

Steroids secreted by the adrenal cortex pass into the blood stream and thence into the extracellular fluid. Paper chromatographic analysis of fluid removed from the pleural space or peritoneal cavity has shown the presence of hydrocortisone and also, in some specimens, very small amounts of tetrahydrocortisone (Cope and Hurlock, 1953, 1954). The 17-hydroxycorticosteroid content of pleural and ascitic fluid is of the same order as that found in blood samples, and this suggests that adrenocortical hormones diffuse readily from the vascular into the interstitial fluid compartments (Bayliss and Steinbeck, unpublished observations).

Utilization

Adrenocortical steroids are metabolized in the tissues and particularly in the liver. In the dog there is a considerable steroid gradient across the liver, and after giving cortisone by mouth the steroid concentration is much higher in the portal venous blood than in blood from the hepatic vein (Bayliss *et al.*, 1954b). In man a dose of 50 mg. of cortisone by mouth causes a rapid increase in the plasma steroid level, but the hormone disappears quickly from the blood stream and the plasma level returns to normal in four to six hours (Bayliss and Steinbeck, 1955).

Little is known of the metabolism of corticosteroids in peripheral tissues. Nelson *et al.* (1951) failed to find a significant arteriovenous difference across the limbs. This is perhaps not surprising, since Louchart and Jailer (1952) found that little disappeared when cortisone was incubated with slices of muscle or brain, but that large losses occurred in the presence of liver, kidney, or spleen slices. On the other hand, when hydrocortisone or cortisone is injected into a knee-joint the steroid is rapidly metabolized, and if some of the joint fluid is withdrawn half an hour later the hormone has been converted into other compounds (Wilson *et al.*, 1953).

It is possible that certain substances may interfere with the metabolism of cortisone or hydrocortisone. It was first observed in Holland that patients taking large amounts of liquorice were liable to develop oedema and hypertension (Borst, 1950). It was suggested that glycyrrhetic acid, believed to be the active ingredient of the liquorice, exerted an effect similar to that of adrenocortical hormones, and that this might be the unwitting reason why salt-depleted miners in certain French coalfields sucked sticks of liquorice at the end of their day's work, just as British miners may add extra salt to their beer. When glycyrrhetic acid was given to Addisonian patients conflicting results were obtained. Some patients showed clinical improvement and maintained their salt balance (Groen *et al.*, 1951; Card *et al.*, 1953); others did not (Borst *et al.*, 1953). It was observed that when an Addisonian patient was given cortisone a smaller dose combined with glycyrrhetic acid produced the same therapeutic effect as a larger dose given alone. This suggests that liquorice may act by blocking the enzyme systems which metabolize corticosteroids. If in an Addisonian patient there is some residual adrenal function and small amounts of steroid are being secreted, glycyrrhetic acid causes clinical improvement by preventing enzymic breakdown of the adrenal steroids; if, on the other hand, adrenal atrophy is complete and no steroids are being secreted, glycyrrhetic acid has no effect. Proof of this hypothesis has not yet been obtained.

Urinary Excretion

Although studies with C^{14} -labelled cortisone have shown that eventually about 80% of the radioactivity is eliminated in the urine, much of this material is probably no longer steroidal, because only 5 to 10% of a 50-mg. dose of cortisone is recovered in the urine as corticosteroids and an even smaller amount as neutral 17-ketosteroids. The quantitative estimation of urinary corticosteroids has proved difficult, because the hormones and their metabolites are excreted partly as free compounds and partly as conjugates. The difficulty has been to hydrolyse the conjugated compounds. The method evolved by Norymberski *et al.* (1953) circumvents this difficulty and is likely to prove a most valuable tool in the study of adrenocortical function. The method of Reddy *et al.* (1952) is also promising: it has the great merit of simplicity, but its accuracy has still to be proved. By estimating the 17-hydroxycorticosteroid concentration in plasma and urine the renal clearance of corticosteroids has been measured in the same way as the clearance of urea or creatinine is measured. About 1 ml. or less of plasma is cleared of 17-hydroxycorticosteroids per minute. Since data from studying the steroid concentration in ascitic and pleural fluid indicate that these hormones are diffusible, the low clearance must be due to active reabsorption in the tubular lumen, which is the method used for conserving substances important to the body economy.

These, then, are some of the factors which may influence the concentration of 17-hydroxycorticosteroids in the plasma.

In normal healthy subjects the plasma steroid level ranges from 3 to 17 μ g. per 100 ml., with a mean of 9 μ g. per 100 ml. It is necessary to point out, however, that isolated single determinations may be misleading, because there is evidence, discussed below, that emotional factors

may influence plasma steroid concentration and high values may occur in normal people during an emotional disturbance.

Androgenic Steroid Secretion

The urinary excretion of neutral 17-ketosteroids is generally accepted as an index of androgenic steroid formation in the body. The daily output in the adult male is on the average some 5 mg. higher than in the female—this amount being contributed by androgens of testicular origin. Unfortunately, hydrocortisone and cortisone are in part excreted as 17-ketosteroids, and the total excretion of 17-ketosteroids—derived from both corticosteroids and androgenic steroids and probably other precursors as well—is an imperfect index of androgenic hormone formation. By more complicated chromatographic techniques it is possible to separate 17-ketosteroids into several constituent fractions and determine how much of the total has been derived from corticosteroids and how much from androgenic hormones and other precursors (Dingemans *et al.*, 1952; Kellie, 1953; Lakshmanan, 1954).

FACTORS INFLUENCING CORTICOSTEROID SECRETION

Corticotrophin

The pituitary trophic hormone A.C.T.H. is the principal factor directly regulating the secretion of corticosteroids (Sayers and Sayers, 1948; Sayers, 1950; Long, 1952). Whether corticotrophin is a protein or a polypeptide, and whether it is one hormone or several, is still undecided (Astwood *et al.*, 1952; Stack-Dunne, 1953; Forsham, 1955), nor is the mechanism by which it increases corticosteroid secretion fully understood. Perfusion studies of ox adrenal glands, carried out at the Worcester Foundation over a number of years, indicate that its action is to accelerate the early stages in the biosynthesis of hydrocortisone and corticosterone from cholesterol and acetate precursors (Pincus, 1954).

The degree of increased adrenocortical activity produced by A.C.T.H. is dependent upon two factors—the amount of hormone administered (Bayliss and Steinbeck, 1954a) and the length of time the stimulating action of the hormone is applied (Renold *et al.*, 1952).

If solutions of A.C.T.H. are infused over a constant time, the degree of adrenocortical stimulation produced is directly related to the dose given. Over a 6-hour period as little as 0.25 unit an hour will cause a significant increase in adrenal activity. If this response is plotted against the logarithm of the dose a straight-line relationship is obtained. The slope of the line is rather flat, so that with increasing doses above 2 units an hour there is little further elevation of the plasma steroid concentration, and for practical purposes it can be assumed that 2 units an hour over a six-hour period will cause maximum adrenal stimulation.

The degree of adrenocortical response to a constant dose of A.C.T.H. is directly proportional to the duration of A.C.T.H. administration (Renold *et al.*, 1952). If a single dose of 20 units is injected intravenously the response of the adrenal cortex is often short-lived and evanescent. In contrast the same amount of hormone dissolved in saline and infused over a six- or eight-hour period causes a profound increase in adrenocortical secretion. These differences are due to the rapid destruction of A.C.T.H. in the body (Sayers *et al.*, 1949; Greenspan *et al.*, 1950; Reiss *et al.*, 1951; Pincus *et al.*, 1952). If A.C.T.H. is dissolved in saline and injected intramuscularly it causes a relatively brief increase in plasma 17-hydroxycorticosteroid concentration lasting about four hours. If the same dose is given intramuscularly in a gelatin menstruum, combined with a zinc precipitant or an oxycellulose adsorbant, a more prolonged effect is observed, the vehicle allowing a gradual release of the A.C.T.H. and preventing its destruction at the site of injection (Bayliss and Steinbeck, 1954a; Oudsten

et al., 1954; Greene and Vaughan-Morgan, 1954; Ferri-man *et al.*, 1954; Gemzell and Franksson, 1953).

The degree of adrenal stimulation obtained from intramuscular A.C.T.H. in saline or a gelatin menstruum is too variable from one patient to another and in the same patient at different times to allow a quantitative assessment of adrenocortical response. In our hands consistent results are observed only when the material is given by intravenous infusion (Bayliss and Steinbeck, 1954a). This has an important clinical application: the testing of adrenocortical function by giving intramuscular A.C.T.H. is meaningful only if a positive response is obtained. If the response is negative no conclusions can be drawn and the trophic hormone should be infused intravenously.

Deficiency of A.C.T.H. secretion due to pituitary destruction leads to adrenocortical atrophy and low plasma 17-hydroxycorticosteroid levels. The degree of adrenal atrophy is related to the degree of A.C.T.H. deficiency and this in turn to the degree of pituitary destruction. When pituitary destruction is total, or nearly so, the plasma level of 17-hydroxycorticosteroids may fall to zero, and such values are found in patients with gonadal, thyroid, and adrenal failure who require substitution therapy to remain alive. In others in whom the degree of pituitary destruction is less complete and the clinical features indicate only gonadal failure the plasma steroid levels are within the normal range.

Responsiveness of the Adrenal Gland

The amount of steroid secreted by the adrenal cortex depends not only on the degree of stimulation provided by A.C.T.H. but also on the responsiveness of the gland itself. In normal subjects a continuous infusion of A.C.T.H. calls forth a rapid response, which can be detected in the peripheral blood within 15 to 30 minutes of starting the infusion. After reaching a maximum in about an hour, the plasma steroid level remains relatively constant during the remainder of a six- or eight-hour infusion. When the infusion is stopped the increased adrenocortical activity ceases, and within two to three hours the plasma steroid level has returned towards the pre-infusion level. In normal subjects the level attained six to eight hours after starting an A.C.T.H. infusion at the rate of 2 units an hour is usually of the order of 25–35 μ g. per 100 ml.—that is, 15 μ g. or more above the pre-infusion level. As would be expected, repeated daily infusions cause progressively higher levels, and this suggests that the anatomical hypertrophy of the gland found after repeated infusions is associated with increased functional capacity and heightened steroidogenesis.

Some idea of the total steroid output from adrenal glands receiving maximum stimulation with A.C.T.H. is given by some studies made by Thorn *et al.* (1953). They observed the changes in urinary corticosteroid excretion, eosinophils, electrolyte, and blood glucose concentrations during a four-hour infusion of 3 units of A.C.T.H. an hour and found that quantitatively similar effects were produced in the same subject by infusing 12 mg. of hydrocortisone an hour. From this it may be tentatively inferred that under maximum stimulation the adrenal glands secrete the equivalent of about 300 mg. of compound F per 24 hours.

Addison's Disease

Decreased responsiveness of the adrenal cortex to A.C.T.H. is seen characteristically and diagnostically in Addison's disease. None of the patients we have studied has shown a significant increase in the plasma level after A.C.T.H. infusion. Even those who appear to have some slight residual adrenal function, as evidenced by their symptomatic independence of substitution hormone therapy and by the low but not negligible plasma steroid levels, show no response, and in them the steroid level may actually fall during the infusion, owing perhaps to utilization of the small amount of circulating hormone during

the stress of the procedure. Normal subjects infused with saline alone show little variation in their plasma steroid level, and if during this time there is increased steroid utilization a constant level is maintained by increased A.C.T.H. secretion and increased corticosteroid output. It is tempting to believe that in Addisonian patients with low normal plasma steroid levels, the few remaining adrenocortical cells are responding to their uttermost to large amounts of endogenously produced A.C.T.H. and no further response is possible to exogenous A.C.T.H.

Hypopituitarism

In patients with hypopituitarism the responsiveness of the adrenal glands is often less than in normal subjects, and there is evidence that the degree of responsiveness is related to the duration of the adrenal atrophy. Thus a patient, who was known to have had hypopituitarism for many years following implantation of radon seeds into the sella turcica, and then surgical extirpation of the remaining hypophyseal tissue, showed a rise from 0 μ g. per 100 ml. to only 6 μ g. after a six-hour infusion of A.C.T.H., whereas in a patient who had only recently been hypophysectomized the level rose from zero to 36 μ g.; this large increment may indicate, as occurs in animals, that shortly after hypophysectomy the target gland has a heightened response to its trophic hormone.

Adrenogenital Syndrome

In Addison's disease the activity of the adrenal cortex is impaired in all its functions and the formation of glucocorticoids, mineralocorticoids, and androgens is much reduced or absent. In contrast the adrenal glands of patients with virilization due to congenital adrenal hyperplasia have a more isolated defect which is limited to the biosynthesis of glucocorticoids, and in rare instances the mineralocorticoids as well. In most of these patients the circulating level of 17-hydroxycorticosteroids is abnormally low and there is little or no increase following stimulation with A.C.T.H., whereas the formation of androgens, as indicated by the urinary excretion of 17-ketosteroids, is increased and raised even further after A.C.T.H. (Kelley *et al.*, 1952; Bayliss *et al.*, 1954a; Bongiovanni *et al.*, 1954).

This condition provides information concerning the mechanism by which pituitary-adrenocortical activity is regulated. The secretion of A.C.T.H. is controlled by the plasma level of circulating glucocorticoids, and if the steroid concentration falls the pituitary secretes more A.C.T.H., thereby stimulating the adrenal cortex to maintain the plasma steroid concentration. Conversely, if the steroid level in the blood rises the activity of the pituitary is depressed and less A.C.T.H. is elaborated. In congenital adrenal hyperplasia it appears that because the biosynthesis of glucocorticoids is defective (probably through lack of a particular enzyme system) and the plasma concentration is low, the pituitary responds by secreting increased amounts of A.C.T.H. The adrenal glands are unable to secrete more glucocorticoids and respond to the A.C.T.H. by hypertrophying and elaborating large amounts of androgens which are responsible for the virilization of the patient and for the increased urinary excretion of 17-ketosteroids (Bartter *et al.*, 1951; Wilkins *et al.*, 1952; Jailer *et al.*, 1952).

The validity of this concept has been confirmed by the observation that if cortisone or hydrocortisone is given to such patients the activity of the pituitary is suppressed, less A.C.T.H. is elaborated, and the adrenal glands no longer secrete such large amounts of androgens (Wilkins *et al.*, 1951, 1952; Gardner and Migeon, 1952; Bayliss *et al.*, 1954a; Jailer *et al.*, 1954). Thus these patients are treated by the administration of cortisone in sufficient amounts to suppress pituitary activity and to reduce the urinary excretion of 17-ketosteroids to normal limits.

Cushing's Syndrome

In contrast to the conditions discussed above, in all of which the formation of glucocorticoids is reduced, Cushing's

syndrome is characterized by abnormally high plasma steroid levels, whether the condition is associated with an adenoma of the adrenal cortex, bilateral adrenal hyperplasia, or a carcinoma. If the condition is due to bilateral adrenal hyperplasia an infusion of A.C.T.H. raises the already high steroid level even higher. This finding suggests a possible explanation for the underlying disorder in Cushing's syndrome of this type. Since the plasma level of corticosteroids is abnormally high, it seems probable that the primary defect lies in the pituitary gland itself, which is insensitive to the normal inhibitory influences of large amounts of circulating steroids. It is as though the "thermostatic" mechanism is set at too high a level and pituitary activity is not shut off until abnormally high plasma steroid levels are attained. Proof of this belief must await a reliable method for estimating the A.C.T.H. content of the blood, but it is significant that when hydrocortisone is infused into such patients there is a reduction in the urinary excretion of 17-ketosteroids, suggesting that the exogenously administered hormone raises the plasma level high enough to suppress pituitary activity. This response is not seen if the condition is due to an adrenal adenoma or carcinoma, and so may be of clinical value in determining the pathology of the disease before surgical exploration (Jailer *et al.*, 1954).

Myxoedema

The hormone secreted by the thyroid gland influences the metabolic rate of all tissues, and it might be anticipated that in severe myxoedema the activity of the adrenal cortex would be impaired and the rate of steroidogenesis retarded. However, in many patients with myxoedema the plasma steroid level is within the normal range, although, of course, in the myxoedematous state utilization may be decreased, and the rate of steroidogenesis correspondingly reduced. In a few patients abnormally low levels have been encountered, and these have risen to normal after substitution therapy with thyroid extract or L-thyroxine. In one patient with hypopituitarism characterized by severe secondary myxoedema, the plasma steroid level rose from 1 μ g. per 100 ml. to 6 μ g. when replacement therapy was given with thyroxine only.

In addition to A.C.T.H. and the state of the adrenal cortex, other factors influence adrenocortical activity. Most of these are still incompletely understood, and it is uncertain whether they exert their effect by direct action on the adrenal cortex, or by way of the hypothalamus and anterior pituitary, or by increasing tissue "utilization" of corticosteroids. Their importance lies in the fact that their influence is difficult to control and they may operate, unknown to the investigator, during physiological studies.

Diurnal Variation

Healthy adults show a diurnal variation in adrenocortical activity. It has been known for many years that the urinary excretion of 17-ketosteroids varies throughout the day (Pincus and Hoagland, 1943), and Thorn (1954) has reported that the urinary excretion of 17-hydroxycorticosteroids also varies over a 24-hour period. Similarly, the plasma steroid level varies: lowest values are found at night, around midnight, and the highest levels occur at about 6 a.m. (Tyler *et al.*, 1954; Bayliss, 1955). This variation persists whether the subject is up and about his daily work or whether he is confined to bed and receiving a constant amount of food every two hours. It is not related to the diurnal variation that occurs in the urinary excretion of water, sodium, and other electrolytes. What controls this diurnal change in activity remains unknown, and many obvious investigations need to be carried out: Is this rhythm reversed in night workers? Does it occur in blind people? What effect on it has a lesion of the hypothalamus? Is it disturbed in patients with psychiatric disorders or with Cushing's syndrome?

Emotional Factors

Emotional factors may influence adrenocortical activity in certain subjects. We first observed this phenomenon in 1952, and have since confirmed that in certain patients anxiety, frustration, and fear may cause a significant increase in the plasma 17-hydroxycorticosteroid concentration. Repeated venepunctures, although not more painful than usual, may activate the adrenal cortex by calling forth an emotional response. In certain subjects, delivering a lecture to a critical audience has a similar effect. It is because of these influences that it is difficult to define normal plasma steroid levels. A blood sample taken at random from an out-patient on his first attendance may give an erroneously high value because the patient may be suffering anxiety and tension at the time. Usually the levels induced by an emotional upset do not exceed 20 μ g. per 100 ml. and are not therefore likely to cause confusion in the differential diagnosis of Cushing's syndrome, but in some instances higher levels are observed. In interpreting the results of physiological studies due allowance must be made for these emotionally prompted rises in plasma corticosteroids, and it is necessary to make repeated observations and to use adequate controls to be certain that the responses observed are due to the change in the specific experimental conditions being studied and not to an emotional upset.

Adrenaline

It is not yet known how emotional disturbances influence the plasma steroid level, but release of adrenaline is a possible intermediate mechanism. It has been thought for some time that, because adrenaline causes a fall in circulating eosinophils, directly or indirectly it stimulates the adrenal glands to secrete increased amounts of corticosteroids (Recant *et al.*, 1950). In normal but not in adrenalectomized subjects A.C.T.H. causes a fall in the number of eosinophils (Thorn *et al.*, 1948; Forsham *et al.*, 1948), and, since hydrocortisone or cortisone also causes a fall in eosinophils, it has rightly been assumed that the eosinopenia after A.C.T.H. indicates increased secretion of corticosteroids and a rise in the plasma concentration of adrenocortical hormones. It has been found, however, that adrenaline may cause an eosinopenia in patients who have had both adrenal glands removed (Kark and Muehrcke, 1952), and direct measurement of the steroid concentration in the plasma, and the steroid excretion in the urine after a single injection or a prolonged infusion of adrenaline in normal subjects, has failed to show any increase in adrenocortical activity (Sandberg *et al.*, 1953; Thorn *et al.*, 1953).

We were impressed that following A.C.T.H. the fall in eosinophils is greatest two to three hours after the maximum plasma steroid concentration has been obtained; and that following adrenaline the fall in eosinophils is greatest two hours after the injection. Hence it seemed that any increase in plasma steroids should be looked for within the first few minutes of giving the adrenaline. Despite taking multiple samples at this time, Hunter *et al.* (1955) have failed to detect any consistent increase in plasma steroids, and on the present evidence we must conclude that adrenaline does not cause a detectable increase in adrenocortical activity and is not responsible for the increased plasma steroid levels found in emotional disturbances. It must also be concluded that, although an eosinopenia after administration of A.C.T.H. is a valid index of increased adrenocortical activity, this is not necessarily so under other circumstances.

D-Amphetamine Sulphate

Amphetamine sulphate has many of the pharmacological properties of adrenaline, but a more prolonged action. In 1952 a patient with panhypopituitarism due to a large chromophobe adenoma which was also causing attacks of diencephalic epilepsy was found to have plasma corticosteroid levels above normal—22 μ g. per 100 ml. This

surprising result was obtained at a time when the patient was receiving amphetamine sulphate for his diencephalic epilepsy. When the amphetamine was stopped the plasma steroid level fell to the anticipated low value of 3 μ g. per 100 ml. Subsequently Thorn (1954) has noted that some patients have increased urinary excretion of 17-hydroxycorticosteroids following "benzedrine," and we have found similar changes in the plasma steroid levels.

Stress

Selye (1946) has suggested that a wide variety of factors, such as infections, intoxications, trauma, nervous strain, heat, cold, muscular fatigue, and x-irradiation induce a state of general systemic stress which is associated with increased adrenocortical activity. Whether or not these many different factors do indeed cause increased cortical secretion remains to be proved. Thorn *et al.* (1953) have not observed an increase in the urinary excretion of 17-hydroxycorticosteroids after physical exertion, exposure to cold, anoxia, or mental exertion involving the use of an Air Force pursuit meter; but these results cannot yet be accepted with complete confidence because of the analytical method used. Increased steroid excretion was noted in members of the Harvard boat-race crew, but since the cox and the coach showed a similar response the increased adrenocortical activity seemed more attributable to emotional factors than to the physical exertion *per se*. The plasma steroid level shows no consistent change in patients receiving whole-body x-irradiation sufficient to cause radiation sickness.

Surgical operations do increase the urinary excretion of corticosteroids (Cope *et al.*, 1951; Thorn *et al.*, 1953) and raise plasma steroid levels (Franksson *et al.*, 1954), and increased adrenocortical activity is commonly observed in any painful condition. For example, an elderly patient with severe cephalgia due to temporal and occipital arteritis had consistently high values of 26 μ g. per 100 ml., which returned to normal levels when the pain subsided, although the disease continued to be active. Patients with a myocardial infarct may show high levels. One admitted soon after the onset had a level of 50 μ g. per 100 ml., which rose to 82 μ g. per 100 ml. when she seemed on the point of dying. With recovery the plasma steroid level returned to a normal value of 9 μ g. In several patients studied in the terminal stages of their illness very high steroid levels have been observed. This is not necessarily associated with urea retention and therefore is not attributable to failure of renal excretion. These findings may not, however, represent increased adrenocortical secretion; they may indicate failure of tissue utilization or impaired hepatic metabolism.

Salicylates

It has been suggested that salicylates exert their beneficial action in rheumatic affections by increasing adrenocortical activity (Hetzel and Hine, 1951; van Cauwenberge and Heughebaert, 1951; van Cauwenberge and Betz, 1952). However, in ordinary therapeutic dosage salicylates do not cause a significant or constant increase in the plasma level of 17-hydroxycorticosteroids despite symptomatic relief and mild manifestations of salicylism (Bayliss and Steinbeck, 1954b), although poisoning with salicylates has been reported to increase the level (Done *et al.*, 1954).

Pregnancy

As judged by the urinary excretion of corticosteroids, there is evidence that the activity of the adrenal cortex is increased during pregnancy (Venning, 1946; Tobian, 1949; Cope *et al.*, 1951), and the plasma steroid level is also raised (Gemzell, 1953). Blood samples taken from 30 women at monthly intervals throughout pregnancy show a progressive increase in 17-hydroxycorticosteroids, the mean value for the group rising from 10 to 13 μ g. per 100 ml. during the third and fourth months to 24 μ g. during the last month. The concentration in blood taken from the umbilical cord

at the time of delivery was of the same order—27 μ g. per 100 ml. During the post-partum period the level in the mothers' blood fell, the mean concentration for the group returning to normal by the eighth post-partum day. The levels in individual patients varied considerably from the mean values. About 45% showed a marked increase, with maximum levels exceeding 29 μ g. per 100 ml.; another 45% had more moderate increases, with maximum values of more than 21 μ g.; and in 10% the level did not exceed 20 μ g. per 100 ml. (Bayliss *et al.*, 1955).

One important question which remains unanswered is the origin of this steroidal material. Does it arise in the mother or in the foetus? Since in newborn infants the urinary excretion of 17-ketosteroids, glyconic corticosteroids, and reducing steroids, and the plasma level of 17-hydroxycorticosteroids are all low (Talbot *et al.*, 1943; Venning *et al.*, 1949; Day, 1948; Klein *et al.*, 1954) whereas the level of plasma 17-hydroxycorticosteroids remains high in the maternal circulation for a week after delivery, it seems probable that the site of origin is in the mother. Here three possible sites need consideration—the adrenal glands, which have an increased weight during pregnancy; the placenta, which is known to form other steroids such as progesterone; and the ovaries. Blood samples taken during caesarean section from a uterine vein or a maternal placental sinus and from a peripheral vein have not shown a significant difference in 17-hydroxycorticosteroid concentration, and if the steroidal material were elaborated mainly in the placenta it would be expected that after delivery the concentration in the mother would fall more rapidly than it does. However, observations made in Addisonian patients who have become pregnant suggest that adrenocortical-like hormones are formed in the placenta (Samuels *et al.*, 1943; Knowlton *et al.*, 1949; Jailer and Knowlton, 1950). There is also evidence that an A.C.T.H.-like hormone is formed in the placenta (Jailer and Knowlton, 1950; Opsahl and Long, 1951; Tarantino, 1951; Cohen and Kleinberg, 1952). Thus it may well be that in pregnancy increased amounts of adrenocortical steroids are formed both in the maternal adrenals and to a lesser extent in the placenta.

Two years ago Professor Long (1952) wrote: "I am of the opinion that the greatest obstacle to our understanding lies in the inadequacy of the methods at present employed for the detection of an increased secretory rate from either the anterior pituitary or adrenal cortex." Although some progress has been made, we are still lacking satisfactory methods, and the secretion of many hormones by the adrenal cortex makes a study of its activity complicated and often laborious. I have dealt with only glucocorticoid secretion and with only some of the factors which influence this particular activity, but enough has been said to indicate the changes that occur through the seven stages of man from the high levels in pregnancy, the low levels in the newborn infant, to again the high levels that may be found at the time of death.

Summary

The adrenal cortex elaborates a large number of different hormones which to some degree overlap in their physiological effects. Current investigations are chiefly concerned with 17-hydroxycorticosteroids (such as cortisone and hydrocortisone), androgenic steroids (as reflected in the urinary excretion of 17-ketosteroids), and in the compound which is probably responsible for the control of salt and water metabolism (aldosterone).

In the work reviewed here adrenocortical activity has been assessed by studying the plasma concentration of 17-hydroxycorticosteroids. The plasma level is influenced by the amount of material secreted by the adrenal glands (which is mainly controlled by the release of A.C.T.H. from the pituitary gland), by the "utilization" of the liberated steroids in the tissues (particularly in the liver), and by the rate of urinary excretion.

The plasma level of 17-hydroxycorticosteroids is the same in both sexes. It shows a diurnal variation, and increased values are found in pregnancy, Cushing's syndrome, certain emotional disturbances, following surgical operations, in painful conditions, and at the time of death. No consistent increase in adrenal activity has been observed after administration of adrenaline, salicylates, or deep x-irradiation in ordinary therapeutic dosage. Amphetamine sulphate increases the plasma steroid level in some subjects. The relationship between the adrenal response and the dose of A.C.T.H. and the duration of its administration is discussed.

Low plasma adrenal steroid values are found in Addison's disease (and there is evidence that in these patients adrenocortical failure may be complete or only partial), in patients with extensive pituitary destruction, in congenital adrenal hyperplasia associated with virilism, and in some patients with myxoedema.

ENDOCRINE TREATMENT IN PSYCHIATRY*

BY

R. E. HEMPHILL, M.D.

Lecturer in Charge of Department of Psychiatry, University
of Bristol; Medical Superintendent, Bristol Mental
Hospitals Group

Endocrine therapy has a definite but restricted place in psychiatric practice; in some conditions its use is accepted, in others presumptive. With a few possible exceptions, such as cretinism, there are no psychiatric disorders in which an endocrine disturbance or deficiency has been proved to be an exclusive or major factor in causation. In contrast to the many papers published on research in the endocrinology of psychiatric illness in recent years, there are few about endocrine therapy and fewer that carry conviction.

Since the ductless glands are essential to adaptation and the preservation of physical and emotional stability, and can be disturbed by psychological upset, it is reasonable that psychiatrists should have looked to the field of endocrine treatment.

Although physiological disturbances and abnormalities of body constitution can be seen in any selection of chronic psychotics, the usual symptomatology of endocrine illnesses is rare in psychiatric disorders. Laboratory methods for investigating ductless gland function which have been evolved up to the present are probably not sufficiently precise or reliable to indicate and guide therapy in the absence of clinical signs of endocrine disease, and are not yet convenient for routine use. Thus endocrine treatment is still empirical, and the attempts to make it rational by laboratory methods have not yet been successful.

*From a Maudsley Bequest Lecture given in London on April 5, 1954.

Endocrine preparations may be used because of their physiological and pharmacological effect or as replacement; probably to some extent both aspects enter into successful therapy. It is improbable that lack of one hormone is responsible for any psychiatric disorder, and a replacement therapy is unlikely to be found.

An endocrine disturbance is only one factor in an illness which can be regarded as a reaction between physical and psychological components; but it may be responsible for great difficulties in adjustment. Endocrine therapy aims at improving this factor, so contributing to the total therapeutic effort by benefiting the adaptive or reactive capacity of the patient. It must be preceded by careful psychiatric assessment and investigation, and accompanied by adequate psychotherapy.

Endocrinology in psychiatry can conveniently be considered from the following aspects: (1) conditions encountered in psychiatric practice for which therapy is no longer experimental; (2) psychiatric aspects of endocrine disorders; and (3) experimental endocrine treatment of the psychoses and psychoneuroses.

Conditions Encountered

The Menopause

The features of menopausal depression, irritability, or neurosis need only be mentioned briefly here. There are few women who do not experience psychological changes during the months or years in which ovarian function is failing. The degree to which a woman is disturbed seems to depend upon her capacity for emotional adjustment, general stability, and reaction to ill-health. Many women who suffer most at the menopause report that they have usually experienced mood swings and physical discomfort at some part of the menstrual cycle. It is not correct to assume that a certain kind of personality suffers at the menopause, or is immune; but unbalanced and especially aggressive females often become unreasonable almost to the point of psychosis both at the menstrual cycle and at the menopause. A gradual menopause produces more discomfort than an abrupt cessation. Vasomotor disturbances and hot flushes correspond closely with mood swings. It is believed that these are due to a dysbalance in the relationship between pituitary-stimulating hormones and the peripheral ovarian hormones that are now failing, which has been suggested by high prolactin excretion.

Treatment with synthetic or natural oestrones (stilboestrol, dienoestrol, or oestrone), or, in severe cases, oestrogen by injection, in sufficient quantity to control hot flushes, is all that is required for the somatic disturbances, and makes psychotherapy easier. Stilboestrol is toxic to about 20% of women, especially the older; the dose is about 0.1 mg. daily. The usual dose of oestrone is from 0.2 to 1 mg. daily. A severe menopausal disturbance sometimes occurs years after artificial menopause by radium, or after hysterectomy if the ovaries remain; this is to be treated on the same lines as the normal menopause and is mentioned for this reason. Convulsive therapy—so effective in involutional melancholia—often aggravates menopausal depression and is contraindicated in the presence of hot flushes, because of its stimulating effect on anterior pituitary lobe function.

Involutional Melancholia

Unlike the menopausal reaction, this is a true psychotic depression, with ideas of guilt or of incurable illness, much agitation, and a marked tendency to suicide. It rarely follows a gradual menopause with vasomotor disturbances, and it usually occurs a year or more after sudden cessation of menses. The pre-psychotic personality is conscientious and inflexible, in contrast to the lability of the menopausal reaction. There is often an appearance of rapid physical ageing, and in some cases there seems to be an anterior pituitary insufficiency, which may be benefited by treatment

with A.C.T.H. But, normally, E.C.T. is the treatment of choice. Experience suggests that oestrones are ineffective, or even contraindicated, as they may suppress anterior pituitary activity.

Pre-menstrual Tension

This term indicates a state of mental and physical tension occurring towards the latter half of the menstrual cycle and prominent about a week before menstruation. The current view is that it is due to water retention produced by abnormal elevation of the oestradiol/progesterone ratio (Rees, 1953; Malleon, 1953).

The diagnosis is made on the occurrence of irritability, emotionalism (even unreasonable aggression), mental discomfort, lack of concentration, coupled with physical discomfort, such as a sense of being blown out, a gain in weight, discomfort in the fit of clothes—due presumably to localized adiposity or water retention. There are occasionally attacks of migraine, or of epilepsy in epileptic subjects.

The usual treatment is ammonium nitrate or ammonium chloride in coated tablets, 0.5 to 1 g. thrice daily for 10 to 12 days before the onset of menses. If this is unsuccessful, progesterone injections, 25 mg. twice daily, or ethisterone tablets, 5 to 20 mg. orally, daily or twice daily. Methyltestosterone, 10 mg. daily, is said to be effective, but may cause virilization.

Assuming that the condition is due to endocrine dysbalance, normal regulation may be established in a few months, when treatment can be discontinued.

Abnormal Libido

Impotence.—This is the inability to perform or complete the sexual act in a male. It may be caused by conditions such as hypogonadism and intersexuality; but usually the external genitalia are normal and the impotence is of psychological origin. This is rarely benefited by endocrine therapy, except where it accompanies the male climacteric or depression, or where it is intermittent and has not existed for long. In long-standing cases of psychological impotence, the interest has been displaced from the sexual object to anxiety whether the act can be performed, causing extinction of the sexual stimulus. Where impotence has occurred in a setting of exhaustion or business worries and has not been prolonged, and where there has not been much controversy between husband and wife, testosterone may improve the sense of well-being, increase libido, and, by making one or two performances possible, improve self-confidence so that anxiety disappears. It is best administered by injection—25 mg. of testosterone propionate three times weekly for a month; oral administration of methyltestosterone is insufficient. Treatment should be discontinued after a fortnight if there has been no response. The patient should not be led to believe it will produce a cure, lest it should not be successful. Intensive psychotherapy is essential. It is unwise to attempt treatment with testosterone in long-standing cases, because of the worsening effects produced by disappointment, as it will certainly fail.

Frigidity.—The diagnosis of frigidity is obviously difficult to make, and the term is a relative one. However, loss of sexual desire or enjoyment is not uncommonly complained of by married women, especially after childbirth; and it has been claimed that treatment with small doses of either oestrone or testosterone improves the appreciation of physical sexual stimuli and will therefore reduce temporary frigidity. Testosterone may cause virilization, and for this reason some authors prefer oestrone. Inunction of external genitalia with oestrone or testosterone cream has been advocated. True frigidity of long standing—that is, inability to experience or elaborate psychically sexual stimuli—is a rare condition, and probably cannot be improved by hormones.

Homosexuality and Excessive Sexuality.—The direction of homosexual or heterosexual drives cannot be altered with sex hormones; but the force of sexual drive in males can be reduced by treatment with female sex hormones. There are a number of papers on the subject, and all the

authors are in general agreement about the indications and the rationale. Treatment with female sex hormones reduces the production of gonadotrophic hormones, producing a secondary effect on testicular function and secretion. The reduction of sex drive is comparable to that achieved by surgical castration, although some authors claim that endocrine treatment is more effective (Hamilton, 1943). Stilboestrol is the usual preparation, administered in increasing doses until the nipples become pigmented and the breasts sore; an alternative is ethynol oestradiol, 0.5 or 1 mg. daily. Eventually almost complete testicular atrophy will be produced, but not necessarily a total suppression of the abnormal sex drives. It is interesting that notice has been taken of this treatment at the recent trial of an extreme and persistent homosexual offender, in whom abnormal behaviour had continued in spite of the production of almost complete atrophy of the testes by stilboestrol. The judge took into consideration that the offender had therefore done everything possible that medical treatment could offer, although in his case it had not been completely successful. Persistent homosexual offenders should therefore be encouraged to persevere with this treatment, although in some cases a satisfactory control of sexual behaviour may not necessarily be achieved.

Male Climacteric

The gradual diminution in the production of male sex hormones in middle and later age is held to be responsible for loss of physical and mental powers and libido. The male climacteric as an entity has been well discussed by Spence (1954). The diagnosis of male climacteric reaction cannot often be made with confidence, because arteriosclerosis or other systemic diseases complicate the picture and there is no dramatic event like the cessation of menses to indicate endocrine change. Moodiness, irritability, tearfulness, inability to concentrate, paraesthesiae, and sometimes hot flushes, suggest the diagnosis. Treatment is with testosterone by injection, 25 mg. daily or thrice weekly until there is improvement, methyltestosterone 5 to 10 mg. three times a day being given as continuation therapy for a year or more. There is usually improvement in mental and physical activity, sexual performance, and altered sense of well-being. Better peripheral circulation and flushing of the face are favourable early signs.

Cretinism

A causal association between thyroid deficiency and failure of intellectual and physical development, known as cretinism, was observed early in the history of modern medicine. Some authors make a distinction between juvenile myxoedema and cretinism. The cretin suffers from athyreosis from intrauterine life or early infancy (Means, 1948). The clinical picture is well known, but the results of treatment are less certain, for good results cannot be obtained in infantile myxoedema unless the brain is free from congenital abnormality.

At one time it was believed that only early and cautious treatment was likely to be successful. Surveys by Lewis *et al.* (1937), and by Topper (1951), who gives a good bibliography, indicated that promptness and continuity of thyroid treatment did not altogether decide whether a child remained backward or not. Topper pointed out that, according to electroencephalographic studies, cerebral defect explains much of the mental deficiency of the treated cretin, and that when such a defect is present in infancy no amount of thyroid can improve the brain. In her large series, 39% remained defective in spite of treatment.

Treatment should be pushed to the point of tolerance, which can be found by trial and error. The small doses usually recommended in cretinism are based on requirements necessary for alteration of hair and skin, and do not produce acceleration of growth and intellectual development. While tolerance is being determined the patient should be kept in hospital. Means and Lerman (1935) pointed out that with a constant daily dose the maximum

effect is not produced for about three weeks, and it is not safe to increase the dose oftener than every three to four weeks. Toxic symptoms are rapid pulse, a small rise in temperature initial loss of weight, increased nervousness, and frequent bowel movements; and some authors believe that these occur at the limit of safety and can be tolerated for a while. Dangerous symptoms due to excessive dosage are extreme restlessness, twitching, diarrhoea, vomiting, continued loss of weight, very rapid pulse, high fever, and syncope. As much as 4 gr. (260 mg.) daily is given at 21 months without adverse effect, but average doses are: 6 to 18 months, $\frac{1}{2}$ to $2\frac{1}{2}$ gr. (30 to 160 mg.); 1 $\frac{1}{2}$ to 8 years, 1 to 2 gr. (65 to 130 mg.); 8 to adolescence, $1\frac{1}{2}$ to 3 gr. (100 to 200 mg.). It is worth noting that the dose tolerated is not proportionate to the age and weight, for a young cretin can tolerate as much as a 12-year-old child with hypothyroidism (Brown, 1951).

Psychiatric Disturbances in Endocrine Disorders

Although psychological disturbances are a feature of many endocrine disorders they rarely amount to recognized psychiatric syndromes. Classical psychoses are uncommon even in thyrotoxicosis. Treatment of some endocrine conditions may precipitate a psychotic episode.

Thyrotoxicosis often follows an acute emotional upset, and it has been contended that it occurs usually in frustrated and emotionally dependent individuals who wish to take care of others. Ham *et al.* (1951) have agreed with some others that symptoms of thyrotoxicosis can be understood as the patient's response to early experiences and that although the experiences differ in detail they fall into a pattern characteristic of the disease. In all the patients they studied there were extreme feelings of insecurity in early life, a strong sense of responsibility, but a tendency to suffer in silence; this is in some contrast to the anxious patient, who has no such tendency. From the psychosomatic point of view, some cases of thyrotoxicosis may be an end-result of an endocrine disturbance operating through emotional pathways. Thyroidectomy may be followed by a degree of myxoedema, producing the usual sluggishness. Where there has been a coexisting anxiety state, or the diagnosis should have been an anxiety neurosis and not thyrotoxicosis, sometimes the thyroid requirements of body and brain are not met. The patient will be less able to cope with the anxiety situation than before operation, and the picture will then be continuing anxiety with agitation or even restless delirium. Treatment with thyroid hormone is indicated.

Myxoedema usually produces apathy and sluggishness. The administration of thyroid hormone may activate a paranoid psychosis, as if, by increasing metabolism, an uneasy psychological balance had been disturbed. Withdrawal of thyroid is not necessarily followed by an improvement in the psychiatric state, and cases of chronic paranoid psychosis arising in this way are occasionally seen. Caution is necessary in treating myxoedema in patients of paranoid constitution. Myxoedema may be associated with confusion and depression, especially in later life (Asher, 1949). A picture of organic brain change, with clouding of consciousness, delirium, or agitation, may be due to myxoedema or its cardiac complications (Calvert *et al.*, 1954). In such states of hyperactivity myxoedema may be overlooked unless remembered. Many of these patients improve with thyroid hormone; but care is needed, for an increased metabolism in the aged or in organic brain disorder may produce accentuation of confusion, delirium, and death.

Addison's Disease.—In adrenal hypofunction the capacity for adaptation is reduced. Cleghorn (1953) has compared the psychological changes in Addison's disease with myxoedema, and agrees with Engel and Margolin (1942) that the psychiatric symptoms of apathy, negativism, depression, and irritability occur in more than 50% of cases; he also quotes Stoll (1953), who reported similar disturbances in 35% in the pre-Addisonian state and 66% in the developed con-

dition; according to Stoll, they all improved remarkably under treatment with cortisone.

Adrenogenital Syndrome.—Virilism in females due to adrenocortical hyperplasia or cortical tumours has been the subject of much study. Broster *et al.* (1938) and others have shown that in extreme cases a combination of aggressiveness and paranoid thinking are to be expected. It has been claimed that after operation a more normal adrenal function is accompanied by reduction in psychopathic elements. These are extreme conditions, and operation seems to be very seldom indicated. Nevertheless, this work suggests that further research in the relationship between hypercortical adrenalism and aggressive paranoid behaviour might be worth while.

Experimental Endocrine Treatment

Endocrine treatment in the psychoses is still in the experimental stage, since up to the present no conclusive evidence has been produced about its rationale and value. In spite of the views expressed by some workers there is nothing to suggest that a new system of psychiatric diagnosis or classification can be derived from endocrine investigations, and classical concepts cannot be disregarded nor can laboratory methods replace clinical observation.

Most analytic methods so far evolved lack precision, and it is not certain what are the range and the significance of normal values in non-psychotic individuals, how much variation within the range normally occurs, and how the values are affected by age, sex, physical illness, diet, and state of nutrition.

Therapy directed on the basis of figures alone is notoriously unsatisfactory in general medicine, and is even more open to error in psychiatry. In a series of 150 recent and chronic psychotics, with some psychoneurotics, treated on laboratory indications at the Bristol Mental Hospitals, only 12 showed a significant improvement considered to be due to the hormone therapy. Psychiatric recovery or deterioration does not necessarily correspond with laboratory findings.

Nevertheless, in spite of the limitations of the methods, and the impossibility of defining scientifically the dimensions of psychiatric illnesses and degrees of improvement or deterioration, there is a good deal of evidence to justify research in the field of experimental endocrinology, with a hope of eventual therapy in some conditions.

Gjessing (1938) has shown that in the rare condition called periodic catatonia, alterations in nitrogen balance coincided with the catatonic episodes, and the attacks could be terminated or aborted by treatment with thyroxine and dried thyroid to discharge nitrogen stored. The value of Gjessing's treatment has been confirmed by other workers.

Many psychotics, especially schizophrenics, do not react normally to hormones. It has been shown that schizophrenics are, or soon become, insensitive to thyroid; and insulin resistance in schizophrenia is well known. The same seems to be true for cortisone and A.C.T.H.: neither depressives nor schizophrenics usually exhibit the euphoria and emotional changes described in normals. Hench *et al.* (1950) and others believed that the familiar euphoria was not due to relief of pain, but a positive factor accompanied by increased mental function. Some workers have assumed that psychological changes were most marked where there was some evidence of previous mental illness or psychological maladjustment; this is certainly not the case. Lewis and Fleminger (1954) have shown that of 12 patients with a history of recent mental illness who had been treated with cortisone or A.C.T.H. none developed a severe mental illness. In the Bristol Mental Hospitals, A.C.T.H. has been used extensively, and reactions comparable to those described in normals have never been seen. This suggests that in some psychiatric disorders the ductless gland system is abnormal; it may be insensitive or react in an abnormal way, or metabolic processes may destroy or neutralize the action of hormones.

A great amount of research in the endocrinology of schizophrenia, especially of the adrenal cortex, has been carried out at various centres. Evidence of failure to preserve adequate endocrine equilibrium and of abnormal adrenal responsiveness has been advanced, but the treatment of schizophrenia with A.C.T.H. on the assumption of evidence of lack of adrenal stimulation, attempted by Glaser and Hoch (1951), by the Worcester group (Hope *et al.*, 1952), by Kobbernagel *et al.* (1953) in Scandinavia, and at the Bristol Mental Hospitals and elsewhere, has been practically unsuccessful.

Cortisone has been used, on the whole without much success, but Cohn *et al.* (1953) have reported that 6 out of 21 chronic patients who had been ill for about six years were discharged from hospital. Their patients were treated with between 300 and 800 mg. daily for four weeks. Toxic effects were observed in four at least, with oedema, retention of urine, and renal colic. It is possible that those who improved did so because of the destructive action of cortisone on the hypothalamus.

Castor *et al.* (1951) have shown that A.C.T.H. in rats produced degeneration of the paraventricular nuclei of the thalamus; cortisone did the same, but it also produced changes in the thalamic and hypothalamic nerve cells. These areas are usually affected by prefrontal leucotomy, and it is probable that Cohn's success was due not to the physiological but to the destructive effect of the cortisone.

Treatment with thyroid has been recommended in various conditions. Danziger and Kindwall (1953) have reported success in a number of cases of schizophrenia in which failure to remain in remission after other forms of treatment, or periodic fluctuations, seem to be common features. Their material may include cases of Gjessing's type. It is therefore worth while administering thyroid to the point of toxicity empirically in relapsing schizophrenia after E.C.T. and insulin-coma therapy have been unsuccessful. Thyroid is valuable in reducing apathy in schizophrenics after insulin coma (Mayer-Gross *et al.*, 1954).

Yet the role of the thyroid in psychiatric illness is still quite uncertain. Reiss (1954), using a radioactive technique, has reported that the thyroid activity was within the limits he regarded as normal in about 70% of psychiatric admissions. In a selected series of 450 cases, after treatment by various methods, including hormones, E.C.T. and insulin coma, the thyroid activity was reported as "normal" in 72%. This suggests that the thyroid state is of consequence in only a very small percentage of psychiatric cases, if at all, irrespective of whether the thyroid activity is regarded as causally related to the illness or indirectly as an indicator of the state of the endocrine equilibrium.

In manic-depressive psychosis A.C.T.H. has been used as an alternative to E.C.T., on the assumption that E.C.T. exercises its favourable effect by the mobilization of anterior pituitary hormones. But, although in a very few cases remissions have been seen after a single dose of 25 mg. of A.C.T.H., this hormone is practically valueless in depression and without effect in mania, as Cleghorn *et al.* (1950) and the Worcester group have reported.

Sands (1954) recommends dehydroisoandrosterone ("diandron") for young inadequate psychopaths with timidity, physical immaturity, little energy, and perhaps homosexuality; to combat the residual disabilities after insulin coma therapy in schizophrenia; in stammering, on a basis of inadequacy; and to assist psychotherapy in some cases of neurosis. Strauss *et al.* (1952) originally gave three criteria: abnormal 17-ketosteroid excretion, a mild or slowly deteriorating mental illness, and the appearance of physical immaturity. They regarded the normal ketosteroids as 6 to 21 mg. per 24 hours, and the beta fraction 5 to 15%. Diandron is contraindicated where there is evidence of aggressive traits. Dosage is 5 to 30 mg. orally. Overdosage is suggested by undue irritability and over-activity.

Summary

There is a place for endocrine treatment in psychiatry, and the psychiatrist is often confronted with complications of the menses, the menopause, disturbance of libido, homosexuality, male climacteric, and cretinism. Treatments for these are reviewed.

In the field of the psychoses there is some evidence of endocrine disturbances, the exact nature of which is not yet clear. Random cures of psychotic conditions are always to be expected, but they contribute little to the understanding of the physiology of mental disorders.

Assuming that functional derangements of endocrine balance occur spontaneously and are responsible for psychotic illnesses, spontaneous remissions are to be expected, which must make one extremely cautious in attributing recovery to a particular therapy. It is probable that there is a time lag between alteration in physiological state and the appearance of mental change, which would make a reliable correlation of physiological and clinical observations difficult.

"For doctors in Nyasaland the mango season means a plague of 'mango fractures.' Every year about this time the hospitals, especially in Zomba, the capital, are crowded with piccininnies with broken limbs, plaster-of-paris hall-marks of an over-ambitious pursuit of the delectable fruit. Recently in Zomba there were eight small African boys with fractured legs—all victims of the mango craze, and all very sorry for themselves. But the little devils will never learn so long as their elders fail to set a good example of careful climbing and cautious picking: in a village not far from Zomba two Africans, grandfathers both, broke their arms when falling from mango trees, which often reach a height of sixty and seventy feet. Mangoes, incidentally, which were probably introduced into the Protectorate by Arab slave traders, are the most widely cultivated tropical fruit. They say Buddha often rested in the shade of mango trees. He would be unwise to take the risk in Nyasaland."—*Manchester Guardian*.

SPONTANEOUS AND INDUCED WATER INTOXICATION IN TWO CASES OF HYPOPITUITARISM

BY

VICTOR WYNN, M.D.

Senior Lecturer in Surgery, St. Mary's Hospital,
London, W.2

AND

OLIVER GARROD, M.D., M.R.C.P.

Consultant Physician, Barnet General Hospital; late Senior
Medical Registrar, Postgraduate Medical School of
London, W.12

It has been known for many years that patients with adrenocortical failure, whether this be primary or secondary to anterior hypopituitarism, are unable to excrete ingested water at the normal rate (Rowntree and Snell, 1931; Robinson *et al.*, 1941; Levy *et al.*, 1946). Less recognized is the possibility that patients with hypopituitarism may retain water in excess of electrolytes while on ordinary diets and without apparent forcing of their fluid intake. Such water retention* would lead to dilution of body fluids (hypotonicity) and, finally, to symptoms of water intoxication. Whittaker and Whitehead (1954) have described the case of a patient with hypopituitarism whose death they attributed to spontaneous water intoxication. The present report describes two such cases in which a similar, though reversible, abnormality was observed.

Apart from its spontaneous occurrence, water intoxication is occasionally precipitated by water-diuresis tests in patients with hypopituitarism. Pickford and Watt (1950) have reported this complication, which also occurred in both of our patients.

In primary water retention the plasma sodium concentration falls, although the total body sodium may not be reduced. The plasma sodium concentration may also be low in severe sodium depletion, a finding which, by itself, is often regarded as evidence of depletion of this ion. It is important, therefore, to distinguish between these two hyponatraemic states, since they differ in cause, metabolic effects, and treatment (Wynn and Rob, 1954).

Briefly, sodium depletion leads to loss of body water and haemoconcentration. The patient loses weight, looks haggard, and shows loss of tissue turgor. The circulation is impaired, the blood urea rises, the plasma potassium may be raised, and there is usually a metabolic acidosis. If the kidneys behave normally there is little fall in plasma sodium concentration until loss of this ion is more than 300–500 mEq (McCance, 1936), because water is at first excreted to maintain a normal osmotic pressure of the body fluids.

With primary water retention there is no dehydration but the reverse. The body weight exceeds normal, and the circulation does not fail unless hypotonicity is extreme. The plasma sodium concentration is always

*Unfortunately the term "water retention" is used in two senses in clinical medicine. Most commonly it is used to imply isotonic retention of both water and sodium, a condition which finally results in pitting oedema. The second sense, used in this report, means that water is retained alone or in excess of electrolytes. Since about two-thirds of this water is located in the cells (Wynn and Rob, 1954) the result is not pitting (extracellular) oedema but intracellular overhydration and dilution of body fluids.

low; acidosis and urea retention may be absent, and the plasma potassium concentration may be normal or low. The symptoms of water intoxication are not unlike those of sodium depletion, but with certain differences (Wynn and Rob, 1954). Gross hypotonicity causes weakness or great prostration, lethargy, anorexia, vomiting, mental disturbances, and, finally, convulsions and coma, which may prove fatal.

The following two cases of hypopituitarism illustrate the occurrence of water intoxication, both spontaneously and after a water-excretion test.

Case 1

M. W., a woman aged 53, had suffered from anterior hypopituitarism since 1941, when her pituitary gland was removed for mild acromegaly. In May, 1953, she came into St. Mary's Hospital for investigation, having had no specific treatment for her condition. She had had amenorrhoea since the operation and had long complained of weakness, tiredness, and difficulty in keeping warm; her incapacity was such that she had hardly left her bed for many years. On examination there were slight skeletal signs of acromegaly. She was thin, pale, and expressionless. Her speech was slow, monotonous, and slurred. There was loss of eyebrows and of axillary and pubic hair. The thyroid gland was not palpable. There were no abnormal cardiovascular, urinary, or neurological findings, and the blood pressure was 130/70. There were no signs of dehydration, and her weight was 52.3 kg.

The following investigations were made: urinalysis negative; Hb, 12.6 g.%; plasma sodium 116, potassium 4.1, chloride 83, and total CO₂ 26.2 mEq per litre; plasma non-protein nitrogen, 20 mg. per 100 ml. (Table I).

TABLE I.—Case 1: Blood and Plasma Chemistry, Blood Pressure, and Weight

Day	Hb. (g.%)	Haematocrit	Na (mEq/l.)	K (mEq/l.)	Cl (mEq/l.)	Total CO ₂ (mEq/l.)	N.P.N. (mg./100 ml.)	Protein (g./100 ml.)	B.P. (mm. Hg)	Weight	
										kg.	lb.
—14*	12.6	—	116	4.1	83.0	26.2	20	—	130/70	52.3	115.2
1	10.5	—	125	4.2	88.5	28.0	20	6.2	130/70	52.3	115.2
2	10.6	35.5	125	4.1	88.0	27.2	20	6.5	140/85	52.3	115.2

Tests of endocrine function, showing adrenal and thyroid failure, are summarized in Table II. A water diuresis test of adrenal function, performed in ignorance of the low plasma sodium concentration, caused severe symptoms of water intoxication, including great prostration, nausea, vomiting, mental confusion, and a fall of blood pressure to 80/50. Only 9.5% of the litre of water given was excreted in three hours.

Experimental Observations

Methods.—Fourteen days after the episode of water intoxication described above a metabolic balance study was carried out. The patient was put on a diet containing about 50 mEq of sodium a day. Duplicate diets were bulked for three days and analysed for sodium, potassium, chloride, and nitrogen. Aliquots of three-day stool and 24-hour urine

FIG. 1.—Metabolic balance data in relation to cortisone therapy in Case 1.

collections were also analysed. The patient was weighed daily before breakfast, after emptying the bladder, and when possible after defaecation, on scales sensitive to 30 g. (1 oz). After 24 hours on this diet, body weight and plasma electrolyte concentrations having stayed constant, she was given 100 mg. of cortisone a day by mouth, in four divided doses, for one week; cortisone was then discontinued. After a 12-day interval with no treatment the cortisone therapy was repeated.

Results (Fig. 1, Table I).—Twenty-four hours after starting cortisone the following changes were observed. The body weight had fallen by 2.05 kg. (4.5 lb.) owing to a large water diuresis (4,200 ml. of urine in 24 hours, which contained a total of 48 mEq of sodium and 74 mEq of potassium). The balance of water and electrolytes was: water -2 litres; sodium ± 0 ; potassium -30 mEq. The plasma sodium had risen from 125 to 132, and chloride from 88 to 95 mEq per litre.[†]

During the next 48 hours there was no further change in body weight, and the plasma sodium rose to 136 mEq per

[†]On simple osmotic theory, the expected and the observed rises in plasma sodium were close. Thus, assuming the total body water initially to be 65% of body weight—that is, 34 litres—then the final sodium should have been approximately $\frac{34 \times 125}{32} = 133$ mEq per litre.

litre. At this point—that is, 72 hours after starting cortisone—the cumulative balances were: water -2 litres; sodium +80 mEq; potassium ± 0 . The serum protein and Hb concentrations had risen slightly, suggesting haemoconcentration. The patient felt very much better whilst on cortisone; there was an increase in muscle power and animation, and her facial colour improved.

During the seven-day period of cortisone treatment 195 mEq of sodium was retained and 38 mEq of potassium lost, and during the latter half of this period the gain in weight was 0.4 kg. (0.9 lb.).

On stopping cortisone for 12 days the plasma sodium fell from 136 to 122 mEq per litre. There was a negative sodium balance of 300 mEq. However, instead of the expected fall in body weight, there was a small rise (0.2 kg., Table I). Thus, the usual renal regulation of osmotic pressure did not occur and water was retained in excess of electrolytes, resulting in severe hypotonicity. The patient's previous symptoms of weakness and lethargy returned.

On repeating the cortisone treatment (100 mg. a day) there was a prompt water diuresis, loss of weight (1.7 kg.), and a rise in plasma sodium concentration from 122 to 136 mEq per litre during the first two days (Fig. 1), during which time only 55 mEq of sodium and 45 mEq of potassium were retained. Clinical improvement was immediate.

These data suggest that the low plasma sodium concentrations present on each occasion before cortisone treatment were due mainly to spontaneous water retention. They also

FIG. 2.—Effect of cortisone on water diuresis in Cases 1 and 2.

show that cortisone acutely corrected the sodium dilution. Further tests showed that cortisone acutely restored the ability to excrete a water load rapidly (Fig. 2). Since clinical improvement followed restoration of a normal plasma sodium concentration, it is possible that the symptoms were attributable, partly at any rate, to hypotonicity.

During six weeks of treatment with cortisone (50 mg. a day), later supplemented by D.C.A. (2.5 mg. a day), and a sodium intake of 125-200 mEq a day, the highest weight recorded was 51.5 kg. (113.3 lb.). This was less than the patient's initial weight (52.3 kg.), which further supports the interpretation that there was originally excessive water retention.

Case 2†

J.B., a housewife aged 53, was admitted to Hammer-smith Hospital in January, 1953, with an initial diagnosis of myxoedema. However, at 40 she had had a severe post-partum haemorrhage which had needed blood transfusion and which was followed by complete failure of lactation. The menopause at 51 was followed by the onset of myxoedema, which had become gross by the time of her admission.

[†]This case has already been described briefly in relation to her episodes of hypopituitary coma (Caughy and Garrod, 1954).

Her behaviour, voice, and appearance were those of classical myxoedema, with superadded features of hypopituitarism. In addition to loss of eyebrows and partial baldness of the scalp, there was total loss of axillary and pubic hair and absence of cutaneous pigment. There were no abnormal findings in the cardiovascular, urinary, or neurological systems, and the blood pressure was 140/90.

The following investigations were made: urinalysis, negative; Hb, 11.4 g.%. Tests of endocrine function showing gonadotrophic, adrenal, and thyroid failure are summarized in Table II.

Clinical Observations

The patient gained 3 kg. (6.6 lb.) in weight during her first three days in hospital. Two days later she became nauseated and stuporous after a water diuresis test, and the blood

FIG. 3.—Metabolic changes in relation to therapy in Case 2.

pressure fell to 100/70. She had excreted only 9% of the water dose of 1,320 ml. during four hours, and had remained oliguric during the next 24 hours. The plasma sodium was 116 and the chloride 85 mEq per litre, and blood urea was 21 mg. per 100 ml. She was then given 100 mg. of cortisone by mouth, 5 mg. of D.C.A. by intramuscular injection, and an infusion of 600 ml. of 5% glucose in 0.3% saline. Within 24 hours of starting treatment she passed large volumes of urine, lost 1.9 kg. (4.2 lb.) in weight, and regained full consciousness. Later she was discharged on thyroxine and a testosterone implant.

In November, 1953, she was readmitted in relapse, having omitted to take any treatment for five months. The blood urea was 16 mg. per 100 ml., plasma cholesterol 389 mg. per 100 ml., and B.M.R. -36% (Robertson and Read). Her subsequent course is charted in Fig. 3. By the 13th day in hospital, while on a normal diet and without specific treatment, she had gained 2.5 kg. (5.5 lb.) in weight. The plasma sodium had fallen from 130 to the very low level of 107 mEq per litre, and potassium from 5.7 to 4.2 mEq per litre. On the 12th day she was nauseated, and during the 13th day she became irritable, then drowsy and stuporous, with a blood pressure of 120/90. She was given 200 mg. of cortisone by mouth in divided doses and one 10-mg. injection of D.C.A., followed by 75 mg. of cortisone a day for three

days. During the first two days on cortisone she passed 3.1 litres of urine containing only a trace of sodium, and by the third day she had lost 2 kg. (4.4 lb.) in weight and the plasma sodium had risen to 130 mEq per litre. Full consciousness returned within 24 hours of starting treatment with cortisone. The loss of weight, due to excretion of water without sodium, accompanied by a rise in plasma sodium of 23 mEq, suggests that the hypotonicity was due mainly to water retention.

While still on cortisone, an episode of true sodium depletion occurred, the signs of which differed from those just described. Seven days after starting cortisone therapy the patient became aggressive and mentally confused and began to pass large amounts of sodium in her urine (784 mEq in three days). The body weight fell by a further 2.5 kg. (5.5 lb.) in two days. The exact negative sodium balance was not known, but probably exceeded 500 mEq. On the 10th day of cortisone therapy she needed forcible restraint, and four hours after an injection of paraldehyde (10 ml.) became comatose and pulseless. Her appearance was that of severe dehydration. The systolic blood pressure fell to less than 70 mm. Hg. and at one time could not be measured. The plasma sodium had fallen only to 117 mEq per litre, as compared with 107 mEq during the previous episode of water retention when the circulation was relatively normal. This classic crisis of sodium depletion and dehydration was successfully treated with saline infusion, D.C.A., and intravenous cortisone.

Subsequently, tests showed that normal water diuresis could be restored within three hours by intravenous or oral cortisone, but not by prolonged treatment with testosterone (300-mg. implant) and thyroxine (0.3 mg. a day) (Fig. 2).

Discussion

Both of these patients retained water in excess of electrolytes while on ordinary ward diets. This was shown by a large gain in weight accompanied by a profound fall in plasma sodium concentration—to 116 mEq per litre in Case 1, and to 107 mEq per litre in Case 2. In both patients the water retention was corrected by cortisone, which caused a large water diuresis. The plasma sodium concentration rose towards normal, although there was little change in total body sodium. The stupor which accompanied the hypotonicity in Case 2, and the symptoms of weakness and prostration in Case 1, were relieved when the excess of water was excreted.

Following a water-excretion test, and superimposed on the chronic water retention, there were acute symptoms of water intoxication, including nausea, vomiting, severe prostration, mental confusion, and, in Case 1, a sharp fall of blood pressure. These untoward effects probably occurred because hypotonicity was already significant in both patients when the test was carried out. This interpretation is supported by the fact that later, when the plasma sodium concentration was normal, there were no symptoms from water-excretion tests, although retention of the water dose was roughly the same as before.

Despite much investigation, the cause of the failure of water diuresis in hypo-adrenal states is still uncertain (Lewis, 1953). Cortisone corrects this failure, whereas deoxycortone acetate, testosterone, and thyroid extract are largely ineffective (Slessor, 1951; Garrod and Burston, 1952). Since cortisone also prevents chronic over-retention of water in hypopituitarism, it is likely that the failure of water homeostasis is mainly conditioned by inadequate secretion of 17-hydroxycorticosteroids.

In hypopituitarism it would appear that adrenocortical secretion of steroids may fail in a selective manner. Thus, androgen secretion, measured by 17-ketosteroid output (in the female), fails early; and 17-hydroxycorticosteroid secretion (cortisone and hydrocortisone), as measured in the blood (R. I. S. Bayliss and A. W. Steinbeck, 1954, personal communication) and urine (Cope *et al.*, 1951) is usually very low. Yet mineralo-corticoid secretion, now believed to be

aldosterone (Simpson *et al.*, 1953), which may not be dependent on pituitary control, seems to be adequate for the patient's normal needs; because severe sodium depletion, such as occurs regularly in untreated Addison's disease, is an unusual feature of adrenal failure secondary to hypopituitarism, unless it is provoked by infections, gastroenteritis, or surgical stresses (Peters *et al.*, 1954; Caughey and Garrod, 1954). This conclusion is supported by the results of Luetscher and Axelrad (1954), who found normal amounts of aldosterone in the urine of two cases of severe hypopituitarism, although this steroid was absent in the urine of patients with primary adrenal insufficiency. It is not surprising, therefore, that pure water retention without significant sodium depletion can occur in hypopituitarism. That it may not be uncommon is suggested by reports of very low plasma sodium concentrations, without evidence of dehydration or crisis, in patients with this condition—for example Bartter *et al.* (1950), Waterhouse *et al.* (1952), Peters *et al.* (1954), and Aber *et al.* (1954)—a state of affairs which has usually been attributed to sodium depletion.

As though to protect themselves from water retention, and because of their lowered metabolism, which reduces the solute load to the kidneys, patients with advanced hypopituitarism usually drink very little, and their urinary volumes are correspondingly small (Case 1 was exceptional in that her urine output, when not on cortisone, was around 1.5 litres a day). Admission to hospital may present a definite hazard to such patients because of a tendency to force the fluid intake, especially when urine output is low. This should be avoided by special instructions to the nursing staff.

Daily weighing of the patient is the simplest way to detect large changes in water balance. A gain in weight accompanied by a fall in plasma sodium concentration suggests primary water retention. It should be stressed that dangerous hypotonicity can exist without clinical signs, and that peripheral oedema is not a manifestation of primary water retention (although the two conditions may occur together).

Once the danger of forcing fluids in hypopituitary patients is recognized, it follows that water-excretion tests are unwise when plasma sodium estimations show that significant hypotonicity already exists. If the plasma sodium exceeds 130 mEq per litre the diluting effect of a litre or so of water is unlikely to cause untoward symptoms. Since cortisone acts rapidly to cause water excretion in adrenal failure, it should be available for use whenever water-excretion tests are performed in these patients.

Conclusions and Summary

An abnormality of water balance is described in two patients with anterior hypopituitarism. Although their intake of fluids was not forced, they retained water in excess of electrolytes, causing dilution of the body fluids and symptoms of water intoxication. The diagnosis was suggested by a gain in weight and a very low plasma sodium concentration. When cortisone was given there was a prompt water diuresis and the plasma sodium concentration rose to normal, though there was little change in the total body sodium. Water retention may not be very rare in anterior hypopituitarism, although it appears to have been reported as such in only one other case (Whittaker and Whitehead, 1954).

In addition to chronic water retention, acute symptoms of water intoxication, including nausea, vomiting, extreme prostration, mental confusion, and stupor, were precipitated by water-excretion tests of adrenal function. This untoward effect of the test probably occurred because there was already excessive dilution of body fluids which was not recognized when the tests were performed. To avoid this complication, a water-excretion test should not be carried out until the plasma

sodium concentration is known. If symptoms due to water retention occur in patients with hypo-adrenal function, cortisone should be given, whereupon the excess water will be excreted rapidly.

We wish to thank Professor G. W. Pickering and Dr. Russell Fraser for allowing us to study cases under their care.

RESULTS OF PARTIAL GASTRECTOMY IN TREATMENT OF PEPTIC ULCER

BY

C. D. ANDERSON, M.B., F.R.F.P.S., M.R.C.P.

R. T. S. GUNN, M.B., F.R.F.P.S., M.R.C.P.

AND

J. K. WAIT, M.B., F.R.C.S., F.R.F.P.S.

(From the Peptic Ulcer Clinic, Western Infirmary, Glasgow)

Partial gastrectomy has now gained general acceptance as the operation of choice in the treatment of gastric ulcer, and although it is widely used in the treatment of duodenal ulcer its results therein are not so universally acclaimed. Because of its wide usage, much information has accumulated about the effects of the operation, particular attention being focused on the various disturbing after-effects produced.

This investigation was begun in an attempt to assess the value of the operation, and to determine whether partial gastrectomy was capable of relieving the patient of his ulcer symptoms, freeing him from irksome dietary rules, and restoring him to a satisfactory economic life.

Method of Follow-up

This survey is based on a personal follow-up of cases of peptic ulcer submitted to gastrectomy of the Polya type in one surgical unit in the years 1940 to 1951 inclusive. Of 481 patients surviving partial gastrectomy, both elective and emergency, 23 were found to have died of intercurrent disease. Of the remaining 458, 415 (90.6%) were traced and interviewed. Of these, 379 were interviewed personally by one of us with the aid of an agreed schedule of questions, and the results were graded jointly. Information regarding 36 patients who lived too far away to travel was obtained through the courtesy of their own practitioners. Because mild post-gastrectomy symptoms are common in the immediate post-operative period and usually improve or disappear

during the succeeding six months, no patient was interviewed until at least a year after operation.

An overall assessment of the success, or otherwise, of partial gastrectomy was made by classifying the results into three categories: "good," when a good or excellent result had been obtained; "satisfactory," when the patient was substantially improved in comparison with his pre-operative state; and "poor," when no marked improvement had occurred or the patient's condition was worse than before operation. Each patient was asked for an opinion regarding the success of the operation, and the observer made a separate estimate based on all aspects of the patient's health. No result was adjudged to be "poor" on account of anaemia alone, as this is in most cases correctable by the administration of iron. Seven patients who developed tuberculosis were regarded as "poor" results on the assumption of a close relationship between this disease and gastrectomy.

Clinical Assessment

The results are presented in Table I, and the number of patients satisfied with their post-operative state is seen to be very impressive. Only 16 patients out of 415 considered

TABLE I.—Clinical Assessment

Result	Patient's Opinion	Observer's Assessment
Good	338 (81.4%)	266 (64.1%)
Satisfactory	61 (14.7%)	99 (23.9%)
Poor	16 (3.9%)	50 (12.0%)

that they had obtained no benefit from partial gastrectomy. The stricter criteria of success adopted by the observers produce a different picture, and 50 (12%) were considered to have had a "poor" result from operation.

On analysis there was found to be no significant correlation between the clinical result and such factors as the age of the patient, the duration of ulcer symptoms, and the site of ulcer; nor did variations in operative technique influence the outcome, as there was no significant difference in result between 276 antecolic and 131 retrocolic anastomoses.

In comparing the sexes (Table II) it was found that the number classified as "poor" was essentially the same, but fewer of the women were regarded as having a "good" result, a number of otherwise excellent results being classified as "satisfactory" owing to anaemia.

TABLE II.—Result in Relation to Sex of Patient

Sex	No. of Patients	Result as Assessed by Observer		
		Good	Satisfactory	Poor
Male	355	231 (65.1%)	81 (22.8%)	43 (12.1%)
Female	60	35 (58.3%)	18 (30.0%)	7 (11.7%)

Operative Mortality

With increasing experience of the operation and better pre- and post-operative management (Illingworth, 1953) it was found that the mortality rate of the operation gradually improved throughout the years of the series, and it is now 3.3% (214 cases, 1951-2).

Of all the factors investigated which might influence the mortality rate, the age of the patient was found to be the most important. Over 50 years of age the rate rose steeply and cardiac and respiratory causes of death contributed largely to the higher mortality in the older patients. The duration of ulcer history, the sex of the patient, and the type of operation performed did not affect the mortality rate to a marked extent.

Tuberculosis after Partial Gastrectomy

It is suspected that there is an increased liability to pulmonary tuberculosis after partial gastrectomy. Attention was focused on this possibility by Pulvertaft (1952), who

found that of 23 deaths subsequent to operation 8 were due to tuberculosis. The occurrence of such deaths had previously been noted without comment by other authors (Bruusgaard, 1946; Ransom, 1947), but none found such a high incidence as did Pulvertaft.

In the present series there have been 8 deaths due to pulmonary tuberculosis in a total of 23 intercurrent deaths. In addition, 8 patients still alive were found to have had pulmonary tuberculosis, and in 6 of these the lesion was still active. Thus in 481 patients surviving operation, 16 (3.3%) are known to have developed active tuberculosis.

Such a figure would appear to be definite evidence of an increased liability to tuberculosis in patients who have undergone partial gastrectomy. It is therefore suggested that the presence of active tuberculosis in an ulcer patient should be accepted as an absolute contraindication to partial gastrectomy, and the presence of a latent lesion should give rise to serious consideration of the advisability of this operation. Since 1952 a pre-operative chest film has been taken routinely in this unit, and this would appear to be a wise precaution.

The reason for the increased liability to tuberculosis is not known, but Pulvertaft's suggestion that it is "related to the recognized loss of weight following gastrectomy" seems very reasonable. There is little doubt that the nutrition of many of these patients is inadequate, and this could be the determining factor in the development of tuberculosis.

Anaemia after Partial Gastrectomy

It is generally accepted that macrocytic anaemia with a megaloblastic bone marrow is very rare after partial gastrectomy, though more common after total gastrectomy. Only one case of atypical macrocytic anaemia occurred in this series, and we hesitate to label it as a verified case. Iron-deficiency anaemia, on the other hand, is far from uncommon and is generally thought to be due to the inadequate absorption of food iron after partial gastrectomy.

In this investigation the haemoglobin level, as measured by the Sahli method, was ascertained at each interview, and cases with values below 70% had a full haematological examination carried out. The results are plotted separately

FIG. 1.—Haemoglobin levels. (Sahli: standard 14 g. per 100 ml.)

for males and females in Fig. 1. It will be seen that the haemoglobin level is subnormal in the majority of patients, especially females. The values for men tend to be situated in the range 80-95%, and for women 70-90%.

It is suggested that diminished iron absorption after partial gastrectomy produces, in general, a haemoglobin level lower than that of normal individuals. In some cases symptoms of tiredness or shortness of breath are produced, especially in women in whom the additional factor of menstruation is involved. The administration of iron by mouth is usually curative, and those who do not respond adequately can be controlled by periodic injections of intravenous iron.

Loss of Weight after Partial Gastrectomy

The occurrence of loss of weight after partial gastrectomy is accepted by most authorities (Everson, 1952; Pulvertaft, 1952), the degree of such loss depending on the standards adopted. In this survey, in each patient the post-operative

weight at the time of interview has been compared with his normal weight in health. The findings are presented in Table III and in Fig. 2, the change in weight being indicated according to the formula

$$\frac{\text{Present weight} - \text{Normal pre-illness weight}}{\text{Normal pre-illness weight}} \times 100.$$

TABLE III.—Change in Weight

Change in Weight	Males	Females
+5% or more	27 (8.6%)	4 (7.8%)
-5% to +4%	114 (36.2%)	14 (27.5%)
-6% to -10%	81 (25.7%)	8 (15.7%)
-11% to -15%	56 (17.8%)	14 (27.5%)
-16% to -20%	30 (9.5%)	6 (11.8%)
-20% or more	7 (2.2%)	5 (9.8%)

The change in weight was calculated by expressing the present weight as a percentage of the normal pre-illness weight and thereafter noting the percentage gain or loss.

FIG. 2.—Weight change after partial gastrectomy

$$\frac{\text{Present weight} - \text{Normal pre-illness weight}}{\text{Normal pre-illness weight}} \times 100$$

If it is accepted that a 5% loss of weight is within the limits of normality, 44.8% of males and 35.3% of females regained their pre-illness weight. This compares with Pulvertaft's figures of 53.9% for males and 37.2% for females. A substantial degree of weight loss (more than 10%) is noted in 29.5% of men and 49.1% of women. Such figures leave no doubt that loss of weight after partial gastrectomy is a real entity, and many patients are seriously disturbed by it.

Recurrent Ulceration

The frequency of recurrent ulceration after partial gastrectomy would appear to depend on the level of gastric resection (Visick, 1948). In this unit resection is performed above the lowest of the vasa brevia, and the gastric remnant is a tubular pouch about 2 in. (5 cm.) wide and 6 in. (15 cm.) long. With such a resection, acid secretion has been found to be negligible or absent, and, accordingly, the risk of recurrent ulcer is slight. In this series, recurrent ulcer was proved in only 4 out of 438 partial gastrectomies. Two of these were demonstrated by gastroscopy; one patient died from a gastro-jejuno-colic fistula and the fourth from recurrent haematemesis. Ulcer has been suspected on clinical grounds in another seven patients, but a full investigation, including laparotomy in two, has proved negative. In none of these patients has the pain responded to ulcer therapy, and it is thought that the symptoms are not due to ulcer.

This gives an ascertained recurrence rate of 0.9%. This accords with Visick's (1948) experience of measured radical gastrectomy (an even more extensive resection), when he noted no recurrence in 200 patients. If a less extensive resection is preferred in view of the probable lesser operative risk and the lower incidence of post-gastrectomy symptoms (Pulvertaft, 1952), a higher recurrent ulcer rate must be accepted—for example, 3.7% (Visick, 1948).

Post-Gastrectomy Symptoms

Estimates of the incidence of these symptoms vary enormously with different observers up to the high figure of 75% (Muir, 1949). Symptoms do occur in many patients

soon after operation but tend to diminish or disappear within the first six months, and in some cases are acknowledged only after careful inquiry. As our patients were not interviewed until at least a year had elapsed since operation, it was thought that a reasonable estimate of the incidence of symptoms was possible.

The following classification into four categories was adopted: (a) no symptoms; (b) fullness only—that is, a sensation of epigastric fullness induced by meals of small quantity (two small courses or less) without other symptoms; (c) "dumping"—mild or severe; and (d) bilious vomiting—mild or severe. Frequent overlap was found between the latter two categories.

Our estimate of the frequency of these symptoms is presented in Table IV. Severe symptoms were found to occur in 48 (11.8%), and consisted of severe dumping or severe

TABLE IV.—Post-gastrectomy Symptoms in 408 Patients

Symptoms	Males	Females	Total
Nil	184	26	210
Fullness only	57	10	67
• Dumping { Severe	17	4	21
Mild	40	6	46
• Bilious vomiting { Severe	26	4	30
Mild	32	9	41

* Overlap between these two categories was relatively common.

bilious vomiting or both. Milder symptoms were more common but on the whole relatively unimportant. From a study of the results of other authors (Butt *et al.*, 1948; Visick, 1948; Capper and Butler, 1951; Goligher and Riley, 1952) it would seem reasonable to assume that the incidence of severe symptoms is in the region of 5 to 10%. Unfortunately, it often proves difficult to relieve this minority of their symptoms, and, although a variety of medical and surgical remedies have been tried, the results on the whole are disappointing.

Hypoglycaemia and Vitamin Deficiencies

Hypoglycaemia is generally accepted as the cause of late symptoms two to three hours after a meal. Both the incidence and the resultant disability were found to be of minor importance in this series.

Vitamin-C deficiency was seen in one of our cases, and vitamin-B deficiency occurred in 17 patients, mainly in the form of cheilosis and glossitis. No gross deficiencies were noted such as were recorded by Wells and Welbourn (1951), and response to treatment was satisfactory.

Economic Results of Partial Gastrectomy

After discharge from hospital, usually 10 days after operation, patients are encouraged to return to their original work as soon as they are reasonably capable of so doing. Those performing heavy manual labour naturally tend to restart after a longer period and sometimes have to change to a lighter occupation. It is highly desirable that patients should resume work as soon as possible, both for economic and for psychological reasons.

From Table V it is seen that convalescence need not be unduly prolonged, as 84.3% were able to resume full work within six months. Only 3% of patients have failed to

TABLE V.—Time of Return to Work after Operation: 395 Patients

Time of Return after Operation	No. of Patients
1 month	38 (9.6%)
2 months	109 (27.6%)
3 months	100 (25.3%)
4-6 "	86 (21.8%)
7-9 "	20 (5.1%)
10-12 "	13 (3.3%)
Over 12 months	17 (4.3%)
No return to work	12 (3.0%)

return to work at any time since operation, though a larger number (7.3%) were not working at the time of the survey for various reasons—for example, unemployment, intercurrent illness, etc.

If partial gastrectomy is to be regarded as a satisfactory operation, patients must not only return to work within a reasonable period but be able to retain their jobs in competition with other workers. That they are eminently capable of remaining in employment is shown by Table VI, in which

TABLE VI.—Loss of Working Time (Male Workers)

Time Lost	Year Before Operation	Year Before Follow-up	
		All Workers	Heavy Workers
Nil	21.6%	79.9%	84.0%
1 month	16.6%	6.1%	6.4%
2 months	13.4%	4.3%	5.3%
3 "	15.3%	1.8%	—
4-5 "	21.3%	1.8%	1.1%
7-9 "	7.3%	2.4%	3.2%
10-11 "	4.5%	4.3%	—

the amount of work lost in the year prior to interview is recorded. Little or no work had been lost by 79.9%, and, indeed, many of these had never lost even a day since their return to work. In fairness, it must be admitted that some with post-gastrectomy symptoms were fortunate that they were able to take things easily after meals.

To illustrate the improvement in economic status after operation, a comparison is made of the loss of work before and after operation (Table VI). The comparison is impressive and indicates the economic value to the patient of a satisfactory partial gastrectomy. So satisfied with these results are the patients that the annoyance of mild symptoms is usually ignored.

The ability of heavy manual workers to perform their original job was next investigated. Various occupations were classed as "heavy" (involving heavy manual labour or requiring physical exertion beyond that of the average worker) or "light" (sedentary work or work requiring relatively little physical effort), and the class of work to which each patient returned was noted. As is seen in Table VII,

TABLE VII.—Return to Work after Operation: 134 Heavy Workers: 261 Light Workers

	Heavy Workers	Light Workers
Return to original or equivalent work	97 (72.4%)	220 (84.2%)
" " lighter work	30 (22.4%)	19 (7.3%)
Unemployed (labour market, other health reasons, etc.)	6 (4.5%)	14 (5.4%)
Unemployed (due to post-gastrectomy symptoms)	1 (0.7%)	8 (3.1%)

72.4% of heavy workers returned to their former occupation or to one involving equivalent or, in some cases, even heavier duties. Not only do the majority of heavy workers return to their former occupation, but they lose surprisingly little work after they have restarted (Table VI). From this evidence it is seen that the majority of heavy workers can be restored to a satisfactory economic life by partial gastrectomy.

Discussion

The satisfaction expressed by the large majority of patients with the results of partial gastrectomy underlines its value, and the low percentage of dissatisfied patients (3.9%) is reassuring. Unfortunately, those patients frequently do not respond to treatment, and this gives grounds for disquiet when considering the results as a whole. A large number (29.4%) are troubled by mild or severe post-gastrectomy symptoms, but they usually feel that these are tolerable by comparison with the disabling pain of ulcer.

The attraction which gastro-enterostomy still holds for the surgeon lies in the lower mortality of the operation and the rarity of symptoms of "dumping," bilious vomiting, loss of weight, and anaemia, but the price paid in recurrent ulceration is high. In spite of this, gastro-enterostomy still has a place in the treatment of duodenal ulcer. Because women are more liable to anaemia and weight loss after partial gastrectomy, and the severity, though not the inci-

dence, of stomal ulcer symptoms after gastro-enterostomy is less in women than in men (Clark, 1951), it is possible that the latter operation is to be preferred in females. Furthermore, in both sexes over 50 years of age the risk of stomal ulcer after simple anastomosis is less than average (Clark, 1951), and, as the mortality of partial gastrectomy rises so definitely with age, the simpler operation would appear to be preferable in older people.

In the largest group of duodenal ulcer patients—namely, adult males between 20 and 50 years of age—the risk of recurrent ulceration is such that it is considered that an extensive partial gastrectomy is desirable. In view of the evidence presented in this investigation, the results to be expected are good.

Even in those who do well, however, it is felt that something is lacking. Nutrition is substandard. In the majority the intake of food is limited to a less than average size of meal, and in some there is deficient absorption of fats with the occurrence of borderline fat absorption or actual steatorrhea. The extent of the deficiency in the individual patient is indicated by the degree of weight loss, which is substantial in nearly 50% of cases. The absorption defect is also evident in the case of iron and vitamin B. In most cases absorption of these is sufficient to meet normal requirements, but in some a clinical deficiency results.

From the evidence of deficient absorption of proteins and fat (Wollaege *et al.*, 1946), the tendency to loss of weight, the frequent presence of a subnormal haemoglobin level (Fig. 1), and the relatively frequent occurrence of vitamin deficiencies, it seems to us that a state not of malnutrition but of subnormal or substandard nutrition exists in a considerable number of cases after partial gastrectomy. This seems likely to be the precipitating factor in the development of tuberculosis or the reactivation of a quiescent lesion.

Summary

An assessment of the value of partial gastrectomy in the treatment of peptic ulcer is presented, based on a personal follow-up of cases operated on between 1940 and 1951. Particular attention was paid to the effect of the operation on the patient's working capacity, and the incidence of pulmonary tuberculosis, recurrent ulceration, loss of weight, anaemia, and post-gastrectomy symptoms was investigated.

Our thanks are due to Professor C. F. W. Illingworth for giving us access to the records of all these cases in which partial gastrectomy was performed in his unit in the Western Infirmary, Glasgow, and also for his advice and encouragement throughout this investigation. We are grateful to Miss Murray, the secretary of the Peptic Ulcer Clinic, for valuable clerical assistance.

The Second Panhellenic Congress of Hygiene was held in Athens from December 5 to 11, 1954, under the honorary chairmanship of the Minister of Social Welfare, Dr. CHRISTOS S. SOLOMONIDES. Among the 500 who attended were members of the Academy of Athens, the University of Athens, the Athens School of Hygiene, the Panhellenic Medical Association, and the Athens Medical Association, together with representatives of public health, social welfare, and engineering.

TREATMENT OF HAEMORRHAGE FROM PEPTIC ULCER BY CONTINUOUS INTRAGASTRIC MILK DRIP

BY

DESMOND W. ASHBY, M.D., M.R.C.P.

Physician to the Gateshead Group of Hospitals

AND

DENNIS WHITEHOUSE, M.R.C.P.

Senior Paediatric Registrar, Royal Victoria Infirmary,
Newcastle-upon-Tyne

"Where is the man who can live without dining?"

—EDWARD BULWER-LYTTON (*Owen Meredith*).

During the last century haemorrhage from peptic ulcer was treated by rest, starvation, and opium. The patient, anxious and weakened from blood loss, lay flat, enduring starvation and dehydration, ice being applied to his abdomen and parched lips. In a widespread belief that the giving of blood restarted haemorrhage, transfusion was withheld and enfeeblement prolonged.

Literature

Early in the present century, Lenhartz (1904) advised feeding with milk and raw eggs from the first day. However, many hospitals in this country continued to employ initial starvation until Meulengracht (1934) introduced a further plea for early generous feeding. "It seems doubtful," he wrote, "whether it be particularly expedient to pick out for weakening dietetic measures the very point of time when a patient has lost a considerable amount of blood and is rather poorly." The 'thirties saw other important therapeutic advances: Marriott and Kekwick (1935) demonstrated the importance of adequate transfusion; Finsterer (1933) made, and Gordon-Taylor (1935) successfully defended, the case for early operation in patients with established ulceration and severe haemorrhage, pointing to lower mortalities if the gastrectomy was performed in the first 48 hours. Those tempted to question whether this advice is applicable now the patient has adequate food and transfusion during the first two days should note that Tanner (1951) has proposed, and is at present employing, a return to the Finsterer regime. Recent authors, such as Ogilvie *et al.* (1952), have stressed the importance of medico-surgical team-work in the management of bleeding ulcers.

With what appeared to be steady therapeutic advances in the first half of this century one would have expected a comparable decline in mortality. However, there was a rise during the first quarter of the century. The factors which caused this and led to subsequent confusion were stated by Avery Jones (1947) in the Goulstonian Lectures. Those wishing to learn the pitfalls of drawing conclusions from published mortalities are referred to these lectures.

Briefly, from 1902 to 1907 published ulcer mortalities were 7% or under. Some of these low figures gave a false impression of the mortality in the country as a whole as they came from teaching hospitals having a smaller proportion of indigent and elderly patients. Some series excluded cases transferred to surgical wards or did not take into account the overall hospital results. Omissions of deaths from causes related to the management of the haemorrhage were also common. Nevertheless, making

allowances for these factors, Avery Jones was able to show that there was still a lower mortality due to the greater prevalence of acute ulcers in young women at this time, whereas after 1920 there were many more chronic ulcers in males over 40.

Between 1920 and 1932 relatively high mortalities were published. In 1927 Bulmer reported a mortality of 10.7% and in 1932 one of 13.5%. More reports came in from municipal hospitals which had poorer and older patients, among whom there was a greater proportion of gastric ulcer and a greater expectation of death from peptic ulcer haemorrhage. Of Avery Jones's patients, 33% were over 60, whereas former voluntary hospital series might have had only 10% of patients above this age. Mass hospital surveys might show even higher figures, and Chiesman (1932) reported a mortality of 25%. Comparable figures did not come from other parts of the world, and in Denmark, Meulengracht (1939), using generous feeding, showed only 1% mortality. However, only 30% of these patients showed radiological confirmation of ulcer.

Between 1935 and 1953 the mortality fell once more, and Avery Jones's (1947) figure of 8% may now be taken as a standard. These years reflected the improvement following adequate transfusion (Marriott and Kekwick, 1935), generous feeding (Meulengracht, 1939), and planned surgery (Finsterer, 1936; Gordon-Taylor, 1937).

Treatment by Continuous Intra-gastric Milk Drip

Impressed by the ulcer patient's rapid recovery from pain on a continuous intra-gastric milk drip, we looked for further improvement in feeding methods for bleeding peptic ulcer by combining the continuous intra-gastric milk drip employed by Winkelstein (1933) with early generous feeding as recommended by Meulengracht, the former being given as soon as the patient had settled in hospital and had received his morphine, the latter as soon as he wanted it, usually the morning of the second day. It was argued that such a regime would give adequate fluid replacement, complete nourishment, relieve the patient's shock, and reassure him. Furthermore, the continuous buffering action of the milk would bring early relief from pain, set the stage for early healing, and prevent pepsin from dissolving blood clot in the vessel mouth and ulcer base. The high morale and freedom from exhaustion and prostration in these patients has encouraged us to continue with this regime, although there is statistically little difference in its results from the one, previously adopted, of one-hourly milk feeds on the first day followed by a liberal diet on the second. It should be pointed out that the earlier group were fed generously and must not be regarded as a control group treated by restricted feeding. Both groups of patients received adequate transfusion.

Technique

The apparatus was simple, consisting of a Ryle stomach tube, a glass connexion, two lengths of rubber tubing, a drip chamber from a transfusion set, and a flask to hold the milk (see Fig. 1). The siphoning bottles used by Woldman (1936) for the continuous aluminium hydroxide drip were not employed. The mechanism of the drip was explained to the patient in simple terms: "This neutralizes the acid in your stomach and allows healing to go on during the night." The Ryle tube was passed nasally to the second mark or until gastric juice was obtained, when it was withdrawn slightly and strapped to the side of the face. It was considered an advantage to have the tip of the tube high in the stomach in order to "bathe" the ulcer area, while avoiding direct trauma from the tube. The American authors used a Levin tube or a collapsible tube made of latex (Woldman, 1937). The Ryle tube did not block easily,

and when the drip stopped it could often be restarted by milking the tube. The tube would be changed at varying times determined by discomfort or blocking, usually 48 hours; sometimes it was used for as long as seven days without replacement.

Initially milk was contained in blood transfusion bottles, but later vacoliter flasks were used instead, these having to be changed less often. The smaller bottles were still employed during the hot summer months. Five or six pints (2.8 or 3.4 litres) of milk was run in during 24 hours. The

FIG. 1.—Simple gravity feed with vacoliter bottle and Ryle tube.

patient received a generous bland diet at four-hourly intervals while the drip was still running, and thus the total intake was in the region of 3,700 calories. This high-calorie feeding would be difficult to procure without employing continuous intra-gastric milk throughout the night.

The milk was usually unadulterated; on rare occasions aluminium hydroxide gel was added if there was some persistent

pain unrelieved by the milk drip. In the earlier cases with recurrent bleeding, viper venom was added to the drip, but as it did not appear to influence the tendency to recurrences this practice was later discontinued. We have no experience of the addition of thrombin. Winkelstein's (1933) method of adding sodium bicarbonate was rejected, as continuous buffering was considered to be more important than rapid neutralization, and it was thought wiser to avoid the danger of alkalosis. The milk drip was preferred to the aluminium hydroxide drip employed by Woldman (1936), as the value of early nourishment with generous supply of calories, protein, and electrolyte was felt to outweigh the dangers of promoting peristalsis.

Nature of Series

The patients comprising this series have all been admitted to one of two of a small group of regional hospitals as emergencies with haematemesis or melaena due to peptic ulceration. They constitute the entire admissions of such cases in the group during the period between the summer of 1950 and the winter of 1953-4. In assessing the mortality no exclusions have been made for related deaths or the late complications of surgery. The proportion of peptic ulcer patients among the overall cases of haematemesis of the group is shown in Table I. The sex incidence, ulcer site, and mortality are shown in Table II.

TABLE I.—Total Emergency Cases of Haematemesis or Melaena During Same Period

Peptic ulcer	153
Carcinoma of stomach	8
Cirrhosis of liver	6
Oesophageal varices	1
Telangiectasis	1
Haemophilia	1
Uraemia	1

As the majority of patients were treated by the continuous intra-gastric milk drip after the summer of 1951, and the accuracy of the diagnostic indexing could not be ensured before the summer of 1950, the control group is a much smaller one.

Table III shows the distribution of the age groups and compares the mortalities with those of Cullinan and Price (1932) and Avery Jones (1943).

* Avery Jones excluded melaena alone from his figures for better comparison with Cullinan and Price's series. Our numbers are no larger enough to make this worth while. Of our patients 27% were over the age of 60 and 47% over the age of 50. There were no deaths below the age of 52 and only one below the age of 60.

Analysis of Deaths.—In Table IV summaries of the seven fatal cases in the 100 drip-treated patients are given. In two cases death was directly due to haemorrhage. In two it was due to conditions associated with the management of the haemorrhage, and in three to later complications of surgery.

TABLE IV.—Analysis of Deaths

Age and Sex	Type of Ulcer	Operation	Day of Opn.	Cause of Death	Day of Death	Comments
M 52	G.U.	None		Haemorrhage	3rd	Sudden collapse. Necropsy: ruptured aneurysm of splenic artery in base of ulcer

F 62	Acute G.U.	"		Pulmonary oedema	1st	Necropsy: aortic stenosis, acute pulmonary oedema, acute gastric ulcer
M 71	D.U.	Gastrectomy. Further opn.	1st 4th	Haemorrhage Duodenal fistula and peritonitis	5th	Haemostasis not secured at first operation
M 70	D.U.	Gastrectomy	2nd	"	24th	"
M 63	D.U.	"	14th	"	23rd	"
F 60	D.U.	"	6th	"	12th	"

Duration of Bleeding.—Fig. 2 is an assessment of the presence of occult blood in the stools (estimated in the laboratory by the benzidine test and in the ward by Gregerson's modification of it). A larger proportion in the continuous milk-drip group than the control group stopped bleeding between the 5th and 10th day, whereas the peak in the conventionally treated group was between

FIG. 2.—Showing duration of occult blood in stool.

the 10th and the 15th day. Turnbull and Sagi (1939) and Meulengracht (1934) have claimed earlier cessation of bleeding in groups of patients treated by initial feeding.

Recurrences.—At first sight the drip-treated group, though twice the size of the conventional one, gave rise to only six more recurrent bleedings. This figure is unconvincing when allowance is made for eight of the recurrences in the conventional group having occurred in one patient. If this patient is excluded one is unable to demonstrate a reduction in the number of recurrent bleeds in hospital as a result of drip treatment. Nevertheless it can be stated that to have more than two recurrences was exceptional in these 100 patients. The one with four recurrences had a deep penetrating posterior gastric ulcer, and his operation was deferred because of auricular fibrillation and congestive heart failure. Despite these handicaps he survived on medical treatment. The patient with eight recurrences in the conventionally treated group was bleeding from multiple gastric erosions, and died.

TABLE V.—*Recurrent Haemorrhages in Hospital*

	No. Treated	No. of Recurrences						Total
		1	2	3	4	5	6	
Conventionally treated	53	6	2	1	1	1	1	9 (21)
Drip treated	100	8	6	1	1	1	1	16 (27)

Patients' Views on Treatment

Few patients objected to the technique. Those who had had previous treatment of haemorrhage preferred the milk drip, particularly if the former treatment included a few days of restricted diet. They looked and felt confident and reassured on their second day. Confidence was often enhanced by seeing others in the same ward undergoing the same type of therapy. Some complained of mild nasal irritation and soreness of the throat, not severe enough to warrant discontinuation of treatment. By the end of the

first week this complaint became more frequent, and at this time it was usual to discontinue the drip but to maintain it at night for a further week. If there had been recurrent bleeding or if occult blood persisted in the stools the drips were continued for longer periods.

Patients could tolerate the drip for periods of six weeks. A few, asked to write down their impressions, even referred to a soothing effect of the steady flow. One man and one woman objected initially: the woman had objected to other forms of therapy; the man was old and querulous at 71 years. Two other women would not have the tube replaced after the fourth or fifth day. One of these had three recurrent bleeds but could not be induced to change her mind.

Views of Medical Attendants on Treatment

The doctors and nursing staff were impressed by the apparent well-being, reassurance, and confidence of the 84 patients out of the 100 who did not bleed again or who were not moribund on admission. The patients were propped up on the second day, taking generous meals in addition to the milk drip, looking and feeling comfortable. Sweating and anxiety were the exception, pulse and blood pressure had usually been restored. Their condition was in notable contrast to that of patients treated by initial starvation, and a further improvement on the state of those treated by early feeding without continuous milk drip. The 16 who bled again were more distressed, as the rejection of their tube with a bloody vomitus, sometimes repeated, would impair confidence. Nevertheless eight of these resumed their drip and progressed steadily to recovery. Some of the patients' minor discomforts might have been relieved by the use of the latex tube, advocated by Woldman (1936). It is unfortunate that the treatment is difficult to establish in elderly people with early recurrent haematemesis, as the danger lies with this group.

In only one patient, a man with an aneurysm of the splenic artery in the base of a large gastric ulcer, who died suddenly with massive bleeding, may the use of the tube have aggravated the haemorrhage.

Conclusions

The results are given of the treatment of 153 ulcer patients admitted to hospital as emergency cases for haematemesis or melaena. Of these, 100 were treated with a continuous intragastric milk drip given from the time of admission, and 53 were treated as a control group by one-hourly milk feeds and early generous step-up regimes. The drip-treated group received purées from the first or second day. Both groups were adequately transfused. The therapy does not prevent the occasion for surgery with continued bleeding in old people, nor has it so far produced a fall in the mortality of this group.

There was a tendency to diminished duration of bleeding in the drip-treated group. More than two recurrent bleedings in hospital were very uncommon in this group, but the numbers of recurrences under treatment do not differ significantly in the two groups.

The drip-treated group displayed earlier reassurance, confidence, and freedom from shock than the control.

Continuous milk-drip therapy for peptic ulcer haemorrhage can be carried out in hospital for periods of two or more weeks without inconvenience to the patient.

It can be affirmed that this is a safe treatment comparable in results to one-hourly feeding and transfusion regimes.

We would like to express our thanks to Dr. C. N. Armstrong for permission to include in the present series patients admitted under his care at the Queen Elizabeth Hospital, Gateshead.

STANDARDS OF FITNESS AMONG DRIVERS OF COMMERCIAL VEHICLES

A SOCIO-MEDICAL INVESTIGATION BASED ON WARTIME RECORDS OF CIVILIAN MEDICAL BOARDS

BY

JOSEFINE WEBB,* M.B., D.P.H., D.I.H.

(From the Social Medicine Unit, University of Oxford)

A recent lecture by the senior medical officer of the London Transport Executive describes in detail the steps taken to ensure that the drivers of London's motor-buses are healthy when recruited and maintain a satisfactory standard of fitness throughout their period of service (Norman, 1954). This leads one to consider what comparable steps are taken with reference to other professional drivers. So far as public service vehicles are concerned, the precautions taken seem to be adequate. The licensing authority, before granting permission to drive a bus or a coach, requires the applicant to have a general medical examination (including tests of vision) and to pass a special driving test. Many of the larger bus companies, including London Transport, conduct their own medical examinations and have even higher standards of vision and health than the statutory licensing authorities.

In contrast, no medical test is required of drivers of commercial vehicles, and inquiries into their fitness to drive are both limited and ill-defined. Whatever the type of vehicle may be—and it may be anything from a three-wheel van to a five-ton lorry—the applicant for a licence has merely to answer four questions regarding the state of his health and declare the answers to be true. The four questions (which appear on all driving licence forms) are well known:

1. Do you suffer from epilepsy or from sudden attacks of disabling giddiness or faintness?
2. Can you read at a distance of 25 yards in good daylight (with glasses if worn) a motor-car number plate containing six letters and figures?
3. Are you without either hand or foot or are you suffering from any defect in movement, control, or muscular power of either arm or leg?
4. Are you suffering from any other disease, mental or physical, or disability which would be likely to cause the driving by you of a motor-car to be a source of danger to the public?

Question 2 is checked by the examiners who conduct the official driving tests. They would presumably also notice so gross a defect as absence of a limb. Otherwise

*In receipt of a grant from the Medical Research Council.

the physical competence of an applicant for a driving licence depends on his truthfulness, his knowledge of his own health, and the construction he puts on the phrase "likely . . . to be a source of danger." Medical men frequently experience difficulty in convincing patients that they are no longer fit to drive, and know that (if they choose) even persons who are obviously a danger to the public can ignore their advice.

At a meeting of the Royal Society of Medicine a doctor stated that one of his elderly patients "who drove a high-powered car at reckless speed" was extremely annoyed at the advice that he should give up driving after he had had three blackouts in one year and had been found to have developed petit mal (Crosby, 1953). On another occasion, a neurologist deplored the number of epileptic and paralytic patients who drive cars, and added, "The patient in every case considers himself entirely fit to drive" (Campbell, 1952).

Present Investigation

To amplify the evidence of these isolated instances the civilian medical board records of 1,276 men who earned their living as drivers of road vehicles were scrutinized. The records, which were compiled during the years 1941-4, were drawn from three areas† and referred to 761 lorry drivers, 406 drivers of vans or other light commercial vehicles, 31 drivers of public service vehicles, and a miscellaneous group of 78 chauffeurs, drivers of ambulances, and A.A. men.

TABLE I.—*Professional Drivers of Road Vehicles*

Reasons for Rejections	Lorries	Vans	P.S.V.	Other	Total
Eyes:					
High myopia	3	4		1	8
Pathological defects	2				2
Ears:					
Defective hearing	5	2			7
Pathological conditions	6				6
C.N.S.					
Epilepsy + unconsciousness	3	1		1	5
Neurological conditions		2			2
Mental defectiveness	4				4
Mental instability	3	3			6
Skeletal:

Hernia	7		1	1	9
Other		1			1
General:					
Diabetes	2			1	3
Other endocrine disorders		2			2
Skin conditions	2				2
Other	5	1		1	7
All disabilities	101	62	4	16	183
No. of men examined	761	406	31	78	1,276
Rejection rate	13%	15%	13%	20%	14%

Of these 1,276 men, 28% were under 20 years of age, 43% were between 20 and 34, and 28% were between 35 and 45. At the end of the medical examination each man was graded according to his general standard of fitness. Briefly these grades were: (1) fit for all forms of military service; (2) minor or remediable defects; (3) fit for light duties only; and (4) not fit for any form of military service. In practice men in Grades 1 and 2 were called up for national service, and men in Grades 3 and 4 were rejected. Ninety-nine of the professional drivers were placed in Medical Grade 4 and 83 in Medical Grade 3, making a total rejection rate of 14%. The main reason for down-grading was identified in every case, and the results are summarized in Table I.

†Essex, 577; Leicester, 273; Northampton, 426.

Needless to say, the records of the men who were rejected did not specifically state that the examinees were not fit to drive. It is apparent, however, from what was discovered at the civilian medical board examination that the four questions on the standard driving licence form had, either intentionally or from lack of medical knowledge, been incorrectly answered by several men. Thus question 1 (epilepsy) should have disqualified 5 of the group, a further 49 were either unaware that they had defective eyesight or had chosen to hide the fact, and 34 had failed to state that they were suffering from defects of "movement, control, or muscular power" (provided, that is to say, none of the men were holders of "cripple" licences).

The fourth question on the driving licence form is extremely difficult for anyone to answer correctly. For, besides assuming a lively social conscience on the part of every applicant, it demands much more medical knowledge than most people possess. Even members of the medical profession are not unanimous about which diseases should be described as "likely to cause the driving of a car to be a source of danger to the public." Dr. Norman, for instance, considers that any condition that may cause either momentary attacks of unconsciousness or giddiness, or increased liability to fatigue, is potentially dangerous. If this is the standard of health expected for all professional drivers of road vehicles, then none of the national service recruits should have been holding a driving licence. For, whatever the nature of their complaints, the fact that they had (in the middle of a war) been found unfit to serve in the armed Forces was a sure indication that they at least suffered from "increased liability to fatigue."

If, however, a lower standard of health is acceptable then an arbitrary selection of the diseases which apply to the fourth question would have to be made. If, for instance, it is considered that only pathological conditions of the eyes, deafness, mental defectiveness, and instability, neurological disorders, diabetes, and cardiovascular diseases (other than varicose veins) are "likely . . . to be a source of danger to the public," then only 53 of the 172 men who were rejected need have answered the fourth question in the affirmative. Even so, the total number of drivers who fell below the (presumed) standard of fitness for holders of ordinary driving licences would be 143, or one in eleven of the total group.

Vision (Table II)

Included in the civilian medical board examination was a vision test, based on the well-known Snellen type, and performed, if necessary, with or without spectacles. An

TABLE II.—Visual Standards Among 1,276 Professional Drivers

Below Standard Required for	Lorry	Van	P.S.V.	Other	Total
P.S.V. licence*	31	15	—	3	49†
L.T.B. (re-employment)‡	66	28	1	4	99
L.T.B. (initial employment)‡	103	63	4	8	178
	13.5%	15.5%	16.1%	19.3%	14.0%

* That is, Snellen type 6/12: 6/36, or ability to read a motor-car plate at 25 yards.

† Including 8 men with severe myopia (6/60 both eyes) and 22 who were blind in one eye.

‡ The corresponding figures include men who would have failed the easier tests.

ophthalmologist's report was obtained in all cases of eye disease and for all men whose corrected vision failed to reach either 6/12:6/12 or 6/6:6/36 Snellen type. Some of the drivers with defective vision did not wear spectacles and others were not fully corrected by the spectacles they were wearing. Thus there were three men with 6/60:6/60 who had no spectacles, four who had 6/60:6/36 after correction, and four whose good eye could not be improved beyond 6/24. The overall rate for standards below the one regarded as safe for driving was 3.8%.

The standards of vision required by the London Transport Board at their initial and re-employment examinations are respectively 6/9:6/12 (without spectacles) and 6/9:6/36

(with spectacles). This means that 178, or 14%, of the men examined by the civilian medical boards would not have obtained employment as a London bus driver and 99, or 8%, would, in spite of being experienced drivers, have been transferred to other jobs.

Types of Vehicles.—The all-causes rejection rate was highest for the miscellaneous group and lowest for the drivers of public service vehicles, but the difference between these men and the group of lorry drivers was marginal. Failure to reach the licensing authority visual standard was roughly the same for lorry drivers, van drivers, and men in the miscellaneous group, but there were no drivers of public service vehicles with vision below 6/12:6/36.

Accidents Due to Commercial Vehicles.—For the two years 1948 and 1949 the Registrar-General has analysed 7,999 deaths on the road by victim and vehicle involved (Registrar-General, 1950, 1951). From this analysis it appears that the number of pedestrians and pedal-cyclists killed in road accidents was 5,541 (see Table III). Of these,

TABLE III.—Analysis of 7,999 Deaths on the Road by Victim and by Vehicle Involved

Vehicles involved, other than that carrying Victim	Victim was:							Total of First 3 Col.
	On Foot	On Pedal Cycle	On Motor-Cycle	In Private Car	In Bus	In Motor Goods Vehicle	In Other Type of Vehicle	
Goods transport vehicle*	1,568	471	375					(2,414)
Bus, tram or train	702	167	72					(941)
Private car	1,190	394	245					(1,829)
Motor-cycle	247	35	42	326	19	137	125	(324)
Pedal-cycle	164	37	24					(225)
Coaches and taxis	129	29	16					(174)
Other vehicles	63	13	27					(103)
No other vehicle	—	332	477	179	142	247		(809)
Total	4,063	1,478	1,278	505	161	384	125	(6,819)

* In 1954 there were 945,127 licences issued for goods transport vehicles.

2,039 were knocked down by goods transport vehicles, 809 by buses or trams, and 158 by coaches or taxis. Thus, in more than half of the pedestrian and pedal-cyclists' deaths, the mechanically propelled vehicle was in charge of a professional driver.

Discussion

Compared with men in other occupations, the percentage of physically defective drivers is slightly below average (Stewart, Webb, and Hewitt, 1955). But, considered in relation to the number of licences issued annually to goods transport vehicles (just under one million in 1954), it suggests that there are—not counting private-car owners—a formidable number of potentially dangerous drivers on the roads. It is possible that some of the men who were examined by the civilian medical boards had applied for, and been given, the special licences issued to physically defective people. There may also have been a number of cases where driving experience outweighed other deficiencies, for opinion varies on how much different defects affect a man's competence as a driver. Nevertheless, the fact remains that the final decision in this matter rests not on an unbiased assessment of fitness, but with the man who is applying for a licence. Whether or not he passes as fit depends entirely on his veracity, his self-knowledge, and his ability to answer certain difficult medical questions. In these circumstances there is nothing to prevent a man with a serious defect (or vision that has deteriorated to danger levels since he first passed his driving test) from driving a heavy lorry to the public danger. Civilian medical board records support the view that this source of public danger actually exists.

Viewed from the angle of road safety, we cannot afford to be complacent about the fact that the percentage of physically defective men who earn their living as drivers is not exceptionally great. There should be no such men.

Those interested in reducing the appalling number of deaths on the road might do well to press for a radical revision of the present system of granting driving licences to professional drivers.

Summary

Civilian medical board records of 1,276 professional drivers were examined for causes of rejection from military service. Physical defects and impairment of vision found were considered in relation to the declaration of physical fitness made on the application form for a driving licence.

HYDROCORTISONE OINTMENT IN THE ECZEMAS

BY

RONALD CHURCH, M.A., M.D., M.R.C.P.Ed.

Senior Registrar, Rupert Hallam Department of Dermatology, Royal Infirmary, Sheffield

Cortisone has been used with dramatic effect in diseases of the skin. Unfortunately, the side-effects of cortisone therapy are hazardous and limit its use in dermatological practice to potentially fatal illnesses such as pemphigus, disseminated lupus erythematosus, and exfoliative dermatitis. The local application of cortisone has little or no anti-inflammatory effect on the skin, though it has been of value as an ophthalmic application, being readily absorbed through the conjunctiva.

Hydrocortisone has been found to exert anti-inflammatory effects when applied to the skin as well as when administered systemically. No systemic effects have been reported in the hundreds of patients who have used hydrocortisone ointment, and Smith (1953) found no significant change in the circulating eosinophil count when ointment containing 150 mg. of hydrocortisone was applied to normal or diseased skin.

Literature

Sufficient reports on the use of hydrocortisone ointment have been published for some assessment of the type of case in which it is of most value. With one exception (Goldman and Preston, 1953) the accounts have been enthusiastic.

There is general agreement that the ointment is of no value in psoriasis, lichen planus, pemphigus vulgaris, generalized exfoliative dermatitis, and alopecia areata. Evidence of the response of chronic discoid lupus erythematosus is conflicting; Sidi and Bourgeois-Gavardin (1953) report improvement or healing in seven cases, while Sulzberger *et al.* (1953) found only slight improvement in one of five cases, and other observers have observed the same lack of response.

The effect of hydrocortisone ointment in atopic eczema has been extensively studied (Sulzberger and Witten, 1952; Sulzberger *et al.*, 1953; Robinson, 1953; Sidi and Bourgeois-Gavardin, 1953; Malkinson and Wells, 1954; Witten *et al.*, 1954), and the results have shown a remarkable uniformity, about two-thirds of the cases responding in each series. McCarrison (1954), in a series of 104 cases, obtained even

better results and records a good response in each case. Most observers found that response was apparent within a week and that benefit was sometimes visible within 24 to 48 hours from the beginning of treatment.

Several series were controlled by the use of the "symmetrical paired comparison" method, and it was noted that some improvement often occurred on the side of the body on which the inert ointment was used. Also in cases using hydrocortisone on one area only, improvement was observed in remote areas. Systemic absorption or contamination with hydrocortisone has been suggested as the cause, but a more likely explanation is the "sympathetic" improvement which is also seen with other forms of local treatment.

McCarrison found that 60% of cases of atopic eczema maintained improvement on stopping treatment, but others (Robinson, 1953; Malkinson and Wells, 1954) have observed a relapse in most cases, or even an exacerbation.

The treatment has been found most effective in eczema or dermatitis affecting the eyelids, pinnae, and ano-genital regions (Sidi and Bourgeois-Gavardin, 1953; Alexander and Manheim, 1953; Malkinson and Wells, 1954), probably because of improved absorption from these areas. Acute contact dermatitis, lichen simplex, nummular eczema, and seborrhoeic dermatitis are also reported as responding to hydrocortisone ointment. Sidi and Bourgeois-Gavardin (1953) warn against the danger of secondary infection in acute contact dermatitis; they also state that the antipruritic effect is slight in cases in which much lichenification is present.

The American work has been criticized on the grounds that the patients were selected private patients who knew they were having some special remedy applied. In the present series the patients were hospital patients who were aware that they were receiving a special remedy, and the control cases were, of necessity, under a similar impression. Those patients were selected whose diagnosis was firmly established and in whom the areas affected were not too extensive.

Method

A series of 105 cases of various types of eczema and dermatitis were treated with an ointment containing 1% hydrocortisone acetate; in a few of the more resistant cases 24% hydrocortisone was used. The base consisted of anhydrous lanolin, petrolatum, and mineral oil ("cortef" ointment).

A further 23 cases of eczema were used as controls, at the beginning of the trial alternate patients being issued with the ointment base in a similar packing and given the same instructions.

Patients were instructed to use a thin smear of the ointment twice daily, to avoid soap and water on the affected areas, and to use liquid paraffin or olive oil for cleaning.

Results

Nummular Eczema.—This was separated from other endogenous forms of eczema on account of its distinctive pattern. Of the 25 cases treated, 18 had had previous treatment with x rays and tar preparations without healing. Ten healed completely, most within one week, 11 improved but did not heal, three showed no response, and one became worse under treatment. Five cases which had healed or improved relapsed within seven to ten days of stopping treatment. Three of the 10 controls showed some improvement, and the remaining seven became worse.

Eczema.—This group contained an assortment of cases of eczema which were considered to be endogenous and which affected various areas of the body. Of the 24 patients treated, 17 had had previous treatments without healing. Eight healed completely, eight improved, three showed no response, and five became worse; one of the last-named appeared to be aggravated by the ointment. Of the six controls, one healed, two remained static, and three became worse. Half of those not responding to treatment had

eczema of the hands which involved the palmar surface, and it seems probable that lack of penetration of the thickened horny layer may have contributed to failure. In another of the failures, infection, which was present when treatment began, spread rapidly. Of the cases which improved, four relapsed within seven to ten days of stopping treatment.

Atopic Eczema.—This group comprised 30 patients varying in age from 1 year to 50 years. Twenty-five were old patients, the majority of whom had been difficult to control with the usual treatments. Three patients were treated during admission to hospital. Nine healed completely, 13 improved, six showed no response, and two became worse. Of the four controls, three showed no response and one became worse. Most of the cases which responded to treatment showed maximum improvement within a week. The more lichenified and chronic the eczema the less effective was the treatment, and in these resistant cases 2½% hydrocortisone ointment did not seem to be more effective than the 1% ointment.

Lichen Simplex.—Of the 10 patients treated, nine had very long-standing lesions which had resisted the usual occlusive and x-ray therapies. Three healed completely after three to four weeks of treatment, and have remained healed. Three improved and gained relief from itching, but despite the use of 2½% ointment their lichenified patches remained, to be scratched again when treatment ceased. Four showed no response to 2½% ointment. Of the three controls, two became worse and one remained static.

Contact Dermatitis.—Six new cases of acute and weeping contact dermatitis were treated. All were due to medications. One did not respond. Improvement in the others was dramatic, the lesions drying and subsiding almost completely within two to three days.

Pruritus Ani.—Ten cases of pruritus ani were treated; six of them had resisted various therapies, including x rays. Four healed and remained symptom-free, four improved but did not lose all their irritation, and two derived no benefit. No controls were included in this series, and it is recognized that a fairly high proportion of these cases derive benefit from any new treatment. Nevertheless, knowing the chronic cases which admitted improvement, one is impressed with the therapeutic effect.

Comment

Improvement or complete healing was observed in 76% of the 105 treated cases and in 17% of the 23 controls. Deterioration occurred in only 7.5% of the treated cases and in 56% of the controls. It is evident that the psychological effect of the "new treatment" (packed in impressively small 5-g. tubes) was slight. Although there was an overall high rate of improvement certain conditions improved more readily than others.

Those which improved most rapidly were cases with a raw weeping skin lesion which allowed rapid absorption of the hydrocortisone. Acute contact dermatitis responded dramatically and almost healed in two or three days. Two of the treated patients presented with an acute weeping dermatitis of the face a few days before they were due to go for their summer holiday. With the usual bland applications recovery might have taken 10 to 14 days. In three days after application of hydrocortisone the rash was almost healed in each case and these patients did not miss their holiday.

A high proportion of cases of nummular eczema healed completely in a week; and here, too, the more acute and weeping the eczema the better the response. Relapse followed cessation of treatment in some cases, but application of a minute amount of ointment every day, or even every second to third day, was sufficient to prevent recurrence. In some cases healing was not complete, but hydrocortisone was useful in rapidly controlling exudation and rendering the eruption suitable for applications of tar pastes.

Patients suffering from an acute skin eruption may be prepared to endure messy applications with the prospect of recovery in sight, but the atopic eczema subject spends a lifetime fighting unpleasant attacks of eczema with almost equally unpleasant remedies. The freedom from sting, stain, and stench (as Sulzberger puts it) makes hydrocortisone a welcome treatment for the "atopic." Unfortunately the results are variable and unpredictable. Some cases healed completely in less than a week and derived complete relief from itching. Others improved more than with any other local application. Healing or improvement occurred in two-thirds of the cases treated. Those which did not respond well had very lichenified eczema that was not easily penetrated by the ointment. Patients in whom excoriations were more marked than eczema did not respond well, possibly because their scratching had become a habit. In some of the milder cases the patients still complained of itching, though the skin had apparently returned to normal; this may explain the continuation of scratching. Infection tended to be spread by the ointment, and should be regarded as a contraindication until it has been controlled by appropriate antibiotic therapy. The types of eczema outlined can easily be recognized and hydrocortisone avoided in these cases, but there remained in this series a few cases which were not improved by the ointment, though clinically indistinguishable from cases in which it worked like a charm.

Most cases of atopic eczema relapsed when treatment was stopped. It has been suggested that 2½% hydrocortisone ointment may be useful for controlling the eczema and that 1% can be used for maintenance therapy. In this series it was found that cases either responded to 1% ointment or not at all. Maintenance therapy is possible, but may prove expensive when large areas are affected. Once the rash was controlled the patient could revert to the usual tar applications with every hope of maintaining improvement; only when treatment was stopped completely was there a severe relapse. It seems likely that hydrocortisone may prove most useful as something on which the atopic eczema subject can rely to control the exacerbations to which he is so prone. The very knowledge that he has this weapon available will probably make its use less often necessary.

In other cases of localized areas of eczema the results depended largely on the site and nature of the eruption, raw and exuding areas responding well to treatment and lichenified chronic cases deriving little benefit. Eczema of the hands which involved the palmar surface responded poorly, presumably because of lack of penetration of hydrocortisone through the thickened horny layer.

Similarly, lack of penetration probably explains the poor results in lichen simplex. The 2½% ointment was used on all cases, and treatment was maintained for three to eight weeks, but only 30% of the cases healed.

In pruritus ani the degree of improvement depended on the extent and nature of the perianal dermatitis. Those patients with an active eroded and excoriated eruption experienced rapid relief, which in several chronic cases proved lasting. Those with much lichenification derived some relief from itching but did not heal. Persistent cases with intractable itching but with little or no abnormality of the skin did not respond to hydrocortisone therapy, presumably because the site of origin of their irritation was in the head rather than the seat.

From these results it is evident that hydrocortisone is not the complete answer to the treatment of eczema and dermatitis. It is, however, a potent weapon whose value can be compared to that of x-ray therapy, provided that it is used with the same circumspection.

Summary

A series of 105 cases of eczema and dermatitis were treated with 1% and 2½% hydrocortisone ointment. A further 23 cases were treated as controls with an inert ointment. Improvement or healing occurred in 76% of the treated cases and in 17% of controls.

Response appeared to depend on the ease of absorption of hydrocortisone, eroded and exuding eczema and dermatitis healing rapidly, while lichenified eczema showed little improvement.

Good results were obtained in acute contact dermatitis, nummular eczema, atopic eczema, and perianal dermatitis. Lichen simplex, lichenified atopic eczema, and lichenified cases of ano-genital pruritus responded poorly. Infection was spread by the ointment unless controlled before its use.

Relapse occurred in many chronic cases on stopping treatment, and could be prevented by using the ointment less frequently as maintenance therapy or by reverting to the use of tar applications.

I am grateful to Dr. H. R. Vickers and Dr. I. B. Sneddon for permission to treat their patients for this survey, and to Upjohn of England Ltd. for their generous supply of cortef ointment.

A SEARCH FOR ABNORMAL HAEMOGLOBINS IN SOME SOUTHERN SUDANESE PEOPLES

BY

D. F. ROBERTS, M.A., D.Phil.

*Anthropology Laboratory, Department of Human
Anatomy, Oxford*

AND

H. LEHMANN, M.D., Ph.D., F.R.I.C.

(St. Bartholomew's Hospital, London)

Sickle-cell Tests

Nilotic peoples are found in two main areas—the southern Nilotes in Uganda and round the eastern shores of Lake Victoria, the northern Nilotes in the Southern Sudan. During the course of investigations among the northern Nilotes of Upper Nile Province, Sudan, the blood of a large number of individuals was examined for sickling. Some specimens were sent to laboratories for testing; in London, where positive specimens from West Africa could be used as controls, 344 specimens were tested, 83 by one of us (H.L.) and 261 by Dr. J. N. M. Chalmers, of St. George's Hospital; in Khartoum 215 were examined by Professor Dean Smith of the Kitchener School of Medicine.

These specimens were obtained from unrelated adult individuals; details of the sampling methods employed are given elsewhere (Roberts, Ikin, and Mourant, 1955). In the field, testing was largely restricted to specimens from children, 10 adults and 170 children of all ages being examined by D.F.R.; these children constituted the major part of the child population of one Dinka and two Shilluk villages, and the individuals from each village were therefore not all unrelated. As regards technique, in London and in the field, 2% solutions of potassium

metabisulphite were used, freshly made up on each occasion with distilled water; in Khartoum, each specimen was carefully enclosed bubble-free under a cover-slip ringed with petroleum jelly, and examined after 24, 48, and 72 hours.

Altogether specimens from 739 individuals were examined, representing the different indigenous peoples as follows:

People	Adults	Children
Northern Dinka	217	103
Shilluk	204	67
Nuer	100	
Mabaan	34	
Dinka/Shilluk/Nuer-hybrids	14	

Since in no individual of this large sample was the sickle-cell trait observed, it is concluded that the absence of the trait is a characteristic typical of the northern Nilotic peoples. This finding is similar to that of Foy *et al.* (1954).

Examination by Electrophoresis

Seventy-five specimens were further examined by paper electrophoresis according to the procedure described by Lehmann and Smith (1954). Of these, 64 specimens were from northern Dinka individuals, 4 were from Mabaan, 3 were from Dinka/Nuer hybrids, and 4 from Dinka/Shilluk hybrids.

All blood specimens contained nothing but normal adult haemoglobin. No haemoglobin S (or D), C, E, or G was found. The results of this survey are in striking contrast to those obtained in the Gold Coast (Edington and Lehmann, 1954a, 1954b), where out of 211 West Africans examined 41 were found to possess haemoglobin S, 29 haemoglobin C, and 1 haemoglobin G. On the other hand, in Tanganyika (Dar es Salaam) 100 out-patients of mixed tribal origin but mainly Bantu were recently examined by us through the kindness of Dr. Mackey; although 12 individuals with a haemoglobin showing the electrophoretic properties of S were noted, no haemoglobin C or any of the other known variants was found.

Discussion

In several recent publications the view has been advanced that the sickle-cell gene provides an example of balanced polymorphism in man. Neel (1953) discussed the possibility that the balance was attained through increased fertility on the part of the heterozygote. Allison's (1954a, 1954b, 1954c) experiment in Kampala, and his examination of the geographical distribution of the sickle-cell trait in East Africa, with high and low frequencies respectively confined to endemic and non-endemic malarious areas, provide some evidence, implementing that of Brain (1952), Mackey and Vivarelli (1952, 1954), and others, that possession of the trait confers selective advantage in malarious regions. He postulates a condition of balanced polymorphism, selection acting against the sickling homozygote through sickle-cell anaemia, against the non-sickling homozygote through malarial susceptibility, the heterozygote, however, being at an advantage over both homozygotes through the protection afforded by the sickle-cell trait against malaria, especially subtertian.

The role of malarial endemicity in determining sickle-cell frequency once the gene is introduced, however, should not be exaggerated. Many tribal areas are not sufficiently local in extent to be assigned to a single category of endemicity: the range of flight of the mosquito may admittedly be greater than the limit of several hundred yards generally quoted; but it is essentially local, and many "hyper-endemic" tribal territories must consist of intensely malarious and less malarious districts. Hence differences in selection pressure will occur within the territory, and if mating tends to be to any extent local differences in gene frequency will result. The actual value found for any sample will depend on a combination of social and ecological factors, the mating system of the people, the

length of time their economy requires individuals to spend in malarious areas, and the intensity of malarial infection in those areas. From these considerations it would seem that Allison's (1954b) attempt at a geographical analysis by means of a simple table is not sufficiently detailed to be convincing. Nor should the degree of selection pressure be overestimated. If, as is generally recognized (Taliaferro, 1949), malarial immunity is of two types, innate and acquired, then presumably the hypothetical immunity given by the sickle-cell trait falls into the former category. Is the non-sickling homozygote in endemic areas not protected to some extent by acquired immunity? Too little attention has been given to established work on malarial immunity during recent developments in this field.

Undoubtedly the functional approach to the problem of the sickle-cell trait represents a stimulating advance on the purely descriptive. The unequivocal establishment of this first example in man of balanced polymorphism would represent a considerable advance in anthropological theory. Hence the importance of clarifying the several points weighing against outright acceptance of the hypothesis in its present form.

As Edington (1953, 1954) and Lehmann (1954) have pointed out, the assumption that the simple homozygous theory of the inheritance of sickle-cell anaemia is correct remains difficult to accept completely. There are other factors to be considered; for example, those relating to the proportions of different haemoglobins such as are noted above, of which little is yet known. Certainly in areas where haemoglobin C exists, sickle-cell crises must occur in individuals heterozygous for S and C; and malarial infection, since it may precipitate such crises, may thereby adversely affect the proportion of heterozygotes. Some advantage of the non-sickling homozygote over sickling individuals could indeed be postulated to explain the several studies noted by Neel (1950), in which the sickle-cell frequency appeared to diminish with age, though other explanations can be advanced.

The assumption that malarial susceptibility is proportional to malarial mortality is not necessarily correct. As regards the demographic situation, Christophers (1949) concluded that in indigenous tropical populations "no obviously greater infant and child mortality rate accrues under hyperendemic conditions [of malaria] than is generally normal apart from malaria."

Neither Moore *et al.* (1954), in two samples, nor Edington (1954) in two samples, have been able to confirm any association between parasite rate and sickling such as is claimed by Allison (1954a) on a barely significant test of data relating to Baganda children; nor does either of Beet's (1946, 1947) investigations show any significant association; when the aggregate of the seven sets of data published by these authors is considered no significant relationship emerges. It should be pointed out that the χ^2 values given by Allison (1954a), if calculated by recognized procedures, are all incorrect; using Fisher's method with Yates's correction for continuity, χ^2 values of 1.64, 3.64, and 4.05, each with one degree of freedom, should replace those of 19.3, 4.1, and 5.1 calculated by Allison. In Raper's (1954) recent sample of 1,675 children, among those in the second year of life there was a significantly lower malarial rate in sicklers, but at no other age nor in the whole series was this association shown. It appears, then, that sickling has no effect on parasite rate in adults, though it may have an effect during a very limited period in early infancy. It is thus difficult to accept without further confirmation Allison's results on Luo adults, where in only 2 out of 15 adult sicklers, but in 14 out of 15 adult non-sicklers, malaria parasites were observed after repeated artificial inoculation. On each of the above points the evidence is unfortunately limited.

The findings reported here concerning the northern Nilotes, however, are not equivocal. Among the Shilluk, Dinka, and Nuer, by reason of their ways of life and the nature of their habitats, malaria is endemic. The Shilluk are a riverain people; they make more use of the rivers for

purposes of communication than do the Dinka: most of their villages are within a few hundred yards of the river, and a number are actually at the waterside. Most Dinka and Nuer spend the dry season by the rivers, and the wet season, when swamps abound, in inland villages. Malaria incidence would be expected to be at its lowest for the Dinka in the early dry season when the swamps inland have dried but immediately before the depletion of water in their wells, waterholes, and "hafirs" (waterholes of human construction) necessitates the movement of cattle and humans to the rivers. In a Dinka inland village, during the week before the move to the riverside cattle camp, out of a total village population estimated at 350, 11 individuals (3.1%) were seen to be suffering from a fever seemingly malaria, which responded to treatment with mepacrine; from only one of these individuals, unfortunately, could blood smears be obtained, in which instance M.T. rings were observed.

In the absence of published data concerning malaria in these peoples, the opinions of two authorities are quoted. Professor P. C. C. Garnham, of the London School of Hygiene and Tropical Medicine, states (personal communication) that "there is no doubt that the malaria incidence is very high in the Southern Sudan near Malakal." Dr. G. J. Clark, Province Medical Inspector, Malakal, states (personal communication) that new cases attending the out-patient department of Malakal Hospital for the year 1953-4 included 2,605 malarial cases, some 2% of the total, though many more were diagnosed as malaria which were either not proved or were probably relapses; that the majority of proved cases were *P. falciparum*, there being 2,488 positive M.T. slides; that malaria is endemic in the Malakal region; and that its incidence is reckoned to be greater than in the Nile region of Equatoria Province (where considerable frequencies of the sickle-cell trait occur).

Hospital figures are of course not representative of these primitive populations, since only a small proportion of individuals ever reach hospital; malarial cases are adequately treated at the outlying dispensaries, whereas more serious cases are sent to hospital; yet in the majority of many villages visited during the present investigation clinical malaria appeared to be the most frequent complaint. Thus all the evidence points to a high malarial endemicity in the region. This group of northern Nilotes, then, provides one exception to Allison's statement that "the world distribution of the trait is also in accordance with the view presented"—namely, the relationship of the sickle-cell trait to malarial endemicity. There are other exceptions. The sickle-cell trait is absent from aborigines of Malaya despite the high malarial incidence (Polunin, 1953); and the trait is virtually absent in the Union of South Africa. Budtz-Olsen and Burgers (1955) have tabulated surveys of nearly 6,000 Africans from that area, and have pointed out that at least in Zululand malaria has been present for generations.

Anthropological Interpretations

The differences noted here between West Africans and Nilotes in frequency of abnormal haemoglobins other than S suggest that further investigations may yield information of considerable anthropological interest. Haemoglobin E, for example, first found in a child of an Asian father (Itano *et al.*, 1954), has also been found in Siamese (Chernoff *et al.*, 1954) and in the Veddas of Ceylon (Graffe *et al.*, 1954), but not in the limited number of Africans so far examined.

As regards S haemoglobin, the present unresolved state of the hypothesis of marked association between sickling and malaria necessitates dual attempts at anthropological interpretation of the sickle-cell findings of the present survey.

If the hypothesis of balanced polymorphism associated with malaria is correct, then with this observed incidence of malaria the sickle-cell trait ought to be present among the northern Nilotes. To explain its absence, two suggestions may be offered. There may be insufficient malarial

mortality of the non-sickling homozygote in these peoples to raise the frequency of the gene if introduced—that is, there may be other genetic factors besides sickling which protect against death through malaria. Alternatively, the gene may never have been introduced (by mutation or intermarriage with individuals from populations possessing the sickle-cell) among the northern Nilotes. Had they received it, then selection would have increased its frequency to that at which equilibrium occurred, its diffusion among these peoples being broadened by their mating systems: the increase in gene frequency would have been rapid at first, since its introduction would presumably be in the heterozygous condition, matings between heterozygotes would occur much more rarely than between heterozygote and non-sickling homozygote, and the sickling homozygote would therefore in the initial stages very rarely be produced; loss of the gene in appreciable quantities would only occur after its frequency had reached such a level that heterozygotes were mating.

The finding by Foy *et al.* (1954) of the sickle-cell trait in one or two individuals among the southernmost groups of the northern Nilotes suggests that the gene is only now beginning to enter this region from the south. Certainly such Shilluk as migrated to their present territory from the south could not have brought the gene and subsequently lost it. Nor could the southward-moving Lwo groups, who according to Crazzolar's reconstruction of traditions subsequently became the peoples known to-day as the central and southern Nilotes, have taken the gene with them when they diverged from the northern Nilotic peoples. Since the southern Nilotes now possess the trait in appreciable frequencies (Lehmann and Raper, 1949; Foy *et al.*, 1954; Allison, 1954b), they must have received it at a date later than that at which they diverged from the northern groups.

If, on the other hand, the postulated selective advantage under malarial conditions of the sickle-cell trait should prove to be more apparent than real, then the presence of the trait among the southern Nilotes would seem to be due to hybridization with peoples of high sickling frequency in the areas to which they wandered. On this hypothesis, the alternative explanation for the difference in sickling between northern and southern Nilotic groups—that a northward-moving Shilluk group possessing the gene interbred with non-sickling groups in their new territory, with subsequent dilution of the gene frequency—seems less feasible, since in this instance the gene would be expected to occur at low frequency among the northern Nilotes, which the data do not show.

The above discussion shows clearly the increase in anthropological interest that may accompany increased knowledge of a particular gene. Whatever the explanation, the sickle-cell trait to-day is a physical criterion distinguishing between the northern and southern Nilotic groups, being absent in the former and present at medium frequency in the latter. Some degree of genetic divergence is thereby implied—less if the trait is selectively advantageous, greater if it is not.

Summary

No abnormal haemoglobin was discovered by paper electrophoresis of 75 blood specimens from northern Nilotes of the Southern Sudan. In 739 specimens examined no sickling was found. These findings suggest that the association between malaria and sickling is more complex than might at first appear; their anthropological significance is discussed.

We acknowledge the practical assistance given by Dr. J. N. M. Chalmers and Professor D. Smith in the examination of the specimens; the help and interest of Professor P. C. C. Garnham and Dr. G. J. Clarke; and, in Khartoum, the technical assistance of Miss K. Dobbins and Mr. L. B. Greenhalgh through the courtesy of Professor H. V. Morgan.

A SURVEY FOR HAEMOGLOBINS C AND D IN UGANDA

BY

G. F. JACOB, M.B., B.Chir., D.T.M.&H.
 Pathologist, Uganda Medical Service

The sickle-cell trait and sickle-cell anaemia, which have long been known, are associated with an abnormal shape of the red cell at reduced oxygen tensions. In 1949, Pauling *et al.* demonstrated that the potentiality for sickling is associated with a variety of haemoglobin which differs from the normal in its electrophoretic mobility.

This sickle-cell haemoglobin was at first called haemoglobin B (the normal being haemoglobin A), but it is now generally known as haemoglobin S. In the sickle-cell trait haemoglobin S usually forms from 25 to 45% of the total haemoglobin, and in sickle-cell anaemia from 85 to 100%. The former state is regarded as characterizing persons who are heterozygous for the sickle-cell gene, and the latter those who are homozygous (Neel, 1951).

Incidence

During the course of family studies of cases of haemolytic anaemia associated with sickling, Itano and Neel (1950) found a further abnormal haemoglobin, since designated haemoglobin C. This differs in electrophoretic mobility from both haemoglobins A and S. It is not associated with anaemia in the heterozygous C/A combination. The C/S combination, however, produces a haemolytic anaemia which is in many ways similar to sickle-cell anaemia though milder in degree (Kaplan *et al.*, 1953).

The incidence of haemoglobin C in the negro population of Detroit was estimated by Lawrence *et al.* (1952) to be about 0.3%; Smith and Conley (1953) found an incidence of 1.8% in 500 unselected negroes in Baltimore, while Edington and Lehmann (1954) found it to be as high as 12% in Gold Coast Africans. A further abnormal haemoglobin has been described by Itano (1953) which has the same mobility as haemoglobin S but differs in its solubility and in that it does not cause sickling. Like haemoglobin C this haemoglobin, now known as D, will cause a haemolytic

anaemia when in combination with S. Its incidence in American negroes is not known, but it must be much rarer than C. Apart from the studies of Edington and Lehmann on haemoglobin C in persons from the Gold Coast, haemoglobins C and D have so far been described only as occurring in American negroes. The combination of the single gene for sickling and the single gene for thalassaemia can also produce a haemolytic anaemia (Powell *et al.*, 1950). Thus, of all the cases of a haemolytic anaemia with sickling that are seen in America, most are true sickle-cell anaemia, but a proportion are due to the combination of the sickling gene with some other inherited abnormality of haemoglobin synthesis.

Thalassaemia, which is readily recognizable, is not known to occur in the Africans of tropical Africa, and hence it is unlikely that there are in Uganda any cases of anaemia due to the combination of the sickle-cell gene and the thalassaemia gene. It, however, appeared possible that some of the cases of apparent sickle-cell anaemia were due to the coexistence of haemoglobin S with C or D. In order to determine this, it seemed easiest to examine only non-sickling bloods—in other words, to screen the population for possible haemoglobins C and D in combination with A rather than S and to preserve any of these bloods showing a double haemoglobin for identification elsewhere.

Method

Bloods sent in to the laboratory for routine Khan tests were used. A sickling test was done, using a 24-hour *Bact. coli* culture and reading the unsealed preparation in two hours. All sicklers were discarded except one out of each batch, which was used as a control. As much serum as possible was drawn from the clot and discarded, and, after shaking, a drop of concentrated red cell suspension was withdrawn. To this was added a drop of 0.5% saponin in watery solution to cause lysis. Paper strip electrophoresis was performed in the Shandon apparatus with the apex height adjusted to 4½ in. (11.4 cm.) instead of the standard 7½ in. (19 cm.). A barbituric acid/sodium barbitone buffer of pH 8.6 and ionic strength 0.06 was used, and, with eight strips of Whatman No. 3, each 1½ in. (3.8 cm.) wide, electrophoresis was allowed to proceed at a voltage of 90–110, giving a current of 1.5–2 mA, for 12 to 18 hours. A sickling control was included in each run. The position of the haemoglobin could readily be seen without further staining provided the solutions were concentrated enough. If there was any doubt a washed and cleared preparation was made from the original clot and the procedure repeated.

Results

Of 500 bloods examined, 250 were male and 250 female. They were almost entirely adults. The tribal composition is not accurately known but is largely Bantu, of which the majority are Baganda. There were probably some 40 to 50 Nilotics. No case was found with a double haemoglobin, and all the haemoglobins migrated with the same speed as normal adult haemoglobin.

Conclusion

In a series of 500 non-sickling bloods examined in Kampala no example of haemoglobins C or D has been found. Since, on the other hand, there is known to be a considerable amount of haemoglobin C in West Africa, it is probable that this area is the source of the genes for haemoglobin C found in American negroes. This is, in any case, the most likely source, since the slaves largely came from this area. Most, if not all, of the haemolytic anaemias in Uganda, in which sickling appears to play a part, may therefore prove to be true cases of homozygosity for the sickling gene. There remains, however, the possibility that other/modifying haemoglobins exist here which could be distinguished by properties other than electrophoretic mobility at alkaline pH.

I am indebted to the Director of Medical Services, Uganda, for permission to publish.

Medical Memoranda

Death from Hexamethonium Ileus

In view of the increasing use of ganglion-blocking drugs in the treatment of patients with severe hypertension, this report of an avoidable death caused by one of these drugs may be of interest.

CASE RECORD

A carpenter, aged 54, was admitted to another hospital in April, 1953, in congestive cardiac failure, due to hypertension. He was discharged, improved by orthodox treatment, after three weeks.

In August, 1953, he was admitted to this hospital in a further attack of congestive cardiac failure with a blood pressure of 250/180 mm. Hg. He had now developed bilateral papilloedema with retinal haemorrhages and exudates. In view of the severe retinopathy it was decided to begin treatment with hexamethonium bromide in addition to full doses of digitalis and mersalyl.

On discharge, five weeks later, he was giving himself 280 mg. of hexamethonium subcutaneously three times daily. His blood pressure was fluctuating between 180/110 and 140/95 mm. Hg, whilst the papilloedema was beginning to regress.

At follow-up his dose was reduced to 200 mg. thrice daily, and he was advised to take 7½ mg. of neostigmine orally for his alimentary dysfunction. He took this dose for three days, when both eructation and diarrhoea ceased. However, on the fourth day he became obstructed and began to vomit, and on the fifth day he developed colicky abdominal pain. He continued to inject full doses of hexamethonium in spite of having been told to reduce the dosage if the diarrhoea or constipation should become severe. Only on the sixth day did he permit his wife to arrange for urgent readmission to hospital. He was found to be very dehydrated, with a thready, regular pulse and a blood pressure of 110/90 mm. Hg. The abdomen was greatly distended, particularly over the upper quadrants. There was some lower abdominal tenderness and guarding, and almost complete absence of bowel sounds. A radiograph of the abdomen showed gaseous distension of the small gut with fluid levels. Small amounts of gas and faeces were present as far as the hepatic flexure.

Ileus due to hexamethonium was provisionally diagnosed, and treatment was started with gastric suction and intravenous glucose-saline. A total of four pints of black fluid was aspirated from the stomach within the next four hours, during which time the patient's condition improved greatly. Further improvement seemed to justify continuation of conservative treatment, but 16 hours after admission the pulse rate rose to 120 a minute over the space of an hour, and his condition gravely deteriorated. Immediate operation was decided upon, as it was now thought likely that a perforation had taken place. The patient died before he could be got to the theatre.

Post-mortem examination within 3½ hours of death showed that operative intervention would have been valueless. The stomach and 5 to 6 ft. (1.5 to 1.8 metres) of small intestine were dilated and filled with foul faecal fluid. No perforation was found, but throughout the small intestine there were areas showing thinning of the bowel wall

with fibrinous reaction on the serosal surface. These areas ruptured on the slightest handling. The other findings were those expected in a case of malignant hypertension.

COMMENT

Bowel disturbances ranging from constipation with or without diarrhoea to complete ileus are not uncommon during the early stages of effective treatment with ganglion-blocking drugs. Most patients on treatment report occasional bouts of constipation, often accompanied by diarrhoea, though these attacks tend to become less frequent as time passes. During these episodes the urinary output falls. As hexamethonium compounds are not destroyed to any extent in the body, but are almost wholly excreted in the urine (Zaimis, 1950), oliguria leads to the building up of a dangerous concentration of the drug in the body, unless the dosage is cut down. This in turn can lead to further bowel atony, progressing to ileus, unless the situation is recognized and all drug treatment is withheld. This state of affairs may not be very obvious from clinical examination, as blood concentrations of the drug beyond a certain point do not necessarily produce a progressive fall of blood pressure. The ileus thus produced can lead to loss of bowel viability with consequent peritonitis.

In the ganglion-blocking drugs we have a powerful weapon which is life-saving in suitable cases. Their use does, however, require close and careful supervision. The patient should be warned to cut down or omit his injections when constipation becomes too obstinate, or when fever, vomiting, sweating, or diarrhoea threatens his urinary output. He should always consult his doctor when in doubt or in difficulties.

My thanks are due to Mr. P. F. Jones for sharing in the management of this case, and to Dr. R. A. J. Asher for permission to publish.

Carbuncle of the Kidney

Perinephric abscess is not uncommon as a complication of a transient bacteraemia, but a carbuncle of the kidney occurs only infrequently. Brady was able to review only 88 recorded cases up to 1932, and the condition is apt to be overlooked in considering the differential diagnosis of a possible perinephric abscess. For this reason the following case, in which the diagnosis was made with some certainty before operation, is presented in detail.

CASE HISTORY

A man aged 28 attended the out-patient department complaining of pain in the right loin and of anorexia, both of seven days' duration. The pain was continuous, of gradual onset, did not radiate, and was felt posteriorly below the last rib. There was no nausea or vomiting, micturition was entirely normal, and there were no symptoms referable to the other systems. He could remember no pustule or other possible septic focus in the previous two months.

The temperature was 100.2° F. (37.9° C.) and the pulse rate 86. In the right loin a smooth tender swelling was palpated bimanually, which moved slightly with respiration and appeared to be the lower pole of the kidney. There was no muscular rigidity, and no other abnormal physical signs were elicited. The urine was normal to chemical and microscopical examination. The patient was admitted and penicillin therapy was begun.

Investigations.—Urine: culture sterile after 24 hours. Blood: Hb, 75%; R.B.C., 4,000,000; W.B.C., 18,500 (polymorphs, 85%); urea, 34 mg. per 100 ml. X-ray report: "The outline of the upper two-thirds of the right kidney is normal, but the lower pole cannot be identified. The edge of the right psoas shadow is not seen. Slight lumbar scoliosis to the left. Normal left kidney and psoas shadows."

Intravenous pyelogram: normal appearance of calices and pelvis on both sides. Cystoscopy: bladder normal in all respects. Retrograde pyelogram normal.

On these findings a confident diagnosis of carbuncle of the lower pole of the right kidney was made.

Operation.—The right kidney was exposed by the lumbar route on the second day after admission. There was oedema of the perinephric tissues, but no evidence of suppuration. The lower pole of the kidney was enlarged and fluctuant, but the surface appeared normal. A needle was inserted and thick yellow pus aspirated. The abscess was opened along the needle track, a finger swept round to break down any septa, and a drainage tube inserted around which the wound was closed. Some 5 fl. oz. (140 ml.) of pus was evacuated.

Culture of the pus secured at operation yielded a growth of *Staph. aureus* sensitive to penicillin. The temperature fell by lysis and was normal on the third post-operative day. Penicillin was discontinued the following day. The drainage tube was shortened on the 10th day and removed on the 13th. When the patient was discharged on the 20th day the wound was soundly healed and an intravenous pyelogram report stated: "Normal pelvis and calices, but the lower pole of the right kidney appears larger than normal. The psoas shadow is seen on both sides."

The patient has been seen at the follow-up clinic and has remained well.

COMMENT

The diagnosis of renal carbuncle is of importance in that, whereas observation of a perinephric abscess does relatively little harm, delay in treating a carbuncle damages more of an irreplaceable tissue at a time when the other kidney may also be infected. The demand for surgery is therefore urgent for two reasons—to drain the abscess in order to limit destruction of the kidney tissue and to secure pus for sensitivity tests.

The clinical features are admirably portrayed by this case, but whether the kidney is palpable depends first on the normal position of the kidney in the individual patient, and, secondly, on the site and size of the carbuncle. The degree of perinephritis determines movement on respiration. The findings in this case suggest that fixity occurs late, as this quite large carbuncle was still mobile on the ninth day of symptoms.

One would expect the outline of the enlarged kidney to show on an x-ray film of the abdomen, and Thomson-Walker (1948) gives this as a radiological sign of carbuncle, but in the above case it remained undefined until after operation, and clearly it and the psoas shadow were obscured by the perirenal oedema. A pyelogram may show the nearest calix to be deformed by the mass.

Fleming (1950) recommends treatment with penicillin only, but he stipulates that it must be continued for from three to four weeks and that a normal temperature and feeling of well-being are insufficient indications to stop treatment. He suggests that the drug may be stopped when the pyelogram returns to normal, but in the above case it was never abnormal. Even in this chemotherapeutic age the old adage, "Where there is pus, let it out," remains as true as when it was coined, for thereby toxæmia is relieved and resolution accelerated. Excessive fibrosis is known to occur as a result of delayed drainage of a pyogenic abscess treated with antibiotics (Stammers, 1953), and I have seen several breasts destroyed and a "frozen" hand from this cause. Antibiotics aid but do not replace the surgeon. If a carbuncle is suspected the kidney should be explored without undue delay, any abscess drained, and the pus submitted for sensitivity tests to indicate the most suitable antibiotic should one be required. Only rarely should nephrectomy, freely advocated in earlier writings, be necessary.

AMPUTATIONS

Amputations. By Leon Gillis, M.B.E., M.B., B.Ch., M.Ch.Orth., D.L.O., F.R.C.S. Foreword by Sir Harry Platt. (Pp. 423+x; illustrated. 84s.) London: William Heinemann Ltd. 1954.

This is the first comprehensive book on amputations published in this country. It contains a great deal of information on all aspects of a small but not unimportant branch of surgery. It should be useful to those who treat traumatic conditions, to orthopaedic surgeons, and to those who fit prostheses; but it is not intended for the student who is required to learn the elements of the subject. The author's experience has been unique, and he has made full use of the teaching of those who started and developed the principles of modern amputation and the "service for amputees." The book is the outcome of years of work dealing with the amputees still alive from the First World War, with a large number of those from the last war, and an increasing number of civilians who have lost limbs.

It appears that Mr. Gillis realizes that this very specialized subject makes dull reading, and in order to induce surgeons to read the book and not merely use it as a work of reference he has illustrated it profusely and placed apt quotations, classical or modern, at the head of each chapter. The routine procedures and technique employed at Roehampton are described simply and clearly, and the index enables the reader to discover quickly what he wants, but he may have to refer to several chapters to get the information he requires.

The general instructions and information regarding the use of a tourniquet are helpful. The reader will find details of every type of amputation carried out to-day, and will be interested to find that Lisfranc, Hey, Chopart, and Pirogoff are still with us. There is particularly useful information on affections of and operations on stumps, on painful stumps, and on phantom limbs. The chapter on kineplastic procedures, including the Krukenberg operation, does not condemn them, but is written from only a limited personal experience. The management of children's amputations and prostheses is lucid and should be most helpful. The subject of amputation for vascular disease, including diabetes, is dealt with in rather too narrow a way to be of value.

This book has been written with authoritative knowledge and is to be followed by a sequel—*Artificial Limbs*. The production is of high standard which would not suffer from the exclusion of a number of illustrations.

ST. J. D. BUXTON.

SCIENTIFIC BIBLIOGRAPHY

Scientific Books, Libraries and Collectors: A Study of Bibliography and the Book Trade in Relation to Science. By John L. Thornton, A.L.A., and R. I. J. Tully, F.L.A. (Pp. 288+x. 24s.) London: The Library Association. 1954.

The authors succinctly sum up this book in their preface as follows: "The professional historian of science will find little new in these pages, but the student of the subject, and the scientist searching for 'bibliographical gaps,' will find between two covers an accumulated wealth of material on the bibliography of science." Even so, the scope of this book is too wide. In 12 chapters the authors have surveyed scientific literature before the invention of printing, scientific incunabula, scientific books from the sixteenth to the nineteenth century, the rise of scientific societies, the growth of scientific periodical literature, scientific bibliographies and bibliographers, private scientific libraries, scientific publishing and book-selling, and scientific libraries of to-day. With so extensive a field to cover, a book of this size had been better planned as an introduction to the subject of scientific bibliography, which could be read with profit by one embarking on the

study for the first time. Instead, it is overweighted with erudition. It is too learned for the beginner, and, as the authors admit, is not adequate enough for the scientific historian, who will find many gaps in the chronology.

Some points of interest are the following: Dr. John Dee (p. 51) was an empiric, not "a medical man," as stated. He is believed to have had the degree of LL.D. of Cambridge University. Paracelsus (p. 53), so often regarded as a charlatan, receives his meed of recognition. The bibliographical study of Robert Boyle (pp. 71-4), based upon the writings of Geoffrey Keynes and John F. Fulton, is well done. Notable physicians in other branches of science were Claude Perrault (p. 83), who made contributions to comparative anatomy and then became a distinguished architect, and Martin Lister (p. 91), the founder of British conchology. Perrault's brother, Charles, achieved fame as a poet and a teller of fairy-tales. Scientific botany is the offspring of physicians, and Linnaeus had a medical degree. William Prout (pp. 142, 143) is mentioned as a British chemist. He was also a physician and a pioneer in biochemistry. So, too, was J. W. Thudichum, who is not mentioned, neither is E. B. Bancroft's *Philosophy of Permanent Colours*. Francis Buckland (p. 161) is cited, but not his father, Dean Buckland, so eminent as geologist and palaeontologist.

It is the duty of a reviewer to point out defects as well as merits. At the same time this book has many merits, much knowledge on every page, an excellent bibliography, and a full index. It should find a place in every large scientific and medical library.

ARTHUR S. MACNALT.

TEXTBOOK OF ANATOMY

Anatomy: Regional and Applied. By R. J. Last, M.B., B.S., F.R.C.S. (Pp. 665+xii; 309 illustrations, many in colour. 55s.) London: J. and A. Churchill, Ltd. 1954.

During the last few years there have been several new books on human anatomy, and Professor Last's is the latest addition. It might be thought that there is no room for another book on anatomy, but this is not the case; there is always a place for a new book on this subject provided that it is a good one. And this is certainly the case with this book, for Professor Last has approached his subject from a new angle. He has placed emphasis on general principles to illustrate why structures are arranged in a definite manner. The practical and applied sides of anatomy have been stressed. Professor Last has the great advantage over the majority of anatomists in that he practised general surgery for over 20 years, and therefore is in a position to apply this practical background to his book.

It is certainly encouraging to find such a wealth of new and original illustrations in it, many of them from the author's own pen.

The arrangement of the volume, designed to meet the requirements of those reading for an examination in anatomy, is sensible and practical, for both the undergraduate and the postgraduate like to study the body region by region. The book can be read in the museum or in the quiet of the home, and the author intends it to be read with the appropriate bones and the dissected part or museum specimen at hand for constant reference. Miss Jessie Dobson has written a series of biographical notes on famous anatomists of the past—a very useful addition to a work which is bound to prove popular.

Cecil Wakeley.

JUNG'S PSYCHOTHERAPY

The Practice of Psychotherapy: Essays on the Psychology of the Transference and Other Subjects. By C. G. Jung. Translated by R. F. C. Hull. (Pp. 377+xii; 14 illustrations. 30s.) London: Routledge and Kegan Paul. 1954.

Analytical Psychology is by no means a neatly systematized discipline resting on a few simple ideas and capable of application in treatment by means of a settled technique. This volume will be of special value to those who are interested in the clinical application of Jung's ideas, for particular attention is paid here to this aspect of his work. Part I

contains all of his papers on psychotherapy, and Part II his latest exposition of the transference situation. With one exception (the chapter on the principles of psychotherapy) the general papers have already appeared in English. Two of the papers were written in English by Professor Jung; the remainder have been excellently translated. Repetition is unavoidable in an assembly of eleven papers on therapy; but this is probably an advantage, as the reader will be able to see the development of Jung's ideas through the years.

Almost the whole of Part II is devoted to the only English translation of *Die Psychologie der Übertragung* ("The Psychology of the Transference"), which appeared as a separate publication in 1946; its inclusion here alongside the papers on psychotherapy is a sound plan and provides a fairly comprehensive picture of Jungian treatment. Analysis—as all agree—involves a reciprocal relation between patient and therapist, but this is hardly considered in some forms of psychotherapy, and in others it is given the central place. Jung's understanding of the transference makes it clear that the therapist is *in* the treatment and shares it with the patient.

Alchemical symbolism is extensively used in describing transference phenomena. This will strike some readers as rather odd, and they may wonder what link there can be between alchemy and present-day psychotherapy. They will find that Jung's study of alchemy is essentially practical and throws a clear light upon the transference situation in psychotherapy. Every psychiatrist using psychotherapy will find this chapter on transference worthy of his attention. The material does not make easy reading and it is not intended for the beginner. There is an excellent index and an impressive bibliography.

E. A. BENNET.

DUST HAZARDS

Dust is Dangerous. By C. N. Davies, D.Sc. Foreword by Sir George Barnett. (Pp. 116+xvii; illustrated. 21s.) London: Faber and Faber, Ltd. 1954.

In this book Dr. Davies has presented an outline of the medical and technical problems of dust diseases. He reviews the dust hazards of industrial workers, the methods and problems of dust assessment, and preventive measures. There are also chapters on radioactive dusts and on house and non-industrial dusts. These diverse and complicated problems are covered in 105 pages, so that the author has been forced to use a rather telegraphic style which often leads to some obscurity; but there are excellent illustrations and a good bibliography to lead the interested reader to sources of fuller information.

The book is presumably intended to awaken interest and to act as an introduction to the subject for those concerned with the practice of industrial hygiene but who have no expert knowledge of the subject. For them a glossary of technical terms would have been helpful, and perhaps a little more guidance as to the border-line between established practice and recent untried developments. Thus, illustrations are given of three dust-sampling devices which have not yet been accepted for general use, while the account of established instruments is rather cursory. In the clinical and pathological sections there are a number of minor errors and oversimplifications to which the medical reader may take objection, but on the whole the book is accurate and informative and should provide a useful stimulus to many people who do not realize how serious and complicated are the medical and technical problems of diseases caused by dust.

C. M. FLETCHER.

WARTIME PSYCHIATRY

Wartime Psychiatry: A Compendium of the International Literature. Edited by Nolan D. C. Lewis, M.D., and Bernice Engle, A.B., M.A. (Pp. 952. 46s.) New York: Oxford University Press. 1954.

The editors claim that "the material in this book attempts a general survey of all the important psychiatric aspects of the problems of selection, administration, combat, demobilization, and rehabilitation of members of the armed forces.

When possible, articles have also been included that bear on the application of new methods and knowledge to the field of civilian psychiatric practice."

In fact, no general survey, summary, or sifting of the vast literature has been attempted, for the volume consists of abstracts, varying in length, of individual books and papers. The selection of what should be included is in keeping with a most hospitable democracy. The abstracts are roughly grouped under 14 different general headings, sometimes for no very obvious reason. For example, the 17th abstract in the first section, "Administration," is:

"*Psychiatric Voice Recordings in the Military Service*

" (Albert A. Rosner, *War Med.*, 6:38-41 (July) 1944)

The author describes use of psychiatric voice recordings to supplement the printed word by the spoken word with its accompanying revelation of personality, feeling, character. The disks of one patient can later be cut as wished and transcribed to a single disk, but 10-20 per cent loss of clarity must be anticipated.

The author presents 4 cases; case 1 is that of a psychotic soldier with dementia precox, paranoid type, which illustrates fantasy formation as a symptom."

The volume may possess some value as a work of reference, but the index refers only to the names of authors; it is therefore impossible to look up any subject or article unless the name of the author is known. Much labour by stenographers must have gone into this compilation. The printing is clear and the binding good.

DESMOND CURRAN.

HOSPITAL PLANNING

Hospital Planning Requirements. By Guy Aldis, A.R.I.B.A., A.A.Dipl. With a foreword by Professor H. W. C. Vines, James B. Ewen, M.D., D.P.H., and the late Lionel G. Pearson, F.R.I.B.A. (Pp. 257; illustrated. 85s.) London: Sir Isaac Pitman and Sons, Ltd. 1954.

The author in this excellent work displays considerable genius, including that part which consists in a capacity for taking infinite pains. His study of the complex problem of hospital planning shows much evidence of prolonged and careful inquiry and observation, constructive thought, and perfected description, both verbal and diagrammatic. Indeed, he deals with clinical departments and their ancillary departments so ably that it is to be hoped he will not delay long in presenting his suggested similar work on non-clinical hospital departments, such as the kitchens and engineering services.

Each section has a general pattern of text and numerous diagrams. The latter illustrate the functional circulation within the department under discussion and give examples of typical layouts, indicating clearly the author's preference. With so many diagrams the text can be commendably brief, but it contains a wealth of material; it gives explanatory notes and a schedule of the accommodation required in each department. This is therefore a book to be studied carefully, section by section, then retained as a reference-book for frequent use. It is not one to be borrowed for a single rapid reading. Whenever a new hospital department is being planned—and, just as important, whenever an existing department is to be adapted or extended—the team concerned (architect, doctor, nurse, and hospital administrator) will be well advised to digest the appropriate section of this book, and, having produced their plan, to re-examine it in detail against the functional circulation and the schedule of accommodation described by Mr. Aldis.

The production of the book is excellent, the print being good and the diagrams models of clarity. Mr. Aldis is to be congratulated on having made such good use of the opportunity for research on hospital planning afforded by his position as a Regional Architect in the National Health Service. His book fills an important gap in the literature of hospital planning and is worthy to be a standard textbook. A copy should be made available in the reference library of every hospital management committee and of all doctors and nurses closely associated with hospital planning.

W. G. PATTERSON.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY FEBRUARY 26 1955

EXPERIMENTS ON HUMAN BEINGS

The question asked in Parliament last week whether an experiment on patients recently described in this *Journal* was ethical is but another example of a fairly widespread anxiety. At a meeting of medical editors in Rome last September, under the auspices of the World Medical Association, Dr. W. A. R. Thomson,¹ joint editor of the *Practitioner*, and Dr. G. C. Heringa, editor of the Netherlands journal *Medisch Contact*, read papers on the responsibility of editors in publishing the results of experiments on human beings, the nature of which might be abhorrent to the ethical conscience. The W.M.A. General Assembly passed a resolution on the ethics of human experimentation, and in his address to a large gathering of W.M.A. delegates the Pope lent the weight of his high authority to a series of pronouncements on this form of medical responsibility. The Pope recognized that Medicine could not do without human experiments: "Que la recherche et la pratique médicale ne puissent se passer de toute expérimentation sur l'homme vivant, on le comprend sans peine,"² to give his actual words. The conditions under which such experiments can be justified—are ethical—are not necessarily easy to determine. What to the doctor may be a seemingly harmless procedure may to the onlooker in Parliament or to the Press be something to be challenged in the name of ethics or morality. But doctors themselves have been the first to examine the ethical problems of human experimentation, feeling, perhaps, more than ever conscious of their responsibilities in this after learning of the black record of certain German doctors in the last war.

"Clinical investigators," W. B. Bean³ has said, "rarely meditate upon the wide cleavage which separates clinician from investigator in their split personality." The physician caring for the sick person joins forces with him in the closest of all alliances against a common enemy—the affliction that has laid the patient low. In the face of an intractable disease for which there is no specific remedy the physician—and still more the surgeon—may offer the patient a

drastic remedy which may fail to do good or may do actual harm. Each such intervention by the doctor is an experiment. The first appendicectomy was an experiment, as were the first lobectomy, the first removal of a cerebral tumour, the first administration of penicillin. Both patient and physician in the face of disease or disablement feel a strong urge to intervene actively, and in the days when therapeutics was only barely rational the bleeding bowl, the cupping instruments, and the enema syringe were always at hand for use and misuse. A mediaeval physician proposing to put bleeding to a controlled trial in the treatment of a given disease would have been looked on as beyond the pale. But a simple trial might have saved thousands from being bled to death. The modern clinician must be clear in his own mind what he is doing when taking part in a trial of a new drug in treatment or a new vaccine in prevention of infection, both presumed to have the possibility of being effective or they would not be on trial. If a large-scale trial of, say, pertussis vaccine or a poliomyelitis vaccine is undertaken, with comparable groups of children serving as controls to those receiving the prophylactic, in what scale of ethics is one to weigh the increased morbidity and mortality subsequently found in the control group—a large enough difference being found to justify widespread inoculation of later generations of children against these diseases? Of course every safeguard is introduced. Parents and schoolteachers are informed with the greatest scrupulousness of the nature of the experiment, of its object, of the risks entailed; and the investigation is then conducted on a voluntary basis. But however careful and conscientious the explanation—unfortunately often described as propaganda—there is a limit to the layman's understanding of it. Probably what finally tips the balance in most cases is trust and faith in the doctor, in the wonders of modern medicine. Yet without such controlled trials it is difficult, if not impossible, to prove the prophylactic value of a vaccine or the superiority of a new variant over an old one. The history of B.C.G. shows what confusion may prevail for more than a quarter of a century in the absence of proof—the proof that only an experiment can provide. In therapeutic trials it is interesting to note that only strict limitation of supplies of the drug made it possible for controlled trials of streptomycin in the treatment of tuberculosis to be conducted in this country: in this instance necessity was the mother of ethics; indeed, it would have been unethical not to have controlled the trial that was made. No one can doubt the great benefit conferred on tuberculous persons the world over as a result. Much heartaching

disappointment would be avoided if no new drug were made generally available except after previous carefully conducted clinical trials, except after, in other words, the essential test of human experimentation. The story of cortisone is a warning.

The stronger the influence of the laboratory in Medicine, the more tempting it is for the investigator to look upon his patients or the patients of his colleagues as "experimental material," as cases of this, that, or the other disorder, rather than as sick and anxious human beings longing to be relieved of distress of mind and body. To some extent such detachment of viewpoint is essential if the doctor is to do his best for the patient, by looking on him with complete objectivity. But modern instruments and techniques make it easy for the medical man to satisfy his scientific curiosity by subjecting patients to procedures not essential to the relief of the condition for which they are being investigated or treated. When these procedures are simple and free from risk, then surely there is everything to be said for them when knowledge is added to. The main requirement is full explanation to patient or parent before permission is obtained. And some would distinguish sharply between experiments on the sick and experiments on the healthy. In the former an experiment may lessen the consequences of disease. A doctor voluntarily contracting a tropical disease to discover some link in the chain of causation is one thing; to subject a lay person—even a volunteer—to a similar experience is another, especially if the lay person is in a subordinate position.

What safeguards should the medical profession erect to protect the public and to preserve its traditional *mores*? The first, and the oldest, and the most obvious imperative lies in the nature of the doctor's first task—to care for the sick person, the man or woman in pain or distress, to submit himself to the rigorous demands of the doctor-patient relationship, to do nothing to his patient that he would not do or have done to his own family. Mr. B. Shimkin⁴ considers that the clearest rules for guidance were those laid down at the Nuremberg trials. The first of these is here given in full:

"The voluntary consent of the human subject is absolutely essential. This means that the person involved should have legal capacity to give consent; should be so situated as to be able to exercise free power of choice, without the intervention of any element of force, fraud, deceit, duress, overreaching, or other ulterior form of constraint or coercion; and should have sufficient knowledge and comprehension of the elements of the subject matter involved as to enable him to make an understanding and enlightened decision. This latter element requires that before the acceptance of an affirmative decision by the experimental subject there should be made known to him the nature, duration, and purpose of the experi-

ment; the method and means by which it is to be conducted; all inconveniences and hazards reasonably to be expected; and the effects upon his health or person which may possibly come from his participation in the experiment.

"The duty and responsibility for ascertaining the quality of the consent rests upon each individual who initiates, directs, or engages in the experiment. It is a personal duty and responsibility which may not be delegated to another with impunity."

Some hold that editors of scientific journals have a prime responsibility in this matter in being able to reject articles recording the results of allegedly unethical experiments. But it might be argued that an editor should publish papers which contribute to knowledge and should not act as a censor of morals. It might with more force be argued that it is only by publication that undesirable methods of investigation are brought to light and exposed to public criticism. Whatever may turn out to be the best methods of discouraging and preventing undesirable experiments on human beings, it is heartening to note that medical men all over the world are alert to the dangers; and it is deeply satisfying to record that human experimentation has contributed immeasurably to the health and well-being of countless millions. The continued progress of Medicine will depend upon its continued use under wise and humane guidance.

ADRENAL CORTEX

The review by Dr. R. I. S. Bayliss of recent advances in our knowledge of adrenocortical function, which appears in our opening pages this week, may be welcome to those many medical men who are apt to be somewhat daunted by the intricate chemistry and terminology of the subject. The adrenal cortex secretes five groups of substances, all of which are related in chemical structure to cholesterol. This sterol is widely distributed throughout the body, and from it all the adrenocortical hormones, regardless of their function, are thought to be derived. Two groups of hormones have been most widely investigated, chiefly because their absence is most dramatically marked by the inability of the deprived animal to go on living. These are, first, the hormones whose primary effects are on carbohydrate, nitrogen, and fat metabolism, and, secondly, the most recently isolated steroid aldosterone; this exerts its most powerful effect on sodium, potassium, and water metabolism. The functional distinction between the two is not clear-cut, since the steroids concerned with carbohydrates, commonly known as corticosteroids, exert some effect on sodium, potassium, and water conservation, while aldosterone to some extent corrects the tendency to hypoglycaemia from which patients with decreased or

¹ *Med. J. Aust.*, 1954, 2, 953.² *L'Osservatore Romano*, October 2, 1954.³ *J. Lab. clin. Med.*, 1952, 38, 3.⁴ *Science*, 1953, 117, 205.

absent adrenocortical function suffer. So far little is known of how aldosterone is secreted, or of how it produces its effects, and most research has been concerned with the secretion of the carbohydrate-active compounds, of which cortisone and hydrocortisone are important examples.

The secretory activity of the adrenal cortex is under the control of the corticotrophic hormone (A.C.T.H.) of the pituitary. This substance is not itself a steroid, but is either a protein or a polypeptide, and there is some disagreement whether it is one hormone or several. It exerts its effect on the adrenal cortex by causing increased synthesis of cortical hormones from cholesterol and acetate, the intermediate chemical keystone of the whole process probably being the hormone progesterone. Since there are at present no reliable methods by which the A.C.T.H. concentration in body fluids may be estimated, little is known about the levels which are necessary to ensure adequate adrenocortical secretion for coping with the vicissitudes of everyday healthy life. When A.C.T.H. is not secreted because of hypopituitarism, the suprarenals atrophy and secretion of corticoids is minimal. When a patient is given A.C.T.H., corticoid secretion increases, as shown by increased corticoid levels in the blood, by increased excretion of corticoids in the urine, and by the effects of the corticoids themselves on the level of circulating eosinophils, lymphocytes, and blood-sugar concentrations. The amount of stimulus exerted by administered A.C.T.H. depends on the dose of A.C.T.H. given and on the time over which a constant dosage can be maintained without intermission. A single dose of A.C.T.H., which must be given parenterally, produces a transient enhancement of adrenocortical secretion; laboratory evidence of this may be missed in the commonly used Thorn test of adrenocortical function. Therefore negative results to this test, as usually done, should be confirmed by a stimulus of longer duration. This can be provided by intramuscular injection of A.C.T.H. mixed in a gel, or preferably by intravenous infusion.

The level of corticosteroids in the blood probably controls the release of A.C.T.H., while corticosteroids are secreted into the blood in response to stimulation of the adrenal cortex by A.C.T.H. In healthy subjects the mean plasma corticosteroid concentration averages 9 μ g. per 100 ml., ranging from 3 to 17 μ g. per 100 ml. The method estimates chiefly hydrocortisone (compound F). Its value as a method of assessing adrenocortical function is limited by the same considerations which apply to all estimations of blood concentrations—namely, that the blood level of any substance is a resultant of the rate at which the substance is discharged into the blood and the rate at

which it is removed by metabolism or excretion. Corticosteroids are excreted in the urine and probably in the faeces. They may be estimated in urine, in which they are excreted partly metabolized to 17-ketosteroids and other steroids and partly unchanged as water-soluble conjugates with glucuronic and sulphuric acids. Unfortunately there are not yet any satisfactory routine methods for determining specific corticosteroids in the urine. This is because of the difficulty of hydrolysing the conjugated excretion product without altering the chemical structure of the hormone beyond recognition. It is known that 5–10% of an administered dose of cortisone is excreted in the urine as cortisone, and a very small amount appears as 17-ketosteroids. The fate of corticosteroids in the tissues is obscure. They diffuse freely throughout the extracellular fluid and are metabolized by synovial tissue, kidney, spleen, and liver. In the liver they may undergo chemical reduction and conjugation with acid radicles, and are partly excreted in the bile. The renal clearance of corticosteroids is low, and they are probably actively reabsorbed in the renal tubules.

While the pathogenesis of Addison's disease and hypopituitarism are obvious enough, it is clear that in such a complex system there is plenty of room for disorders of steroid production, consumption, and excretion, and these may be reflected in clinical syndromes whose aetiology is at present only dimly understood, if at all. Much remains to be done in this field of research.

ENDOCRINES IN PSYCHIATRY

A lucid and compendious account of endocrine treatment in psychiatry is given by Dr. R. E. Hemphill at p. 501 of the *Journal* this week. The story is, admittedly, a somewhat disappointing one. Almost everywhere in psychiatry the endocrine balance seems to play some part—in the psychoses, in many forms of neurotic reaction, and in personality and constitution; and yet the points at which the endocrinologist can effectively enter into treatment are few and far between. Dr. Hemphill has himself drawn attention to some of the reasons why this is so; there are also others. However, things are not quite so bad as they seem at first. When some form of psychiatric disorder proves to have a physical cause, diagnosis and treatment are taken from the hands of the psychiatrist and reserved for the physician. It is not so long since dysmenorrhoea was regarded mainly as a neurotic disturbance; either no treatment was given or it was a case for psychotherapy. More is now known about the physical basis—for instance, that the pain may be

related to ovulation. If ovulation is suppressed, as it may be by giving oestrogen early in the menstrual cycle, the pain may disappear. Superficially the cycle appears to be the same, though its hormonal balance is now different. The treatment, which might once have been regarded as a successful application of endocrinology to psychiatry, would not now be thought of as having anything to do with psychiatry at all. The same position has been reached with the premenstrual tension state, and, to a large extent, with the emotional instabilities of the menopause. Such endocrine disorders as Graves's disease, myxoedema, Addison's disease, and Cushing's disease, despite their important psychiatric aspects, rarely come the way of the psychiatrist and are treated with some success by physicians without recourse to the psychiatrist. This has the disadvantage that the psychiatrist never sees this kind of clinical material, though it would be of great educational value to him. The cases that the endocrinologist refers to the psychiatrist, like the cases passing in the opposite direction, are those with atypical features, in which on each side the clinician feels at a loss. Here are the unsolved problems involving both specialties, which neither side can tackle alone.

Early studies of glandular disorders gave an altogether false impression of their aetiology, suggesting that every such illness should fall into the simple pattern of diabetes, in which the replacement of a single hormone is effective treatment. In the endocrinopathies this is a most unusual state of affairs. Generally it is the balance of a number of internal secretions which is at fault, and there is no simple replacement that can be carried out. In treating the premenstrual tension state, for example, administration of ethisterone in the latter half of the cycle is only moderately successful, and sometimes does not avail. At this time the oestrogen level is at its maximum, and the progesterone level should be rising to compensate for it. The imbalance may arise through deficient corpus luteum formation and inadequate absorption of progesterone; in that case the administration of a progesterone compound may give benefit. But the imbalance may also arise through an excessive production of oestrogen; then the giving of oestrogen in the first half of the cycle, influencing the production of follicle-stimulating hormone (F.S.H.) by the pituitary and suppressing the formation of a corpus luteum, will so alter the cycle as a whole that the same therapeutic end is attained by what would seem to be physiologically contrary means.

The administration of a single endocrine preparation often fails to restore normal balance; furthermore, it cannot be given without repercussions.

Supplying an extra amount of one internal secretion not only alters the level of that one compound but also affects the level of many others, and the prolonged administration of any one endocrine substance will probably depress the function of the gland that makes it. While no general rule can be formulated, it is safer when the pathology is not clearly understood to give balanced complexes rather than single gland products, and to give treatment intermittently—in short courses with rests between. There are yet other dangers of inexpert treatment, many still not fully known. It seems rather doubtful whether there is such a condition as a male climacteric—that is, a revolution rather than an evolution of hormonal balance—but the diagnosis is sometimes made, and hormones are sometimes given for it. But the risk is by no means negligible that the administration of androgens may start up a prostatic carcinoma. Even when the nature of the disease is known and the treatment is uncontroversial, caution is often necessary. Deaths from myxoedema have been reported (for example, in cases in which adrenal function was depressed) caused by the administration of thyroid extract in a dose too high for the patient, though moderate by ordinary standards.

The future of endocrine treatment in psychiatry is encouraging enough. More research is still needed, though not crude experiments matching degrees of mental improvement in treated and control series of patients whose hormonal balance is entirely unknown, for these can give only misleading results. And it is to be hoped that official bodies responsible for the distribution of scarce preparations, such as cortisone, will be more sensitive to psychiatric claims.

NUMBERS OF DOCTORS

The news that a Government committee has been set up to consider the intake of students into the medical schools is welcome. As reported in our Parliamentary news (p. 546), the Minister of Health and the Secretary of State for Scotland have appointed Mr. Henry Willink, Q.C., as chairman; the ten other members of the committee comprise seven medical men and three laymen. Their combined experience of medical affairs, both clinical and administrative, will provide a firm foundation for their debates. Not quite so much can be said for their terms of reference. They read as follows:

"To estimate, on a long-term basis and with due regard to all relevant considerations, the number of medical practitioners likely to be engaged in all branches of the profession in the future, and the consequential intake of medical students required."

Though the total number of doctors practising at some future time may be estimated fairly accurately, provided

certain common-sense assumptions are made, the distribution of those doctors between the branches of the profession may well change unexpectedly in response to the development of medical science and its clinical applications. No good purpose is served by trying to work out, on the basis of the existing distribution, the numbers required to fill complex hierarchies in the hospital or public health branches. Moreover, the distribution between even the main branches of the profession has changed, and continues to change, in accordance with the needs of efficient medical practice. Flexibility of response is apt to be lost sight of in a State service, and it is to be hoped the committee will so interpret their terms of reference as not to impair it. The ambiguity in these instructions about what the size of intake is to be a consequence of, and what requirements it ought to meet, is presumably intentional. No doubt the committee will treat them as a starting-point rather than a boundary.

It was two years ago that the Council of the B.M.A. accepted a suggestion made by the chairman of the General Medical Services Committee that the G.M.S. Committee should look into these questions of supply and demand, and last year the Council asked the Minister "to set up a working party to review the whole problem."¹ Since then nothing has happened to make it any less urgent. As we pointed out last year,² there were in 1953 about 900 persons in England and Wales to one doctor and rather under 600 in Scotland. These figures, still the latest obtainable, are derived from the numbers of doctors shown in the *Medical Directory* as living in these countries. Some may be retired, and others who are practising do not have their names listed, but these are only trivial sources of error. The corresponding figure for Ireland is 730 persons per doctor, though, since Northern Ireland and the Republic are not treated separately, the figures are difficult to interpret. In 1900 England and Wales had 1,410 persons to every doctor and Scotland 1,300. From about 1930, when England and Wales had 1,250 persons per doctor, the proportion steadily fell to the 1953 figure of 900. In Scotland as far back as 1920 there were only about 1,000 persons to every doctor; during the 'thirties there were about 800, in 1953 there were about 570. Meanwhile students have been pressing at the gates for admission to medical schools in considerably greater numbers than are finally admitted, and as a result of their exertions the average annual increase of names on the *Medical Register* has been more than 1,000 for at least the last 20 years. In 1934 there were 57,496 names, in 1953, 83,090; this is an increase of 25,594, or 45%. Evidently, therefore, one of the most "relevant considerations" before the new committee will be the swiftly growing body of registered medical practitioners, for when the present new intake emerge from the chrysalis in 1960 their names will be added to a *Register* whose list will then have increased by five or six thousand. The committee may well feel some urgency about its work.

TOPICAL HYDROCORTISONE

Cortisone and corticotrophin have been available for long enough now to give a fairly clear impression of their value in the treatment of skin diseases. They are used in two principal types of case: the severe but self-limiting disorder in which steroids will cut short an attack and tide the patient over until natural remission sets in; and those long-term cases which are otherwise fatal or severely disabling and for which no alternative treatment gives much benefit. In the former type of case the patient is often treated for only a few days at a time, and the well-known complications of treatment with these substances scarcely have time to develop. But when treatment is prolonged over many weeks and months a formidable list of complications may appear, some of them well-nigh unavoidable. It is therefore of particular interest to determine what benefit may be expected from the local application of steroids.

It was early discovered that cortisone and A.C.T.H. are almost, if not completely, without effect when applied to the surface of the skin, but that hydrocortisone (compound F) exerts a profound influence on certain eruptions. It is evidently absorbed through the skin, particularly if the corneous layer of the skin is damaged by disease; but the experiments of C. C. Smith¹ failed to demonstrate any eosinophil response to the application of relatively large amounts to the intact skin surface. Similarly, the application of hydrocortisone to the skin over periods of many weeks is not followed by any signs of systemic absorption. The precise mechanism and level of action of topical hydrocortisone therefore remain unknown.

Although the therapeutic effects of systemic cortisone and local hydrocortisone are not quite the same, they correspond fairly closely, and in many disorders local application is preferable in that the risk of the complications and side-effects of its systemic administration is avoided. Moreover, local application of hydrocortisone appears to be surprisingly free from irritation. In all those cases where irritant action has been recorded, it appears to have been due to the base, usually carbowax, in which it was incorporated; true epidermal sensitivity to hydrocortisone has not been demonstrated. Dr. R. Church, whose results are reported on another page, used a base of lanolin, soft paraffin, and mineral oil, and does not record any irritation from this.

M. B. Sulzburger² has listed those disorders in which hydrocortisone appears to be beneficial. Most belong to the eczema group, whether of the so-called constitutional type or the type of case due to contact sensitivity. Atopic eczema, both the infantile and the flexural, otitis externa, and pruritus ani are also likely to respond. Dr. Church confines his account mainly to those disorders which have already been shown to improve with this kind of treatment, and his results, successful in about three-quarters of the cases, are comparable to those of other authors. It is notable that most of these diseases

¹ Smith, C. C., *Arch. Derm. Syph. (Chicago)*, 1953, 68, 50.
² Sulzburger, M. B., in *Modern Trends in Dermatology*, 2nd series, Editor, R. M. B. MacKenna, 1954, London.
³ — and Baer, R. L., Editors, *Year Book of Dermatology*, 1953-4, Chicago.

are of unknown, or only partly understood, causation, and that they run an unpredictable course with spontaneous exacerbations and remissions. To measure the benefit conferred by any new treatment is thus a matter of the greatest difficulty, and the final assessment of hydrocortisone ointment will not be made for some years. However, even when allowance is made for natural optimism, it seems likely that M. B. Sulzburger and R. L. Baer³ will be proved right when they surmise that it bids fair to being one of the most important advances ever made in local treatment of the skin. The disorders which will or will not respond to hydrocortisone ointment are now fairly clearly defined. Suitable vehicles and bases in which to incorporate the active substance have yet to be decided, as have the mode and frequency of application required in different cases. The combination of hydrocortisone with antibiotics and other drugs has already been considered, but so far hardly studied: combinations of local treatment with systemic steroid therapy also need investigation.

TREATMENT OF BACTERIAL ENDOCARDITIS

Since the conclusion of the Medical Research Council study of the penicillin treatment of subacute bacterial endocarditis, the findings of which were reported by Cates and Christie,⁴ it has been left to individual effort to pursue this subject. Possibly the lessons learned in that study are still being applied, but there is almost no means of knowing how successful their application is proving, or whether any improvement in the method of treatment has had an adequate trial. It would be interesting in particular to know whether, and if so in what circumstances, the disease can safely be treated by less frequent injections of a slowly absorbed penicillin preparation, a modification which would be welcomed by patients who have to endure a course lasting six weeks. The results obtained with procaine penicillin by Roston and Stollerman⁵ in six patients, and by Volini, Hoffman, and Hughes⁶ in sixteen appear to have been very satisfactory and fully warrant more extended trial.

Not only the method of treatment but the grounds of the decision to institute it are matters of importance, and on the second of these subjects Newman, Torres, and Guck⁷ have decided and somewhat controversial views. Their material consisted of 52 cases, all men, admitted to the Veterans' Administration Hospital, Bronx, N.Y., between 1946 and 1953. Only 12 of these were diagnosed before admission, and apparently 8 died undiagnosed. Blood cultures were made in 48, of which only 32 were positive: in "some" cases daily cultures were made for 15 to 20 days, and in none was a positive culture obtained after the fourth when the first four had been negative. On this basis these authors propose the following policy. It depends on the presence or absence of signs of the disease, classified as "major" (these, apart from a positive blood culture, are heart

murmur, fever, and anaemia), and "minor" (palpable spleen, petechiae, clubbing, microscopical haematuria, arterial emboli, and Osler's nodes). If a patient with a cardiac or vascular lesion predisposing to infection has one or more of these signs inexplicable in another way, he should have four blood cultures on successive days and then be submitted to a full course of treatment without awaiting the results of these cultures. The authors say earlier that if a murmur associated with one other major or two minor signs had been accepted as diagnostic, 47 of their cases could have been diagnosed. This policy is well expressed in their dictum: "We must have a very high index of suspicion for this disease even if it means treating some patients unnecessarily."

This series of patients is not altogether satisfactory for several reasons: at least three and possibly five were infected by organisms which place them outside the category of a "subacute" endocarditis, no sensitivity tests were reported, and treatment in some of the early cases was inadequate. Even "adequate" treatment is defined as a certain dose given for "at least two weeks," which in most people's estimation is much too short a period. Nevertheless, some other conclusions, even though based on small numbers, are interesting. Of 39 adequately treated patients 27 recovered, of whom one-third each died of sequelae, are alive but disabled, and alive and symptom-free. The duration of the disease, if not exceeding six months, did not appear to affect the amenability of the infection to treatment, nor did the presence of congestive heart failure, which actually preceded the onset of the infection in five patients, and was the first sign of it in eight. On the other hand, the mortality in such patients is much higher. Positive blood cultures were obtained in three afebrile patients. Provided the infection could be cured, recovery from renal damage was possible. Previous inadequate antibiotic therapy did not affect either the chances of obtaining a positive blood culture or the outcome of subsequent treatment. Two of the more heterodox of these conclusions—namely, that neither the duration of the disease nor the existence of heart failure appears to affect the results of treatment—are also reached by Bunn and Cook⁸ from a study of 48 patients, of whom 33 recovered. These authors are insistent that the dose of penicillin must be adjusted to the sensitivity of the infecting organism. Inadequate dosage was a probable cause of failure in 4 of their patients; in 6 others rupture or perforation of an aortic valve cusp was the immediate cause of death. It is emphasized that the outlook when the lesion is aortic is far less favourable than in involvement of the mitral valve or of congenital defects. Analyses such as these, even though some of the conclusions rest on a slender basis, provide helpful information, and those in a position to report on such a series should be encouraged to do so, particularly if it illustrates the effects of any newer method of treatment.

We record with regret the death on February 21 of Sir Henry Wade, the eminent urological surgeon, who was on the staff of the Edinburgh Royal Infirmary for nearly thirty years before his retirement in 1939.

EMERGENCIES IN GENERAL PRACTICE

"FITS"

BY

DENIS WILLIAMS, M.D., D.Sc., F.R.C.P.

Neurological Physician, St. George's Hospital and the National Hospital, Queen Square, London

By the time he gets to the house the doctor will find that the fit itself is over and that the patient is either recovering or is in post-epileptic coma or in a restless confused state. It is best then to do as little as possible, for restraint or restriction will cause an increase in restlessness or aggression; the sleeping patient is best undisturbed.

If this is the first fit the question to be answered is whether it was an epileptic convulsion, an hysterical attack, apoplexy, a subarachnoid haemorrhage, or even an unsuspected head injury with subsequent coma. A witness's account will usually establish the characteristic train of events in a convulsion—sudden tonic spasm occurring without cause, followed by gradually decreasing clonus with tongue-biting and cyanosis, and then coma with flaccidity, incontinence, and stertorous breathing. If there is doubt about the nature of the attack, it is best not to hurry into action because time and the recovery of the patient will in most circumstances make the diagnosis clear. He will recover from post-epileptic coma in a few minutes or a few hours with no sequel other than a headache, a badly bitten tongue, and incidental soreness and bruising. The family will probably need more treatment than the patient, and the advice given should be very conservative. It is best to tell relatives that a fit itself does the patient little harm, barring accidents, that it is an explosive affair affecting the whole body, and that like any other explosion there is nothing that can be done until it is over. Then the thing to do is to repair the damage and try to prevent a recurrence.

When a patient falls in a fit he should be left where he lies, furniture and obstructions being removed from the area of movement to prevent injury. There is no need to loosen clothes or to try to modify his activity in any way. In the early tonic phase the mouth opens and there is plenty of time to remove dentures and to rest something against the upper premolar teeth to prevent subsequent tongue damage: a bit of stick or a screw of stuff will do, or the patient's diary, a pencil, a handkerchief, or the corner of his coat collar. Once the clonic phase is over the patient can be laid somewhere comfortable and allowed to recover without interruption. At this stage a brief examination of the nervous system may show weakness of one limb after the others have recovered, or a unilateral extensor plantar response, which may provide a valuable clue concerning the cause, which will completely disappear and be lost in a few minutes.

After recovery from the fit—perhaps the next day—the reasons for the attack must be considered. There are immediate precipitants and remote causes. The more potent the immediate causes, the less serious are the remote ones likely to be. A normal person may have a solitary fit after excessive beer-drinking, through sheer hydration, and some will complicate pneumonia with a convulsion. Others will have a solitary fit during a period of prolonged emotional and physical strain. When immediate causes have been considered, the more remote ones will be looked for—sugar or albumin in the urine, raised blood pressure, an enlarged liver, or a history of recent ill-health will suggest a host of general medical conditions which may give rise to convulsions. The local cerebral causes, revealed by signs of local dysfunction or the symptoms of raised intracranial pressure, will then be excluded. Every adult who has had a solitary fit without known cause should be fully examined by the

physician, have his urine tested, and then be referred for an electroencephalogram, radiology of the chest, blood Wassermann reaction, and radiology of the skull in that order of importance.

No person who has had one solitary convulsion should be given anticonvulsants—he may never have another fit. Unless there are special circumstances, it is more reasonable to allow a period of time to elapse, to withhold treatment until investigations have been completed, and, other diseases having been excluded, to begin treatment if two more fits occur. Three attacks may give some indication of the natural periodicity without treatment, which will help in the assessment and consequent management of the case.

A Convulsion in a Child

A convulsion occurring in childhood has much less serious significance than in later life, as regards both prognosis and causation; for the younger the infant, the more readily do transient bodily changes induce a fit. There is no difference between a teething convulsion and any other sort of fit; it is simply that the tendency to convulsions with similar causes is progressively diminished with maturation of the nervous system. As in the adult, the more closely the convulsion can be related to an immediate cause, the less intensive need be the search for remote causes; in infancy, pertussis, pneumonia, measles, chicken-pox, or teething, in that order of frequency, may be the whole and sole cause of a convulsion. Do not treat these symptomatic convulsions, but begin to consider the matter to be serious if a fit is repeated more than once, whatever the cause; if there are several convulsions in one illness; or if there is a single fit without an adequate recognized cause. If any of these circumstances obtain, the time has probably come to begin anticonvulsant therapy.

Focal Attacks

So far generalized convulsions only have been mentioned, but the same management may be adopted for the focal epileptic attack. Here, however, the immediate event is less dramatic and exacting, but a searching investigation of the patient for evidences of a local cause should be made. At this stage the physician will generally find negative results of his initial investigations, and it is rather worrying to know how far to pursue them. As neurological investigations carried out in hospital, including as they do carotid arteriography and air encephalography, are both complex and distressing, it is often wise merely to re-examine the patient and to have an electroencephalogram done at infrequent intervals—perhaps every other month.

Status Epilepticus

Status epilepticus is the most deadly complication of epilepsy and sometimes is the first event in the illness. It is said to occur when a patient has more than two fits without recovering consciousness, and at that stage it must be treated as a grave emergency. It is too late to save his life if you wait until the patient begins to look as if he may die, because death usually occurs through acute myocardial failure, which rapidly progresses if fits continue after its onset. Consequently a patient in status epilepticus, if possible, should be sent to hospital after initial treatment. Intramuscular sodium phenobarbitone, 5 gr. (0.32 g.), is most often given first, but an intramuscular injection of sterile paraldehyde, 5 or 10 ml., repeated in an hour if the fits continue, is more effective. It is best to err in giving

EDUCATING THE PUBLIC IN MENTAL HEALTH

The education of the general public in mental health was the theme of discussion at the final session of the quarterly meeting of the Royal Medico-Psychological Association held in London on February 17. Dr. NOEL G. HARRIS, the president of the association, was in the chair.

Miss P. HORNSBY-SMITH, M.P., Parliamentary Secretary to the Ministry of Health, who opened the discussion, said that it was generally agreed that there were few fields of medicine which had made more dramatic advances in the last 20 years than mental health. Indeed, there was now such a "new look" in mental health that it was no longer just a case of care and custody but of care and treatment, and in many cases cure. That fact was not generally appreciated. The workings of the mind, particularly the sick mind, were a very difficult subject for the man in the street to understand. There was still need to obliterate from popular speech such phrases as "padded cell," "put away," and "put in an asylum."

Why Bother?

Why bother about educating the public? So far as Parliament was concerned, vast sums of money could not be spent on mental health and priority could not be given to it unless people generally recognized the size of the problem and fully understood the need. The incidence of mental illness could not be kept down unless people were better informed and encouraged to come forward for treatment at an early stage. There must be a general realization that nursing the sick mind was just as important a service as nursing the sick body. The spread of knowledge of the principles of mental health would pay very handsome dividends. That had already been shown in the field of physical health, and the public now had to be persuaded that in safeguarding their physical health an essential concomitant was the safeguarding of their mental health.

Miss Hornsby-Smith added that she was well aware that the whole tendency to express scientific matters in colloquial terms was abhorrent to the average professional man, but if mental specialists were going to take the public with them they must give reasons understandable by the common man. And it was far better, if colloquial terms had to be used, that this should be done by those who were fully qualified than by the less skilled who might make a botch of it. She appealed therefore to mental health specialists to study the value and the best method of educating the public in their specialty. Mental specialists could not say too often or make too well known the fact that seven out of every ten who entered mental hospitals did so as voluntary patients and that the average stay of those discharged was just over two months. Recognition of such facts would help to build up in the mind of the public a better-informed picture of the service provided to-day.

Some of the Dangers

Dr. R. R. BOMFORD (The London Hospital) said that all doctors suffered to a considerable extent because they were expected to work magic: when their magic was successful they were irrationally praised, and when it was unsuccessful they were equally abused. He believed the mantle of the magician was now falling on mental specialists. Whilst there was a great deal of unconscious rejection of psychiatric theories for indefinite reasons, there was also a danger of people accepting psychiatry in an unreasonable fashion.

Dr. W. S. MACLAY (Board of Control) suggested that the many aspects of mental health needed to be more closely defined if there was ever to be a satisfactory assessment of the value of the effort and money expended on it. It was much easier for people to have sympathy with the aims of the mental hygienist than for the hygienist to be scientific.

Mr. FRANCOIS LAFITTE thought it would be helpful if all newspapers employed a competent medical correspondent.

a large rather than a small amount. If the patient is in a hospital where an anaesthetic apparatus for positive-pressure respiration is available, intravenous thiopentone or amyl-barbitone sodium, both given very slowly until the movements stop, are highly effective. The injection should cease when clonic movements cease, to be repeated later if necessary, for, as the patient is already in deep coma, it is impossible to judge the depth of anaesthetic coma, and respiratory and cardiac action may cease. It used to be said that a half of all patients in status epilepticus die, but death should now be thought to be due to delay in instituting parenteral treatment.

When the actual clonic movements of the limbs of a patient who is in status epilepticus cease, post-epileptic coma may continue for many hours, and confusion for days, but if the patient's general condition is good there is now no need for immediate concern. During the coma any feeding should be by a Ryle tube, in small amounts, to prevent the possibility of aspiration pneumonia. Intravenous infusion of glucose-saline should not be needed, and in any case fluids should be given sparingly, as hydration of the patient may well precipitate further fits. Sometimes after freedom from convulsions for some hours they will repeatedly recur; then it is wise to put up a slow intravenous saline drip with thiopentone and to inject into the tube from time to time, but in those circumstances a whole team made up of physician, anaesthetist, and nurses is needed. A patient should remain in bed several days after status epilepticus has been controlled, even if there are no complications, both for recovery and for repeated examination.

Recurrent Fits

When more than two fits have happened, and investigation has failed to show a cause requiring specific treatment, continued anticonvulsant treatment will be needed, but before beginning this the physician should face the fact that he is implying that medical treatment must continue for at least three years after the last attack. This is a consequently serious step requiring much consideration; I think some doctors are far too apt to "put him on phenobarb." to ease domestic tension as much as anything else, when it would be more logical, effective, and economical to give the relatives phenobarbitone for a few days instead.

Although this paper is dealing with emergencies, it is logical to consider the treatment of repeated convulsions. For the major fit phenobarbitone remains the anticonvulsant of choice—it is so often effective, and its side-effects are usually so trivial. I generally begin in an adult with $\frac{1}{2}$ gr. (32 mg.) twice a day, increasing to thrice a day if necessary. Children tolerate phenobarbitone well, and as a rule they are given too small a dose in attempting to control convulsions; a suitable dose is $\frac{1}{2}$ to $\frac{1}{4}$ gr. (16 to 32 mg.) twice a day. The timing of the dose should depend on the usual time of occurrence of the fits—a large dose in the evening if they are mainly nocturnal, but on rising if they are diurnal. Similarly, menstrual or pre-menstrual convulsions can be treated with much larger doses in the week before the period than at other times.

The hydantoins (tab. phenytoin sod., $\frac{1}{4}$ gr.—0.1 g.), in a variety of proprietary forms, should next be used, preferably with phenobarbitone, and they may be combined in a ratio of phenytoin 2 to phenobarbitone 1 in the same capsule. If toxic effects arise with one of the hydantoins, two different kinds may be given together in smaller doses to obviate them. If fits are not controlled, I then use primidone up to four or five tablets in the day, mainly because this substance is particularly effective for pure major convulsions without evidence of organic brain disease. Since focal attacks and petit mal cannot be regarded as emergencies, I may be excused from including their treatment in this short review.

Next article on Emergencies in General Practice.—"Attempted Suicide," by Dr. I. R. C. Batchelor.

Reports of Societies

TEACHING OF DERMATOLOGY

The teaching of dermatology for general practice was one of the subjects discussed at a joint meeting of the Sections of General Practice and Dermatology at the Royal Society of Medicine on February 16.

Dr. BERNARD PECK, speaking first, presented a strong case for improving undergraduate training in dermatology. Five to eleven per cent. of consultations were for skin disorders. In his own practice in Plymouth he had noted some seasonal variation, but on the average dermatological conditions accounted for 8.8% of all diagnoses. Reports on prescribing showed that some 12% of prescriptions were for skin preparations, and since this figure presumably included only local applications the actual percentage of prescriptions for the relief of skin conditions must be considerably higher. Of all patients referred for consultant opinions to a general hospital in Plymouth, 4.7% were referred to the dermatological department.

In most areas the opportunities of gaining knowledge of dermatology as a postgraduate were poor: and in any event Dr. Peck thought that it was not easy to acquire new knowledge after qualifying. A circular letter had been sent to the 27 medical schools in Great Britain. The 26 replies indicated a wide variation in the time allocated to dermatology in the undergraduate course. At some schools the same number of hours were devoted to dermatology as to radiotherapy and to thoracic surgery. Most schools allowed about 20 hours for out-patient demonstrations, and in only one were the patients for these specially selected. With very few exceptions most qualifying examinations did not regularly contain questions on dermatology, and, although an occasional skin condition might be included in the clinical examination, the knowledge required from candidates was likely to be superficial, since there were no dermatologists among the examiners.

In summing up, Dr. Peck suggested that an undergraduate training which ignored almost entirely one-tenth of the graduate's future work was unrealistic. He did not advocate any increase in the length of the present training, but felt that further time might be devoted to dermatology at the expense of the technical aspects of operative surgery and of other subjects which were not of such value to the future general practitioner. Moreover, apart from its direct importance to the practitioner, dermatology offered an excellent field for training in accurate observation and in the correlation of clinical and pathological findings.

Examination Questions

Dr. R. T. BRAIN, opening the discussion, said that dermatologists had long felt that the specialty had not received sufficient recognition in the medical curriculum. Dr. J. E. M. WIGLEY said that the fundamental problem was the lack of dermatological questions in qualifying examinations. Most students had perforce to concentrate on passing examinations, and until they knew that they would be examined in dermatology they would tend to be disinterested in the subject. There should always be a dermatologist on the board of examiners.

Dr. W. B. ADAM was critical of the postgraduate teaching in dermatology which he had received, and Dr. W. P. HEDGECOCK suggested that special training might be given during the period of trainee-assistantship. After several other speakers had taken part in the discussion Dr. C. H. WHITTLE pointed out that as a result of the shortage of registrars more appointments for general practitioners as clinical assistants in dermatology would probably become available. But Dr. M. FEIWEL thought that a practitioner derived much more benefit from sitting with a dermatologist

in his clinics for some weeks than from acting as a clinical assistant seeing the old patients. Dr. G. B. DOWLING, from his experience of the postgraduate teaching of general practitioners, disagreed with Dr. Peck's implication that a general practitioner would not acquire much knowledge of dermatology from practical experience. He had found that many had gained a very sound knowledge of the subject. Dr. G. M. KERR, while agreeing that dermatology was inadequately taught, did not believe that this subject should be singled out for special consideration. The entire medical curriculum needed revision, because the general practitioner was taught very little about many other conditions which he frequently encountered in practice, including diseases of ear, nose, and throat, and of the eyes.

Nova et Vetera

AN EARLY X-RAY PICTURE

Last August Dr. Cochrane Shanks told in the *Journal's* correspondence columns¹ the story of an early x-ray picture taken in March, 1896, by a 16-year-old boy, W. E. DAVIES. The boy was spending the Easter holidays in Hanover and had with him a quarter-plate camera. One of the local entertainments was a hall with side-shows, automatic machines, and the like, and among them was an automatic x-ray machine which, in return for a pfennig in the slot, showed up the bones of the hand or any other opaque object inserted through an aperture by the customer. On top of the machine was an eye-piece to look through. The boy, interested, as well he might be, in this novelty, and with a commendable scientific curiosity, visited the showplace armed with a sensitive quarter plate in light-tight box in which he had also placed some small metal objects. This he inserted into the apparatus, and, with the aid of the appropriate coins, gave it an exposure to the x rays of about one minute. The result (reproduced with Dr. Shanks's letter) was probably the first amateur x-ray photograph.

Dr. J. F. Brailsford² questioned the accuracy of the story. He pointed out that, though Roentgen made his discovery on November 8, 1895, he did not announce it publicly until December of that year. According to Glasser,³ Edison, in May, 1896, was among the first publicly to demonstrate the fluoroscopic characters of x rays. It was remarkable, therefore, Dr. Brailsford thought, that the "show business" should be able to adopt this new scientific discovery so early as March, 1896. Reports of diagnostic skiagraphs first began to appear in the *British Medical Journal* in June, 1896, and in the issue for June 6 (p. 1412) it was announced that "a Roentgen laboratory has been established in the Glasgow Royal Infirmary."

The correspondence ceased after Dr. Brailsford's contribution, but the matter has not rested there. A Hanoverian reader of the *Journal* wrote to the editor of the *Hannoversche Allgemeine Zeitung*, who published the story and the doubts cast on it, and appealed to local memory. The response was immediate: the editor was able to publish the evidence of some 26 replies from senior inhabitants of Hanover who championed the accuracy of the boy photographer's story. One, Herr K., said that while he was in the fifth or sixth form at school he went to the exhibition, which contained the apparatus referred to. He was not certain whether it was in 1896 or 1897, but was in no doubt about the place where the exhibition was held. It was in a house in Georgstrasse, which is now the Basse Bank. Herr K. F. also could not quite fix the date, but added something to the story. "At the same time," he wrote, "there was also a Lilliputian married couple to be seen. The man was wearing Hussar uniform and had a big moustache and pointed beard, which we were allowed to pull to prove its genuineness." Herr K. M. wrote that he was an employee of the German Automaton-

Renal Biopsy

SIR.—Your leading article on renal biopsy (*Journal*, December 18, 1954, p. 1468) seems to us to imply that our technique of percutaneous biopsy of the kidney in the prone position is a simple matter which can be done by anybody. This is not so. We believe that indiscriminate use of the technique by untrained people will certainly lead to accidents. We feel that for the present the operation should be done only by those physicians or surgeons who are going to use the technique frequently as part of a programme for the study of patients with renal or related diseases.

Since our report¹ in May of last year we have done a further 150 biopsies, making in all a total of just under 200 biopsies to date. We have encountered no serious complications with our technique and have extracted adequate tissue for histological diagnosis in over 95% of our attempts at biopsy. The dangers of renal biopsy are retroperitoneal haemorrhage, severe laceration of the kidney, renal infarct, anuria, and spread of infection. We have been fortunate in that our only complications so far have been transitory renal colic in three patients, mild loin pain in six, and a sharp haemorrhage into the bladder in an old gentleman with severe calcific atherosclerosis.

In order to secure the safety of the patient, particular pains have been taken in the selection of patients, and meticulous attention has been given to their pre- and post-operative care. At present our contraindications for doing a biopsy are: an uncooperative patient, individuals with a bleeding tendency, patients with one kidney, and patients with oliguria whose non-protein nitrogen is above 100 mg. per 100 ml. of blood and rising. We do not advise a biopsy on patients who have severe calcific atherosclerosis, a perinephric abscess, hydro- or pyonephrosis, renal neoplasm, or large cysts. Although Cazal² has done a few biopsies on patients with renal neoplasm, we believe that the danger of spreading neoplastic cells along the needle track is too likely to warrant biopsy.

The hazards of kidney biopsy have been overcome by accurate localization of the kidney with intravenous pyelograms and the exploring needle, by the thin Franklin Vim-Silverman needle, which secures a small core of renal tissue without aspiration, and by the use of the sandbag in the prone position, which ensures post-biopsy haemostasis. Biopsy of the kidney is more accurate than any other method in making an exact diagnosis. There is no need to labour this point, but it must be obvious that, as time goes on, biopsy of the kidney will become more and more valuable as new therapeutic measures are found to combat each of the many disease processes which involve the kidney. We find that renal biopsy is a more accurate method than culture of the urine or blood in determining exactly the type of organisms which are responsible for infection within the kidney, and we have been using it to select patients with nephrotic syndrome for therapy with steroids. Besides its clinical value in diagnosis, prognosis, and therapy, it is a most valuable tool for studying the natural history of diseases of the kidney.

We have already trained a number of British physicians to do biopsies of the kidney in the prone position, and we look forward, as you do, to reports on its usefulness.—I am, etc.,

ROBERT M. KARK.

Company, Stollwerk and Co., of Cologne, in 1900-5 at the house in Georgstrasse. He says that there were automatic chocolate machines, automatic music machines, electric pianos, weighing machines, the x-ray apparatus, automatic peasant bands, and a peepshow of the Frenchman Lumière. In the cellar of the house a cinematograph apparatus functioned from time to time. Although Herr K. M. could not confirm the year 1896, Herr B. S. produced the answer to the key question. He could say for certain that he had seen the x-ray apparatus in 1896 because he was married that year, and he had gone to the showplace with his new brother-in-law.

Further confirmation of the date 1896 came from a 78-year-old reader, Herr K. K., who became a soldier in 1897 and was quite definite that he went to the automaton show the year before. Dr. B. reported that in 1896 he already owned an x-ray apparatus in his practice, purchased through the firm of Nicolai, Leinstrasse, from Reiniger, Gebhard, and Schall. Herr O. R. also reported that a doctor in Gehrden owned an x-ray apparatus in 1896.

It seems, therefore, that Hanover and the show business were right up to date in March, 1896.

FLUORIDATION OF DOMESTIC WATER SUPPLIES

The Board of Faculty of Dental Surgery of the Royal College of Surgeons of England was asked some time ago by the Minister of Health to consider the question of the fluoridation of domestic water supplies. The following report was therefore drawn up, and last week it was accepted and approved by the Board of Faculty of Dental Surgery and by the council of the Royal College of Surgeons. The Board is satisfied that the incidence of dental caries is much less among children and adults who have spent the whole of their pre-natal and post-natal life in areas where the drinking water naturally contains fluoride at a level of one part per million or more than among those in areas where the water is practically free from fluoride.

In 1945 the fluoridation of domestic water supplies for reducing the incidence of dental caries was started in certain selected communities in the United States of America and in one in Canada. Eight of these communities in which fluoridation was started from 1945-48 have been used as study centres. The results obtained each year have been compared with the base-line data, and in some centres, as an additional control, dental examinations have been undertaken in adjoining and comparable communities.

The evidence to date shows a reduction in dental caries incidence of 40% to 50% in children of the youngest age groups, which is comparable to what is observed in areas where the water has naturally a fluoride content of one part per million or more. In the older age groups the teeth have not been subjected to fluoridation during all their formative period, and the reduction is not as yet so marked. There is nothing to suggest that a water naturally containing fluoride has properties different from those to which fluoride has been added.

In a temperate climate, with a population of adequate nutritional standard, fluoride at a concentration of 1-1.5 parts per million as fluorine in the water produces an occasional white fleck on the enamel, but this cannot be detected without expert dental examination, and is found in only about 10% of children. The appearance of the teeth is excellent.

There is no scientific evidence of toxicity or of harmful effects in districts with the water supply fluoridated at this level.

The Board considers that there is very strong evidence in support of fluoridation, and welcomes the proposal that this procedure should be adopted in the first place in some selected districts that can be used as study centres.

Misuse of Penicillin

SIR.—The spectacular effect of penicillin in the treatment of certain severe acute infections, and recently increased availability, have led to the use of this drug on a large scale in comparatively mild respiratory infections. It is sometimes forgotten that penicillin does not suit some individuals, and it is likely that we shall see a variety of patients who are complaining of symptoms which could be referred to the treatment which they have undergone.

In recent years, in particular during the present winter, I have seen a number of adult patients who complain of asthma which they date from a minor respiratory infection, usually labelled a "chill" or "bronchitis." The common factor in these cases appears to be that all have received penicillin, usually by injection, but sometimes by inhalation. Skin tests in several of these cases have demonstrated sensitivity to penicillin, and in other cases I have found a positive skin reaction to the Bencard group of moulds. There seems little doubt that penicillin may provoke an onset of asthmatic symptoms in patients who are sensitive to it, and the treatment of the sequel may be much more troublesome than the treatment of the initial complaint.

It would seem, therefore, that care should be exercised in the selection of patients who are regarded as being suitable for penicillin treatment. It is my impression that the milder infections respond quite well to the methods of treatment which were used before penicillin was discovered.—I am, etc.,

JAMES MAXWELL.

Chlorpromazine

SIR.—Clinical investigators are entirely dependent on the laboratory work of our colleagues the pharmacologists. It is disconcerting when two sets of workers apparently meet in head-on collision (*Journal*, February 5, p. 338). The experiments of Holzbauer and Vogt¹ in Edinburgh and the Frenchmen Aron, Chambon, and Voisin² are not, however, comparable. The French workers performed a neat and simple series of experiments; they removed one suprarenal from unmedicated rats and estimated the ascorbic acid content. This was the control, and also constituted the stress. An hour later the other suprarenal was removed, and the fall in ascorbic acid noted. In another series of rats, chlorpromazine was given at varying times before the first operation, and the two operations repeated as before. The fall in the ascorbic acid content of the second suprarenal was found to be considerably less in the animals that had chlorpromazine. From these results they reasonably concluded that the drug modified the normal effect of trauma on the suprarenal ascorbic acid content. They were careful not to claim that the drug caused a chemical hypophysectomy.

In Edinburgh the animals were medicated with urethane. A laparotomy was performed. An hour and a half later the animals were killed while still anaesthetized and the ascorbic acid content of both suprarenals estimated. In another series of animals they were given chlorpromazine prior to the experiment. This made little difference to the fall in the ascorbic acid content of the suprarenals. This experiment shows that, in rats given urethane, trauma causes a fall in the ascorbic acid content. Chlorpromazine added to the urethane does not modify the fall to any greater extent than does urethane itself.

We must be careful not to apply results found in rats at dosage of 10 mg. per kg. to those obtained in man at a dosage of less than 1 mg. per kg.

Pronouncements about this drug show laudable *ex cathedra* negativism, but the details of the experiments on which the findings are based should be more widely known.—I am, etc.,

London, N.W.1.

SIR.—Your recommendation of caution in the use of chlorpromazine should certainly receive careful consideration by all those who have found this drug useful and employed it extensively. For three or four months I have been giving it to patients suffering from dermatoses in which the mental aspect was deemed to be of importance, and I would estimate the incidence of jaundice at no more than two cases in about one hundred.

The first patient phoned my clinic one day to report that he had developed shivering attacks eight days after being put on 25 mg. of the drug three times a day. On the following day he noticed dark urine. I subsequently confirmed from his family doctor that he was suffering from jaundice. The second case developed after 24 days on an identical dose. The patient developed vomiting followed on the next day by dark urine. As he was feeling so much better generally since taking the drug, he continued taking it until seen three days later, when he showed marked clinical jaundice.—I am, etc.,

W. G. TILLMAN.

Lead-poisoning

SIR.—The papers by Drs. J. W. G. Gibb and J. F. MacMahon and by Dr. H. B. Marsden and Miss V. K. Wilson (*Journal*, February 5, pp. 320 and 324) rightly emphasize the disastrous consequences of lead-poisoning and the difficulty of early diagnosis. Even when lead-poisoning is suspected, it is often not easy to obtain confirmation, particularly in those mild cases whose prospects for successful treatment should be brightest. Isolated examinations of the blood for stippled cells or of the urine for albumin and sugar may be negative, radiological changes may be inconclusive, and lead assays in blood or urine are impracticable as a screening test. In these circumstances, the qualitative test for urinary coproporphyrin is valuable. This consists in adding 5 drops glacial acetic acid, 3–4 drops of hydrogen peroxide, and 1–2 ml. ether to 5 ml. of urine in a test-tube; after 10 minutes the tube is inspected in a "Wood's light." If excess of coproporphyrin is present, there is reddish-pink fluorescence of the ether layer. The test is a simple one requiring little time; it is generally positive in active lead-poisoning and sometimes may be the only readily demonstrable sign. Coproporphyrinuria of course occurs in certain other conditions, but none of these is likely to be mistaken for lead-poisoning.

As Drs. Gibb and MacMahon remark, children who have recovered from acute lead-poisoning remain during childhood and adolescence (because of skeletal storage of lead) in a precarious plight. However, since the introduction by Bessman *et al.*¹ in 1952 of treatment with the chelating agent calcium disodium ethylenediamine tetraacetate (calcium disodium versenate) it is no longer correct to say that "successful therapy merely diverts lead to the bones." There is much evidence that, in addition to relieving the symptoms of acute plumbism, calcium disodium versenate therapy increases the total excretion of lead from the body, and in fact leads to removal of lead from the bones.—I am, etc.,

Silver Stool Sign

SIR.—I was greatly interested by Sir Heneage Ogilvie's memorandum (*Journal*, January 22, p. 209) concerning the silver stool sign, and by the correspondence which has followed it. Twice during the past six months I have been shown silver stools. On one occasion the stool was well formed and had a distinctly metallic sheen. The production of such a stool was an isolated occurrence in a patient who had had a myocardial infarction and was being treated with phenylindandione.

The other and much more remarkable event was the production of an "aluminium paint stool," which I think must have been exactly similar to that described by Dr. Arnold S. Aldis (*Journal*, February 12, p. 414). The bright silver

appearance of the exterior of this stool was only slightly less marked throughout its substance.

The patient concerned, a man aged 58, had been admitted to hospital five days previously, complaining of severe substernal pain since the preceding day. He gave a history of anginal pain for three months, and fifteen months before he had been admitted to the same ward because of a severe melaena. Radiological examination following this episode showed no evidence of gastric or duodenal ulceration. The more recent event was diagnosed as a myocardial infarction and this was confirmed by E.C.G. Anticoagulant treatment was started with ethyl biscoumacetate. On the same day as he produced the silver stool, the prothrombin time was 8.8 times normal and the prothrombin index was 11. Anticoagulant treatment was stopped, and by this time he had received a total of 3.6 g. tromexan. On the seventh day after admission his condition suddenly deteriorated and he died. No more silver stools had been passed. Post-mortem examination confirmed the presence of a large postero-septal myocardial infarct which was thought to be about three weeks old. Because of his history of melaena the gastro-intestinal tract was carefully examined. There was no evidence of past or recent haemorrhage or ulceration, nor was there any macroscopic evidence of neoplasm. The pancreas appeared normal, as did the other viscera.

If a silver stool is evidence of altered blood in the gastro-intestinal tract, then I feel that the production of silver stools by two patients, both of whom were being treated with anticoagulant drugs, may well be significant, and such an occurrence should be regarded as an indication for increased caution in the handling of these drugs. I should be most interested to know whether others have noted a similar association.—I am, etc.,

Carshalton.

JOHN WEEKS.

S.T.H. and Tuberculosis

SIR.—In his lecture on "The Role of the Host in the Chemotherapy of Tuberculosis," reproduced some time ago in the *Journal* (October 2, 1954, p. 767), and which I read otherwise with much interest, Dr. P. D'Arcy Hart mentions our work in the following terms: "... We have been unable to antagonize the protuberous effect [of cortisone] by any structurally similar steroid; and although Lemonde *et al.* have claimed to have done this with somatotropic hormone (S.T.H.) in rats, and even to suppress experimental tuberculosis in mice with this hormone, we have failed to produce either effect in mice."

I feel that the author exaggerates a little. It is true that we have found, in repeated experiments, that the somatotropic hormone (S.T.H.) prevents the extension of tuberculous infection, catabolism, and death in cortisone-treated rats, but we never claimed to suppress tuberculosis in mice with S.T.H. What we saw is the following: (1) In mice affected with a stable, chronic form of tuberculous infection, S.T.H. decreased the number and extent of pulmonary lesions, as well as the number of bacilli in the lesions.^{1,2} (2) With a rapidly evolving disease—whether this was achieved by inoculating a larger amount or a more virulent type of bacilli or by treating the animals with A.C.T.H.—and in spite of the fact that we repeated the experiments several times under various conditions, we never succeeded in obtaining any prolongation of survival, even though the lesions and the number of bacilli were generally reduced.²

May I add that a group of investigators, working with the guinea-pig, have reported recently some results which are in accord with ours—i.e., that S.T.H. diminished the extent of tuberculous lesions³ and potentiated the action of isoniazid.⁴—I am, etc.,

Montreal, Canada.

Tuberculous Mesenteric Adenitis

SIR.—I was much interested in the account given by Dr. H. R. E. Wallis of tuberculous mesenteric adenitis in children (*Journal*, January 15, p. 128), because of the enormous contrast between past years and now. Referring to Colt and

Clark,¹ who dealt chiefly with adult cases, we described some surgical aspects of tuberculous disease of the abdominal lymphatic glands. There is an excellent, brief, comprehensive, and easily accessible abstract of the relevant parts of the latter paper in the *British Medical Journal*.² G. N. Clark is not now in England and cannot join with me in this letter.

In those days the condition of the udders of the cattle on the farms was bad. Tuberculin-tested herds were supposed to yield milk that was free of tubercle; indeed one herd has never been known to show infection since then, but two fatal cases of tuberculous meningitis were admitted to the Sick Children's Hospital on the day that one of our patients came under our care. This patient, aged 5 years, had been looked after at home and fed on boiled milk until put on certified milk. Acute peritonitis very soon followed with temperatures of 101°–103° F. (38.3–39.4° C.) daily for 13 weeks, and marked ascites. Now, after 20 years of married life and with no detectable disability, the patient remains sterile. On two occasions doctors have suspected appendicitis, but, as will be shown presently, operation has been avoided.

At that time there was prejudice and fear amongst the farmers that they would lose on compensation and on their established reputations in the markets. Once these items had been adjusted there was a great improvement, but it was not sufficiently rapid to appear in our articles. I believe that a good co-operative drive at that time would have eradicated the disease in about two years. Why after all this long time the disease has not been completely eradicated is difficult to understand, but Dr. Wallis's article shows that it has not. Importation of cattle may be a factor.

Our articles were as complete and comprehensive as could be attained at the time. They dealt with 239 consecutive cases admitted into a general adult surgical ward, many of them—in fact most—as abdominal emergencies. 207 of the cases were traced and 118 patients were seen and examined. In 38 caseous cases the patients were operated on. In the later calcified cases, as well as in the caseous, the presence of acetone in quantity in the breath (which does not seem to have been noticed by previous observers) was so common that this alone was sufficient and safe to enable urgent operation to be avoided. Hyperaesthesia and increased tonus of the muscles in the right iliac fossa, though more diffuse and less intense than in appendicitis, were not so certain in their indications. Lockwood's sign always proved invaluable, and on one occasion it was possible to actually demonstrate its mechanism on the exposed viscera, which I do not think Lockwood actually did.

Now that the State pays for radiological investigations and facilities have also improved, it would be a great help in coming to a decision to be able to observe, by serial x-ray examination, the rate of calcification of glands and whether there is any difference in the rate of deposition of calcium when either milk is fed or any of the other more modern preparations. Judging by our observations it is impossible to be sure of the facts by ordinary clinical methods, palpation and so on, but with careful adjustment of tests with x-ray tubes it should be possible to obtain comparable pictures of the amount of calcium present. Some of the aluminium alloys should match up the degree of opacity. In former days no two tubes could ever be made to give comparable results on the same day, and even the penetration of one tube varied with its temperature. The difference in fuzziness of the dendrons is important as well as the gross density of calcification.

If this letter has re-established a link with our articles, which were comprehensive, and gave a chronological approach to the subject by the references, it will be of some satisfaction, because it will help to demonstrate the great advance in the factors of the state of the public health which have come about in the last 15 years. For details the papers themselves should be consulted.—I am, etc.,

London, W.1.

Treatment of Pulmonary Tuberculosis

SIR.—Artificial pneumothorax began to lose popularity as its complications became widely appreciated and as surgical alternatives multiplied. Dr. J. L. Livingstone (*Journal*, January 29, p. 243) considers that it still has a limited place in the treatment of tuberculosis, especially since chemotherapy is likely to reduce the complication rate; and you, Sir, in a leading article of the same date (p. 273), find it difficult to believe that it "can really have no useful part to play in the future."

I myself do not think that there is any place for artificial pneumothorax treatment to-day, and hardly any for pneumoperitoneum. The disadvantage of having to attend a doctor every week or two for air refills is one of which little was made when alternative methods were few. Yet it is in fact so considerable that, even if no risk whatever were involved, the physician should seek other methods wherever practicable. No one would deny that artificial pneumothorax has had good results as well as bad, but other methods are making it redundant. Current developments in the use of chemotherapy appear to be giving as good results, or better, in every respect, and it is my view that all forms of pneumatic treatment should now be abandoned as not having merit enough, compared with prolonged chemotherapy, to set against their obvious disadvantages. Only if some unforeseen snag is discovered in the use of chemotherapy for long periods should we consider reopening the refill clinics.—I am, etc.,

Malvern.

T. W. LLOYD.

Treatment Abroad of Tuberculous Children

SIR.—This association is having considerable success with sending British tuberculous children for treatment at Vordingborg Sanatorium, Denmark. In the last three years some 235 children have been sent across, with exceedingly good results. At the present moment 47 patients are under treatment at Vordingborg.

It is true, as Dr. F. J. Bentley says (*Journal*, February 12, p. 418), that there is less need for treatment abroad than there was a few years ago, but we find that from Clydeside, Merseyside, and Northern Ireland there are still children whom the chest physicians wish to send. This Anglo-Danish scheme is free of cost to the parents or our Health Service. Children are kept at Vordingborg at the expense of Anglo-Danish sympathizers. The whole scheme owes its origin to the success which Denmark has had in eradicating childhood tuberculosis, and which has set free beds in the sanatoria. The psychological benefit to these children of a stay abroad during the impressionable years of life is certainly not the least important part of the scheme.—I am, etc.,

HARLEY WILLIAMS,

Secretary-General, The National Association for the Prevention of Tuberculosis.

Paraffin Stoves

SIR.—In these days of expensive fuels there is an increasing tendency to use paraffin-burning stoves in sickrooms and living-rooms of domestic dwellings. It appears that this method of heating is not without danger. A few days ago I was called to see a man and his wife of 40 years of age who had retired to bed in excellent health the night before and had been found by neighbours at 11 a.m. the following day in very bad shape. When I arrived at the house the woman was still in bed and comatose. The husband had managed to crawl downstairs in answer to repeated and persistent ringing of the doorbell. He was very weak and drowsy and complained of headache. In the bedroom was a small paraffin stove of modern design which had been allowed to burn throughout the night. The bedroom door had been tightly closed, also the window, and the only ventilation was by means of the chimney. Fortunately the stove had run out of paraffin, otherwise a tragedy might have resulted. The stove had used up oxygen and had given out carbon monoxide.

It appears that the general public is largely unaware that any harm can result from an oil stove burning in a confined space. I suggest that a word of warning by the doctor finding one in a sickroom might not be out of place and might help to prevent serious and even tragic results.—I am, etc.,

Blackburn.

F. C. REIDY.

Fluoridation of Public Water Supplies

SIR.—Dr. A. M. Thomson's letter (*Journal*, January 22, p. 224) provides an excellent example of the methods by which fluoridation has been promoted—namely, by sweeping assertions of knowledge in matters in which more cautious, or perhaps more humble, people admit their ignorance, supplemented by attempts to discredit opponents by a display of contemptuous language. It would have saved much trouble if the mission to the U.S.A., of which Dr. Thomson was a member, had presented both sides of the question fairly instead of behaving as a team of advocates for the proponent side. According to the report¹ of this mission (p. 11) the case against fluoridation was given full prominence while they were in the U.S.A. at the hearings before the Delaney Committee.² This committee, in fact, examined eighteen scientific witnesses, of whom seven were critical of fluoridation. Nevertheless, there is no evidence in the mission's report that they had visited or consulted any of these scientists; and, although a few words of the Delaney report are quoted and some criticisms of fluoridation are mentioned with a view to refutation, it is quite clear that the opposition case has been seen only through the eyes of its opponents. This bias is even clearer in Dr. Thomson's letter; and when it comes to the *ex cathedra* statements of public health officials there is no attempt to present the opposition case to the public, which is why persons such as myself have had to take a hand in the matter.

I cannot see what Dr. Thomson gains by jibbing at a plain accurate description of what he advocates. If "medical treatment" is limited to "cure" and excludes "prevention," the "medical" profession can have no status in the matter. If dosing everybody with something required only by children is not "indiscriminate," what is? Or does he hold that the scientific "discrimination" exercised in putting the fluorides in the right reservoir is sufficient? And I fail to see why this medical Big-Brotherism, with its insistence on invading every home and everybody through the water tap, should be regarded as "scientific," and an objection to it as "unscientific," except, of course, for propaganda purposes. Nice as it is to find the *North Wales Chronicle* so carefully read in Aberdeen, I think he was unwise to drag into this discussion from its pages a reference, quite correct in its context, to "civilized European opinion" and to the precedents for medical tampering with the human body without consent. The ten standards laid down at the Nuremberg trials on August 9, 1947, for persons who initiate or engage in medical research on, or treatment of, human beings, start with this statement: "*The voluntary consent of the human subject is absolutely essential*," and I have yet to learn that the British medical profession regards itself as exempt from this standard of conduct. In France, I am informed, the Dental Convention in Paris has recently rejected fluoridation as contrary to human rights, local governments have no power to order it, and the Institut Pasteur and the Ministre de Santé Publique have not approved it.

If it is true, as Dr. Thomson clearly implies, that the medical profession, which is not without experience with dangerous drugs, can yet find no safe way of administering fluoride, under normal conditions of consent, only to those who may be expected to benefit, I cannot see how the public can be expected to consent to the putting of this substance in the general water supply. The statement that "variations in the amounts of fluoridated water ingested by individual consumers are known to be without significance for health" would be sufficiently staggering if the word "fluoridated" were omitted. With the bottom limit for "chronic low grade poisoning" officially placed as low as

2 mg. daily, as compared with 1 to 1.5 mg. of fluoride daily for "preventive dentistry," it makes no sense to me.

Finally, I come to the actual evidence upon which the proponents of fluoridation base their astonishing claims to knowledge of its harmlessness to individuals. The evidence is almost entirely statistical, and, considered as such, unconvincing to the point of absurdity. The Bartlett-Cameron comparison reviewed in your annotation "Fluoride in Water" (*Journal*, January 22, p. 215) seems to be, to date, the most careful long-term investigation into the effects of fluorides upon health, other than dental decay. But here we find, not the "evidence from millions of people" mentioned by Dr. Thomson, but a comparison of two populations of about 120, of an age-distribution so different that 14 deaths in one is not significantly different from 4 deaths in the other. Just to make it funnier, the younger population turns out to have nearly twice the incidence of cardiovascular disease found in the older, and, to round it off, the water of the "control" town has more than the average amount of fluoride in it (0.4 p.p.m.). Certainly it is quite true to say that this comparison has produced no evidence of damage due to fluoride at 8 p.p.m., but such a statement is completely misleading unless accompanied by an estimate of the number of people in Bartlett who would have had to suffer death or observable damage through ingesting fluoride in order to produce a significant result. It seems obvious, even on the limited data available, that, with samples of this size and variability of this order, the disaster to health in Bartlett would have had to have been catastrophic to have reached statistical significance. So far as I know, no one has entertained the idea that fluoride at such low concentrations could produce damage of that kind, so that the "evidence" is entirely irrelevant to the question of the possible hazards of fluoridation. The mortality statistics for 22 Illinois cities, published in the British mission's report¹ (p. 62) are equally unconvincing. The only thing demonstrated is the irrelevance of the statistical approach to this matter.—I am, etc.,

Bangor.

Slippery Floors in Hospitals

SIR.—May I draw attention to a subject which receives very little? I refer to the large number of minor and major accidents which occur to the staff and patients of hospitals, many instances of which I can quote, including fractures of limb bones, due to slippery floors. Most hospitals have some system of recording such accidents because of possible litigation, and when injury is caused this process is usually carried out, but many more accidents causing damage to hospital property, mainly crockery, glassware, and thermometers, due to nursing and domestic staff slipping in wards or ward annexes, probably go unreported. When post-operative patients, the infirm and aged, and those recovering from limb fractures are being encouraged to get on their feet, there is in most of them a natural loss of confidence resulting in muscular incoordination, and a slippery floor is the worst possible surface on which to try their first hesitating steps; not only are their feet liable to slip but also their walking-sticks or crutches, with resulting falls. The lethal effect of fractured neck of the femur in the aged is of course well known.

A tendency to slip depends on several factors, which briefly are those associated with the person, such as some locomotor disability and also the material composing the soles and heels of his footwear, and factors relating to the composition, texture, and polish of the floor. The problem is a difficult one, because some shoe surfaces will slip on

some flooring materials and not on others, but in my view much of the trouble is caused by the excessive and un-intelligent use of floor waxes and polishes, so as to produce the shining appearance beloved by administrative nursing staff. Polish which is claimed to have a non-slip quality is, I believe, available, but the accepted view seems to be that if it is non-slip it cannot polish. I suggest that this is a problem of some importance which deserves the attention of hospital architects and administrators. Slippery floors in hospitals are a serious hazard to patients and staff and they should no longer be tolerated.—I am, etc.,

London, N.W.9.

W. E. SNELL.

Ward Rounds and Myocardial Infarction

SIR.—I was much interested in Dr. Klaus A. J. Järvinen's article (*Journal*, February 5, p. 318). The importance of his findings on the unfavourable response of patients with acute myocardial infarction to the hazards of hospital routine can hardly be exaggerated. The emotional stress causing a fatal issue in six of his patients is perhaps too narrowly defined as the result of the visiting physician's ward round, many other factors—partly mentioned by the author—connected with the daily hospital experience of such patients combining in the production of an anxiety state so dangerous for those affected with coronary artery disease.

But does not the logical conclusion present itself that such a patient is best treated in his own home whenever circumstances permit? In an extensive cardiological practice, before I came to this country, I had made it a rule to treat all my patients with acute coronary occlusion in their home, in surroundings best suited for safeguarding mental rest, and had no cause to regret this procedure. Only so is it possible to disguise the diagnosis in spite of the difficulty of persuading the patient to keep his six weeks' absolute rest. Though often enough, owing to socio-economic conditions, I had to dispense with the expert help of a day and night nurse and had to entrust the care of the patient to a reliable member of the family, the results were satisfactory and the mortality rate among my patients was considerably low. The small inconvenience of taking my portable electrocardiograph to the patient and of performing simple laboratory tests like E.S.R. and urine examinations at the bedside was highly compensated for by the beneficial effect of allowing the patient to remain in his familiar surroundings.

It must, of course, be admitted that modern anticoagulant treatment may make it difficult for the practitioner to decide in favour of this management, but I am certain that many general practitioners will agree with me that, provided all available facilities are used (and the home help service should be mentioned in the first place), home treatment can be assured with benefit to the patient in the majority of cases. As a mere onlooker I feel hardly entitled to comment on the value of anticoagulant therapy in coronary artery disease, a treatment unknown in the 'thirties, but do the results so far obtained really justify the frequent unavoidable risks of interfering with the patient's most-needed rest? Four patients of the six cases reported in Dr. Järvinen's paper had died in spite of anticoagulant treatment.—I am, etc.,

Leicester.

LEO HAHN.

Treatment of Phenylketonuria

SIR.—We have read with great interest the important paper, "Treatment of Phenylketonuria with a Diet Low in Phenylalanine," by Dr. L. I. Woolf, Dr. Ruth Griffiths, and Professor Alan Moncrieff (*Journal*, January 8, p. 57). The psychological findings provoked a great deal of discussion here, during which we felt that certain aspects should have been taken into consideration before placing too much reliance upon the apparent improvement in intellectual level in the three cases involved in the investigation. It is known that mentally defective children are subject to fluctuations on their test scores, and any extra attention on the part of

the investigators might easily have produced some improvement. A control group in this case would have been very desirable. The prediction of educability based on pre-school tests, to which Dr. Griffiths's valuable test belongs, is not highly reliable, because of their nature. Allowance should be made for practice effect on the same test and also for improvement in adjustment to the test situation with repeated testing. We look forward with much interest to further findings.—We are, etc.,

Ipswich.

W. PAWLICK.

Disk Lesions and Low Backache

SIR.—When reading the paper by Dr. James Cyriax (*Journal*, January 15, p. 140) I felt certain it would provoke a lively correspondence; this has proved to be the case. While thoroughly agreeing with Dr. Cyriax that manipulation or traction is often successful in the treatment of acute and chronic back conditions, I think it should be recognized that such treatment, even in the most expert of hands, sometimes makes the patient worse.

Being quite unable to accept the contention of Dr. Cyriax that practically every case of low back or sciatic pain is caused by a disk lesion, I was delighted to read the letters of Mr. W. Grant Waugh and Dr. A. C. Elkin (*Journal*, February 12, pp. 412 and 413), pointing out the importance of the apophyseal joints as a source of low back and sciatic pain, for I have long held similar views.¹ The fact that one can so often give the patient relief by a single manipulation, in my opinion, makes it exceedingly unlikely that a disk protrusion could be the cause of the symptoms. The nucleus is contained within the annulus under very considerable pressure, and, although it is easy to visualize lumbar traction reducing the protrusion, it is difficult to understand why the protrusion should not recur as soon as traction is released. If anyone doubts the importance of the posterior joints as a source of low back or sciatic pain I would suggest they read the papers by Putti,² Kraft and Levinthal,³ and Harris and MacNab.⁴

We should beware of "omnibus" diagnosis and treatment. Mr. Grant Waugh rightly points out that the intervertebral articulation comprises three elements—the disk, the spinal ligaments, and the apophyseal joints—and that any pathological condition which affects one affects all. Therefore if we must have an "omnibus" diagnosis let it be "intervertebral derangement."

As for treatment, each and every case should be considered on its merits. Many cases recover with rest alone, while others do equally well with physiotherapy. Though manipulation or traction often provides a short cut to recovery, there are exceptions, and for these cases the plaster jacket still remains the most effectual remedy. Furthermore, if one had succeeded in reducing a disk protrusion by traction, it would appear rational to follow up with a plaster jacket to enable repair to take place and prevent recurrence. Fortunately Nature is very wonderful, and many patients recover "in spite of" rather than "because of" what we do for them.—I am, etc.,

SIR.—Mr. John Charnley's admirable article on this subject (*Journal*, February 5, p. 344) imparts a constructively sane approach towards this condition. As a G.P. surgeon I can testify to the cost and burden borne by the hospital and general-practitioner services since the British public began to take lumbago and sciatica seriously. Shortly after the war I worked for two years as a clinical assistant in the orthopaedic department of my old teaching hospital. Drove of patients with varying degrees of backache clogged the department. One of the two consultants, who was contemporary with me as a student, asked me: "As a G.P., what did you do with all these cases before the war?"

My reply was: "Before the war these cases did not exist. Severe sciatica was relatively rare, while lumbago, though common enough, was not regarded seriously either by doctor or patient, and they soon got well."

It must be agreed that we had no satisfactory explanation for these conditions, or for "fibrositis," "neuritis," etc. Now that we have a logical explanation, I cannot agree too much with Mr. Charnley's recommendation that a robust attitude by both doctor and patient towards this tiresome condition will do much to reduce invalidism and waste of time and money in the Health Service. Dr. James Cyriax has, without doubt, hit on a line of therapy which works in a large number of cases. One cannot, however, help retaining some scepticism with regard to the claims for so many instant cures, on a purely physical basis. Successful psychotherapy *does* produce instant cure in all the faithful, and one wonders whether indeed many of Dr. Cyriax's cases lie in this category. "Laying on" of healing hands. . . ?

It is to me certain that many "backache" cases are psychologically inadequate and conform to a psychosomatic type easily recognized in general practice. Mr. Charnley mentions fluid retention in the nucleus pulposus as the cause of increased tension, and associates glaucoma in the comment. Glaucoma is undoubtedly psychosomatic in many cases. May it be that further research into the biochemistry and endocrinology of localized fluid retention will shortly provide that link between mind and body which will present both practitioner and patient with a satisfactory explanation for these and allied states?—I am, etc.,

Reigate

L. DULAKE.

SIR.—Although a personal admirer of Mr. John Charnley's attitude to chronic backache (*Journal*, January 15, p. 163), I find it very hard to be convinced over his explanation of acute lumbago on a disk basis. To me the fulminating onset does seem quite easily explicable on an inflammatory basis, since the pain is not due to ordinary inflammatory tension but to a sudden cramp in the affected muscle. Anyone who has ever had acute lumbago will never forget the tightening up of the muscles in the excruciatingly painful spasms. These painful cramps occur in other conditions where muscles are irritated, which we all know of and where no disk lesion is in question, such as in cold (ranging from cold sheets to cold water—where it can cause drowning) and in anoxic states. One would like to know how Mr. Charnley would explain on a disk basis the exactly analogous condition of stiff neck, where the intensely painful spasm is on the side that was exposed to the draught. Unless he can explain this, it is hard for one to be convinced over the acute lumbago. Needless to say, I am not referring to the syndrome of an acute disk lesion, which is often accompanied by trauma, and where the pain shoots down the leg and is a longer time going away, and still less to chronic backache. I am merely referring to the ordinary attack of acute lumbago that disappears completely.—I am, etc.,

Alverstoke, Hants.

T. L. CLEAVE.

SIR.—As a general practitioner the question of backache has always been of great interest to me, and the recent articles and letters in the *Journal* have prompted me to tell of another line of approach that I have taken.

I have found that a good number of patients trace their backache to some previous injury or sprain. As so many people can explain almost everything from a boil on the nose to a carcinoma of the breast by a blow they once received, I determined to follow up a number of cases of minor injury to the back and see whether the patients returned complaining of backache. In some six years I have managed to collect 60, mostly young, people who have had minor sprains and injuries to their backs. Each case was carefully examined and charted on a diagram—the greater the tenderness the bigger the spot on the diagram.

I divided them into three groups: (1) 24 Cases: Treated with rest, heat, aspirin, and some massage. Allowed to return to work when they felt they "could make it." No further instructions given to them. Of these, 20 returned within weeks or months complaining of backache, and 18 had their chief tenderness localized to the area of previous tenderness as marked on the diagram—especially in the "big spots." (2) 26 Cases: Treated in same way as (1) but told about my chart and asked to return if backache returned. Of these, 18 returned—all with pain in the marked areas. (3) 10 Cases: These were made to rest till all signs of pain had gone—given more prolonged massage. Told to return at slightest suggestion of pain. Only one returned.

It seems, therefore, that a case can be made out for not "neglecting" minor injuries to the back as a means of preventing some cases of backache.—I am, etc.,

London, W.7.

Hyperpyrexia and Anaesthesia

SIR.—Dr. R. Cecil Brown (*Journal*, December 25, 1954, p. 1526) has given an interesting account of hyperpyrexia and convulsions occurring in a patient anaesthetized with thiopentone, nitrous oxide, and trichlorethylene. It is well known that carbon dioxide can produce cerebral congestion and convulsions. The high metabolic rate associated with hyperpyrexia and a convulsion would result in increased carbon dioxide production, and it would be interesting to know how much was given, and for how long, in the treatment of the laryngeal stridor.—I am, etc.,

Newcastle-upon-Tyne, 4.

J. D. WHITBY.

The National Formulary, 1955

SIR.—There will be widespread agreement with your leading article (*Journal*, February 12, p. 402) on the new edition of the *National Formulary*, but to say that the committee's decision to revert to Latin for group and individual titles "will undoubtedly occasion some controversy" is indeed an understatement. It is quite incredible that the 1955 committee should reverse in its tracks. Instead of, as outlined in the preface, completing the change-over to "a more rational grouping and transition to the use of English in prescribing, in conformity with modern trends," it has decided that because the 1952 compromise was "unwelcome to the majority of those who use the *Formulary*" therefore the next rational step is to retreat to Latin instead of to advance logically to the adoption of English throughout the *Formulary*.

This reversion to a traditional although outmoded pharmaceutical convention involves the ridiculous pseudo-Latinization of approved names of drugs; cyanocobalamin injection is a sufficient mouthful without the absurdity of injectio cyanocobalamini being substituted for it. Furthermore, it is completely unreal to attempt to justify the step by pleading that the Latinization of drugs makes them thereby more easily understood internationally. A prescription written for inj. insulin, protaminat. c. zinc, is no more easily interpreted in Chile or China than protamine zinc insulin injection. The argument that a national *Formulary*—which is in daily use in town and country, general practice and hospitals, throughout the United Kingdom—must be in Latin because the *Pharmacopoea Internationalis* is in Latin is as absurd as to maintain that the key and explanations at the foot of Ordnance Survey maps should be in Latin because many foreign tourists visit this country. In any case, the national equivalent to the *Pharmacopoea Internationalis* is not the *National Formulary* 1955, but the *British Pharmacopoeia* 1953—which has adopted English usage. It would be amusing to discover how many, or rather how few, prescriptions are in fact written in this country and subsequently presented to foreign pharmacists. No, Sir, neither by this nor any other hackneyed argument, such as the necessity to conceal the contents of a prescription from a patient, can this reactionary, retrograde, and misguided decision be justified. There is no place in modern medicine for such rigid adherence to pharmaceutical tradi-

tion, and few, if any, medical schools throughout the country train students to prescribe in Latin. Many doctors will therefore welcome the proposed edition of a companion volume to the *Formulary* in which English is to be used throughout, and the formulae grouped according to their pharmacological classification. Such a formulary will meet with more general acceptance, and would be the appropriate guide for young doctors starting practice uninfluenced by previous contact with the archaic mystique of Latin prescriptions.—I am, etc.,

Edinburgh, 3.

ALASTAIR G. MACGREGOR.

SIR.—Your leading article (*Journal*, February 12, p. 402) on the above publication surely reflects the views of the majority of practitioners. It is inevitable that a book of this nature will not meet with the approval of all its readers in every respect. Difference of opinion is understandable, but inconsistency is not. The declared policy of the Joint Committee is to include "a preparation even if its justification on pharmacological grounds is disputed, if it is still being frequently prescribed." Why, then, is bismuth carbonate not included among the remedies for dyspepsia? Much has already been written concerning the relative merits of antacid preparations, and one must accept that difference of opinion exists. In 1949 the Committee suggested analogous preparations were as good as bismuth carbonate: they did not categorically deny it to be of value. The question as to whether bismuth carbonate is frequently prescribed cannot be a matter for conjecture when the overall consumption of bismuth carbonate in this country is increasing.

There is every indication that bismuth carbonate is frequently prescribed, and this warrants its inclusion in the *National Formulary*. If there is some other reason for its exclusion, then the Joint Committee should make it perfectly clear, for their present attitude is inexplicable and lacking in logic. Those who have found bismuth carbonate of value will no doubt be disappointed at its exclusion; those who do not prescribe the preparation must surely agree that its exclusion is inconsistent and the reason for it obscure.—I am, etc.,

London, W.1.

PETER R. BATESON.

SIR.—Space forbids the detailed criticism of your leading article on the new *National Formulary* (*Journal*, February 12, p. 402) which I—and no doubt others—would like to make. I will therefore only say about "bottles of medicine" that they allow a much more flexible control of dosage than do tablets, and that the modern tendency to tablets involves tablets of an ever-increasing multiplicity of sizes and combinations which is becoming an overpowering burden to the prescriber and an added expense to the State.

To suggest that the *N.F.* is "slavishly following customs which may be ill-informed" because it reinserts the ammonia and senega mixture is, I submit, prejudice rather than therapeutics. Unfortunately pharmacology is largely based on normal animals and defines an expectorant as a substance that increases the bronchial secretion. This is difficult to determine and few substances seem to do it. But the physician is concerned with inflamed surfaces, and is not worried too much about the amount of secretion but whether or not his mixture eases the patient; and at least three generations of doctors and patients have experienced the striking relief that this mixture will give in the early stages of a hard cough. This stage may seldom be seen in hospital—and anyhow few pharmacologists nowadays would be willing to try the mixture—but in general practice we do see such cases and also the relief afforded. Incidentally, the omission of the monograph on expectorants does not "reflect the contemporary opinion that they are unnecessary and ineffectual" but was due to quite other causes.

Academic pharmacologists may well criticize some other features, but they should remember that the *Formulary* is not a textbook: and they might even welcome its apparent vagaries if they remembered the danger which both practical and academic medicine run of being cribbed, cabined, and

confined in a national health service which is potentially authoritarian. There is a strong feeling among practitioners that the *Formulary* is in some way an attempt to direct their prescribing, and it is essential to demonstrate that it is, and indeed only can be, merely a help, if the increasing drift to proprietary preparations is to be arrested. Actually your leading article suggests that the writer's mind is not far removed from a dictator's in his concluding remarks on "the development of sensible, honest, logical, and economical prescribing habits," for his first two epithets unconsciously (I hope) ascribe mental perversity and moral obliquity to those who do not agree with him. We do not expect this attitude in the *British Medical Journal*.

I think that those who remember the story of the ergot alkaloids will agree that "contemporary opinion" may be at fault and G.P. experience not quite negligible. At least the compilers tried to hold the scales even. The final result inevitably represents the pressures as well as "the dispensing habits of its country of origin," but I hope it also reflects the whole-hearted efforts of us all to make it as worthy and helpful a volume as we could. I should like to say what a privilege and honour I felt it to be one of the B.M.A. representatives on the revision committee, and what a pleasure and education I found it to work with so many people with whom I often disagreed but from whom I also learned so much. I trust that the doctors of the country will give the *Formulary* a more cordial welcome than your leading article, and, above all, that, in spite of its many shortcomings, they will use as much of it as they can and find the value of some formulae which they have not used hitherto.—I am, etc.,

Winsford, Cheshire.

W. N. LEAK.

Laryngeal Paralysis Following Thyroidectomy

SIR.—The recent medico-legal case of complete laryngeal paralysis following thyroidectomy (*Journal*, February 12, p. 426) should stress the essential pre-operative examination which is often neglected—namely, laryngoscopy. This simple procedure would prevent irreparable damage.

It is not uncommon in cases of thyrotoxicosis for a symptomless unilateral abductor laryngeal paralysis to be present. It only requires damage to the other side to make the paralysis complete. A preliminary laryngoscopy and an awareness of a unilateral paralysis would allow for an alternative treatment to be adopted.—I am, etc.,

London, E.11.

C. J. SCOTT.

Fatal Pulmonary Embolism in Psychiatric Patient

SIR.—I was interested to see the memorandum on pulmonary embolism in a psychiatric patient by Dr. Donald Blair (*Journal*, February 5, p. 335), as it immediately reminded me of a similar case which recently came under my care.

The patient was a woman of some 40 years, suffering from severe endogenous depression of sudden onset. After being kept in bed for a few days on fairly heavy sedation, and while awaiting air evacuation to the U.K., she was commenced on a course of unmodified E.C.T. A few hours after the second session she complained of pleuritic pain in the left side of her chest, and over the next few days developed a haemorrhagic pleural effusion associated with persistent blood-staining of the sputum and a low-grade pyrexia. Following aspiration the remaining fluid absorbed quite quickly and her chest x-ray revealed no evidence of rib fracture. There was at no time any evidence of phlebothrombosis in the legs, and her heart was normal.

I concluded at the time that her pulmonary infarct was probably caused by a pulmonary arteriolar thrombosis consequent upon the period of anoxia and disturbed pulmonary blood flow at the time of her E.C.T. As Dr. Blair points out, small segments of calf-vein thrombosis can be notoriously difficult to detect clinically, and it may well be that her infarct too was embolic in origin. Certainly the immobility in bed of some of these heavily sedated patients combined perhaps with some degree of dehydration, in the absence of energetic tube-feeding, must predispose to venous thrombosis in the legs. I would be interested to learn of

any similar cases to the one described above, particularly with regard to whether the incident followed E.C.T. or not.—I am, etc.,

Luton.

P. G. JACKSON.

Premedication of Children for Tonsillectomy

SIR.—In his letter (*Journal*, January 29, p. 285) Dr. W. N. Rollason describes a variety of premedications and anaesthetic techniques for this operation. I am surprised he found method (4) (chloral, atropine, ethyl chloride, and ether) too time-consuming. Using atropine only, followed by nitrous oxide, oxygen, and ethyl chloride administered from the Y-piece attachment to the Boyle's machine as already described,^{1,2} about 10 cases can be done in an hour.

While "a trace of trichlorethylene" is a valuable adjunct to nitrous oxide in operations *not requiring relaxation*, it would appear to be unsuitable here on account of its inability to relax the jaw and the pillars of the fauces (as is essential for a clean guillotine tonsillectomy) without producing tachypnoea in the child.^{3,4} Perhaps the secret lies in the phrase "correctly administered from a McKesson machine."—I am, etc.,

Aberdeen.

Toxicity of D.A.D.P.S.

SIR.—Since the reports of Esteves and Brandao in 1950¹ and of Cornbleet in 1951,² di-amino-diphenyl sulphone (D.A.D.P.S.) has been widely used for the control of dermatitis herpetiformis, and it is generally agreed that toxic symptoms are infrequent and mild. The following brief case history suggests, however, that occasionally severe and rapidly developing toxic effects may occur, with the small doses usually employed.

A rather frail woman, aged 68, developed blisters in the mouth. Several months later there were grouped irritable papules on the forearms, with occasional small blisters. Biopsy showed a sub-epidermal blister containing polymorphs with an inflammatory cell infiltrate in the underlying corium. No other physical abnormality was found. She was given D.A.D.P.S. 50 mg. daily. When seen one week later she complained that the tablets had made her feel ill, with nausea and some vomiting. For two days she had become yellow, with dark urine and light-coloured stools. She had only taken the tablets for four days. On examination she was not jaundiced and there were no abnormal physical signs apart from the blisters. Hb, 65%; R.B.C., 3,000,000; C.I., 1; M.C.D., 7.9; W.B.C., 5,000; neutrophils, 67%; eosinophils, 9%; basophils, 2%; leucocytes, 20%; monocytes, 2%; total plasma protein, 4.5 g. per 100 ml.; albumin, 3.8 g. per 100 ml.; globulin, 0.7 g. per 100 ml.; serum bilirubin, 0.4 mg. per 100 ml. One week later these tests showed: Hb, 75%; R.B.C., 3,800,000; reticulocytes, 1/100 red cells; W.B.C., 6,000; polymorphs, 56%; leucocytes, 34%; plasma protein, 5.7 g. per 100 ml.; albumin, 4.4 g. per 100 ml.; globulin, 1.3 g. per 100 ml. Eight weeks previous to this episode the blood count was: Hb, 95%; M.C.D., 7.3; W.B.C., 5,000; polymorphs, 60%; leucocytes, 34%; eosinophils, 3%; monocytes, 2%; basophils 1%.

It seems probable that in this case D.A.D.P.S. in a dose of 50 mg. daily for four days produced a rapidly developing anaemia and also hepatitis. The evidence is not, of course, conclusive, but strongly suggests this. Haemolytic anaemia is a well-known complication of sulphone therapy, but usually develops gradually in the first weeks of treatment. Allergic hepatitis and exfoliative dermatitis are described occurring during the first nine weeks of treatment.³ Previous sensitization with D.A.D.P.S. or sulphonamides might result in the onset of allergic hepatitis or aplastic anaemia at the beginning of D.A.D.P.S. treatment, but as far as is known she had never been given these drugs.—I am, etc.,

London, W.2.

Dyspareunia Clinic

SIR.—We were glad to see Mr. R. Christie Brown's reference (*Journal*, January 8, p. 106) to a new clinic which is to deal with dyspareunia cases. Up to the present University College Hospital is, we believe, the only teaching hospital to provide special sessions for work of this sort. Cases of introital spasm, leading to dyspareunia or to total unconsummation, are common and can be tedious to treat. Invariably the patients are anxious, and their resulting sexual maladjustments and infertility require time for suitable management and advice. At such sessions the methods used are mainly those of persuasion, whereby the patient is shown how to insert graduated dilators and how to ensure, by alterations of posture, the optimum relaxation of the levator spasm. Such tuition should, as correspondents have pointed out, be given in a normal out-patients session, provided there is leisure and opportunity for weekly return visits. But surely this could be true only of non-teaching hospitals? It would hardly be possible for a nervous woman to spend several minutes learning to insert vaginal dilators in front of a group of students. In practice, therefore, the case must be passed on to a house-surgeon, a delegation that, as another correspondent observes (*Journal*, February 12, p. 415), is a most unsuitable arrangement.

At University College Hospital the cases received are inter-departmental, being referred from the sub-fertility, gynaecological, and obstetric clinics. There are seldom less than one or two new cases at the weekly session, and generally three or four old ones. One student only is accepted for tuition at a time, and privacy from nursing staff, and so on, is assured. Patients who reach this clinic have frequently drifted on from other hospitals where no such facilities have existed. Some of them have delayed renewing their efforts until it is already too late for childbearing or until their marriages are breaking up. We therefore welcome this new clinic under the auspices of the Family Planning Association, and we believe that some hospitals and general practitioners will be glad of its services. We understand that patients are attended by a consulting gynaecological surgeon with special experience of psychoneurotic disorders.—We are, etc.,

London, W.C.1.

W. C. W. NIXON.

JOAN MALLESON.

POINTS FROM LETTERS

Negative Tuberculin Test and Positive X-ray

Dr. R. CHAKRAVERTY (Yeovil) writes: The observations of Dr. R. Stevenson Doig (*Journal*, January 22, p. 225) are very interesting, warranting careful study. . . . His suggestion that an individual who had an infection and then lost sensitivity (allergy) later, and yet showed x-ray evidence of a lesion following the infection, would react more markedly to B.C.G. vaccination than a totally non-infected one is a very problematical one and cannot be so dogmatically answered. Schwabaker and Wilson (*J. Path. Bact.*, 1938, 46, 535) and Wells and Brook (*Brit. J. exp. Path.*, 1940, 21, 104) experimentally reproduced this condition and found that the return of hypersensitivity (allergy) was not accelerated, but on the contrary markedly delayed and suppressed. It would be very interesting to know further investigation results.

Gelatin-walled Suppositories

Dr. R. F. MILLER (London, W.1) writes: It has always seemed strange to me why manufacturers do not make gelatin-walled capsules containing glycerin, rather than the solid and almost insoluble product which goes under the name of glyc. suppos. B.P. The latter can be retained for as long as 10 minutes or more without any obvious reduction in size or appreciable action on the lower bowel. A thin-walled capsule on the other hand would dissolve in no time, scattering its contents as effectively as a glycerin syringe. I have asked several chemists if such a suppository is available, and they say no. It would be particularly useful with babies, where a quick action is desirable before they can "push it out." It need not be made with a soft or semi-soft wall. Indeed, a rigid capsule, like the oral variety, would probably lend itself to easier self-insertion.

Obituary

Sir CHARLES J. MARTIN, C.M.G., D.Sc., LL.D.
D.C.L., M.B., F.R.C.P., F.R.S.

A long career in medical research and medical education, spent on two continents and reaching high distinction in both, is closed with the death on February 15 of Sir Charles Martin. He was 89 years of age.

For more than a quarter of a century Martin was director of the Lister Institute of Preventive Medicine in London, but before he took up that appointment he had already, in his twenties and thirties, built up a reputation in Australia, where his name is still acclaimed after half a century as one of the founders of Australian medical research. When in 1952 the Jubilee of the Australian Commonwealth was celebrated, Mr. R. G. Menzies, the Prime Minister, sent Martin, then 86 years of age, a letter extending the greetings and good wishes of the medical research workers throughout the Commonwealth and announcing that the National Health and Medical Research Council of Australia had created

(Press Portrait Bureau)

two Fellowships in medical science named after him, to be awarded periodically to young Australians in order to give them overseas experience. The same Council addressed to him a memorial letter signed by all its members which said, "Your work and teaching in Australian institutions laid a solid foundation of research in this country and your example and encouragement stimulated its progress through its formative years. Your inspiration still permeates its whole fabric, and you are remembered by Australian workers as one of their most distinguished masters."

Charles James Martin was born in London in 1866 and was privately educated before entering St. Thomas's Hospital, where he won a scholarship in his second year. Later he was exhibitioner, gold medallist and university scholar in physiology, demonstrator in biology and physiology, and lecturer in comparative anatomy at King's College. He also studied at the University of Leipzig, where he was the devoted pupil of Karl Ludwig, the famous German physiologist. He had among his friends at that time two great physiologists, William Bayliss, who was at University College, and Ernest Starling, who was at Guy's, both of them born in the same year as Martin himself. He qualified in medicine in 1889, graduating M.B. in the following year, and in 1891 he went out to Sydney as successor to Almoth Wright, who had been demonstrator of physiology at the University. He remained in that post until 1887, when he became lecturer in physiology at the University of Melbourne, being appointed professor four years later.

The period was a formative one, both in Martin's career and in Australian medicine. Not only did he help to lay the foundation of Australian medical research, but he had great influence on medical education in the

Commonwealth. As professor of physiology at Melbourne he worked in company with that fine group of teachers, Halford the anatomist, Lambert the physicist, Baldwin Spencer the anthropologist, and others. Martin was a man who had not only great skill in medical research but that intuition which makes all the difference between pedestrian accomplishment and genius. He had also the gift, invaluable in those early pioneer days in Australia, of making laboratory equipment out of all sorts of odd materials. Even in his old age he described his chief recreation as "tinkering." Moreover he had the gift of stimulating research workers, a faculty which came into full play in later years when he was director of the Lister Institute.

Many medical men who received their training in Australia and afterwards rose to eminence in medicine in Great Britain—men like Sir Thomas Dunhill, Sir Howard Florey, Sir Hamilton Fairley, Professor G. R. Cameron, the late Sir Hugh Cairns, and others—were either Martin's pupils or the product of the system of medical education in the Commonwealth which he was active in helping to form. Indeed, from one point of view Australia regarded the position with some dismay. Here she was training at her new universities men whose talents found fulfilment in the mother country. Martin had been heard to declare that the quality of the medical students he met on the other side of the world was higher than at home: he found intellectual adventure more congenial to them and the experimental method of approach more natural.

In 1903, when he was 37 years of age, Martin returned to London to take charge of the Lister Institute of Preventive Medicine. This Institute, of which Lister himself was one of the founders in 1891, was modelled on the Pasteur Institute in Paris, and from year to year it has carried out mostly long-term researches in various fields. Among the problems of medical research which owed much to Martin's stimulus and interest were plague, caisson disease, infantile diarrhoea, the chemistry and metabolism of fat, adrenaline, fermentation, calcification of bone, and the role of vitamins in nutrition. In problems of nutrition and also of immunology he still continued to take an active interest in spite of the claims made upon him as director of the Institute and also as professor of experimental pathology in the University of London—a post to which he was appointed in 1912. From 1904 to 1907 he acted as chairman of the War Office committee on anti-typhoid inoculation; later he was a member of the advisory committee for the investigation of plague in India. This committee, whose work extended over eight years, was appointed jointly by the India Office, the Royal Society, and the Lister Institute. Martin himself went to India on behalf of the committee to organize the investigation.

During all this time his contacts with Australia continued, especially through the constant flow of Australian graduates to the Lister Institute. He had himself two further experiences of Australia. One of these was in the first world war, when he served, with the rank of lieutenant-colonel, in the Australian Army Medical Corps. He was at Gallipoli, where he organized laboratory services and resolved difficulties which had arisen in the field of amoebic and bacillary dysentery and the different typhoid fevers. He served also in Egypt, Palestine, and France, and in his service in France he superintended laboratories in Rouen. He was twice mentioned in dispatches and received the C.M.G. in 1919. In the 'thirties, immediately after his retirement

from the Lister Institute, he visited Australia at the request of the Australian Government to assist in some problems closely connected with its health and economy, including work on myxomatosis in rabbits. From 1931 to 1933 he was chief of the Division of Animal Nutrition of the Australian Council for Scientific and Industrial Research, and during the same period Adelaide—his third Australian university—welcomed him with open arms to its research institute as professor of biochemistry and general physiology.

Sir Charles Martin, who was elected F.R.S. in 1901, received the Royal Medal of the Royal Society in 1923, and was appointed a member of the Medical Research Council in 1926. He was a Doctor of Science of London and Melbourne and held honorary doctorates of the universities of Sheffield, Edinburgh, Durham, and Trinity College, Dublin, and the honorary M.A. of Cambridge. He was knighted in 1927. Over the course of years he gave valuable advice and help to the B.M.A. At the Annual Meeting in 1908 he was president of the Section of Pathology, and two years later he was president of the Section of Bacteriology. He was first elected to Council in 1904 and served off and on until 1916. After the first world war he was a member of several committees, including the Science, Arrangements, and Postgraduate Committees.

Sir Charles Martin married Edythe, daughter of Alfred Cross, of Hastings, and had one daughter. His wife died in March, 1954, at the age of 94, after 63 years of happy married life.

We are indebted to Sir ALAN DRURY for the following appreciation: Although I had known Sir Charles Martin as a scientist for many years, it was when I came to direct the institute he had created and to learn its intimate history that I realized what a rare personality he had. The development of the Lister Institute during his directorship, both in the quality of its science and in the men it produced, was remarkable, and was due entirely to his inspiring and enthusiastic leadership.

Martin was essentially the man of the laboratory. Within the laboratory he was supremely competent, and he found his happiness in making the "bits and pieces" for his or other workers' experiments and in carrying out the experiment himself. He had an intense and wide curiosity, an uncanny knack of appreciating the essence of a problem and the lines upon which its solution might be possible. Widely read and with an excellent memory, he was able to help many colleagues, and he could give completely of himself, because self-advancement did not appeal to him. A severe critic, he demanded high standards of performance and would not tolerate slipshod work.

Whimsical in word and manner, humble and straightforward, there was no one who would hesitate to seek his help and advice. It is easy to see why he was so successful a director and why he was so beloved. Living to a great age, he kept his scientific curiosity to the end. He followed the careers of those he had trained and helped and kept abreast of the literature. He seemed able even to regard the disabilities of his advancing years as scientific problems, so that when he spoke of them one felt he was still within the laboratory. There was nothing he enjoyed more than the visits of his colleagues. One can only hope that he appreciated that they came, not from a sense of duty, but because they wanted to hear his comments upon their activities, which they knew would still be valuable, and to meet again a man who was so unique and endearing.

Dr. LESLIE J. HARRIS writes: May I be permitted to add my tribute to the many that will be paid to the memory of Sir Charles Martin? It was in his capacity as chairman, from 1935 to 1946, of the committee of the Dunn Nutritional Laboratory that I had the privilege of getting

to know him well, and so of coming to respect, to admire, and to love him. Intellectually, what stood out most was his astonishing width of interest and knowledge, in the most varied fields of medical research. Equally at home in many specialized departments of pathology, physiology, bacteriology, or biochemistry, he had the gift of seeing right into the heart of a problem; and, knowing as he did how the present knowledge had been won, he quickly sensed what gaps still remained to be filled in. He was interested in knowledge for its own sake, and, unlike some lesser men, judged a research finding on its merits alone, not by its authorship. In consequence he was able to recognize talent and originality where others might miss seeing it, and, as a result, had the satisfaction of fostering young and sometimes precarious, research careers—leading in one instance at least to a later Nobel Laureateship. He was never one of those prone to put his own name on the title of the papers of his assistants and students published from his institute. On the contrary, it was an open secret that during the years that he was director of the Lister Institute much of the now classical work appearing under other names was really suggested, inspired, and directed—sometimes even down to the smallest technical details—by "Sir Charles," who took a pride in being a competent technician and handyman.

His scientific integrity was marked by a robust sense of right and wrong and fair dealing, combined with practical common sense. He was prepared, in no uncertain voice when occasion demanded, to stand up against established authority, when he knew that authority to be in the wrong; and his courageous determination more than once won the day. To his junior colleagues and to his friends he could at times be blunt and outspoken to a degree, but his direct speech never caused resentment, and it was in fact appreciated because one recognized the kindly heart behind it, and one was warmed by the friendly, welcoming smile always lurking below. Although in his own tastes simple to a degree, he could prove himself a man of the world in dealing with officialdom. He himself had the gift of handling men, and of dealing effectively with committees and organizations: indeed, one of his maxims was that people who failed to rub shoulders with their contemporaries had not succeeded in learning one of the elementary "techniques" of their trade. Another of his maxims was that it is useless to appeal to reason where a person's emotions have become involved. Up to the end Sir Charles retained both his charm and his penetrating intellectual faculty; and it was an experience to hear him, at the end of the ninth decade of his life, giving his stimulating comments on some future scientific developments which he foreshadowed after reading a paper that had just appeared in the current issue of a scientific journal.

PHILIP TURNER, M.S., F.R.C.S.

Mr. Philip Turner, consulting surgeon to Guy's Hospital, died on February 16 at St. Mary Abbots Hospital. He was 81 years of age.

Philip Turner was born in Kensington on December 27, 1873. Before studying medicine he graduated B.Sc., with honours in zoology, at University College, London. He then went on to Guy's Hospital, qualifying in 1897. Two years later he took the M.B., and in 1901 he became F.R.C.S. and proceeded to the degree of M.S. At Guy's he won the Treasurer's gold medal in clinical surgery, and his early appointments there included those of medical registrar from 1902 to 1903, and demonstrator in anatomy from 1903 to 1908. Meanwhile he had obtained the appointment of assistant surgeon at the Belgrave Hospital for Children, but he relinquished this in 1908 on his election to the staff at Guy's as assistant surgeon and demonstrator of operative surgery. For several years he was in charge of the ear department. Mr. Turner was not one to seek the limelight, but his excellent qualities earned for him a

solid and enduring reputation as a general surgeon, and among other hospitals to which he was attached were the Eltham and Hornsey Cottage Hospitals and the Surrey Dispensary. He had retired from the active staff of Guy's before the second world war, but in 1940 he joined the E.M.S., and for ten years thereafter worked as a surgeon at Joyce Green Hospital, Dartford, where his vitality and keenness will be long remembered.

He wrote numerous articles on surgical subjects for the medical journals, and several books. In 1908 he had two books published on the subject of osteology, *The Pocket Osteology* and *Aids to Osteology*, and he described some of his own contributions to operative surgery in *Inguinal Hernia, the Imperfectly Descended Testicle, and Varicocele* (1919). With Mr. R. P. Rowlands he edited *The Operations of Surgery*, and he contributed to Latham and English's *System of Treatment* and Choyce's *System of Surgery*. In 1908 he married Miss Helen B. Lambert, who was formerly a sister at Guy's and during the first world war matron of the Central Red Cross Workrooms at the Royal Academy. She died in 1932.

We are indebted to Sir HENRAGE OGILVIE for the following appreciation: Philip Turner will be remembered with affection by all who have passed through Guy's in the last 50 years. To the world of medicine as a whole he was a little-known figure, for he was quiet and shy in his manner, dressed formally, entertained little, and made surgery and his hospital his life. With R. P. Rowlands he edited the several editions of Jacobson's *Operations of Surgery*, and was largely responsible, after Rowlands's death, for the eighth edition. He himself wrote on hernia and scrotal conditions, and described the operation of trans-scrotal fixation of the undescended testis that bears his name and that remains the best method to-day.

As an operator he was scrupulous rather than spectacular. Whatever he did he did gently and bloodlessly, displaying a craftsman's hands and an anatomist's knowledge of topography. At a time when operating by the clock was fashionable and dramatic surgery was more admired than it is to-day, he taught to many generations the value of careful technique.

When I first knew him he was assistant surgeon to Sir Alfred Fripp, and his gentle, almost apologetic manner stood in marked contrast to the masterful personality and easy address of "The Baron." He grew in stature year by year as his sterling worth came to be appreciated by successive generations. Having retired from the staff when at the height of his powers, he was called back into harness at the outbreak of the second world war and given the post of chief surgeon at a large E.M.S. hospital in the Guy's sector. He entered into this assignment with a boyish enthusiasm, and in his new duties developed a new personality, a power of leadership, and social gifts that had hitherto lain dormant. I saw him last when he took the chair at the Guy's Biennial Dinner in October, 1954. It was moving to see the universal affection in which "Philip" was held, and the pride with which he looked round that great gathering of Guy's men, most of whom had been his pupils.

The death took place on February 19, within nine days of his 81st birthday, of Dr. EDGAR F. CYRIAX, manipulative surgeon and physiotherapist, apostle of physical fitness, and one of the earliest and most ardent exponents in this country of Swedish gymnastics. Edgar Ferdinand Cyriax was born in London and educated at University College School and University College, afterwards taking his medical training in Edinburgh, where he graduated in 1898, proceeding to the Edinburgh M.D. in 1901. He was attracted to the Swedish methods and became a graduate of the Central Gymnastic Institute of Stockholm. One of his earliest monographs, published in 1903, was on the elements of the manipulative treatment practised there by the director, Henrik Kellgren.

whose daughter, herself a medical woman, Dr. Cyriax married. During the first world war he was visiting physician to the Swedish War Hospital, and afterwards, from 1919, visiting physician to the British Hospital for Functional Mental and Nervous Disorders, Camden Town. Until his retirement only a short time ago he continued in private consulting practice, describing himself as a specialist in mechano-therapeutics. During his lifetime he wrote a number of papers on subjects connected with physical medicine: one, entitled "Minor Displacements of the Vertebrae and Ilii," was published in the *Practitioner* in 1916, and another, about the differences between blood-pressure readings in the two arms, in the *Quarterly Journal of Medicine*. Dr. Cyriax achieved a great reputation in the field of sport. He was the grand old man of Rugby fives, a game which he had learned at University College School 70 years ago, and which he continued to play well into his old age. He did much to popularize the game in public schools. His prowess in physical achievement became something of a legend. He disdained the car—"You just sit there and go flabby"—and cycled between his Welbeck Street surgery and his Hampstead home. Similarly he preferred the staircase to the lift. He hardly ever wore hat, overcoat, or gloves even in winter, and he boasted of his cold bath every morning. He was a Knight of the Royal Swedish Order of Vasa (First Class) and a member of the French and Belgian Societies of Physiotherapy, and he had been a member of the British Medical Association for more than 50 years. Dr. Cyriax is survived by his widow and by his son, Dr. James Cyriax, and his daughter, Dr. A. V. K. Cyriax.

A memorial service for the late Sir EDWARD MELLANBY will be held at St. Martin-in-the-Fields at 11.30 a.m. on Thursday, March 17.

Medico-Legal

VACCINATION CLAIM WON

On February 14 Dr. Brian Quinn, of Mytholmroyd, near Halifax, successfully claimed for £62 15s. against Halifax Corporation Health Department in respect of 251 vaccinations and the compiling of records while house-physician at St. John's Hospital, Halifax, during 1953. The judge granted a stay of execution for 14 days in case of an appeal.

Dr. Quinn's case was that in March, 1953, there was a smallpox scare in the Halifax area and many vaccinations were carried out. The corporation paid a total of £445 to general practitioners who did vaccinations and submitted records, but it had declined to pay any hospital doctors who did the same work. Dr. Quinn contended there was no possible distinction between hospital doctors and general practitioners who carried out vaccination work. Questions of fact which arose were: Did the local authority in fact make arrangements with Dr. Quinn through the medium of the senior medical officer, and was there a request expressed or implied that a record should be completed and submitted to the local authority?

In March, 1953, there were two suspected cases of smallpox—one at Halifax General Hospital and another at St. John's Hospital. Conferences were held between the hospital authorities and the medical officer of health for Halifax, and at all these conferences the M.O.H. or his assistant was present. Ultimately instructions were given by the acting M.O.H. to the senior medical officer at St. John's Hospital that vaccinations should be carried out on anyone likely to have come in contact with a suspected smallpox case. Dr. Quinn was told to get on with the work, vaccine was supplied free of charge, and record cards were sent.

Dr. Quinn said that he did not regard it as part of his job at the hospital to vaccinate patients and send in record cards.

Mr. R. W. Ranson, group secretary, Halifax Hospitals Management Committee, expressed the view that if any fees were paid they should be retained by the doctor.

The Corporation contended that neither it nor its agents made arrangements with Dr. Quinn. Any action should have been brought by Dr. Quinn's employers, as the arrangements were made with his superior on behalf of the hospital management committee. Vaccination of contacts was one of the incidental duties a doctor might have to do in the course of his ordinary work in the hospital.

Judge Myles Archibald said he found there was the clearest intention by the health department that these doctors should be invited to do the work. He did not think a hospital was the sort of place where one would normally expect this sort of work to be done. It was not part of Dr. Quinn's duty to carry out vaccinations in this sense or to fill in record cards.

The Medical Defence Union instructed Messrs. Hempsons, solicitors, to act for Dr. Quinn.

Medical Notes in Parliament

ETHICS OF CLINICAL INVESTIGATIONS

The conduct of clinical trials in hospitals, and the right of the patient to be informed and to give or withhold his consent, were discussed in the House of Commons on February 16. It was raised by Mr. STEPHEN SWINGLER (Newcastle-under-Lyme, Lab.), and arose out of trials conducted at Bristol Maternity Hospital and reported in the *British Medical Journal*, December 11, 1954, p. 1392.

Mr. Swingler said that, while the community should give to medical scientists and doctors the best possible facilities and conditions for research, medical scientists and doctors should be extremely careful not to use their privileged position to treat human beings as laboratory specimens. He put forward two principles: medical experiments on patients should not be conducted unless there was a chance of patients benefiting; and clinical experiments in hospitals should not be conducted unless the consent of the patients had been freely given, in the knowledge of the nature of the experiments. The doctor should explain to a patient that experimental treatment was necessary, the nature of the experiment, the risks involved, and the benefits that might be obtained or the injury that might result.

In the Bristol case, he said, penicillin was administered to newly born babies for the purely scientific purpose of observing their reaction to penicillin and to establish the properties of the preparations. The penicillin was not required by the babies, and there was no question of its having any beneficial effect on the babies. It had been established by the Minister of Health on inquiry that the consent of the parents was not sought. In his opinion, even if consent had been given, the experiment was ethically dubious. In the opinion of those who conducted this experiment, and of the Minister, there was no possibility of harm being done. But in the same issue of the *Journal* in which the experiment was reported there was a report of a speech by a distinguished doctor to a meeting of the Royal Society of Medicine about the uses and abuses of antibiotics, in which he was reported to have said that a doctor should think twice before prescribing the first-ever dose of penicillin to any patient.

A search of the medical press over the past two or three years had shown him at least half a dozen reported cases of clinical experiments on children in hospitals, not designed to benefit the children in any way, but said to have been carried out merely to test the reaction to certain drugs. That was treating children as guinea-pigs. The Minister had said that judgment could be left to the clinician in charge, but he (Mr. Swingler) would point out that some clinicians allowed their enthusiasm for science to override all moral objections. He would have thought that it was the responsibility of the Minister of Health, in conjunction with the

Ethical Committee of the B.M.A. and the Medical Research Council, to lay down some guiding principles. He urged the Minister to consult with his advisers and with these organizations, to see if some directive or code could be sent to hospitals to prevent and prohibit experiments, especially on children, which were for purely scientific purposes and not designed in any way for the promotion of health. In this way some ethical guidance might be given which would act as a necessary and desirable curb on the enthusiasm for enlarging scientific knowledge.

Major W. J. ANSTRUTHER-GRAY (Berwick and East Lothian, Con.) was concerned that all consideration of the parents appeared to have been overlooked. He quoted extracts from the *Journal* report, and said that he had no doubt the experiment was quite harmless. There was a note at the foot of the article in which a lot of people were thanked. But the parents were not only not thanked, they were not even consulted.

Future to Benefit

Mr. IAIN MACLEOD, Minister of Health, said it was admitted that the consent of the parents should have been asked for. The people responsible, who were of the greatest authority and competence, regretted very much—as he did—that that was not done. What the House was discussing was whether such experiments were proper, and whether any action should be taken by the Minister in these matters. He disagreed with Mr. Swingler's proposition that it would be wrong and unethical for any clinical investigation to be carried out which would not immediately benefit the person concerned. If it was to add to future knowledge he did not see how that could be so. The reward to those who tried to catch the common cold at the Salisbury research unit was not that they would derive direct benefit themselves, but that the general pool of knowledge might be increased and others helped in the future. The answer to Mr. Swingler, therefore, was that babies yet unborn might benefit from this continued thrusting forward to new frontiers.

There were two propositions with which he thought most of the House would agree. First, there was bound to be clinical investigation and experiment. If that were not so, knowledge of surgery and medicine would not have changed over the centuries. Second, only the clinician in charge could say what was right and proper and what safeguards were needed in the action he took. Mr. Swingler had asked, in questions on February 14, that before further clinical experiments on children were undertaken the nature of such experiments should be reported to the Ministry of Health so that the medical staff of the Ministry could ensure that there were adequate safeguards against harmful effects; and also that the Minister should issue a directive to hospital management committees on the ethical principles involved. That was in his (Mr. Macleod's) view a wrong conception of the duty of the Minister of Health. He thought it would be wholly improper for him to try to lay down what ethical and medical principles should govern the conduct of professional men in the work they undertook at hospitals.

In this instance there was undertaken an experiment which all those concerned, who were of the highest capability, were quite certain was completely harmless. If a small child of his, or a child of any age, was in hospital, and he was told by people of the standing, for example, of professor of medicine and child health at the university concerned, "We are interested to know the effects of a perfectly safe clinical investigation; it may very well be that we can learn from what is done, and as a result can drive still lower the infant mortality rate," he would be more than ready to give his consent.

The common sense of the matter was that where a clinician intended to undertake an investigation which was so novel as to amount to an experiment he would be wise to seek consent from the patient or parent for what was proposed. But he was absolutely convinced that it would be quite wrong for a Minister of Health to issue directives

on a matter that was essentially one of medical ethics to those concerned. He was sure it was best to leave the matter to the profession, and not to have a lay Minister interfering in a matter that was very precious to those professionally concerned.

Some Guidance Needed

Mr. SWINGLER said he appreciated why the Minister should resist the idea that he should himself go into this matter and issue a directive. But in view of the complexity of the situation, did he not think it was the duty and responsibility of the heads of the medical profession to give some ethical guidance? As it had been brought to his attention that there were cases where, for example, consent had not been obtained, and where experiments were being conducted which had nothing to do with actual treatment, would he not use his good offices to ask the heads of the medical profession to give some guidance on that?

Mr. MACLEOD said that was a very different matter and one with which he was in some sympathy. If he had the slightest reason to believe that the position was not fully understood, then he would informally—and it could only be informally in a matter like this—draw the attention of those responsible to what had been said. The Medical Research Council sent out a confidential memorandum rather on those lines. If he had any reason to believe that the position was not completely clear, and that it was desirable for these things to be drawn to the attention of those responsible, then of course he would not object at all to what he might call an informal notification from himself. Of one thing he was clear: no directive must come from the Ministry of Health on a matter of this delicacy.

The discussion was part of the debate on a Supplementary Estimate for the National Health Service, which was agreed to.

HEALTH SERVICE COSTS

The supplementary estimate of £4,848,000 for the Health Service (*Supplement*, February 19, p. 56) was presented to the House of Commons on February 16 by Miss PAT HORNSBY-SMITH, the Parliamentary Secretary. She pointed out that in spite of the stricter basis on which the main estimates had been prepared, in accordance with the recommendations of the Public Accounts Committee, the net additional amount asked for was only slightly over 1% of the original sum. For a service which covered nearly 3,000 hospitals, 20,000 doctors, 10,000 dentists, 8,000 ophthalmic medical practitioners and opticians, and 15,000 chemists and suppliers of appliances the smallness of the margin was very creditable. The total sum asked for was made up of various increases which amounted to £8,562,000, reduced to the net figure by savings.

The increase for hospital maintenance accounted for £2,608,000, which included increases in pay totalling £1,200,000, additional to the £1,000,000 in the original estimates; increases in costs which accounted for £900,000; and £500,000 to meet expenditure which it had been estimated would be met by running down costs. Last year there was an increase of 8,000 in the daily average of occupied beds, of 125,000 in the number of new out-patients, and of 270,000 in casualty attendances. An additional £2,133,000 for the pharmaceutical services was due mainly to an increase in the average cost per prescription and in the number dispensed, and to a wider use of the newer and often more expensive drugs and preparations. Doctors were continually being kept cost-conscious in various ways, most recently through the introduction of arrangements by which a doctor could compare the cost of his own prescribing with that of his colleagues. Discussions between the Ministry and the manufacturers on price investigations had resulted in a number of reductions, and prescription had been kept reasonably stable over the past three years in spite of the almost continuous introduction of new drugs. The average cost in 1952-3 and in

1953-4 was 4s. 1d., and this year was expected to be about 4s. 2d., and the increase in the number was expected to be about 4,500,000. The bad summer last year produced a higher incidence of prescriptions than was normal, and the July figure was the highest on record for that month.

The estimated increase in expenditure on the supplementary ophthalmic and general dental services was also due to increased demand.

Pharmaceutical Costs Debated

Mr. H. A. MARQUAND (Middlesbrough, East, Lab.) commented that the largest proportionate increases were in the services provided by the executive councils—pharmaceutical, dental, and ophthalmic—on which charges to the public had been imposed. As there had been no epidemics since last May it looked as if the charges were less of a deterrent than they had been. A fortunate aspect of the increases for dental and ophthalmic treatment was that there was no suggestion of any increase in cost. The pharmaceutical service, however, showed an increase in both demand and cost, and that deserved more scrutiny. Why was the cost still going up?

Mr. IAIN MACLEOD, Minister of Health, stated that since the Estimates were prepared it had been decided to make the two most expensive drugs, aureomycin and terramycin, freely prescribable. The fact that they could now be prescribed on Form E.C.10 would be a major factor in the increased amount for which the House was being asked.

Sir HUGH LINSTEAD (Putney, Con.) said that the increased cost of the pharmaceutical service was basically due to the fact that medicine was advancing very rapidly, and that new and inevitably more expensive drugs were replacing the traditional and cheaper drugs. These generally reached the market in the form of proprietary medicines, and there was a heavy development and research bill attached to them. In 1950 18% of prescriptions were proprietary; in 1953 the proportion was 27% and in 1954 29%.

Of the report of the working party into hospital pharmaceutical services of which he was chairman, he said there were substantial economies still to be secured in costs, but they would be secured only in so far as the chief pharmacist in each hospital was a person of substantial scientific knowledge, whose advice was listened to by the consultants and medical staff.

Mr. MACLEOD, answering the debate, said that the inevitable concentration on what was wrong in Parliamentary debates and questions did not give an accurate picture of what was happening in this great service. It was worth remembering that since 1948 the number of beds available, the number staffed, and the number occupied, and the number of out-patients, had all gone up every year. There was a very great deal of progress against which the difficulties must be looked at. The general investigation into the secondary manufacture and compounding of drugs had been completed, and they had stated a preliminary view that there was no evidence to show that excessive profits were being made. On basic drugs they were still considering the accountants' report.

There had been a general downward tendency in price of proprietary preparations, and he had no reason to suppose that the investigations were the only, if indeed they were the main, reason for the reductions. Although there were preparations unworthy of being sold under the Health Service, the industry had made a wonderful advance in recent years. It had an export trade of great importance, and research was absolutely vital to it.

Vaccine Tests on Children

Mr. JOHN RANKIN (Glasgow, Tradeston, Lab.) asked the Secretary of State for Scotland if he was aware that 600 children belonging to the Orphan Homes of Scotland, Bridge of Weir, Renfrewshire, had been used for the purpose of research into a new antituberculosis vaccine; that this experiment had been going on for the last three years; that

now, as a result, a number of the children were suffering from a chronic skin infection; and if he would make a statement on the matter. Commander T. D. GALBRAITH, the Under Secretary, replied on February 15 that in the course of vaccinating these children against tuberculosis it was arranged in the spring of 1951 between the Department of Health and the county council, with the consent and co-operation of the management, to use B.C.G. vaccine for some of the children and an alternative vaccine—the "vole" vaccine—for others. Earlier studies had suggested that vole vaccine was likely to give as good protection with less local reaction, but late skin reactions on the site of the vaccination had been noted in 20 of 280 children who received this vaccine. He was assured that these reactions had been slight and were all clearing up, while the general health of the children had been entirely unaffected.

Medical Man-power Inquiry

The MINISTER OF HEALTH announced on February 21 the composition and terms of reference of the committee to investigate future needs in medical man-power.

The chairman is to be Mr. HENRY WILLINK, Q.C., Vice-Chancellor of Cambridge, and a former Minister of Health, and the members are:

Dr. J. T. Baldwin, Sir Harold Boldero, Sir John Charles, Sir Henry Cohen, Sir Andrew Davidson, Dr. A. B. Davies, Mr. J. P. Dodds, Sir Geoffrey Jefferson, F.R.S., Mr. L. G. K. Starke, Mr. A. B. Taylor, D.Litt.

The terms of reference are:

To estimate, on a long-term basis and with due regard to all relevant considerations, the number of medical practitioners likely to be engaged in all branches of the profession in the future, and the consequential intake of medical students required.

Mr. P. V. Muston, of the Ministry of Health, will be the secretary to the committee.

Mr. Henry Willink (chairman), aged 60, is Master of Magdalen College, Cambridge, and Vice-Chancellor of Cambridge University. He was Minister of Health in the Coalition Government, 1943-5, and chairman of the Royal Commission on Betting, 1949.

Dr. J. T. Baldwin is a general medical practitioner in Midlothian, a member of the Scottish Health Services Council, and a member of the General Medical Services Committee of the B.M.A.

Sir Harold Boldero, aged 65, is a registrar of the Royal College of Physicians and was dean of Middlesex Hospital Medical School. He holds the position of examiner in medicine at the Universities of Oxford, Cambridge, and Birmingham. He is also a member of the North-west Metropolitan Regional Hospital Board.

Sir John Charles, aged 61, has been Chief Medical Officer at the Ministry of Health since 1950. After being medical officer of health at Newcastle during 1932-44, he was appointed a deputy chief medical officer at the Ministry of Health in 1944.

Sir Henry Cohen, aged 55, is professor of medicine at the University of Liverpool. He is also vice-chairman of the Central Health Services Council, and chairman of its Standing Medical Advisory Committee. He has been chairman of several special committees, including those on general practice and the prescribing of proprietary preparations. He is a member of the United Liverpool Teaching Hospitals and Liverpool Regional Hospital Board.

Sir Andrew Davidson, aged 62, was Chief Medical Officer to the Department of Health for Scotland during 1941-54. He is chairman of the Advisory Committee on Medical Research in Scotland and a member of the General Medical Council.

Dr. A. B. Davies is a general medical practitioner in Walsall who has had experience in industrial medicine, and is a member of the General Medical Services Committee of the B.M.A.

Mr. J. P. Dodds, aged 42, is Under Secretary, Health Services Remuneration and Staffing Division, at the Ministry of Health.

Sir Geoffrey Jefferson, F.R.S., aged 68, is emeritus professor of neurosurgery, Manchester University, and consultant adviser in neurosurgery to the Ministry of Health. He is a member of the Medical Research Council and chairman of the Clinical Research Board.

Mr. L. G. K. Starke is a principal actuary in the Government Actuary's Department.

Mr. A. B. Taylor, aged 50, is an assistant secretary in the Health Services Division, Department of Health for Scotland.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending February 5 (No. 5) and corresponding week 1954.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES In Countries and London	1955					1954

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Vital Statistics

Influenza

The 84 deaths from influenza in the great towns of England and Wales reported in the week ending February 12 showed a decrease of 22 from the preceding week's figures. This is the third successive week in which the total has fallen. 71 of these 84 deaths were of people aged 55 or over. The outbreak of virus-B influenza is evidently continuing to wane, and there is no evidence that any outbreaks of virus-A influenza are developing.

Typhoid in Yorkshire

The cause of the typhoid outbreak at Pickering, in Yorkshire (*Journal*, February 12, page 430), is reported to be contaminated tinned tongue. It was all sold on one day, December 11, 1954. On December 13 an epidemic of an apparently upper respiratory infection, labelled influenza, started in Pickering after (not before, as we previously reported) a similar condition had affected people in surrounding districts. Chloramphenicol was administered to those patients suspected of pulmonary complications, and most of the primary cases subsequently diagnosed as typhoid received a course. The clinical picture was an unusual one—pyrexia, nose-bleeds, headache, and prostration.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the nine years 1946-54 (influenza, 1952-4) are shown thus -----, the figures for 1955 thus ———. Except for the curves showing notifications in 1955, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

¹ *Yorkshire Post*, February 17, 1955.

Infectious Diseases

The rises in the number of notifications of infectious diseases in England and Wales during the week ending February 5 included 2,032 for measles, from 10,697 to 12,729, 301 for dysentery, from 678 to 979, 95 for acute pneumonia from 1,062 to 1,157, and 46 for scarlet fever, from 745 to 791.

The largest increases in the local incidence of measles were 389 in Yorkshire West Riding from 1,464 to 1,853, 280 in Kent, from 286 to 566, 204 in Warwickshire, from 372 to 576, 198 in Nottinghamshire, from 469 to 667, 158 in London, from 1,137 to 1,295, 122 in Durham, from 443 to 565, 104 in Surrey, from 276 to 380, and 101 in Northumberland, from 190 to 291. Only small variations occurred in the local trends of scarlet fever. 2,213 cases of whooping-cough, 24 fewer than in the preceding week, were notified. The largest variation was a rise of 38 in Kent, from 99 to 137. 16 cases of diphtheria were notified, being 7 fewer than in the preceding week. Multiple notifications of diphtheria came from Birmingham C.B. 3, Kingston-upon-Hull C.B. 2, and Liverpool C.B. 2. 13 cases of acute poliomyelitis were notified during the week, and these were 7 fewer for paralytic and 3 fewer for non-paralytic cases than in the preceding week. No multiple cases were reported.

The incidence of dysentery was the largest for 34 weeks. The chief centres of infection were Lancashire 368 (Oldham C.B. 86, Stretford M.B. 61, Blackpool C.B. 59, Manchester C.B. 30, Liverpool C.B. 27, Royton U.D. 15, Chadderton U.D. 14, Huyton-with-Roby U.D. 11), Suffolk 103 (Woodbridge U.D. 78, Blyth R.D. 17), Yorkshire West Riding 67 (Leeds C.B. 26, Rotherham C.B. 17), London 61 (Southwark 23), Norfolk 60 (Norwich C.B. 28, Blofield and Flegg R.D. 15, Forehoe and Henstead R.D. 10), Durham 42 (Lanchester R.D. 23), Glamorganshire 33 (Swansea C.B. 10), Warwickshire 30 (Birmingham C.B. 23), Leicestershire 29 (Leicester C.B. 23), Lincolnshire 28 (Scunthorpe M.B. 27), Yorkshire North Riding 23 (Middlesbrough C.B. 16), and Northumberland 20 (Newcastle-upon-Tyne C.B. 16).

Week Ending February 12

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 746, whooping-cough 2,065, diphtheria 14, measles 18,363, acute pneumonia 1,156, acute poliomyelitis 16, dysentery 1,110, paratyphoid fever 4, and typhoid fever 1.

Medical News

Duke of Edinburgh.—The Royal College of Surgeons of Edinburgh is to confer its Honorary Fellowship on the Duke of Edinburgh on June 20 as part of the College's 450th anniversary celebrations. The last member of the Royal Family to receive the Hon.F.R.C.S.Ed. was the Duke of Cumberland, the younger son of George II. On his return from his victory over the Young Pretender at Culloden Moor in 1746, he was made an honorary freeman of each of the City Crafts of Edinburgh, in gratitude for having come to that part of the kingdom "to maintain, protect, and defend our valuable Constitution of Church and State, most unjustly and unreasonably attacked by the present rebellion."

Sir Godfrey Huggins, C.H., F.R.C.S.—The Queen has approved the conferment of a Viscounty on Sir GODFREY HUGGINS, Prime Minister of the Federation of Rhodesia and Nyasaland. On February 18, the day the honour was announced, Sir Godfrey broke the Commonwealth record for service as a Prime Minister. He first attained this high office in 1933 as Prime Minister of Southern Rhodesia, a position he held unbroken for 20 years, until in 1953 he became Prime Minister of the newly created Federation of Rhodesia and Nyasaland. The previous record was made by the late Mr. Mackenzie King, who was Prime Minister of Canada for 7,828 days in three separate periods. The son of a doctor, Sir Godfrey Huggins qualified from St. Thomas's Hospital in 1906, and after holding appointments there he became house-physician and ultimately medical superintendent at the Hospital for Sick Children, Great Ormond Street. In 1908 he took his F.R.C.S., but a serious illness three years later compelled him to go abroad. For ten years he was a general practitioner in Salisbury, Southern Rhodesia, but in 1921 he became a consulting surgeon. In the same year he made his first entry into Southern Rhodesian politics. Only last week Sir Godfrey Huggins was in London attending the meeting of Commonwealth Prime Ministers, and while here he found time to go to the Hunterian Festival Dinner at the Royal College of Surgeons (*Journal*, February 19, p. 491). On the day of Sir Godfrey's return to Africa Sir Winston Churchill sent him this message: "I and my colleagues in the United Kingdom wish to send you our warm congratulations and good wishes for the future on your achievement in surpassing all records for the longest tenure of office of a British Prime Minister."

National Spastics Society.—The Lord Mayor of London, Alderman SEYMOUR HOWARD, presided at a dinner held at the Mansion House on February 15, when Mrs. CLEMENT ATTLEE and Mr. TED LEATHER, M.P., spoke in aid of the five-year medical research programme of the National Spastics Society. It is hoped that £45,000 will be subscribed to finance this research, which is only one of several projects which the society has in hand, including the setting

[Barratt's Photo Press]

up of special schools and local treatment centres for spastic children and adults. Dr. P. E. POLANI, the society's research director, speaking at the dinner, said that the main task of research in this field was to find out the causes of cerebral palsy, but investigations would also be made to assist diagnosis and to assess the potentialities of the handicapped child and the results of treatment.

Royal College of Surgeons in Ireland.—The annual Charter Day dinner was held in the College on February 12, when over two hundred Fellows and guests attended, among them members of the Surgical Travellers' Club. The toast of "The Guests" was proposed by the vice-president, Mr. A. B. CLERY, and was replied to in most felicitous terms by Professor ERIC ASHBY, vice-chancellor of the Queen's University, Belfast, and Sir STANFORD CADE. The toast of "The College" was proposed by Sir HENRAGE OGILVIE, and to this the president, Mr. IAN FRASER, replied.

Liquid Paraffin and Cancer.—One of the studies mentioned in the current annual report of the London School of Hygiene and Tropical Medicine is an analysis of data on the use of purgatives by patients with cancer of the gastro-intestinal tract and by patients with other diseases. These data were collected during the investigations into the aetiology of lung cancer which were published in the *British Medical Journal* (1950, 2, 739; 1952, 2, 1271). "The results," says the annual report, "suggest that the use of liquid paraffin may be associated with the development of a small proportion of the cases of cancer of the stomach and of the large bowel."

Dermatology and the G.P.—The reality of the demand from general practitioners for courses in dermatology (see page 534) is attested by figures published last week in the *Cambridge University Reporter* of the attendances at clinical symposia arranged for them at the Cambridge Medical School. Of the eleven symposia, that on dermatology was easily the most popular, 61 practitioners attending it. Next in popularity were those on paediatrics (53), disorders of blood (45), cardiovascular diseases (43), and obstetrics and gynaecology (42). At the bottom of the list were orthopaedics (18) and E.N.T. diseases (12).

French Government Exchange Scholarships.—Under the terms of a reciprocal arrangement with the Centre National de la Recherche Scientifique, the Medical Research Council invites applications from British workers in medical science (excluding clinical medicine) for two scholarships, valued at between 50,000 and 70,000 francs a month and tenable at research institutions in France during the academic year 1955-6. Further details and forms of application from the secretary, Medical Research Council, 38, Old Queen Street, London, S.W.1, with whom applications must be lodged by March 31.

Travelling Fellowships in Ophthalmology and Otology.—The Medical Research Council invites applications for Travelling Fellowships in ophthalmology and otology for the academic year 1955-6 for which special provision has been made by the Alexander Pigott Wernher Memorial Trustees. The Fellowships are intended for medical graduates who are likely to profit by a period of work at a centre abroad before taking up positions for higher teaching and research. The rate of payment is £650 per annum for a single Fellow or £900 per annum for a married Fellow, with allowances for travelling and other approved expenses. Further details and forms of application from the secretary, Medical Research Council, 38, Old Queen Street, London, S.W.1, with whom applications must be lodged by March 31.

Committee on Trial-case Lenses.—The Minister of Health has appointed a committee, under the chairmanship of Sir STEWART DUKE-ELDER, "to review standards for trial-case lenses and the method of measuring lens powers." Among the eight members are two other medical men, Mr. J. E. AYUB, F.R.C.S., and Mr. F. W. LAW, F.R.C.S.

Journal on Viruses.—The forthcoming publication of a new journal, *Virology*, is announced by the Academic Press, New York. The aim of this journal will be to publish papers on the biological, biochemical, and biophysical aspects of the subject, with emphasis on the comparative approach. The new journal will fill an obvious gap in the literature. *Virology* will be edited by Dr. G. K. HIRST, of the Public Health Research Institute, New York, 9, and Dr. C. H. ANDREWS, F.R.S., of the National Institute for Medical Research, London. It will be one of the associate editors. Volume 1, 1955, will comprise five issues, the first of which will appear in April. Annual subscription is \$9.00, and the British agents are Academic Books Ltd., 129, Queensway, London, W.2.

Aircraft Seats.—Under new Air Navigation Regulations all new civil airliners imported into Australia after January 1, 1957, must have their passenger seats facing the rear of the aircraft. The Australian Director-General of Civil Aviation, Air Marshal Sir RICHARD WILLIAMS, is quoted as saying that such seats give three times the protection of forward-facing seats.

Lawrence Poole Prize.—The Edinburgh branch of the Infantile Paralysis Fellowship has given £1,020 to Edinburgh University for the founding of an annual, biennial, or triennial prize for work on the prevention of poliomyelitis or the treatment or rehabilitation of those suffering from it.

William Hyde Award.—Dr. ROGER BANNISTER has been chosen for this year's William Hyde Award by the Research Board for the Correlation of Medical Science and Physical Education. The award, valued at £300, was instituted by the Nuffield Provincial Hospitals Trust in memory of its first manager.

Lord Adrian, P.R.S., will receive the honorary degree of Doctor of Science of Hull University on July 19.

COMING EVENTS

British Council Courses on Anaesthesia and Plastic Surgery.—Courses for overseas specialists: "Anaesthesia," London, February 27-March 12; "Plastic Surgery," East Grinstead and London, April 17-30. Details from director, Courses Department, British Council, 65, Davies Street, London, W.1 (Tel.: Grosvenor 8011).

Radio.—"Crime Comics and the American Way of Life." Twenty-minute talk on the Third Programme by Irving Sarnoff, Ph.D., senior psychologist, Student Health Service, Michigan University, on Thursday, March 3, at 8.55 p.m.

Otology Lecture.—The first James Yearsley lecture, commemorating the founder of the Metropolitan Ear, Nose, and Throat Hospital, will be delivered by Mr. TERENCE CAWTHORNE at 5.30 p.m. on March 4 at Rushcliffe House, St. Mary Abbots Hospital, Marloes Road, Kensington, W.8. His subject will be "The surgery of the ear in the prevention and treatment of intracranial complications of chronic suppurative otitis media." The lecture will be open to the medical profession without fee.

Alcohol Symposium.—The Nutrition Society will hold a symposium on "Alcohol and its Nutritional Significance," at St. Mary's Hospital Medical School, on March 12. Details from Dr. R. J. L. ALLEN, c/o Monkhouse and Glasscock, Ltd., Snowfields, London, S.E.1.

All-India Obstetric and Gynaecological Congress.—The eighth congress will be held in Bombay from March 24 to 26. Further details from hon. secretaries, Purandare Griha, Chowpaty Sea Face, Bombay, 7.

A.N.Z.A.S., the Australian and New Zealand Association for the Advancement of Science, will hold its thirty-first meeting in Melbourne on August 17-24. Visitors from overseas will be welcome. Details from Professor J. R. A. McMILLAN, Science House, 157, Gloucester Street, Sydney, Australia.

NEW ISSUES

Journal of Clinical Pathology.—The new issue (Vol. 8, No. 1) will be available next week. The contents include:

VISCERO-CUTANEOUS COLLAGENOSIS. Walter Pagel and C. S. Treip.
INTERSTITIAL PLASMACELLULAR PNEUMONIA DUE TO PNEUMOCYSTIS CARINII. H. S. Baar.
THE CELLS OF NORMAL HUMAN URINE. Philip Rofe.
A CASE OF CRYPTOCOCCAL MENINGITIS. D. C. Caldwell and S. S. Raphael.
NEEDLE NECROPSY. Richard Terry.
THE SPLEEN AND BLOOD EOSINOPHILIA. Simon Seviit.
THE USE OF A NEW CETRIMIDE PRODUCT IN A SELECTIVE MEDIUM FOR PSEUDOMONAS PYOCYANEA. E. J. L. Lowbury and A. G. Collins.
THE OCCURRENCE OF PASTURELLA SEPTICA (SYN. MULTOCIDA) IN BRONCHITIS. J. A. Cawson and J. M. Talbot.
THE FATE OF S. TYPHI IN BLOOD CLOT IN RELATION TO THE PROBLEM OF ISOLATION. Kenneth C. Watson.
EFFECT OF CHLORAMPHENICOL ON THE ISOLATION OF S. TYPHI FROM THE BLOOD STREAM. Kenneth C. Watson.
OPTICIN IN THE IDENTIFICATION OF STR. PNEUMONIAE. Eric F. Bowens and Leonard R. Jeffries.
THE ESTIMATION OF EVANS BLUE IN PLASMA. G. A. Bedwell, J. Paterson, and J. Swale.
THE EFFECT OF DIET UPON THE RESPONSE TO ORAL ANTICOAGULANTS. H. Paylor Wright and M. Hayden.
BLOOD COPPER AND ITS RELATIONSHIP TO THE GLOBULINS. J. N. Cumings, H. J. Goodwin, and C. J. Earl.
ISOLATION AND EXAMINATION OF URINARY METABOLITES CONTAINING AN AROMATIC SYSTEM. C. E. Dalgleish.
A SIMPLIFIED METHOD OF INVESTIGATING STEATORRHOEA. Dorothy Woodman and W. B. Yeoman.
A METHOD FOR THE DETERMINATION OF GLUTAMINE IN CEREBROSPINAL FLUID AND THE RESULTS IN HEPATIC COMA. T. P. Whitehead and S. R. F. Whitaker.
TECHNICAL METHOD: A SIMPLE METHOD FOR THE ESTIMATION OF PEPSIN IN GASTRIC JUICE. A. Wynn Williams.

Issued quarterly: annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Friday, February 25

CAMBRIDGE MEDICAL SOCIETY.—At Addenbrooke's Hospital, 3 p.m., Miss M. Moore White: Infertility.

Monday, February 28

LEEDS UNIVERSITY.—At Littlewood Hall, General Infirmary at Leeds, 4 p.m., talk and demonstration by Sir Howard Florey, F.R.S.: Cinematographic Illustration of Some of the Phenomena of Inflammation.
MEDICAL SOCIETY OF LONDON.—8.30 p.m., discussion to be introduced by Mr. D. J. Browne and Mr. N. L. Eckhoff: Common Congenital Deformities.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.—At Physiology Theatre, 4.45 p.m., Dr. Joseph Needham, F.R.S.: New Light on Physico-chemical Aspects of Morphogenesis.

Tuesday, March 1

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. C. Hodges: Superficial X-ray Therapy.
OXFORD UNIVERSITY MEDICAL SOCIETY.—At Clarendon Laboratory, 8.15 p.m., Professor J. Rotblat, D.Sc., Ph.D.: Nuclear Physics and Medicine.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Mr. John Beattie: Abnormalities of Bladder Function.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., neurological demonstration by Dr. J. N. Milnes.

Wednesday, March 2

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: *Trichophyton rubrum* Infection.
INSTITUTE OF LARYNGOLOGY AND OTOLGY.—6 p.m., Dr. H. Engrström (Stockholm): Anatomy of the Cochlea by the Electron Microscope.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. A. W. Badenoch: Haematuria.
LIVERPOOL MEDICAL INSTITUTION.—At Manchester University, 4.30 p.m., joint meeting with Manchester Medical Society, Professor A. W. Downie: Virus of Chickenpox and Herpes Zoster; Dr. C. A. Clarke: Some Methods of Investigating Inherited Factors in Disease.
MIDLAND MEDICAL SOCIETY.—At Birmingham Medical Institute, 154, Great Charles Street, 8.15 p.m., Dr. J. F. Brailsford: Lesions of the Inter-vertebral Disks.
ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE: EDINBURGH BRANCH.—At West Medical Theatre, Royal Infirmary, Edinburgh, 5 p.m., Dr. J. R. Innes: Defects in the Present-day Treatment of Leprosy.
ST. MARYLEBONE HOSPITAL FOR PSYCHIATRY AND CHILD GUIDANCE.—5.30 p.m., Dr. E. H. Larkin: Selection of Patients for Physical Treatment (with demonstration of treatment).

Thursday, March 3

●MOTHERS' CLINIC, 108, Whitfield Street, London, W.—2.30 p.m., Dr. Marie Stopes, D.Sc.: lecture and demonstration (on living models) on contraceptive technique.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.30 p.m., Otolaryngology Lecture by Mr. A. J. Gardham: Evolution of Major Surgery in the Mouth and Pharynx from the time of Trotter to the Present Day.
ROYAL EYE HOSPITAL.—5.30 p.m., Dr. T. H. Whittington: Some Aspects of Refraction Work: (2) The Reduced Eye and Retinoscopy.
ST. ANDREWS UNIVERSITY.—At Physiology Department, Medical School, Small's Wynd, Dundee, 5 p.m., Dr. F. G. Spear: Use and Misuse of Radiation.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. D. Curran: psychiatry demonstration.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.—4.30 p.m., demonstration and discussion of clinical cases.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.—At Physiology Theatre, 4.45 p.m., Dr. S. R. Elsdon: Respiratory Mechanisms in Bacteria.

Friday, March 4

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. P. D. Samman: Lichen Planus.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., clinical demonstration by Dr. J. Smart: Lung Abscess.
LONDON UNIVERSITY.—At King's College, 5 p.m., Professor Jerome Hall: Mental Disease and Criminal Responsibility.
●LONDON UNIVERSITY.—At Queen Elizabeth College, 5.30 p.m., Professor J. A. C. Knox: Exercise and the Heart Rate.
METROPOLITAN EAR, NOSE, AND THROAT HOSPITAL.—At Rushcliffe House, St. Mary Abbeys Hospital, 5.30 p.m., Inaugural Address by Mr. T. E. Cawthorne: Surgery of the Ear in the Prevention and Treatment of Intracranial Complications of Chronic Suppurative Otitis Media.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. R. W. Raven: Malignant Melanoma.
●ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Mr. Matthew White: Thoracic Surgery in Children.
ROYAL INSTITUTION OF GREAT BRITAIN.—9 p.m., Sir Frederic Bartlett, F.R.S.: Thinking—An Experimental Approach.
ROYAL MEDICAL SOCIETY, Edinburgh.—8 p.m., Dissertation by Mr. A. McSmith: Some Aspects of General Practice.
ROYAL SANITARY INSTITUTE.—At Guildhall, Kingston-upon-Hull, 10 a.m., Mr. T. H. Jones, M.I.C.E.: Water Supply of Kingston-upon-Hull—Past, Present, and Future; Dr. W. Ferguson: Epidemiological Approach to Health Education.
WHIPPS CROSS HOSPITAL MEDICAL SOCIETY.—8.30 p.m., clinical meeting.

Saturday, March 5

INSTITUTE OF LARYNGOLOGY AND OTOLGY.—12 noon, Dr. H. Engrström (Stockholm): Anatomy of the Vestibule by the Electron Microscope.
MIDLAND TUBERCULOSIS SOCIETY.—At Birmingham Chest Clinic, 3 p.m., Dr. A. L. Cochrane: Epidemiology of Tuberculosis in the Rhondda Pools.

APPOINTMENTS

GREER, C. H., M.B., B.S., Pathologist, Victoria Eye and Ear Hospital, Melbourne, Australia.
INSTITUTE OF OPHTHALMOLOGY.—P. B. Schofield, M.R.C.S., L.R.C.P., Assistant Pathologist; C. M. H. Pedler, M.B., B.S., Junior Pathologist.
NORTH-EAST METROPOLITAN REGIONAL HOSPITAL.—Alexander Russell, M.D., M.R.C.P., D.P.H., D.C.H., Part-time Consultant Physician in Paediatric Endocrinology, Queen Elizabeth Hospital for Children; E. W. Emery, M.B., Ch.B., F.F.R., D.M.R.(T), Full- or Maximum Part-time Consultant Radiotherapist, North Middlesex Hospital and Annexes; K. A. D. Turk, M.D., Full-time Consultant Pathologist, Chelmsford Group of Hospitals; C. G. Nairn, M.B., Ch.B., F.R.C.S.(Ed.), M.R.C.O.G., Part-time Consultant Obstetrician and Gynaecologist, Prince of Wales's and Bearded Memorial Hospitals; G. D. W. McKendrick, B.M., B.Ch., M.R.C.P., Part-time Consultant Physician in Infectious Diseases, St. Ann's General Hospital; A. S. Clark, M.B., B.S., D.P.M., Part-time Consultant Psychiatrist, Edmonton Child Guidance Clinic; J. H. P. Johnson, M.B., M.R.C.P., Full-time Consultant Chest Physician, Tottenham Chest Clinic; W. J. Jenkins, M.D., Full-time Consultant Pathologist and Medical Director, Brentwood Blood Transfusion Centre; J. P. S. Whitehead, M.R.C.S., L.R.C.P., Full-time Consultant Pathologist, Tilbury and South-east Essex Group of Hospitals.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Thomson.—On February 9, 1955, to Nancy S. M. Thomson (formerly Milne), M.B., Ch.B., wife of Thomas Nairn Thomson, B.Sc.(Econ.), B.Com., Ivybank, Blairgowrie, Perthshire, a son.

MARRIAGES

Phillips—Carp.—On February 22, 1955, at Toorak Synagogue, Melbourne, Australia, Leo Phillips, M.B., Ch.B., M.R.C.P., D.C.H., of Auckland, New Zealand, to Anne Carp, of Melbourne.

DEATHS

Johnston.—On January 28, 1955, at Old Court, Wellington, Somerset, Henry Stapleton Johnston, L.R.C.P.&S.I. & L.M., aged 71.
Low.—On January 24, 1955, in London, John Bruce Low, M.B., Ch.B., D.P.H., of 18, Causton Road, Highgate, London, N.
McIver.—On January 13, 1955, William John McIver, M.B., B.Ch., D.P.H. of The Demesne, Wistaston, Nantwich, Cheshire, aged 74.
Marsden.—On January 25, 1955, in London, Norman Spencer Marsden, M.B., Ch.B., Surgeon Commander, R.N.
Mayne.—On January 22, 1955, at "Caradon," Teignmouth, Devon, William Boxer Mayne, M.R.C.S., L.R.C.P.
Meehan.—On January 22, 1955, at "Maryfield," Duns, Berwickshire, Felix Patrick Meehan, M.M., M.B., Ch.B.
Moore.—On January 21, 1955, at 8, Groveley Road, Bournemouth, Hants, Edward James Fleetwood Moore, M.D.
Newton.—On January 27, 1955, at a nursing-home, Arthur Charles Dunca Newton, M.R.C.S., L.R.C.P.
North.—On January 15, 1955, at Axmansford Cottage, Ramsdell, Hants, Thomas North, M.D., F.R.C.S.I., late of New Southgate, London, N., aged 87.
Pooley.—On January 17, 1955, at Hill Rise, Dalton-in-Furness, Lancs, Edward Burdett Pooley, L.R.C.P.(Ed.), L.R.C.S.I. & L.M., aged 91.
Sheehan.—On January 25, 1955, at Norwich, Norfolk, William Joseph Sheehan, M.B., B.Ch.
Stalker.—On January 16, 1955, Alice Stalker, M.B., Ch.B., D.P.H., of Southport, Lancs.
Thompson.—On January 15, 1955, William Alexander Thompson, M.B., Ch.B., of 37, Derby Lane, Stoneycroft, Liverpool, Lancs, aged 33.
Walker.—On January 27, 1955, William Watson Walker, M.R.C.S., L.R.C.P., of 2, Chevening Road, London, N.W., aged 84.
White.—On January 21, 1955, at 187, Queen's Gate, London, S.W., John Duncan White, O.B.E., M.B., Ch.B., D.M.R.E.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Antibiotics and Buccal Ulceration

Q.—What place have antibiotics in the treatment of stomatitis and buccal ulceration? If indicated, how should they be administered?

A.—The answer, as to so many such questions, is that treatment depends on the cause. Antibiotics are worse than useless in *Candida* (Monilia) infection, and may indeed produce it. Penicillin is a specific for Vincent's infection. If there is some underlying condition (agranulocytosis or other blood disease and perhaps others less serious and less easily identified) antibacterial treatment of any kind, since it does not deal with the ultimate cause, may be unsuccessful. If the condition appears to be primary and not due to any resistant species such as *Candida albicans*, penicillin may be tried: none of the newer antibiotics has any special advantage for this purpose. When given in large doses parenterally (not less than 500,000 units daily of sodium penicillin; procaine penicillin does not produce sufficiently high blood levels) penicillin is excreted in the saliva, and this is perhaps the best way of giving it. Alternatively penicillin pastilles made with gelatin may be continuously sucked or penicillin chewing-gum used. Penicillin tablets (saccharose base) are unsatisfactory for prolonged use, and can in fact themselves produce a stomatitis.

Crepe Rubber Soles

Q.—There is a current opinion among orthopaedic staff that the wearing of crepe rubber soles causes pains in the feet. Are there any facts ascertained concerning rubber footwear and the welfare of the feet?

A.—It is a prevalent belief that crepe rubber soles are not suitable for children's feet. In fact, there seems to have been no investigation of this question at all. Certainly there can be no harmful effect on normal feet. In feet that are grossly abnormal there might be some complaint of pain, though I do not believe any harm would come from wearing such shoes. The reason that pain might occur is that a crepe sole does not give any rigid support to the foot. However, it is uncommon for children with foot abnormalities to complain of anything but minor pain. In short, I would say that crepe soles are quite suitable for shoes worn by children.

Alopecia Totalis

Q.—A patient of mine, a man aged 43, has had total alopecia since childhood. He lost all his hair at the age of about 10; no illness is known to have been the cause of it. His hair then grew again and disappeared again each year until he was about 18 years old, since when he has been without hair on head or body. Every spring a few downy hairs appear on his face and scalp, but by mid-summer they have gone again. He is a reticent type of person, sensitive about his baldness. He wears a wig, but can you suggest any treatment for his condition?

A.—Reports from the United States indicate that alopecia totalis may recover completely after systemic treatment with cortisone or A.C.T.H. It seems, however, that the baldness is likely to return very quickly once treatment is stopped, but perhaps this is not always so. The local application of cortisone and A.C.T.H. to the skin seems to be of no effect, but it may be hoped that hydrocortisone may prove successful in treating this condition. As yet, supplies of hydrocortisone in this country are not sufficient for the treatment

of alopecia totalis, and its value is still uncertain. In any case, it is doubtful whether the disorder merits the hazards and expense of systemic steroid therapy. However, no other treatment is likely to be successful.

Obliteration of Tattoo Marks

Q.—I have recently been consulted by a patient who is anxious to have some tattoo marks removed from his arm. They consist of three small initials, and have only been there for a few weeks. Is it possible to bleach them in any way or to lessen the intensity of the pigment? Apparently he is prepared to put up with a considerable amount of inconvenience.

A.—The removal of tattoo marks, except by surgical excision and closure of the wound by a skin-graft or by suture, is not very satisfactory.

The only other method which has been seriously attempted is to use a tattooing machine to drive an escharotic, such as tannic acid, into the skin over the tattoo mark. This causes necrosis of the skin and healing by scar tissue. It therefore leaves an outline of the previous tattoo mark as a scar. It does, however, achieve the removal of the coloured dyes.

Anaemia in Pregnancy

Q.—I should be grateful for information on the treatment of the pregnant woman whose routine haemoglobin estimation at a local authority antenatal clinic is about 60% to 80%.

A.—Although it has recently been disputed, the general view is that the physiological hydraemia of pregnancy results in an apparent anaemia and that a haemoglobin reading of 80% (11.0 g. per 100 ml.) or more is normal for the latter part of pregnancy. If anaemia is present, and if it is the result of an iron deficiency, treatment should be by modification of the diet and, if need be, by the oral administration of iron in the form of ferrous sulphate, ferrous carbonate, ferrous gluconate, iron and ammonium citrate, or proprietary preparations of colloidal iron. While it is true that one or other of these preparations may cause constipation or diarrhoea in certain women, this can only be determined by giving each a trial.

Failure of hypochromic anaemia to respond to oral iron therapy is sometimes explained by achlorhydria, which is not uncommon during pregnancy, so hydrochloric acid may be administered in addition to iron. If this fails, there is a clear indication for reference of the patient from a district antenatal clinic to the nearest hospital where full investigation can be carried out to establish the type of anaemia present, and where further treatment can be arranged or advised according to the findings.

Oversexed Women

Q.—Is there any reliable medical treatment—for example, hormones or sedatives—to lessen the sexual urge in women?

A.—It is worth trying the effect of ethisterone, 5 mg. three times a day. This is an expensive remedy, but it has been known to have the desired effect. Alternatively, small doses of bromide or phenobarbitone thrice daily are effective in some women, as is shown by the fact that some epileptic females cannot reach orgasm as long as they continue with sedation. Sensible advice about behaviour, masturbation, and the avoidance of alcohol would doubtless also help. With regard to masturbation, many children are brought up to believe that any self-relief is an unforgivable sin, and the punishment for it will be diseases of the sexual organs or damage to childbearing capacities. In fact, there seems no reason to consider masturbation as anything but normal in the celibate adult. Of Kinsey's figures from about 5,000 males 96% had masturbated and some 62% of his series of women. There seems to be no valid reason for fearing that a habit will become established: in normal people masturbation is only resorted to in the absence of more satisfactory outlets: certainly for many relief obtained in this

way would seem preferable to making a whole-time effort to repress desire as some young people have to do. A little kindly reassurance from the doctor may bring great relief along these lines. Admittedly the question is a complex one, but such advice would probably be given by most present-day psychiatrists.

Dental Anaesthesia for Children

Q.—*I am often asked by our local dentists to administer a domiciliary anaesthetic to children (3 years and upwards) for the extraction of a varying number of teeth, from two to a total clearance. It is seldom that one can avoid an open fire, especially in winter. What is the best anaesthetic agent to use? On a recent refresher course for general practitioners which I attended hands were raised in horror at the mere suggestion of chloroform, but no alternative (except ethyl chloride and ether) could be suggested. What is your expert's advice?*

A.—The choice of dental anaesthetic for infants and young children varies from single-dose ethyl chloride or divinyl ether for the simplest extraction, to endotracheal anaesthesia with nitrous oxide and oxygen with an adjuvant for the longest operations. The latter would be quite unsuitable in domiciliary practice. Nasal nitrous oxide and oxygen alone is a difficult anaesthetic to give to the very young without some premedication, and on the whole is not advised for the occasional anaesthetist. Ether, ethyl chloride, and divinyl ether are all inflammable and explosive, particularly so in the presence of oxygen or nitrous oxide. They should not be administered in the presence of an open fire. Chloroform is inadmissible because of its special pharmacological dangers, now too well documented to need repetition and out of all proportion to the nature of this operation.

The practical outcome is that unless the anaesthetic can be administered in a room without an open fire or for that matter any other source of ignition, it should not be administered at all. A larger question is whether dental extractions under general anaesthesia should be performed in a patient's home. If the reasons for doing so seem sufficient, any fire should be extinguished and any source of ignition removed from the room before the anaesthetic is administered. Quite apart from the explosion risk, the difficulty of avoiding and treating the by no means rare anaesthetic hazards of overdose, inhalation of vomit, and respiratory obstruction in a private house is very great. The death of a child in these circumstances would be difficult to excuse merely on grounds of expediency.

Paradichlorobenzene

Q.—*A patient sleeps in a room with little ventilation and with wardrobes and drawers so generously treated with paradichlorobenzene that the atmosphere seems constantly charged with it. Is this dangerous, or might it account for vague symptoms otherwise reasonably attributable to advancing years, or for a mild irritating cough?*

A.—Paradichlorobenzene is not usually considered to be a particularly toxic substance, though it is a narcotic and a liver poison. Inhalation of vapour is said to lead to headache, dizziness, and vomiting in sensitive people. I have been able to find only one reference in the literature to occupational poisoning among those handling the material. Wallgren¹ has recently reported poisoning in eight workers producing it. The symptoms were loss of appetite and weight and irritation of the eyes and throat. There were also increased reflexes, fine finger tremors, and some degree of methaemoglobinemia. More serious, however, is a single report² of two women both excessively exposed at home who developed cataract after an attack of jaundice a year previously. The significance of these observations might be questioned in view of the widespread use of paradichlorobenzene, but in any case a reduction of the hazard should be relatively easy to achieve.

Magnesium

Q.—*What is known about the magnesium requirements of man? Does deficiency or excess of this element lead to any ill-effects and, if so, what?*

A.—The usual dietary intake of magnesium is 0.2 to 0.6 g. (15–50 mEq) daily. The minimal requirement of magnesium in man is not known with any accuracy. In animals, deprivation of magnesium has been shown to cause tetany associated with low serum levels of magnesium. In man, the absence of a normal diet during prolonged parenteral feeding has been shown to lead to low serum levels of magnesium; the tremor in delirium tremens has been attributed to magnesium deficiency induced by anorexia, and low values of serum magnesium have been associated with it. Although magnesium is present in a considerable amount in cells, the effects of a cellular deficiency of magnesium in man are not known. High serum levels of magnesium can lead to stupor and coma. Magnesium in the diet could scarcely be adequate to produce this effect, but the giving of magnesium salts to patients with renal failure may elevate the serum level and so accentuate drowsiness.

NOTES AND COMMENTS

Lepers in Revolt.—Dr. M. G. CORCOS (Trinidad, B.W.I.) writes: "In your number of January 15, on p. 175, under 'Medical News' appears the paragraph headed 'Lepers in Revolt,' in which you correctly quote newspaper reports concerning myself. The incident did in fact occur, and has been followed by a considerable amount of publicity in both the world press and in the local press, most of it unfortunately highly favourable to me. I would be very grateful, therefore, if in fairness to me you could see your way to publishing the following disclaimer:

"Subsequently to January 7, 1955, a number of articles, letters, and reports have been appearing in the lay press, some purporting to give my views and practices in the treatment of leprosy patients and in leprosy control, and some including statements by patients and other persons lauding me, my views, and my actions. Please note that none of the articles, letters, and reports purporting to give my views and practices has been or will be published with my written, spoken, or implied consent. Many of the views and practices are not necessarily my own, and are in any case held and practised by a large number of medical practitioners, nurses, and medical auxiliaries throughout the world, as well as by various bodies interested in leprosy and leprosy control, including the World Health Organization. The laudatory statements, articles, letters, and reports by patients and others have been, and will be, in no way solicited by me, and have been, and will be, published without my written, spoken, or implied consent."

Burns from Petroleum Bitumen and Paraffin Wax.—Arising from the reply to the question on the treatment of pitch and tar burns ("Any Questions?" November 27, 1954, p. 1306), it has been asked whether the same treatment would be applicable to burns from petroleum bitumen and paraffin wax. OUR EXPERT replies that the treatment described is equally suitable for these types of burn.

Technique of Artificial Insemination.—Dr. JOAN MALLESON (London, N.W.1) writes: There is a slight error in the reference to the use of the insemination syringe ("Any Questions?" January 29, p. 301). Any apparatus such as this, dealing with sperms, should be washed in plain water and dried in air. A sediment of soap is most detrimental to sperm life. The syringe and glass vessel also need warming, in the axilla, to blood heat, for cold glass is a shock to spermatozoa. Full details of the use of the syringe have been published.¹

TREATMENT OF ACUTE RHEUMATIC FEVER IN CHILDREN

A Co-operative Clinical Trial of A.C.T.H., Cortisone, and Aspirin

A JOINT REPORT* BY

THE RHEUMATIC FEVER WORKING PARTY OF THE MEDICAL RESEARCH COUNCIL OF GREAT BRITAIN
AND

THE SUBCOMMITTEE OF PRINCIPAL INVESTIGATORS OF THE AMERICAN COUNCIL ON RHEUMATIC FEVER AND CONGENITAL HEART DISEASE, AMERICAN HEART ASSOCIATION

Members of the Rheumatic Fever Working Party and United Kingdom participating centres: The late Sir JAMES SPENCE, Royal Victoria Infirmary, Newcastle (chairman); Professor A. BRADFORD HILL, Honorary Director, Statistical Research Unit of the Medical Research Council (vice-chairman, and chairman following the death of Sir JAMES SPENCE); Dr. E. G. L. BYWATERS, Canadian Red Cross Memorial Hospital, Taplow (secretary); Professor STANLEY GRAHAM, Royal Hospital for Sick Children, Glasgow; Professor R. S. ILLINGWORTH, Children's Hospital, Sheffield; Dr. B. E. SCHLESINGER, Hospital for Sick Children, Great Ormond Street, London; Professor A. G. WATKINS, Llandough Hospital, Cardiff.

Members of the Principal Investigators Subcommittee and United States participating centres: Dr. DAVID D. RUTSTEIN (chairman), Co-ordinating Centre, American Heart Association, New York; Dr. ALBERT DOREMAN, La Rabida Jackson Park Sanatorium, Chicago; Dr. EDWARD E. FISCHEL, College of Physicians and Surgeons, Columbia University, New York; Dr. JOHN D. KELTH, Hospital for Sick Children, Toronto (Canada); Dr. JOHN A. LICHTY, University of Colorado Medical Centre, Denver; Dr. BENEDICT F. MASSELL, House of the Good Samaritan, Boston; Dr. CURRIER McEWEN, New York University-Bellevue Medical Centre, New York; and Dr. CHARLES H. RAMMELKAMP, Francis E. Warren Air Force Base, Cheyenne, Wyoming (this centre, treating only adults, contributed no cases to the present report).

Associated investigators at co-operating centres: In the United Kingdom: Drs. O. P. GRAY and J. RENDIE-SHORT, Cardiff; Drs. GAVIN C. ARNEIL and JAMES HUTCHISON, Glasgow; Drs. J. GREAVES and R. G. WELCH, London; Dr. E. ELLIS, Newcastle; Drs. S. DOXIADIS and M. G. PHILPOTT, Sheffield; Dr. G. T. THOMAS, Taplow. In the United States: Drs. JOHN BRAY and ERNEST CRAIGIE, Boston; Drs. ERNEST CLARKE and HAROLD B. HOUSER, Cheyenne; Drs. ANDREW LORINCZ, IRVING ROZENFELD, and KATHERINE SMULL, Chicago; Drs. JAMES FLETT, jun., and JOHN H. GITHENS, Denver; Drs. FELIX E. DEMARTINI and CHARLES W. FRANK, Columbia University, New York; Drs. FRANCES L. BAILEN-ROSE, JANET BALDWIN, JOSEPH J. BUNIM, EUGENIA F. DOYLE, ANN KUTTNER, GENE H. STOLLERMAN, and MORRIS ZIFF, New York University, New York; Drs. A. D. McKELVEY and RICHARD ROWE, Toronto (Canada).

Statistical consultation and services were provided by Miss MARJORIE T. BELLOW, chief statistician of the American Heart Association, and Dr. JOHN KNOWELDEN, London School of Hygiene and Tropical Medicine. Mr. FELIX MOORE, chief, Biometrics Research Branch, National Heart Institute, served as statistical consultant. Dr. A. St. J. DIXON, Taplow, served as co-ordinating registrar for the British centres. Mrs. RUTH E. RUTSTEIN was co-ordinator for the centres in the United States.

Starting in 1949, encouraging reports of A.C.T.H.[†] and cortisone in the treatment of acute rheumatic fever aroused hope that a more effective therapy had at last become available. Conclusions of the early and uncontrolled studies were, however, somewhat contradictory, in that some investigators reported that the hormones altered the course of acute rheumatic fever while others suggested that they merely suppressed its clinical manifestations (see bibliographies in Thorn *et al.* (1950) and Massell (1954)). At that time no data were available concerning the prevention of rheumatic heart disease by these agents, a question which could be answered only by a long follow-up study.

By early 1950 it became evident to both the Council on Rheumatic Fever and Congenital Heart Disease of the American Heart Association and the Medical Research Council of Great Britain that there was need for a controlled study of the efficacy of these hormones in comparison with the previously accepted therapy. It was also clear that no single research centre could provide, in a short period of time, enough cases to give a definitive answer. It was therefore proposed that a group of research centres should collaborate. The co-operative clinical trials of the streptomycin treatment of tuberculosis in Great Britain under the Medical Research Council and similar studies in the United States under

the Veterans Administration pointed the way. Planning funds were soon made available.

There were several advantages in the establishment of a co-operative study on an international basis. It was possible that the general availability of A.C.T.H. and cortisone in the United States might seriously interfere with a strictly controlled clinical trial. Large numbers of cases would be collected rapidly. Much-needed information on the natural history of the disease in two different parts of the world would be made available.

The Committee on Criteria and Standards of the Council on Rheumatic Fever and Congenital Heart Disease, together with a group of American and Canadian rheumatic fever research workers, set up a subcommittee of principal investigators for American planning. It also established liaison with the Working Party on Rheumatic Fever of the Medical Research Council of Great Britain. Joint planning of the United Kingdom-United States Co-operative Rheumatic Fever Study was begun and the design of the study completed in a six months' period.

The trial was designed to compare the therapeutic effects of the hormones, A.C.T.H. and cortisone, with the usual treatment of rheumatic fever at the time—namely, aspirin—all patients to be treated in hospital on bed rest and protected against beta-haemolytic streptococcal

*This report is being published simultaneously in the *British Medical Journal* in the United Kingdom and in *Circulation* in the United States.

†Throughout this paper A.C.T.H. will be used to indicate corticotropin, N.N.R.

infection. Within the limitations imposed by the design of the study, answers were sought to two questions:

(1) What is the relative effectiveness of each of these hormones and of aspirin in altering the course of the acute disease or in suppressing its clinical manifestations?

(2) What is the relative effectiveness of these three agents in preventing rheumatic heart disease?

Information was also collected on the side-effects of the two hormones and of aspirin.

The design created and agreed upon by the principal investigators in both countries, in co-operation with the co-ordinating staff and statistical consultants, provided for diagnostic criteria, random allocation of patients to treatment groups, a uniform six-weeks therapeutic regimen, and a fixed time-pattern for observation and follow-up. It prescribed the type and frequency of clinical and laboratory observations during hospital stay and follow-up period and required reporting on specially prepared forms (see Appendix) to the co-ordinating centres in London and New York City.

This report compares the effects of the three drugs—A.C.T.H., cortisone, and aspirin—on the acute course of rheumatic fever, in children under the age of 16, through 13 weeks from the start of treatment, and on the persistence and development of rheumatic heart disease through one year.* Subsequent reports will include a similar analysis of adult patients and, after longer follow-up, of the relative effectiveness of the three drugs in the prevention of rheumatic heart disease. These extensive data should also provide much information on the natural history of the disease.

Diagnostic Criteria for Admission of a Patient to the Study

To ensure, so far as possible, that in all centres patients admitted to the trial were unquestionable cases of rheumatic fever, and of no other illness, it was necessary to specify precise diagnostic criteria. Since there are no specific diagnostic clinical symptoms or signs or laboratory tests, such criteria must be arbitrary. The criteria had to be broad enough not to exclude many genuine early cases, and yet sufficiently rigid that there should be, among competent clinicians, no reasonable doubt regarding the diagnosis.

The diagnostic criteria were based on those of T. Duckett Jones (1944), modified for the purposes of this study with his advice and assistance.† They divide the manifestations of rheumatic fever into two groups, major and minor. There were five major and five minor manifestations, defined as follows.

Major Manifestations

- (1) **CARDITIS**, as shown by any one of the following: (a) the development of an organic apical systolic murmur or an aortic diastolic murmur under acceptable observation‡; (b) a change of heart size of more than 15% on standard x-ray film by any standard method of measurement; (c) pericarditis revealed by

a definite friction rub or by pericardial effusion; (d) congestive failure, in a patient under 25 years and in the absence of other causes, and shown by one or more of the following: (1) dyspnoea, (2) orthopnoea, (3) enlargement of the liver, (4) basal pulmonary rales, (5) increased jugular venous pressure, or (6) oedema.

In the assessment of carditis as a criterion for entry to the trial, it was assumed in patients with no known pre-existing rheumatic heart disease or history of an attack of acute rheumatic fever, that previous to the current illness the patient's heart was of normal size and that there were no rheumatic murmurs. In other patients, observations of changes in heart size and murmurs were used in determining carditis, and recorded.

- (2) **POLYARTHRITIS**, as shown by pain and either limitation of active motion or tenderness, in two or more joints.
(3) **CHOREA**, with movements of at least moderate severity.
(4) **SUBCUTANEOUS NODULES**.
(5) **ERYTHEMA MARGINATUM** (OF ANNULARE).

Minor Manifestations

- (1) **FEVER**, defined as any temperature above 99.3° F. (37.4° C.) by mouth or 100.3° F. (38° C.) rectally, occurring at least twice in one period of 24 hours, or above 100.3° F. (38° C.) by mouth or 101.3° F. (38.5° C.) rectally, observed on any one occasion.
(2) **ELEVATED SEDIMENTATION RATE**, defined as 15 mm./hr. or above (Wintrobe (1935), corrected by the Whitty and Hines chart to a haematocrit of 45%).
(3) **EVIDENCE OF PREVIOUS STREPTOCOCCAL INFECTION**, as shown by a culture in which beta-haemolytic streptococcus predominated, or by an antistreptolysin O titre of 200 units or greater, or by a reliable history of sore throat with fever preceding the onset of illness by an interval of one week to one month.
(4) **AN INCREASED P-R INTERVAL**, defined as a value at least 0.04 sec. beyond those given in the Ashman and Hull (1947) tables for ages under 16.
(5) **A RELIABLE HISTORY OF RHEUMATIC FEVER**, as defined in these criteria or EVIDENCE OF PRE-EXISTING RHEUMATIC HEART DISEASE—namely, an apical organic systolic murmur, an apical diastolic or a basal diastolic murmur.

These criteria having been specified, it was ruled that to be admitted to the study the patient must (a) at some time during the illness which brought him to the centre have exhibited at least two major manifestations or one major and two minor manifestations, and (b) on the first day of the allotted therapy show evidence of any one major manifestation or of any two of the three following minor manifestations—fever, elevated sedimentation rate, increased P-R interval.

It was arbitrarily decided that an interval of at least three months with no rheumatic activity must have preceded the present illness to justify its being called a new attack. With any shorter interval of time between the present and a previous illness, the present illness was held to be an exacerbation of symptoms of the previous attack and not a new attack. In such instances, the date of onset was referred back to the beginning of the illness.§

Patients who had had previous hormone therapy were excluded from the trial (a single test dose previously administered was not regarded as therapy). If a patient was receiving salicylate therapy, that treatment was discontinued upon admission to the hospital, before the patient was considered for inclusion. If such a patient subsequently satisfied the criteria he was eligible and admitted in the ordinary way.

§“Onset” was defined as the date of the first observation of any major manifestation or any minor manifestation that appeared to be related in a continuous time sequence to the development of any major manifestation.

Treatment Plan

Dosage Schedules

The dosage schedules of A.C.T.H., cortisone, and aspirin were based (in 1950) on published studies, modified by reports from investigators to Armour Laboratories and Merck and Company. From such information, a dosage was selected to be effective for a period of administration short enough to indicate whether the acute attack had been differentially shortened by any one of the three drugs. Provision was made for decreasing the dosage if toxic manifestations appeared and for “tapering off” so that cessation of therapy would not be abrupt.

While the same hormone dosage was used for all patients, the dosage schedule of aspirin was calculated on the basis of body weight. Cortisone and A.C.T.H. were administered intramuscularly, while aspirin was given by mouth.

The dosage schedules were:

A.C.T.H.*—All cases U.K. and eight cases U.S.†: a total daily dosage of 80 U.S.P. units for the first four days, 60 units for the next three days, 40 units for the second and third weeks, 30 units for the fourth and fifth weeks, and 20 units for the sixth week, administered every six hours.

All but eight cases U.S.: a total daily dosage of 120 U.S.P. units for the first four days, 100 units for the next three days, 80 units for the second week, 60 units for the third week, 40 units for the fourth and fifth weeks, 20 units for the sixth week, administered every six hours.

The A.C.T.H. dosage in the U.S. was increased early in the study, because with the relatively poor methods available for lot standardization and the lack of dramatic response in the first few cases treated, it was held possible that optimum dosage was not being administered. In regard to the question of “adequacy” of hormone dosage, it is of interest that practically all cases receiving A.C.T.H. or cortisone had side-effects; the details of which are presented later.

Cortisone.‡—A total daily dosage of 300 mg. for the first day, 200 mg. for the next four days, 100 mg. for the remainder of the first three weeks, 75 mg. for the fourth and fifth weeks, 50 mg. for the sixth week.

In the few cases where the hormone dosage was reduced because of undesirable side-effects, the percentage stepwise reduction in dosage thereafter remained unchanged.

Aspirin (acetylsalicylic acid, U.S.P. or B.P., 0.3 g. (5 gr.) tablets).—A total daily dosage of 60 mg. (1 gr.) per lb. of body weight (140 mg. per kg.) or 10 g. (150 gr.) total dosage, whichever was less, for the first two days; 40 mg. (½ gr.) per lb. (100 mg. per kg.), or 10 g. (150 gr.), whichever was less, for the next five days; 30 mg. (½ gr.) per lb. (70 mg. per kg.) for the remainder of the six weeks. Administered every four hours for 48 hours, every six hours thereafter. Aspirin was administered without bicarbonate of soda.

Patients unable to tolerate aspirin in the scheduled dosage received the largest amounts that they could tolerate as determined by the investigator. This occurred mainly in the older patients where the body-weight dosage produced side-effects. Conversely, because of the weight-dosage formula, small children did not receive aspirin up to the limit of tolerance.§

*A.C.T.H., donated by Armour Laboratories, was in three lots of water-soluble material standardized on both animals and human beings. All the U.K. cases were treated with one lot (K-50601R), while most of the U.S. cases received a second lot (J-24109R), although a few were treated with a third lot (L-56702). The U.S.P. unit is expressed as a milligram equivalent of A.C.T.H. lot number LA-1A.

†One Canadian centre took part in the trial, but for easy reference the term “U.S.” is used to include all North American centres.

‡Cortisone, donated by Merck and Company, was the regular commercial preparation for intramuscular use—namely, the acetate of 17-hydroxy-11-dehydrocorticosterone, suspended in a vehicle consisting of sodium carboxymethyl cellulose, Tween 80, and 1.5% benzyl alcohol in isotonic saline.

§Salicylate blood levels determined in two U.S. centres showed a positive correlation with body weight; lower blood levels found in one U.K. centre revealed no such relationship.

During the three-weeks observation period following the six-weeks course of therapy, none of these drugs was administered unless the investigator believed that the patient's condition was so poor as to endanger life or the polyarthritides so painful that it could not otherwise be controlled. In such cases, re-treatment was given for a period of four weeks, using the same drug and dosage as in the first four weeks of initial therapy; it was followed by a three-weeks observation period as before.

If re-treatment was necessary at any time during the three months following the original course of therapy, then the above four-weeks re-treatment scheme was followed. No patient was re-treated unless he demonstrated rheumatic activity sufficient to have brought him into the study initially.

If after three months without activity the patient developed a new attack of rheumatic fever, he was treated as in the original course—that is, for six weeks on the same drug and dosage, followed by a three-weeks period of observation.

Auxiliary Therapy

Sodium and Potassium Intake.—To minimize salt retention in hormone-treated patients, and to maintain comparability among the three treatment groups, the dietary intake of sodium was restricted to less than 2 g. per day for all patients for at least four weeks. All patients received added potassium chloride by mouth daily, 2 g. for those weighing less than 60 lb. (27.2 kg.) and 3 g. for those 60 lb. (27.2 kg.) or more, except that those few who developed oliguria due to congestive failure received no added potassium. Serum potassium levels were estimated weekly.

Streptococcal Prophylaxis.—Every effort was made through streptococcal prophylaxis to prevent recurrent attacks of rheumatic fever which would introduce an additional variable in the study. All patients, upon admission to the study and on the fourth, seventh, and tenth days of treatment, received procaine penicillin G in aluminium monostearate intramuscularly, 300,000 units for those weighing less than 60 lb. (27.2 kg.), 600,000 units for those 60 lb. (27.2 kg.) or more.¶ On the 14th day after admission to the study, and continuously thereafter, sulphadiazine was administered in a dose of ½ g. per day to those weighing less than 60 lb. (27.2 kg.) and 1 g. per day to those weighing 60 lb. (27.2 kg.) or more. (In a few patients, oral penicillin in a dose of 100,000 units twice a day was substituted when sensitivity to sulphadiazine developed.) Sera were drawn for determination of antistreptolysin-O titres (Massell and Miller's unpublished technique modified from Hodge and Swift, 1933) at weeks 0, 5, 9, and 13, and at each follow-up examination, to detect intercurrent streptococcal infection.

In addition to this routine, throat cultures were made on all patients on admission to hospital, and thereafter whenever there was indication of a throat infection. Those with positive cultures received penicillin therapy, as prescribed by the investigator.

Other Therapy.—All but a few patients were kept at bed rest for the nine weeks of therapy and observation. In a few cases of chorea, sedatives were necessary. No anti-rheumatic drugs other than those allocated for the study were given. Therapy necessary for any complicating illness was recorded.

Allocation of Patients to Treatment

Patients on admission to the study were divided into two age groups, 0 to 15 years and 16 and over, and into three groups according to the length of time in each case between the date of onset of the attack and the date at which therapy began. The three duration-from-onset groups were (1) 14 days or less; (2) 15 to 42 days; (3) 43 days and over.

For each of these three duration groups, within each age group, and separately for each treatment centre, the three treatments, A.C.T.H., cortisone, and aspirin, were listed in

¶At the House of the Good Samaritan (Boston) a variable dosage schedule was used.

*The one year follow-up data represent observations made at a calendar year from the end of the nine-weeks period of treatment and observation (61 weeks from the start of therapy).

†These modified criteria are not necessarily applicable for general use by the practising physician, particularly in questionable cases where continued observation of patients may be necessary for definitive diagnosis.

‡The development of an apical mid-diastolic murmur was also used for the diagnosis of carditis in U.K. centres, but there was only one case in which the diagnosis of carditis rested solely on this murmur, and this case was eligible under other criteria.

TABLE 1.—Details of 15 Cases Admitted to the Study in Which the Treatment and Observation Schedule was not Followed, with Reference to Their Inclusion or Exclusion From the Analysis.

Treatment Group	Treatment Stopped (5 Cases)	Treatment Changed (5 Cases)	Re-treatment (4 Cases)	Treatment Incomplete (1 Case)
A.C.T.H. (4 cases)	(1) U.S. gastric haemorrhage 6th day. Excluded (2) U.S. renal haemorrhage 21st day. Included (3) U.S. toxicity ¹ 27th day. Included (4) U.K. toxicity ² 32nd day. Included			
Cortisone (3 cases)			(11) U.S. re-treated 48th day. Included (12) U.S. re-treated 50th day. Included (13) U.S. re-treated 45th day. Included (14) U.S. re-treated 58th day. Included	(15) U.S. patient left hospital 12th day. ³ Excluded
Aspirin (8 cases)	(5) U.S. discharged from hospital 41st day. ⁴ Included	(6) U.S. in failure. Changed to A.C.T.H. 8th day. Excluded (7) U.S. carditis and failure. Changed to A.C.T.H. 28th day. Included under aspirin (8) U.S. carditis. Changed to A.C.T.H. 28th day. Included under aspirin (9) U.S. carditis. Changed to cortisone 50th day. Included under aspirin (10) U.K. pericarditis and failure. Changed to cortisone 51st day. Included under aspirin		

¹ Unusually rapid weight gain and enlargement of liver not responding to mercurial diuretics. ² Too rapid development of moonface. ³ Family moved to another city. ⁴ Child was an unmanageable behaviour problem.

random order for as many patients as were likely to be admitted, using random sampling numbers and keeping the numbers of patients on the three treatments approximately equal in each centre. The co-ordinating centre in each country issued serially numbered and sealed envelopes to the treatment centres. Thus, on admission of a patient of given age and specified duration-from-onset group, the investigator at the treatment centre had merely to open the next available envelope for that particular group to find a statement of the treatment to be applied. He was therefore unable to predict the treatment for his next case. The allocation was both "blind" and random.*

The admission report on the patient, and the assignment envelope, were then sent to the co-ordinating centre. If for any special reason the investigator decided in advance that a patient fulfilling the criteria should not be admitted to the study, no envelope was opened. In every such case, however, an admission report was required, together with an explanation as to why the patient had not been admitted. Six such cases were reported in the U.S.; none in the U.K.†

The Study Sample

In all, 505 children under 16 years of age were admitted to the study—242 in the U.K. between March 2, 1951, and October 6, 1952, and 263 in the U.S. between January 15, 1951, and June 15, 1952. Four of these cases were subsequently excluded when their illness proved to be a disease other than rheumatic fever. These were a case on cortisone (U.K.) of Henoch-Schönlein purpura, a case on aspirin

*In a few centres, for varying durations of time, the investigators wished to withhold some patients for other studies. In these instances a predetermined proportion of the envelopes contained, as an instruction, "free case." Such exclusions, therefore, were also "blind" and randomly determined, and could not bias the group brought into the study.

†These six cases were: one, with schizoid personality, considered unsuitable for the trial; one, excluded because his private physician insisted upon cortisone therapy; and four severe cases excluded in one centre under provision of the protocol—namely, "If in the opinion of the principal investigator, the patient is severely ill to the point where his life is in danger, that patient may be removed from any group and given therapy at the discretion of the investigator." These four cases were treated with A.C.T.H. as follows: (1) a 12-year-old boy in a sixth attack with acute carditis, mitral insufficiency, and congestive failure made a smooth recovery without residual heart disease; (2) a 9-year-old girl in a second attack with residual heart disease, mitral insufficiency, and congestive failure made a gradual but unremarkable recovery; (3) a 12-year-old girl in a second attack, with residual heart disease, acute carditis, mitral insufficiency, and congestive failure, made, after a stormy course, a slow recovery with persistence of chronic heart disease with increasing cardiac enlargement; and (4) a 9-year-old boy in a first attack with mitral insufficiency, pericarditis, and congestive failure, died after seven days of treatment.

(U.K.) of tuberculous meningitis, a case on A.C.T.H. (U.S.) of lupus erythematosus disseminatus, and a case on A.C.T.H. (U.S.) of salmonella infection. In another case on A.C.T.H. (U.S.) there was x-ray evidence of tuberculous infection superimposed upon the rheumatic fever, and hormone treatment was therefore withheld. These five exclusions present no problem.

In the remaining 500 patients (240 U.K., 260 U.S.) there was only the small number of 15, or 3%, in whom the prescribed treatment and observation schedule was not fully carried out (2 U.K., 13 U.S.). Table 1 shows their nature and the action taken with regard to them. Only three (Cases 1, 6, and 15) have been wholly excluded from the statistical analysis of the trial, since their treatment with the allotted drug was very brief (6, 8, and 12 days). All other cases had been treated for three weeks or longer. Three of them (Cases 2, 3, and 4) fall within the original provision for a reduction of dosage when essential, and four (Cases 11, 12, 13, and 14) within the provisions for re-treatment in active cases. Such patients, together with one (Case 5) that left the hospital after the six weeks of therapy, can be included under the allotted therapy without any difficulty.

There remain four aspirin cases in which, on account of the severity of the illness, the investigator administered hormone treatment. In two (Cases 7 and 8) a change to A.C.T.H. was made during the treatment period (on the 28th day); in two, treatment with cortisone was instituted during the observation period (on the 50th and 51st days), after completion of the aspirin treatment. It was thought better to continue these cases in the aspirin group in spite of the change of treatment, since the exclusion of these four cases from the analysis at these points of time would make the picture of the aspirin group somewhat too favourable, since severely ill cases were being artificially removed from it.

Altogether, it is clear that these three exclusions, four changes of the allotted treatment, and eight variations of the treatment schedule can have had no appreciable effect upon the results of the trial.

Two U.S. and four U.K. patients died during the first year and are included in the analysis.

Taken as a whole, the 497 cases under age 16 show the following features. There were, altogether, 14 cases (3%) aged 3 or 4 years, 200 (40%) aged 5 to 9 years, and 283 (57%) aged 10 to 15 years. In just over one-half (255) the allotted therapy was begun within 14 days of the onset of the attack, and a more detailed analysis shows that 149, or 60%, of these "early" cases were treated within one week of onset. In nearly two-thirds (327 cases) there was neither history of a previous attack of rheumatic fever nor evidence of pre-existing rheumatic heart disease. Only 128,

or approximately one-quarter, of the 497 cases were in fact definitely diagnosed as having pre-existing rheumatic heart disease at the start of therapy. Mitral stenosis as shown by an apical pre-systolic murmur was reported in only 16 cases. In general, therefore, the group contained a large proportion of cases still in the early stages of the disease.

Comparability of Treatment Groups at Start of Therapy

The method of allocation ensured that in each treatment group there was approximately the same number of cases with regard to the duration from onset of attack to start of therapy. Thus, there were on A.C.T.H., cortisone, and aspirin, respectively, 86, 85, and 84 "early" cases (0 to 14 days); 47, 45, and 46 "medium" cases (15 to 42 days); and 29, 37, and 38 "late" cases (43 days or more) (Table 2).

TABLE 2.—Comparison of Treatment Groups at Start of Therapy: Duration of Illness from Onset, Sex, Mean Age, and Mean Weight

Treatment Group	Total Cases	Duration from Onset			Sex		Mean Age (Years)	Mean Weight (lb.)
		0-14 Days	15-42 Days	43+ Days	M	F		
U.K.:								
A.C.T.H.	80	39	27	14	40	40	10.0	66.0
Cortisone	80	38	25	17	34	46	9.9	63.6
Aspirin	80	32	27	21	40	40	9.6	64.4
Total	240	109	79	52	114	126	9.8	64.7
U.S.:								
A.C.T.H.	82	47	20	15	51	31	9.9	71.4
Cortisone	87	47	20	20	45	42	10.1	71.7
Aspirin	88	52	19	17	49	39	10.2	73.6
Total	257	146	59	52	145	112	10.1	72.2
U.K. and U.S.:								
A.C.T.H.	162	86	47	29	91	71	10.0	68.8
Cortisone	167	85	45	37	79	88	10.0	67.9
Aspirin	168	84	46	38	89	79	9.9	69.2
Total	497	255	138	104	259	238	10.0	68.6

The average age and mean body weight in the three treatment groups were almost identical, and the sex distribution was reasonably alike. In general, it is clear that the balance produced by the design of the study permits amalgamation of the duration-from-onset groups and of the data for the two countries.

Clinical features of the three treatment groups at the start of therapy are compared in Table 3. With regard to the first item, temperature, it should be noted that oral temperatures were taken in the U.K. (except at one centre) and rectal temperatures in the U.S. (except at one centre). An arbitrary correction of each oral reading was made by the addition of 1° F., and the tabulations are of the maximum "rectal temperature" recorded on each day. As the distribution of patients in each centre was evenly divided among the three treatment groups, the comparison between treatments should not be biased, even though the arbitrary temperature correction may be imperfect. It will be seen that at the start of therapy there was a larger proportion of U.S. cases (57.6%) with a rectal temperature of 100.4° F. (38° C.) or above than of U.K. cases (45.4%). This difference may be real, but it is possible that the addition of 1° F. to the oral temperature may not make the latter entirely equivalent to the rectal temperatures taken in the U.S.

The proportion of cases initially febrile (those with a temperature of 100.4° F. or greater) among the three treatment groups is dependent upon whether comparison is made on the first day of treatment or on the day before treatment was begun. On the first day of treatment there was a smaller proportion of cases febrile in the aspirin group (40.5%) than in the cortisone (61.1%) or the A.C.T.H. (53.7%) group. These differences were in part due to the more immediate antipyretic effect of aspirin in comparison with A.C.T.H. and the slowly absorbed intramuscular cortisone. This is borne out by the proportions of cases febrile

on the day before therapy was started in the A.C.T.H. (61.7%), cortisone (58.1%), and aspirin (53.0%) groups.

The pulse during sleep and the erythrocyte sedimentation rates reveal no material difference (Table 3). Their mean values also showed no real differences, the average pulse during sleep being 93, 93, and 90, and the average E.S.R. 46.7, 46.2, and 45.1, for the A.C.T.H., cortisone, and aspirin groups respectively.

Within each country, the treatment groups do not differ appreciably in their incidence of joint involvement, subcutaneous nodules, and erythema marginatum, but there appears to be some difference in these respects between the two countries. The proportion of cases showing these signs (Table 3) were: joint involvement U.K. 36.7%, U.S. 49.4%; subcutaneous nodules U.K. 21.7%, U.S. 7.4%; erythema marginatum U.K. 7.9%, U.S. 3.9%. The last difference might well be due to chance, but the first two (joint involvement and subcutaneous nodules) are statistically significant ($P < 0.05$). On the other hand, subdivision of these cases into early, medium, or late (Tables 10 and 15) suggests that there is no real difference between the two countries in the incidence of joint involvement. Nodules were observed more frequently in the U.K. at each stage, and particularly in the late cases.

TABLE 3.—Comparison of Treatment Groups at Start of Therapy: Percentage with Specified Symptoms

		Treatment Group			Total
		A.C.T.H.	Cortisone	Aspirin	
Number of cases					
	U.K.	80	80	80	240
	U.S.	82	87	88	257
	U.K. and U.S.	162	167	168	497
Temperature 100.4° F. (38° C.) or more (rectal)					
	U.K.	47.5	51.2	37.5	45.4
	U.S.	59.8	70.1	43.2	57.6
	U.K. and U.S.	53.7	61.1	40.5	51.7
Pulse during sleep 100 or more per minute

	U.K.	32.5	30.1	24.4	28.9
	U.S.	34.2	38.3	32.1	34.9
	U.K. and U.S.	33.3	34.4	28.3	32.6
No organic murmur					
	U.K.	20.0	13.8	17.5	17.1
	U.S.	26.8	33.3	36.4	32.3
	U.K. and U.S.	23.5	24.0	27.4	24.9
Apical systolic murmur					
	U.K.	75.0	77.5	73.8	75.4
	U.S.	69.5	64.4	59.1	64.2
	U.K. and U.S.	72.2	70.7	66.1	69.6
Apical mid-diastolic murmur					
	U.K.	48.8	46.2	45.0	46.7
	U.S.	34.1	23.0	25.0	27.2
	U.K. and U.S.	41.4	34.1	34.5	36.6
Basal diastolic murmur					
	U.K.	38.8	35.0	33.8	35.8
	U.S.	12.2	12.6	11.4	12.1
	U.K. and U.S.	25.3	23.4	22.0	23.6
Apical presystolic murmur					
	U.K.	5.0	2.5	1.3	2.9
	U.S.	4.9	3.4	2.3	3.5
	U.K. and U.S.	4.9	3.0	1.8	3.2

Returning to Table 3, chorea was recorded more frequently in the U.K.; in both countries chance factors brought fewer cases into the A.C.T.H. group and more into the aspirin. Thus in the total group of 162 on A.C.T.H., 167 on cortisone, and 168 on aspirin there were 9, 19, and 26 cases with chorea as a presenting symptom. Severe cases, however, numbered only four, two, and five.

For a general picture of the status of the heart at start of therapy, the 497 cases have been divided (Table 4) into groups depending on the presence or absence of pre-existing rheumatic heart disease and carditis (as defined in the diagnostic criteria). Groups A and B contain all the cases without evidence of pre-existing heart disease at the time of admission. Group A includes: (1) cases with no carditis; (2) cases with murmurs of questionable significance (doubtful carditis); (3) cases with no, or doubtful, carditis but with a prolonged P-R interval. Group B includes cases with definite carditis at the start of therapy. Within both these groups, the number of cases with a definite previous history of rheumatic fever was negligible. Group C contains all those with definite or doubtful pre-existing rheumatic heart disease, whether or not carditis was also present. Both groups B and C are further subdivided into (1) cases with and (2) cases without pericarditis and/or failure at start of therapy.

Table 4 shows that the cases analysed in this way have in general fallen equally into the three treatment groups. The main departure lies in a somewhat lower number of cases on A.C.T.H. in group B (no pre-existing heart disease, carditis present at start of treatment). In the less important C group, in which the course of the disease is difficult to analyse because of pre-existing rheumatic heart disease,

TABLE 4.—Condition of the Heart at Start of Therapy, by Duration from Onset. U.K. and U.S., all Cases

Cardiac Group and Treatment Group	Total	Duration from Onset		
		0-14 Days	15-42 Days	43+ Days
Cardiac Group A—no or questionable carditis,* no pre-existing heart disease:

Cases with failure and/or pericarditis included in Cardiac Group C:				
A.C.T.H.	14	5	4	5
Cortisone	10	5	3	2
Aspirin	7	3	—	4
Total	31	13	7	11

* Questionable carditis includes 8 A.C.T.H., 6 cortisone, and 7 aspirin cases with a grade P murmur and 13 A.C.T.H., 12 cortisone, and 10 aspirin cases with a prolonged P-R interval and either no murmur or grade P murmur. (For definition of grade P murmur, see footnote to section on Murmurs.)

there is some predominance of cases with pericarditis and/or failure in the A.C.T.H. group.

Returning to the incidence of the individual signs of involvement of the heart at start of therapy, Table 3 shows, for A.C.T.H., cortisone, and aspirin respectively, no appreciable differences for apical systolic murmurs (72.2%, 70.7%, and 66.1%), basal diastolic murmurs (25.3%, 23.4%, and 22.0%), and the proportion of cases with atrio-ventricular conduction time of 0.18 sec. or more (33.3%, 34.4%, and 28.3%). The proportions with a cardio-thoracic ratio of 0.55 or more were not equal, there being a smaller proportion in the aspirin group (22.0%, 18.5%, and 11.8%), but, as will be seen in the section on heart size (Table 20), this is largely due to the unequal distribution of cases with pre-existing heart disease (Group C). There was also a somewhat larger number of cases in failure at the start of therapy in the A.C.T.H. group, compared with the cortisone and aspirin groups (14.2%, 9.0%, and 6.0%).

Between the two countries, the individual signs of cardiac involvement were equally reported except for basal diastolic murmurs. These were more often reported in the U.K. (35.8%) than in the U.S. (12.1%), but this difference came from one U.K. centre only. Ninety-three of the 240 U.K. cases came from this centre, where the incidence of basal diastolic murmurs was 73.1%. In the remainder of the U.K. centres the incidence was 12.2%.

In short, these comparisons show that in many respects the three treatment groups were very similar—namely, in the duration-from-onset, age, sex, body weight, temperature, pulse during sleep, erythrocyte sedimentation rate, frequency of polyarthritides, subcutaneous nodules, erythema marginatum, and in the P-R interval. There are, however, a few differences. The group on aspirin included an undue proportion with chorea as a presenting symptom, although the few severe cases of chorea fell fairly equally in the three treatment groups. The A.C.T.H. group contained a larger proportion of cases with pericarditis and/or failure (particularly in the U.S.), and the aspirin group contained rather fewer (particularly in the U.K.). These differences are not large, but must be borne in mind in the study of the response of the illness to the different treatments.

Results

The course of rheumatic fever was followed in each case after admission to the study during the six-weeks period of treatment, three-weeks period of observation, at monthly intervals for six months following the end of the observation period, and at two-months intervals until the end of the first year (quarterly thereafter). This report includes an analysis of each symptom, sign, and laboratory test considered as evidence of active rheumatic fever or of rheumatic heart disease through a period of one year following the end of the observation period.

Each manifestation is considered at specified points of time and discussed individually. The methods of analysis include: comparison of averages; the proportion with a change greater than an arbitrary maximum amount; the proportion with a manifestation present or absent; the number, or percentage, above or below an arbitrary limit of normal. (With this last method of analysis, a constant number or percentage over a period of time does not indicate that the same cases continue abnormal but that of all the cases at risk the number abnormal remains the same.) In general, when several such indices yielded the same results, the simplest is reported; when two methods yielded differing results, both are reported. When a difference between treatment groups in one of these measurements is significant the probability value is reported; otherwise differences in results between treatments are not significant.

Temperature

Temperatures were measured four times a day throughout the nine-weeks period of treatment and observation. The maximum reading for each day is used in this analysis,

and cases are considered febrile if that reading (rectal) was 100.4° F. (38° C.) or above. The three groups were comparable on the day before treatment (Chart I). Following start of treatment, the proportion of febrile cases decreased rapidly in all three groups, although it was most rapid on the first day in the aspirin group (Chart I, Table 5). During the latter part of the first week the proportion febrile in the A.C.T.H. group was lower than that of the other two groups, but at the end of the week all three groups were in the same range, the aspirin group lagging slightly behind. In the main this lag in the aspirin group persisted throughout the six-weeks period of treatment, and was more prominent among the cases febrile than among those afebrile at start of treatment.

At the end of the sixth week of treatment there was a rise in the proportion of febrile cases in the A.C.T.H.

CHART I.—Temperature. Percentage of cases on each day with a rectal temperature of 100.4° F. (38° C.) or above

TABLE 5.—Temperature: Percentage of Cases with a Rectal Temperature of 100.4° F. (38° C.) or Above at Specified Times.* U.K. and U.S., all Cases

group, persisting into the eighth week and then slowly decreasing. A similar rise occurred in the cortisone group, beginning in the seventh week, reaching a peak in the eighth, and decreasing slowly during the ninth week. The aspirin group showed a smaller rise with its peak in the seventh week, and decreasing during the eighth and ninth weeks. At the end of the ninth week all three groups had about the same proportion of febrile and afebrile cases (Table 6).

Pulse Rate During Sleep

The pulse rate was taken during sleep, between the hours of 12 midnight and 5 a.m. At start of treatment (Table 7), 31% to 36% of the patients in each group had a pulse rate of 100 per minute or more (tachycardia), while less than 5% had a rate of less than 60 per minute (bradycardia).

TABLE 7.—Pulse Rate During Sleep: Percentage of Cases with Bradycardia (under 60) and Tachycardia (100 and over) at Specified Times.* U.K. and U.S., all Cases

* See footnote to Table 5.

Following start of treatment there was a slight rise in the proportion with tachycardia among the cortisone cases during the first two days. Apart from this, the proportion decreased at approximately the same rate in all three groups, reaching the same level in cortisone and aspirin at the end of the first week, the A.C.T.H. group having a slightly higher figure. These relative proportions remained unchanged throughout the treatment period. When therapy

CHART II.—Tachycardia. Percentage of cases on each day with a pulse rate of 100 or more.

was stopped there was a sharp rise in the A.C.T.H. group and a slower rise to the same level in the cortisone group. At the end of the observation period one-fifth of the cases in both groups still had tachycardia. On the other hand, the proportion with tachycardia in the aspirin group remained almost unchanged when treatment ended and throughout the observation period (Table 7 and Chart II).

Detailed analysis showed that in all treatment groups there was the same rapid fall in the proportion with tachycardia among the cases of short duration (0-14 days), while in those of longer duration (15+ days) it fell more slowly. Thus, starting from the same level of 30% to 40% with tachycardia, there was a fall at the end of the first week to only 1% to 8% among the cases of short duration, in comparison with 13% to 22% among those of longer duration. This latter group lagged behind until the fourth or fifth week.

TABLE 8.—Erythrocyte Sedimentation Rate: Percentage of Cases with a Rate of 20 mm./hour or higher (uncorrected) at Specified Times,* U.K. and U.S., all Cases.

Treatment Group	No. of Cases	Start of Therapy	Week of Therapy						Week of Observation			Follow-up	
			1	2	3	4	5	6	7	8	9	13 Wks.	1 Year

* The observations were not always made on the final day of the week, but were in most cases made at weekly intervals. A margin of ± 3 days was allowed in deriving weekly values.

The proportion with bradycardia increased sharply after the start of treatment in both hormone groups, reaching 14.7% in the A.C.T.H. group at the end of the first week and almost 25% in the cortisone group at the end of the

CHART III.—Bradycardia. Percentage of cases on each day with a pulse rate of 60 or less.

second week. From this point the proportion with bradycardia decreased to approximately the starting level by the end of the treatment period. In contrast, bradycardia occurred later in the aspirin group, reaching a peak of a little over 10% in the second to third weeks, and declining thereafter (Table 7 and Chart III).

Erythrocyte Sedimentation Rate

The erythrocyte sedimentation rate was measured by the Wintrobe method (uncorrected)† at the start of treatment, weekly throughout the treatment and observation period, and at each follow-up examination. Its course was followed by tabulation of the proportion of cases with a rate of 20 mm. per hour at specified times.

At the start of treatment, approximately 90% of the cases in each treatment group had an elevated sedimentation rate. This proportion decreased rapidly in the hormone groups, with the A.C.T.H. group showing the sharpest drop, levelling off at the third week, in contrast to the cortisone group, which reached roughly this same level about the fifth week (Chart IV, Table 8). The proportion of those with an elevated rate in the aspirin group lagged distinctly behind that of both hormone groups, not reaching the same level until the last week of treatment. When treatment was stopped, however, there was a sharp rise in the proportion with a raised rate in the A.C.T.H. group, and a slower rise to the same level in the cortisone group, while there was no change in the aspirin group. By the 13th week the proportion in all three groups had reached the same low level of 12-16%. The very similar distribution of values at this point is shown in Table 9; at one year the proportions were relatively unchanged from the 13th-week figures. Separate analysis showed that these trends were the same for all three duration-from-onset groups.

† A corrected sedimentation rate of 15 mm./hr. or above was established as a minor diagnostic criterion for admission to the study, and was so used. In analysing the course of the disease for the first 13 weeks, an uncorrected rate of 20 mm./hr. or above was used, because (1) the centrifuges used in the haematocrit determinations were not standardized, with resulting variations from centre to centre, and (2) analysis of uncorrected and corrected readings for each of the drugs showed the same trends, and it seemed undesirable to introduce an unnecessary variable.

To summarize, during treatment the proportion with an elevated sedimentation rate decreased much more rapidly in the hormone groups than in the aspirin group, but it increased sharply, though temporarily, in both hormone

CHART IV.—Erythrocyte sedimentation rate. Percentage of cases with a rate of 20 mm./hr. or above (uncorrected Wintrobe).

groups after treatment was stopped, in contrast to a negligible change in the aspirin group. It finally reached the same low level in all three groups at 13 weeks, and this equal level was maintained at one year.

TABLE 9.—Erythrocyte Sedimentation Rate: Distribution at 13 Weeks. U.K. and U.S., all Cases

50-59	—	—	2
Not stated	7	12	13
Total	162	167	168

Joint Involvement‡

At start of therapy there was a greater proportion of cases with joint involvement in the U.S. centres (49.4%) than in the U.K. (36.7%), the difference occurring entirely among the early cases (Table 10). In both countries the percentages were about the same in each treatment group.

In each treatment group, cases with joint involvement on admission rapidly lost this symptom. Thus on the third day of therapy joint involvement was still present in 28.6% of A.C.T.H., 56.4% of cortisone, and 36.5% of aspirin cases

‡ Polyarthritides as a major manifestation for diagnosis of rheumatic fever was defined as "pain and either limitation of active motion, or tenderness in two or more joints." For following the course of this manifestation after start of treatment, a system of grading was adopted in which the lowest grade was defined as joint pain without objective joint findings. Since this lowest grade is less than that required for the definition of polyarthritides, the course of the manifestation is referred to as "joint involvement."

TABLE 10.—Joint Involvement: Comparison of U.K. and U.S. Cases at Start of Therapy

Duration from Onset at Start of Therapy (in Days)	U.K.			U.S.		
	Total Cases	With Joint Involvement		Total Cases	With Joint Involvement	
		No.	%		No.	%

Total	240	88	36.7	257	127	49.4

By the eighth day it remained in less than 10% in each treatment group. Throughout the rest of the treatment period joint involvement was present in none of the cortisone cases, in only a rare case in the A.C.T.H. group, and in a few cases in the aspirin group (Table 11). After treatment was stopped there was an insignificant increase of cases with joint involvement in the A.C.T.H. group, and these had disappeared by the 13th week; in the cortisone group there was an immediate rise to 10.3%, followed by complete disappearance at the ninth week and one recurrence at the 13th week; in the aspirin group two cases con-

Aspirin	94	—	4	—

tinued up to the 13th week. Among cases in which joint involvement disappeared it later reappeared in only a few cases (A.C.T.H. 5, cortisone 15, and aspirin 8).

Among cases without joint involvement at start of therapy (Table 12), a few developed it during the 13-weeks period (A.C.T.H. 9, cortisone 9, aspirin 4). In five A.C.T.H., four cortisone, and the four aspirin cases the joint involvement appeared for the first time after the end of treatment.

There is little to choose between the three drugs in their effect on joint involvement, apart from some delay in response to cortisone administered intramuscularly.

Chorea

At the start of therapy there was a larger proportion of cases with chorea in the aspirin group than in either of the hormone groups. Chorea seemed to persist longer in the aspirin than in the hormone groups, but this difference is not significant (Table 13). The persistence of this symptom

was strikingly more pronounced in the U.K. than in the U.S. cases, since at 13 weeks nearly all were in U.K. centres (the A.C.T.H. case, one of three cortisone, and eight of nine aspirin cases).

Among the cases without chorea at the start of therapy, a few in all three treatment groups developed this symptom at some time during the 13-weeks period (Table 14).

The persistence of chorea, as well as its appearance for the first time, was not significantly different between the treatment groups.

Subcutaneous Nodules

At the start of therapy there was a significantly larger proportion of cases with subcutaneous nodules in the U.K. (21.7%) than in the U.S. (7.4%), most of the difference occurring in the group of late cases (Table 15). Among the

TABLE 15.—Nodules: Comparison of U.K. and U.S. Cases at Start of Therapy

Total	240	52	21.7	257	19	7.4

three treatment groups in the two countries, however, such cases were fairly evenly distributed except for slightly fewer in the aspirin group.

In most of the early and medium-duration cases (0-42 days) receiving A.C.T.H. or cortisone, subcutaneous nodules had disappeared by the end of treatment (Table 16). In the aspirin group, although the number with nodules was fairly small, the nodules tended to persist to the end of the sixth week. This tendency was even more apparent among the chronic cases (43+ days), although the rate of disappearance in these cases was perhaps lower with all three drugs. These differences in response came from the U.K. cases, since at the end of six weeks only two, and at 13 weeks only one, with nodules still remaining were U.S. cases.

New subcutaneous nodules developed in some cases during the treatment period in all treatment groups, and particularly among cases with nodules at the start of therapy (Tables 16 and 17). During the treatment period there was a slightly greater tendency for cases in the aspirin group to develop new nodules than among those in the hormone groups. Of the 36 cases in all treatment groups in which new nodules developed during therapy, 25 were U.K. cases.

Thus it may be concluded that new nodules appeared on all treatments and that nodules persisted longer in the aspirin- than in the A.C.T.H.- and cortisone-treated cases,
